Nambisan 4 discusses four dimensions of social media experience that attract healthcare consumers and facilitate sharing health information. “The four dimensions are pragmatic experience, empathic experience, sociability experience, and usability experience”. Facebook is a social media considering these four aspects, resulting in establishment of several self-management support groups among patients, particularly with chronic diseases.

Research purpose
About 9 percent of American shows symptoms of desperate, regret, and sadness that result in depression (CDC 2014). An initial search in Facebook shows that more than 10 self-management groups (English language) created by Facebook members for depression management. The cumulative number of depression groups members (just in English language) is around 40,000 members. Members usually share their feelings towards their life and their family and friends, and usually look for groups’ member sympathy or support. Studies have found that people with depression are attracted to these groups as they may be getting the kind of understanding and support from group members who went through a similar situations 3. While there are plenty of studies that have looked into online depression groups, there haven’t been any that looked at analyzing posts in Facebook depression groups. The purpose of this study is to analyze posts in Facebook depression groups, to classify them into pragmatic, empathic, and social categories. In addition, nature of comments left for post and their relationships with post are analyzed.

Research Methodology
For this study five groups with around 30000 members are considered. Content, questions, and comments that people posted in these groups have been collected using Facebook API.

Latent Dirichlet Allocation (LDA) tool has been used to model topics that group members posted. LDA has been trained based on algorithm suggested by Hong, Davison 5. Topic modeling is applied to explore purposes and expectations of members from the virtual communities of depression diseases. In the first stage, nature of the posts will be analyzed to understand whether posts are (1) pragmatic (information seeking about symptoms or treatment methods) to manage diseases or (2) empathic (seeking sympathy or attention to cope with emotional gaps); and (3) sociable (extending social network by communicating with supportive people experienced the same medical conditions). In the second stage, the nature of comments left for each posts are analyzed and subsequently divided into three categories: Positive (supportive), negative (unfavorable), or neutral. In addition, relationship between posts and comments are analyzed. Detailed findings will be reported.

Preliminary result
Preliminary result of this research shows that people with depression in Facebook depression groups are more likely to experience empathic or sociability aspects than pragmatic aspect. In fact, group members are more willing to post emotional gaps in their life (such as loneliness), depression symptoms such as self-loathing, or sleep/food disorders explicitly or implicitly and subsequently seeking supportive and sympathetic comments. In addition, they would like to extend their social networking by communicating with group members who experienced the same medical conditions. Moreover, unlike other health communities, members are less inclined to ask questions about treatment solutions, such as medications or brain training, which are common treatment methods in healthcare facilities.

Research Implication
Result of this research will help healthcare organizations to understand coping mechanism of people with depression to manage their disease in virtual environment. In addition, it will enable healthcare researchers to design interventions consistent with needs of patients with depression. Designing proper interventions help healthcare organizations to improve level of patient activation and patient engagements among depressed patients, and consequently, transmit clinical services from determining “what is the matter?” to discovering “what matters to a specific patient with depression disease” 8.

Using a Web-based Clinical Pathway and Computerized Order Set to Improve Efficiency of Care for Asthma in a Pediatric Emergency Department

Joseph J. Zorc, MD, MSCE, Ruth Abaya, MD, Eva Delgado, MD, Richard Scarfone, MD.
Department of Pediatrics, The Children’s Hospital of Philadelphia and Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Background: Evidence from clinical trials suggests that increasing use of metered dose inhalers with spacers (MDIs) to treat mild-moderate asthma increases value of care by reducing length of stay (LOS) and improving resource use. Few studies have evaluated effective ways to use clinical decision support (CDS) in an electronic health record (EHR) to support this recommendation in the Emergency Department (ED).

Aim Statement: For mild-moderate acuity ED asthma patients, to use a web-based pathway and EHR order set to increase use of MDIs and reduce LOS.

Methods: A baseline review focused on discharged patients ≥ 2 years with an asthma diagnosis and a non-emergent triage assessment (Emergency Severity Index (ESI) 3 or 4). This review identified a median ED LOS of 3 hours and that 40% received an hour of continuous albuterol (CA). 90% of patients received an MDI at discharge, representing duplicated resources. Our multi-disciplinary team developed an intervention to increase use of MDI instead of CA for acute treatment using the following interventions: 1. Redesign of the ED Asthma pathway (www.chop.edu/clinical-pathway/asthma-clinical-pathway) and order set to provide CDS recommending MDIs for ESI 3/4 patients and encourage early discharge planning. Key elements of the order set included: active suggestion to providers at time of ordering, and discrete, actionable options based on ESI level. 2. Adding conditional order for the Respiratory Therapist to reassess and repeat MDI q20 minutes x3 until patient reached mild assessment. Process and outcome measures were tracked; balancing measures included admission and revisit rates for target patients and higher severity asthma patients.

Outcomes: The interventions were implemented and assessed in 2,667 ESI 3/4 asthma patients treated from July-December 2014. For target ESI 3/4 patients, CA use decreased immediately from 40% to 13%, and the percentage discharged in < 3 hours increased from 53% to 63% (both p<0.05 using process control measures, see Figure). Measures for more severe patients did not change, although overall ED LOS for all asthma patients decreased by 22 minutes after the intervention (p<0.05). Monitoring continues to show sustained change, and ongoing interventions are occurring.

Conclusion: Preliminary data show that a revision to a web-based ED asthma pathway and EHR order set using CDS principles reduced CA treatment, and improved efficiency for the care of mild-moderate asthma patients.

KaryoViz: Designing A Karyotype Visualization Platform for Clinical Decision Support

Zachary B. Abrams, BS\(^{1}\), Satyajeet Raje, MS\(^{1}\)

\(^{1}\)Ohio State University, Columbus, OH

Introduction

Data visualization is a critical step in helping researchers better understand the structure and meaning of their data. In the domain of medical genomics cytogenetic data is frequently used to provide visualization at the chromosomal level. Karyotypes are syntactic descriptions of chromosomes, derived from a microscopic visual examination of chromosomes. Karyotype analyses help detect chromosomal structural and numerical defects that can serve as genetic indicators of disorders or diseases. These tests are more readily available than the more specialized sequencing technologies and are thus a more accessible means of assessing a patient's genetics for diagnosis and/or therapeutic planning purposes.

It has long been observed that karyotype analysis can be used as a diagnostic tool in medicine since many diseases have distinguishable patterns of chromosomal aberrations\(^{1}\). The International System for Human Cytogenetic Nomenclature (ISCN)\(^{2}\) is a domain-specific language that records these chromosomal defects through visual microscopic inspection of chromosomes. However, the karyotype information in this format is difficult to analyze using existing computational methods by virtue of their syntactic variability, information density and potential for human error. Thus, the karyotype data remains severely underutilized.

Prior attempts have parsed ISCN karyotypes but have failed to accurately map them to a structured language biological model\(^{3}\).

In our previous work, we propose, 1: a Loss-Gain-Fusion (LGF) biological model (AMIA citation) that provides a standardized machine-readable representation of the karyotype information and 2: a computational cytogenetic platform that transforms ISCN-encoded karyotypes through a process of parsing and mapping into their standardized representations using the biological model. Thus, the platform provides an automated pipeline that can extracts biologically important information from text-based karyotype data in a form that is ready for reuse. The karyotype data can then be utilized for several clinical as well as applications such as visualization, analysis, etc.

In this paper, we highlight the data processing and visual component of this pipeline. We propose a visualizaion tool, called KaryoViz, that will primarily allow clinicians to input the syntactic representation of a karyotype and analyze it in an intuitive interface. The users would be able to navigate through different granularity of the information extracted from the karyotype data. It would also allow the users to visually browse through the Mitelman database, which is the the largest public repository for karyotype data\(^{4}\). Thus, the tool would be instrumental in augmenting clinical decision support by reusing the karyotype data, which is otherwise be inaccessible to clinicians and researchers alike.

Parsing

The parsing process converts natural language into computer language. To transform ISCN-encoded karyotypes (natural language) into machine-readable constructs (computer language), several parsers were generated using ANTLR (ANother Tool for Language Recognition)\(^{5}\) Context-Free Grammar (CFG), encoded using the Extended Backus-Naur Form, was used to write ISCN-specific production rules. This approach was based on the observation that any ISCN karyotype was describable in its entirety using a recursive walk of its morphological composition using a minimal number of CFGs. Several such production rules were created, starting with a fundamental rule for a karyotype and incrementally adding further rules for recognizing the collection of possible patterns for each aberration in that karyotype. Thus, each complex karyotype was morphologically deconstructed into constituent phrases. Finally, computationally readable “parse trees” were constructed using these phrases for downstream usage in the overarching computational pipeline.
Mapping

Mapping the parsed karyotypes into our machine-readable model required the creation of a domain-specific language used in the mapper function. This nomenclature allowed chromosomal aberrations to be rewritten and then redefined into the LGF model. First, the ISCN abbreviation for the aberration was written, followed by the number of elements that would be extracted from that aberration. Each extracted element consisted of the chromosome, the arm of that chromosome, and the band of that chromosome. A colon was used to distinguish biological events. Then, starting with element zero, each element was assigned to its respective part of the biological model. The biological elements were separated by a "," and different abbreviations represented how that element should be classified based on whether that element was lost, gained and/or involved in a fusion event. Thus, ISCN karyotypes were rewritten to purely represent the biological function at each location. Although antecedent events, such as translocation and deletion, were not preserved in the model, the biological effect of those events was represented, allowing for comparison across aberrations with similar biological effects. Each aberration had its own unique classifier in this domain-specific language. Following the use of the domain-specific language to map the karyotypes into the LGF model, we were generated a matrix in which each row represented a karyotype and each column represented a potential cytogenetic band. Let us now look at how the above workflow can be utilized in the proposed visualization tool.

The Loss-Gain-Fusion (LGF) Biological Model

The design of the LGF model was guided by the three major events known to cause deleterious oncogenic effects at the chromosomal level, viz. loss, gain and fusion. The first event is the loss of a gene, which can disrupt the cell cycle or other critical pathways. Deletion is an example of a loss event on the chromosomal level. Deletion of an entire section of chromosomal DNA represents a loss of DNA, thus the genes in that region are not present on that chromosome. The second event is the gain of an additional copy of the gene. This causes additional gene products to be created that could disrupt the balance of pathway regulation in a comparable manner to the loss event. As with a loss event, a gain event alters one component of a pathway and thus can disrupt that pathway's function. Duplication represents an example of a gain event, wherein a segment of chromosomal DNA is represented twice. If the fully intact gene is present within the duplicated region, that gene may express more product than a non-mutated cell. The third event is a fusion event that can produce a chimeric oncogene that disrupts the cell cycle in some capacity. A fusion event requires a breakage event so there could also be a loss of function at fusion points as well as the possibility of a chimeric oncogene. The chimeric gene is formed from multiple genes; this can occur due to a fusion event. It is possible for chimeric genes to alter cell cycle regulation or other pathways that, when disrupted, can lead to a loss of regulation that leads to oncogenic development.

The proposed Loss-Gain-Fusion (LGF) biological model represents the aberrations in the karyotype based on the biological function (loss, gain, or fusion) occurring at that location in the chromosome as opposed to focusing on the event that caused that particular biological function (e.g., deletion, translocation). This places sole computational emphasis on the underlying biological result of the event rather than on the event itself. This allows researchers to compare across events in the analysis of similar functional outcomes in patients without having to rely on similar events causing those functions.

We began by utilizing the nomenclature found in the ISCN language for writing karyotypes. We then created a set of parser rules that allowed us to break down the text form of the karyotype into a tree structure. By traversing the tree and pulling out the tokenized elements representing the cytogenetic events (e.g., translocation and the location - e.g., 17 P 13), we could reassemble the event and location into pairs. Then we developed a mapping language that would assign each possible cytogenetic event to one of three overall biological events: loss, gain or fusion. This allowed us the ability to map each location and the potential event that could occur at that location. This in turn allowed us to represent the text base karyotype as a binary vector where each cytogenetic region has three representations, i.e., the loss, gain, or fusion form of each location. There are 910 cytogenetic locations within this model, thus the binary vector for each karyotype was represented using 2,730 units. This binary vector is standardized, of a fixed size and can be read computationally for several different applications.
Karyotype Transformation Workflow

This workflow (Left) illustrates the process of converting raw text based karyotypes into the LGF binary vector model. The first step is to parse the raw text karyotypes using a set of production rules. This produces a tokenized form of the karyotype, i.e., all text in the karyotype is broken down into individual elements and then examined based on context in relation to other elements. This allows the chromosomal aberration and the affected band to be isolated and classified into the LGF model. The LGF classification is based on the mapping language that classifies each band based on its corresponding aberration. This outputs a vector representing each chromosomal region, where each region has a three bit code denoting what event has occurred at that location.

Input Data

Traditionally, karyotype data are acquired from a patient’s tumor by selecting tumor cells in mitosis. The researcher then maps the chromosomes into chromosomal pairs and arranges them in order. The patient's aberrations are noted in the ISCN format and an ISCN karyotype is written based on the number of chromosomes and aberrations in the patient’s karyotype. An example ISCN karyotype is presented here: 47,XY,del(20)(q13),+21.

Design Requirements

Potential Use Case: User uploads a particular karyotype to visualize

1. To begin, a researcher will upload a karyotype and our system will parse and map that karyotype into the LGF model as previously presented.
2. Then a personalized ideogram is generated and presented to the researcher. This ideogram shows all chromosomes and color-codes those bands involved in losses, gains, and/or fusions. This allows the researcher to quickly identify those chromosomes and/or individual bands of interest.
3. If a researcher wishes to observe a deeper level of granularity on a particular chromosome, they simply select that chromosome and the system zooms in to a more detailed map of that particular chromosome. Each band and sub-band within the chromosome is still color-coded using the same key so the researcher can identify those areas of interest.
4. By simply clicking on a sub-band, a list of all genes present on that sub-band will appear next to the band. This provides the researcher better visualization of their data and thus enhances the understanding of the various gene level changes caused by the cytogenetic aberrations.
This form of data visualization stands in contrast to the current standard to visually examining the karyotype based on the ISCN text string. This system of visualization thus plays to the human strength of visual pattern recognition to determine potentially important elements within the karyotype.

**Design Elements**

*Ideograms:* Karyotype ideograms, commonly used in cytogenetics\(^2\) proved to be far more visually informative than binary vectors. An ideogram is a map that illustrates all the chromosomes and bands within chromosomes. We took this design concept and created an interactive ideogram that was color-coded based on the researcher’s inputted data. This allowed us to visually display a new form of cytogenetic data utilizing a familiar visual system; the ideogram. This helps make the system more intuitive to cytogeneticist who are used to seeing information displayed in this form.

**Implementation Details**

The KaryoViz tool is under active development both as a web application as well as a mobile application. We are using the D3 visualization library for implementation. The parsed Mitelman data is stored in a no-SQL database. The current focus is on finalizing the user interface design. The details of the current demo interface can be found in the supplemental material (\(s1\)).

**Evaluation**

An important part of the development process is testing the UI. The user interface design will be evaluated in two ways detailed below. Both these involve a “cold” evaluation of the interface, meaning that the UI is not necessarily connected to a functioning and fully working system.

*Heuristic evaluation*

The heuristic evaluation will be performed in two parts. First, the interface is to be evaluated by UI experts based on the HCI principles\(^8\). Next, we would design a survey based on these principles for the users of the interface. The platform will be evaluated as a combination of the expert comments and the user responses.

*Cognitive evaluation*

This is a task-based evaluation. An optimal workflow to perform certain tasks is prerecorded. The tasks are designed around the different functions that the user is expected to perform using the interface. A set of test users will be asked to perform the same tasks. The think-aloud protocol will be used as users are performing the tasks. Both the user actions and the responses will be recorded. An evaluator would also note various aspects of the process, such as whether the user could actually finish the task, the deviation from the optimal flow, time required to complete etc. All of this data will then be analyzed to evaluate the user interface. Additionally the eyeball tracking method can also be used as an additional cognitive response measure of the system.

**Conclusion**

The ability to visually inspect genomic information represents a significant step in cytogenetic research. Our proposed Cytogenetic Platform contains a visualization system that spans the scale of observation from the large-scale chromosome level to the individual gene level. It empowers the researcher or clinician to visually target that level of data that best meets their needs. This represents an important visual tool for cytogenetic researchers.

The EH Tracker: Using Dynamic Environmental Health Data for Improved Personal Health Decision-Making

Juandalyn L. Burke¹, MPH, Dae Hyun Lee¹ and Ryan C. James¹
¹Biomedical Informatics and Medical Education, University of Washington, Seattle, WA

Abstract

Although climate change and environmental health information have been widely dispersed to the public through various channels of communication, from environmental advocate groups to mass media productions, little is known by the public about how the impact of dynamic environmental health hazard data affects their individual health. Existing environmental health applications consist of predominantly pollen allergy and weather forecast based systems, only provide the public with a limited set of environmental health information, lack recommendations for ways to reduce the public’s exposure to predominant pollen allergens, and do not include any data on air pollution levels. In our solution, we aim to provide individuals with user-specific environmental health hazard data using a web-based and mobile application called the Environmental Health (EH) Tracker. The EH Tracker design incorporates actionable recommendations that reduce exposure to pollutants and pollen allergens, and offers features such as electronic health record integration and healthcare provider communication channels. Our design includes machine learning algorithms that provide users with environmental hazard feedback summaries, recommendations for reducing exposure, and healthcare provider notifications triggered by user experiences. Thus, we believe that the EH tracker will aid in reducing individuals’ exposure to environmental health hazards and reduce their chances of having an allergic reaction and/or worsened existing health condition such as chronic and non-communicable diseases.

Introduction

With rapidly evolving weather patterns and increasing levels of air pollutant emissions, public safety has become an enormous challenge. How does the public stay informed about these challenges? How do they discover the types of environmental hazards are affecting their health? How do they protect themselves from being exposed to these hazards? At the 2014 Climate Change Summit President Obama stated that the “climate is changing faster than our efforts to address it...”, and addressed the need to have more technological innovation in an effort to reduce exposure to environmental health hazards¹². The link between disease susceptibility and environmental hazards, such as air pollution which causes climate change, has been well-researched over the past sixty years³⁵. Most notably, in 1948, the national coverage of the citizens of Donora, Pennsylvania being diagnosed with respiratory and cardiovascular illnesses as a result of a “lethal haze” entrapping air pollutants in their community brought about government mandates such as the Clean Air Act of 1970⁶. However, air pollution remained a persistent issue due to the consistent release of air pollutants by power plants and motor vehicles¹. According to the Center for Disease Control, respiratory illnesses such as asthma have become a “national epidemic”, affecting one in twelve people in the United States with a growth rate of 28% from 2001 to 2011¹³. Among various pollutants affecting our air, land, and water, air pollutants are more likely to vary periodically, unexpectedly exposing individuals to high levels of toxic pollutants. Now more than ever, it’s imperative that we build innovative solutions that predict the effects of environmental health hazards and prevent the public from experiencing their negative effects.

Currently, there are several environmental health apps that inform users about city-wide data related to pollen count and weather forecasting¹¹¹³. Each of these apps allow their users to log symptoms in a daily diary. However, the diary has limited functionality for exporting and sharing data with other users or medical professionals, such as their doctor or nurse⁶. Moreover, the existing environmental health apps inform their users of the environmental health hazards present in their community by displaying range values to indicate severity based on the average person¹³. However, these apps do not give users a personalized medical perspective detailing how environmental health hazards affect their individual health. Such an app, based on personalized medical data, can deliver actionable information to users, provoke specific, positive behavior changes on an individual basis, and reduce exposure to harmful effects at the population level.

Thus, we plan to design and develop the Environmental Health (EH) Tracker to provide users with: (1) a more accurate, user-specific environmental exposure and health-risk assessment based on machine learning algorithms, and (2) channels of communication with healthcare providers facilitated by user-specific environmental health
Alternative Solution

As an alternative solution, we considered designing a Geographical Information System (GIS) to present environmental information to susceptible users. Supplementary Figure 8 shows the overall concept of the alternative solution. The preprocessing step collects air pollution data from various sources and feeds the data into a machine learning algorithm that trains an environmental health risk prediction model. The following data were identified as requirements for training models: pollen count, air pollution level, and traffic congestion patterns.

When using a machine learning approach to derive accurate prediction models, it is crucial to prepare with the right training data. Past events can be a great source of data because the outcome is known. Variables in these data sets not only represent pollution levels such as pollen count and dust level, data for confounding variables such as wind speed and precipitation can be used for training as well. In addition, patient outcomes can be obtained from public health surveys such as NIHS (National Health Interview Survey) or BRFSS (Behavioral Risk Factor Surveillance System). We planned to integrate these heterogeneous datasets into a single dataset for training purposes.

With Principal Component Analysis (PCA), distinctive features in the training dataset can be extracted and used for training multiple health risk prediction models. Selecting the important features to analyze within the training dataset is a crucial step in training such models; it not only effects training efficiency, but also each model’s level of prediction accuracy by avoiding over-fitting. We contemplated two ways to use the models after they were generated. First, the model with the highest accuracy would be chosen. For example, the model that performed the best when predicting pollen outcomes would be used to predict pollen. Second, each model would be integrated into an ensemble model, or a meta-predictor would be used to select the best model based on the pollutant under analysis.

However, we identified shortcomings for the alternative solution through persona and scenario-based evaluation sessions. First of all, the design could only manage one profile at a time. Second, although it could convey multiple environmental hazards for a single location, the system could not present any actionable information to users. Lastly, it could not be customized for individual users. Through a deeper understanding of the system’s stakeholders we identified that user-specific information is a crucial feature for the system because the severity of the symptoms caused by poor air quality highly depend on an individual’s pre-existing conditions. In addition, allergic reactions tend to have high specificity to allergens. Therefore, we concluded that this “one-size-fits-all” scoring system was inadequate for an intervention that provides users with meaningful, user-specific health risk prediction and prevention information. After analyzing the alternative solution’s strengths and weaknesses we arrived at our proposed solution—the EH Tracker.

The Solution

Our proposed solution has three main objectives: 1) to present personalized environmental health information to users in an intuitive, user-friendly interface, 2) to provide a tool for individuals to avoid environmental factors that adversely affect their health, and 3) to provide a useful environmental health supplement for clinical visits. We identified these objectives when we conducted background research, which included the identification of stakeholders, the development of personas and scenarios, and a participatory design session conducted with a group of our peers. The objectives also represent a set of gaps that currently exist in environmental health apps on the market today.
Figure 1. The EH Tracker system architecture. Environmental and health data (left) is combined with user-specific data (top) and fed into EH Tracker features (bottom) to provide users with actionable environmental health information to improve their day-to-day lives. These experiences can then be sent to other platforms (right).

Key features

In order for the EH Tracker to fulfill the above objectives, users will need to engage with it and the underlying data in meaningful ways. We aimed to abstract away the ‘big data’ and computational complexity that drives the EH Tracker interface and present the user with a limited set of easy to use features that improve their quality of life. These features, as seen in Figure 1, include: an alert system, an end-of-day user feedback mechanism, a health history view, a profile page, and a home page summary view.

Alerts (Supplementary Figure 1a). When changes in the environment will have an adverse effect on an individual’s health, the individual needs to be informed with actionable information enabling them to avoid harm. If users are required to check for environmentally important information themselves they may check late or not at all, both of which could cause the user serious environmental harm. To avoid these issues we will present users with important information as soon as they need it. Unfortunately, alerting in healthcare has acquired a bad stigma. Alert fatigue associated with Electronic Health Records and other systems has become a pervasive issue. To address potential alert fatigue we designed the EH Tracker alert system to alert based on user preferences. Users will set alert settings when they create their profile and can change alert settings at any time in the future. To determine the appropriate set of alert options we plan to perform an extensive user study. For more information about the user study please see the future work section.

User feedback (Supplementary Figure 2). The EH Tracker’s health risk prediction service is built on top of a machine learning algorithm that is fed user feedback as input. The prediction service is the backbone of the EH Tracker application. It helps users avoid health issues and discover their inherent susceptibility by providing users and their health professional with data they can use to identify and treat symptoms. Because user feedback is such an essential part of the EH Tracker service, we designed a user friendly feedback mechanism that captures information about a user’s health when it is needed. For example, if a user is in an environment with a high pollen count the feedback mechanism may ask them about how they are feeling and which medications, if any, they have or will take. The machine learning algorithm then uses this information to predict the user’s susceptibility to pollen. If they are susceptible the app will notify the user of any future pollen health risks, and summarize their health history information for healthcare professionals.

User Profiles (Supplementary Figure 3). Creating user profiles is essential to the customization of the EH Tracker user interface. Profiles enable the user to have control over much of the information that is displayed after they log in. The creation of the profile page specifically identifies the user’s name, contact information, alert settings, and current medications. It also confirms the sharing of information with other users, and the option to view their own current health status. In addition, the profile page is specific to the type of user using the system. We have identified two main users: direct and indirect. The direct user is in direct contact with the system, such as a student, caregiver, or businessman/businesswoman. These direct users serve as application owners, and are the primary data
susceptible to environmental pollutants. These users have authorization to customize the features displayed in the EH Tracker user interface and are primary contributors to the daily feedback data. In contrast, the indirect users are consumers of information. These users include children or other persons with a caregiver who are unable to use the EH Tracker system. Another user who serves as both a direct and indirect user is the physician or healthcare provider. The physician or healthcare provider profile is able to integrate users’ electronic health record (EHR) information with the EH Tracker’s environmental and user feedback data to provide a comprehensive diagnosis and healthcare recommendation for users. In addition, the healthcare provider’s profile page allows for better patient-provider communication by supporting direct communication with their patients via email, phone, or in an open chat.

**Home page** (Supplementary Figure 1b). The EH Tracker homepage is the first page the user views when opening the app. The homepage serves as the user's brief look into the current status of environmental health hazard levels, access to other page views such as their current health status, links to the prevalent pre-dominant pollen allergens information, notifications for updated information from their healthcare provider or loved one (see Supplementary Figure 1b). Environmental hazard information related to air pollution such as ozone and particulate matter (PM2.5) air quality index ranges are indicated by colored clouds reflecting the Environmental Protection Agency’s Air Quality Index ranges of 0, “Good” with a green bar to 500, “Hazardous” indicated by a maroon color. The predominant pollen allergy type is also specified using a photo of the pollen plant species, and a gradient bar indicating level of severity on the impact of an individual’s health. Major features of the homepage also include the ability for physicians to assist with prescribing and notifying patients about recommended medications, and the ability for users to briefly view actionable information they may be able to include in their day, such as running recycled air in their car or wearing a mask when they go outside during certain times of day.

**Implementation and Evaluation plan**

![Timeline for implementation and evaluation](image)

**Figure 2.** Timeline for implementation and evaluation. Each development phase has implementing features, conducting usability test, releasing, conducting post-user survey, and fixing identified defects. See Supplementary Figure 4 for the detail.

To continually help individuals that are susceptible to environmental pollutants we developed a detailed implementation and evaluation plan for our solution. To date, much of the work has been completed. At the beginning of April we performed in depth background research to converge upon a problem statement and set of primary, secondary, and tertiary stakeholders. To gain a better understanding of these stakeholders, we leveraged design literature to guide the development of three personas (see Supplementary Figure 5-7) and several scenarios (see Supplementary Figure Box 1). These artifacts were then used to aid in the development of a detailed evaluation plan.

Our evaluation plan (see Supplementary Figure Box 3) describes design characteristics, methods, and procedures for evaluating our first design iteration—the product of our first development phase. We plan to revisit the plan during the first development phase to address any changes between now and then. In this day and age users’ needs can change quickly, highlighting the importance of iterative design. We plan to use this methodology to continually monitor and understand user needs, and maintain confidence that we are building the best solution for individuals susceptible to environmental pollutants. In addition, we plan to conduct a similar evaluation as part of each
following development phase. Continual evaluation will help our research identify design problems, increase understanding of our users’ needs, and increase the value added to the collection of environmental health research artifacts used by other researchers in this area.

**Conclusion**

In this abstract we present the EH tracker—a cross platform application that provides user-specific health information to individuals at risk of environmental pollutants by leveraging user interactions, machine learning algorithms, and multiple dynamic environmental health data streams. EH Tracker’s ability to present users with actionable data that’s specific to their environmental health needs is what sets it apart from existing apps, and what makes it essential for individuals affected by environmental pollutants. We believe that EH tracker is better positioned to help consumers make environmentally conscious health decisions. By merging user-specific data with environmental data, the system will present more accurate predictions accompanied by actionable information based on user-specific trends. In addition, EH tracker will aid in effective patient-clinician communication by exporting user feedback and health history in a structured format. With detailed information about environmental hazards and patient symptoms, clinicians can use EH Tracker summaries to facilitate understanding symptoms, formulate diagnoses, discuss personalized treatment options, and improve patient care.

Demographics
- **Age:** 33 years old
- **Marital Status:** Married
- **Children:** 1 kid (8 months old)
- **Pets:** none
- **Location:** Chicago, IL -> Atlanta, GA
- **Occupation:** Public Health Researcher
- **Income:** $65,000
- **Education:** Spelman College and Univ. of Michigan

Health Status
- **Allergies:** Pollen, Dust, and Air Pollutants
- **Diseases:** Asthma
- **Medication(s):**
  - Advair or Symbicort; Albuterol; Systemic corticosteroids
  - (depending on severity of symptoms)
- **Physical Activities:** not physically active; trying to avoid any asthma attacks

Her Life
- Frequently checks email
- Daughter has frequent ear infections while at daycare.
- Loves to dance and garden, but doesn't have the time or energy
- Passionate about career but requires her to work long hours, and occasionally travel.

Environmentally Conscious
- Knows that pollution affects her asthma.
- Does not know how to better her health other than through taking medication.
- Checks weather updates to prepare proper attire for herself and her child
- Does not have time to become well-versed in environmental health; relies on clinical information.
Supplementary Figure 6. Persona of young active user
Supplementary Figure 7. Persona of frequent traveler
Supplementary Figure 8. Overall design for the alternative solution
Supplementary Box 1. Value-sensitive scenarios for the EH Tracker

Scenario 1: The Parent
Claire is a helicopter parent who does not have time to check on her 2 year old child while at daycare. Her 2 year old has increasingly severe reactions such as runny nose, puffy, red eyes, and the oozing of mucus coming out of her ears. These symptoms are also accompanied by fevers and frequent ear infections. When she inquires with the daycare provider about when and how these symptoms have occurred, the daycare provider tells her she is unsure. The daycare provider then explains that if her 2 year old continues to exhibit these symptoms, she will have to take her child to the doctor and her child will not be able to come back to the daycare without a cleared doctor's notice. Claire usually is unable to take time off of work due to budget cuts that left the office short staffed. Thus, she feels hopeless in finding ways to track and prevent her child's allergic reactions. She does not want to jeopardize her job by having to take off of work. Claire decides to call her healthcare provider to see if there is another option she can use to help monitor her child's allergic reactions. The doctor tells her to download the environmental health tracker app which may better assist her in managing her child's allergic reactions. The mother shares this information with her daycare provider to ensure that they are well-informed about the possibility of her child exhibiting symptoms today and the appropriate medications to use. Once the child is at daycare, the mother is able to be alerted by the app when the daycare provider selects different symptoms her child may be presenting and/or if any medication was taken. This information is shared with the pediatrician, as well.

The next day, as she is cooking breakfast, she is alerted by a message on her phone. The EH Tracker suggests that the ozone and particulate matter levels, pollen count and type of pollen may affect her and her child that day. From the air pollution levels, the app makes the suggestion to make sure she uses re-cycled air when running her car's air conditioning. From the pollen forecast, the app then makes suggestions about possible medications like Benadryl that the child should take if an allergic reaction occurs. Given the side effects on the medication, it also tells her when may be the appropriate time to take the medication (such as 30 minutes before nap time). The mother shares this information with her daycare provider to ensure that they are well-informed about the possibility of her child exhibiting symptoms today and the appropriate medications to use. Once the child is at daycare, the mother is able to be alerted by the app when the daycare provider selects different symptoms her child may be presenting and/or if any medication was taken. This information is shared with the pediatrician, as well.

Scenario 2: The Traveler
Kenneth receives an email on his phone with the time and location of his upcoming meeting. In an effort to stay organized and have a reminder to attend the meeting, he clicks on a hyperlink in the email which adds an event to his calendar. After the event is added, the Environmental Health (EH) Tracker pop-up window appears on his mobile device and asks him if he wants to add any EH Tracker alerts to his calendar for that day. Simultaneously, the tracker also provides more information about the predicted discomfort he will suffer based on prior data about his health conditions, including previous interactions with environmental pollutants. Since the EH tracker predicted a high discomfort score, he decided to add the EH Tracker alert to his calendar. The night before the meeting the EH Tracker alert popped up with a more accurate, high discomfort score. Unfortunately, he ran out of medication, so he opens the app and clicks on the prepared button. The EH Tracker launches the navigation service and provides locations where he can buy his medication near his travel route. He decides to buy Zyrtec at the Walgreen next to his meeting location. On his way back home after work, the EH Tracker pops up on his phone to ask him about his experience that day. He provides specific information about his experience that day, not by typing, but by selecting choices. He indicates that (1) he had a swollen nose, (2) it was not significant enough to take his medication, and (3) that he may be allergic to a specific type of pollen that he suspects is causing his symptoms. The tracker also provides a way to log the estimated exposure time for the pollen.
Scenario 3: The Student

Dave wakes up in the morning and heads to the bathroom to wash up and brush his teeth. While he brushes his teeth he thinks about his schedule for the day--school, then home. As he finishes up in the bathroom he spots the allergy medicine he's been trying out next to the sink, but ignores it since his day will be spent primarily indoors. He heads back to his room, gets dressed, grabs his things and prepares to head to school. When he picks up his phone he notices an alert from the environmental health tracker app--it's notifying him of a high pollen count in a nearby city. He wonders why he received the alert, so he selects it to find out more. To his surprise the app remembered he had a soccer game in a nearby city, and suggested he take his medicine as a precaution since last time he was in an area with high pollen count he suffered from a runny nose and frequent sneezing. Feeling well informed, he grabs his medicine before heading to school.

Later that night Dave receives another alert asking him how his day went. He selects the alert, and when the app opens he presses the smiley face, indicating he had an allergy free day. The app then suggests with high confidence that Dave is allergic pollen, and shows him his past responses that led to this conclusion--on several occasions Dave pressed the sad face when he was in areas with high pollen counts. Dave appreciates that the app remembered his responses and used them to help him stay healthy over time. He is confident that the app's notifications and apparent machine learning algorithm will help him improve his health and quality of life. From now on he plans to check the app first thing when he wakes up.

</table>
Supplementary Box 3. Detailed evaluation plan for EH Tracker

In order to successfully design and maintain such a complex system for our diverse set of target users, our system will need to be evaluated continuously. This evaluation, the first of many, has several goals: 1) to define the characteristics of the EH Tracker design that will be measured, 2) to define methodology for measuring each EH Tracker characteristic, 3) to define administrative and participant evaluation procedures, and 4) to provide justifications for goals 1-3. It is our hope that successfully meeting each of these goals will guide a well-executed evaluation of the EH Tracker that helps our research team identify design problems, increase our understanding of user needs, and add to the collection of environmental health research artifacts that can be used by future research.

Design Characteristics

This evaluation targets the following design characteristics: ease of use, usefulness, action potential, and clarity. They were chosen for measurement based on their importance to users and to the overall system. It is imperative that the EH Tracker is easy to use. If users find the EH Tracker system difficult to use they may stop using it and miss out on its potential health benefits. In addition to being easy to use our system needs to provide useful information. Our overall goal, as stated in the introduction, is to enable our users to better understand how pollutants affect their health. Our assumption is that users who find this app useful will reap health benefits from such a detailed understanding of their environment. The underlying mechanism for health improvement in the EH Tracker system is behavioral change experienced through the provisioning of clear, actionable information. When a user is threatened by exposure to environmental pollutants, the EH Tracker needs to inform the user of the potential threat to their health and of steps they can take to avoid it. It is clear that each design characteristic plays a fundamental role in how the target users interact with the EH Tracker system. Thus, in addition to understanding these design characteristics, we also need to understand the design features that embody them.

In the context of this paper, a design feature is the manifestation of one or more design characteristics, and a design session is the evaluation of a single design feature. Thus, we can use a design session to simultaneously evaluate a single design feature and set of design characteristics. Design sessions will be created for the following design features: reminders, alerts, feedback entry, and the summary view. These features were chosen for two reasons: 1) each is comprised of measurable, target design characteristics, and 2) they are core features--the pillars of functionality that stand up the rest of the system—and therefore they are the most important features to evaluate. Table 1 defines each design feature and specifies the set of design characteristics that they will measure. Issues that are found during the evaluation of each feature will be cataloged and used to improve the feature after the session is complete. For example, if during the alert session users find that an alert icon is non-specific and confusing, evaluators will take note and use the user feedback to improve the design of the icon after the evaluation is complete. As a result, by validating design characteristics within core design features—the features that enable the rest of the system to function—we get the added benefit of improving the features that are the most important to the EH Tracker’s design.

Methods

Each design session will conduct a user based usability study followed by a user survey. The goal of each session is to better understand how users interact with and feel about the design features and characteristics under test. We chose to analyze our design features and characteristics in usability studies (instead of using another evaluation methodology) because evaluating how our users interact with our system in a controlled environment is an imperative insight to gain at this stage in the design process. At this point in our design development we have conducted extensive user research and developed detailed personas, scenarios, and prototypes, but we have not yet put our designs in front of users. Before we spend more time and energy further developing our designs we need to understand how our users interact with what we have. A user based usability study was chosen, as opposed to an expert based or automated usability study, because it's an affordable way for the evaluators to observe and record actual users of the EH Tracker system. An automated usability study would not allow us to capture real users using our system, and recruiting users in an expert based study would be difficult given that the EH Tracker system is in its infancy.
Supplementary Box 3. Continued

Following each usability study, a survey will be given to users to solicit feelings about the performed usability task. Surveys were chosen because they are a cheap yet effective way to capture detailed user feelings, which we will pair with our observations from the usability study to strengthen the results of our measurements.

Each design session, composed of a usability study followed by a survey, has the potential to provide a detailed understanding about specific user needs. Thus, it is imperative that each session is executed successfully. Below we define procedures for evaluators and participant to follow to increase the likelihood of a successful evaluation.

Procedure

Each evaluator will follow a set of procedures to conduct each design session, and each participant will be given a set of instructions to follow in order to successfully participate in the usability study and survey. At the beginning of each session evaluators will receive user consent to record the session on video. Once recording begins evaluators will provide participants with instructions on how to complete the usability study. These instructions will include how to properly use any devices, how to interpret the usability task description (see Supplementary Table 4), and other information specific to the usability task being tested. Users will be given adequate time to digest the instructions and read the scenario description. When the evaluators feel each user is adequately prepared to perform the usability task, the test will begin. Task completion time will be recorded for each user, then used to measure ease of use--each time will be compared to a predefined benchmark associated with the task. A time greater than the benchmark indicates the task took the user longer than expected and may be difficult to perform. A time less than the benchmark indicates the task took the user less time than expected and may be easy to perform. Right after usability tasks are complete, evaluators will hand out a short survey to each user containing questions about the task they just completed. Users will be asked to fill out the survey to the best of their ability, and will be given enough time to do so. When users are finished, evaluators will collect their surveys and catalog them for the research team to analyze when all design sessions are complete.

Supplementary Table 4. The usability tasks that users will be asked to carry out on each design feature, and the design characteristics that will be evaluated in each design feature.

Improving user engagement and insight through Contextualized Quantified Self

Tiffany J. Callahan, BA\textsuperscript{1,3*}, Tal Lorberbaum, BS\textsuperscript{2,3*}, Alexandre Yahi, MS\textsuperscript{2,3*}
\textsuperscript{1}University of Colorado Denver, Anschutz Medical Campus, Aurora, CO; \textsuperscript{2}Department of Biomedical Informatics, Columbia University, New York, NY; \textsuperscript{3}Plurl Health (http://www.plurlhealth.com)
* These authors contributed equally to the work; order is alphabetical.

Definition of the selected challenge related to the interaction between humans and data-analytic systems
The proliferation of smartphones and commoditization of health sensors (including step trackers, heart rate sensors, and blood pressure monitors) has enabled a process of self-digitization known as the “quantified self” (QS).\textsuperscript{1} The QS movement has caught the attention of the research community seeing in self-quantification systems (SQS)\textsuperscript{2} an opportunity to tackle P4 Medicine issues (i.e. predictive, preventive, personalized and participatory)\textsuperscript{3} by exploring the unique datasets generated by QS users.\textsuperscript{4,5} Companies such as Fitbit, Jawbone, Misfit, Withings, Apple, and others sell a range of reliable health and lifestyle tracking sensors\textsuperscript{6} and accompanying applications which have been met with sales exceeding 43 million units\textsuperscript{7} in 2015 and predicted to reach over 100 million by 2017.\textsuperscript{8} Coupled with health apps such as MyFitnessPal, Moves, and Lifesum, this ecosystem promises to combine lifestyle data and analytics to derive insights into health and suggestions for improvement.\textsuperscript{9}

However, a recent study highlights the striking reality that half of activity tracker owners stop using their devices, and one-third stop after only six months.\textsuperscript{10} The early-stage venture fund Rock Health recently suggested one of the potential reasons for this drop: wearable devices makers usually leave the use cases of their product to the imagination of their customers.\textsuperscript{9} Among the many challenges that need to be addressed, building software that identifies meaning in lifestyle data and can close the loop to provide actionable suggestions is critical. In addition, the market is very fragmented with apps and devices that are either single-purpose or so oriented towards the general market that they end up providing no insights at all. A population of core users called Quantified-selfers has overcome the multiple barriers discouraging many users\textsuperscript{11} but several pitfalls remain unaddressed. These include poor interface design (e.g. complicated data entry menus) and insufficient analytics in determining lifestyle patterns that are predictive of phenotypes important to the user.\textsuperscript{12} Apps often strive for entry granularity that is so high that it creates a burden on users, leading to less data collected than if the entry process were streamlined.\textsuperscript{13} Additionally, current data visualizations are limited to progress bars and individual plots for each dimension of data, making it challenging to observe trends in lifestyle data and opportunities for changes.\textsuperscript{14} Users often view their data in a vacuum with no context, making algorithmic suggestions for improvement unclear and further contributing to issues with user acceptance.\textsuperscript{15}

We propose an interactive user interface for Contextualized Quantified-Self (CQS). This interface puts quantitative and qualitative user data in the context of the user’s activities (e.g. meetings), environment (e.g. weather, pollution), and other users. By representing a user’s day with a unique visualization, it is possible to go beyond the “what to do” and break it up into actionable tasks to guide the user on “how to do it” when associated with a Learning Health System (LHS).\textsuperscript{16}

We present this visualization system’s ability to compare a day between users and between a user and a group using high blood pressure (HBP) as a case study.

Identified health problem
According to the American Heart Association, roughly 78 million American adults have high blood pressure (BP),\textsuperscript{17} only half of which have their high BP under control.\textsuperscript{18} What is more shocking is that in 2010 alone, more than 362,895 American adults died from high BP-related major cardiovascular disease,\textsuperscript{19} leading to an estimated cost of over $69.9 billion dollars.\textsuperscript{20} High BP can be diagnosed by a healthcare provider at a hospital, clinic or even at a local health fair. While the health risks of untreated high BP are concerning, it can be prevented and controlled. In fact, roughly 46,000 deaths each year could be prevented if 70% of adults with high BP received appropriate treatment.\textsuperscript{21} The American Heart Association made hypertension a primary focus of its 2014-2017 strategic plan and is hoping to improve cardiovascular health by 20% through reducing cardiovascular disease and stroke by 20% by 2010.\textsuperscript{22}
The Healthcare Effectiveness Data and Information Set (HEDIS) quality indicator is measured by determining, “the percentage of members 18 years of age and older who had a diagnosis of hypertension (HTN) and whose BP was adequately controlled during the measurement year using the following criteria”.

We believe that such an interactive system can have an impact on this type of quality indicators by displaying both recommended measurements and encouraging self-tracking. A versatile platform able to support a LHS for wellness is more likely to engage a patient to monitor his/her physiological parameters and could help hospitals reach out to their outpatient population.

Figure 1: Overview of Contextualized Quantified Self (CQS) visualization. (A) User interface displaying calendar (top), Day Ring (center), and Goals Panel (bottom). Each entry is added to the user’s timeline (Blue arc: sleep; red curves: steps with exercise intensity; pins: blood pressure measurement, meals, mood, water). The user’s day is surrounded by environmental information (e.g. weather). Personalized daily goals generated using a Learning Health System aggregating many users’ data are presented as a checklist, and the user can tap on the button to the right of each goal to see its justification. Remaining goals are listed as “ghost entries” on the timeline providing a suggested time for completion. Detail View in center displays additional information. (B) One vs. one comparison view allowing a user to compare him/herself against their activity on a previous day. Green bars indicate lines of agreement; red bars indicate discordant times and opportunities for improvement. (C) One vs. many comparison view. Inner circle displays time range during which team has completed activities. Textual summaries are also included for motivation.

Description of the proposed solution
We designed this interface to work with a Learning Health System (LHS) providing personalized goals leading to a long-term objective, and suggested time-dependent tasks on the visualization as guides toward goal completion. While the specifications of the LHS are beyond the scope of this design challenge, we will generate personalized daily goals for each user by comparing him or her against similar users to find lifestyles that are predictive of improved outcomes for the given objective. We then wish to display the results of these analytics in a clear and consolidated way. To do this, our interface is composed of three elements: the central Day Ring, the calendar at the top, and the Goals Panel at the bottom (Figure 1).
The central Day Ring contains several elements that allow the user to quickly see their data in context, view temporal relationships between their data, and see remaining goals for the day. A 24-hour clock contains the user’s timeline for a given day. Instead of treating each data type as its own isolated graph, we acknowledge and highlight the temporal relationships between different data types by displaying each actively or passively logged entry (including sleep, steps, meals, drinks, mood, and blood pressure measurements) sequentially on the timeline (Figure 1A). A user can tap on any entry to view more detail. Remaining goals from the LHS and suggested times for their completion are displayed on the user’s timeline as “ghost entries” that summarize the context-driven goals generated from many users back onto each individual user’s timeline.

The Day Ring supports three types of comparison: one versus one (e.g. one user against a previous day or one user versus another user), one vs. many (e.g. one user against the day of their team), and many vs. many (e.g. their team compared to the entire user population). In the center of the Day Ring is a Detail View that allows the user to see progress towards completing their goal, detailed measurement information, and environmental data such as the weather forecast.

Above the Day Ring is a calendar from which users can elect to display their previous days. At the bottom of the page, a panel displays the goals for that day. Unlike many QS apps where users must laboriously keep a diary, our interface represents goals using a checklist format that automatically updates when they have been reached. This rationale conveys more closure, and each goal can be expanded to get access to its algorithmic justification. The ability to expand goals to view the analytic basis for their inclusion will help relieve symptoms of the “black box” models and invite users to understand the rationale for suggested lifestyle changes.

Using our case study of monitoring blood pressure, our goals would take into account common recommendations for blood pressure measurement (e.g. consistent time of day for measurement, frequency of measurement, leaving adequate time after awakening and before meals and exercise to measure blood pressure) as well as diet and exercise suggestions. We will also be able to leverage environmental factors such as weather or pollen levels to suggest appropriate times for achieving exercise requirements for the day. Finally, lifestyle patterns identified using our LHS for both a user over time as well as multiple similar users would be summarized in the daily goals and ghost entries.

**Discussion of alternative solutions considered**

As alternatives we considered bar graph solutions as well as different shapes for the timeline. Bar graphs would entail having an individual chart for each data type collected. We also considered alternate shapes for the timeline as well as simplifications such as grouping times into morning, afternoon, and evening. Finally, we iterated on the proposed solution, beginning with just the timeline before adding the Detail View and environmental data. This was inspired by our realization that it was necessary to correlate a user’s activities with external factors such as environment.

**Discussion of the strengths and weakness of the chosen solution as compared to the alternatives**

The major strength of our design is that it can be adapted to a variety of screen sizes including smartphones and smart watches. The concentric design is adapted to concisely visualize multiple layers of information (e.g. physical activity, meals, sleep, mood, beverages, schedule, and environment). The weakness is that users may not be familiar seeing data visualized in this way compared to standard visualizations such as bar graphs. However, we believe that seeing many dimensions of data consolidated together will facilitate better understanding of the emergent trends our LHS finds in the data.

**Proposed implementation and dissemination plan**

As mentioned above, this interactive visualization interface is designed to directly interact with a LHS that, for a given objective, compares one user to many similar users to provide personalized daily goals broken up into time-dependent tasks displayed on the Day Ring. To this end, we are actively implementing the presented design in the form of an iOS app. Users will contribute both passively collected data (e.g. steps and sleep from wearable devices that communicate with HealthKit) and actively collected data (entered using a majorly optimized and simplified data entry menu also beyond the scope of this abstract). The data generated by users will be stored on a HIPAA-compliant server. This implementation is scalable since both the data storage and computing power necessary to support the LHS will grow with the user base. We will disseminate the app through Apple’s App Store.
Proposed evaluation plan
This interactive visualization interface aims to be objective-agnostic and therefore fulfill the expectations of a wide variety of profiles. We identified three different sub-populations for evaluation: users with no chronic medical conditions and not used to practicing self-tracking, core quantified-selfers already engaged in one or several SQS, and users with high blood pressure who require frequent monitoring. The recruitment of these users will go through an IRB protocol and they will sign a consent form to agree on sharing their data after de-identification.

Supplementary video demoing the visualization features can be found at:

Take a Breather: Empowering Adherence & Patient Centered Research Through Interactive Data Visualization, Social Engagement, & Gamification in Patients with Sleep Apnea

Ashley Choi, Benjamin Cordier, Prerna Das, Jason Li
Division of Bioinformatics and Computational Biology
Department of Medical Informatics & Clinical Epidemiology
Oregon Health & Science University, Portland, OR

Abstract

Sleep apnea is a chronic condition that affects over 100 million people worldwide, lowering their quality of life and productivity. Treatment of sleep apnea involves long-term management characterized by regular usage of a continuous positive airway pressure (CPAP) device and lifestyle modifications, such as reducing alcohol consumption and promoting weight loss through exercise and dietary adjustments. Together, these treatments have been shown to be highly effective in alleviating sleep apnea, however, adherence to CPAP therapy remains a primary obstacle to treatment success. To encourage adherence, we propose an interactive dashboard application that provides support and empowers patients to take ownership of their treatment regimen. Using this dashboard, patients will log their CPAP usage hours alongside biometric data (e.g. weight, blood pressure, heart rate) and sleep quality measures on a regular basis. From this effort, patients will gain the ability to visualize their health data and progress over time, in addition to being able to compare their advances to that of the overall cohort of participating patients. Patients will further be rewarded with socially visible awards for achieving preset health and community participation benchmarks. We expect that this application will encourage sleep apnea patients to participate in their own healthcare and take charge of their treatment plans. It is hoped that by fostering such positive dynamics, patients will experience improved health outcomes and quality of life.

Summary

With a geographically consistent prevalence of 4% in men and 2% in women, it is estimated that over 430 million people worldwide (and over 19 million in the United States) are affected by sleep apnea, with many remaining undiagnosed (1). Sleep apnea is characterized by the frequent occurrence of nighttime apneas, with an apnea defined as an episode of complete or near complete cessation of airflow due to upper respiratory collapse lasting at least 10 seconds (1). Perhaps of greatest concern, sleep apnea is associated with numerous serious health concerns such as hypertension, stroke, cardiovascular disease, diminished neurocognitive function, insulin resistance (1, 2), and sleep fragmentation, which has been found to increase the risk for motor vehicle accidents and a reduced quality of life (3).

As prevalence and awareness have increased, there has been continued focus on treatment options (4). Fortunately, effective treatments for sleep apnea do exist. Research has shown a linear relationship between the hours of CPAP use and improvements in quality of life and sleep (5). Similarly, it has been found that weight loss and abstinence from alcohol may reduce symptoms (1, 6). Yet, despite the established effectiveness of CPAP therapy, adherence remains a significant barrier to the treatment of this condition with compliance potentially being as low as 46% (7). Thus, a primary challenge in the management of sleep apnea and its associated risks are the adherence and long-term adoption of healthy behaviors to mitigate (and potentially eliminate) symptoms of the condition (8).

MyApnea.org, part of the Patient Centered Outcomes Research Institutes (PCORI) network, is focused on building a patient-centered community that empowers patients with sleep apnea to engage with sleep apnea research and facilitate adherence to their treatment plan. Despite being in the earlier stages of deployment, MyApnea has quickly gained traction with over 5,300 members and over 200 actively participating in MyApnea’s forum. Consequently, the desire to integrate features that engage users, encourage retention, and provide patients with a means of understanding their data in an intuitive fashion has grown significantly.

After connecting with the MyApnea team and assessing the user and site needs, we proposed the creation of an interactive dashboard with a data visualization centerpiece for MyApnea.org, with the aim of
fostering long-term engagement by patients with their health and treatment plan and encouraging user retention. While there are no universally agreed-upon feature sets or web design standards to achieve these objectives in the context of patient engagement, general principles and methodologies can be taken from popular, well-designed websites and web applications currently in existence. One such methodology that is widely employed by websites seeking to communicate novel ideas, complex datasets, or engage in data-driven storytelling is interactive visualization.

For the AMIA 2015 Student Design Challenge, our aim was to build a prototype of a tool capable of achieving these objectives. During our initial ideation, we came to feel that the integration of two additional methodologies would increase the potential of the tool achieving its objectives: social dynamics and gamification. Specifically, it was felt that by 1) providing users with the ability to compare personal progress with site-wide progress, a competition for better health may ensue and 2) allowing users to set their own personal health improvement goals, in addition to attaining preset, socially visible, shareable achievements, a sense of accomplishment and satisfaction—ultimately encouraging site engagement, retention, and perhaps treatment adherence—could be facilitated. Together, these features would be presented in an intuitive and appealing dashboard using established and readily comprehensible data visualization techniques.

The Challenge

MyApnea.org is part of a patient-powered research network that brings patients, doctors and researchers together to improve the health of patients with sleep apnea. There are currently about 5,300 registered members in every state of the U.S and in 41 countries worldwide, with an enrollment goal for the project of 50,000 patients. Within the site, there are information sections about sleep apnea and the various treatments, a community forum where users can interact with one another, and a Rank the Research tool where patients can influence the direction of sleep apnea research by voting for topics that they find to be relevant to their experience. Additionally, there are 11 research surveys that collect a wide variety of patient data regarding family history, health conditions, sleep patterns, sleep quality, and quality of life. Each survey has about 10 questions and, upon completion, shows the user their answers in the context of individual answers across the community using a pie chart visualization. At the time of writing, over 1,000 users have completed 36,000 surveys. To assess the needs of MyApnea, we consulted with the researchers, software developers, and a leader of the MyApnea participating patient cohort. Across these stakeholder groups, a commonly cited need was that of a feature to promote website retention; a critical component to achieve high-frequency, large cohort data collection and conduct an anticipated longitudinal study.

At the time of writing, the MyApnea team was working on implementing a semi-annual survey to collect data for the aforementioned longitudinal study, however, it was felt that a more frequent mode of engagement would be advantageous by allowing for more opportunities to collect data from participating sleep apnea patients. From such increased participation, a more complete record of each patient’s sleep apnea could be created and, perhaps, through research, a more granular understanding of the data could be yielded. This, along with the possible added benefit of increased nightly CPAP usage by the engaged patients. Thus, broadly, the challenge: Create a feature set capable of increasing patient engagement and data contribution and, if and when engagement does increase, have the feature set be capable of leveraging this engagement to create a positive feedback, further encouraging patient participation.

Evaluation of Possible Solutions

A number of methods were considered to increase user retention, including 1) providing new and regularly updated content, 2) building a community, 3) making a game-like experience, and 4) providing monetary incentives or similar benefits.

New and updated content can come in the form of either curated articles, as on a news site, or user-generated content (updates, photos, etc.) on a social media site. Given that news updates specific to sleep apnea may be fairly sparse, they represent an unreliable source of updated content. Consequently, the primary source of updated content would likely be user-generated, through each user’s own surveys, their regularly submitted health data, and similar site-wide data.

Online community building can come in the form of user forums, comments sections, and other forms of social media. Size often plays a significant role in the vibrancy of any community. Social sharing is a fantastic way of expanding a community and publicizing a website’s mission. By allowing users to share visualizations of their progress and achievement medals through social media websites such as Face-
book, Twitter, Instagram, etc. pre-existing personal connections within the MyApnea community are reinforced while the website is shared family and friends who may have similar interests or suffer from sleep apnea themselves.

Gamification is a serious business. Smartphone games such as Candy Crush Saga account for an estimated $30 billion in revenue worldwide in 2015 (9). According to a survey conducted in late 2014, people spent over 2 hours a day playing games on mobile devices, up from 1 hour and 20 minutes in 2012 (10). Often, there are no tangible rewards for playing these games, but the psychological boost from achieving predetermined goals or gaining the next level is addictive. Giving out rewards like badges and stars for completing surveys, filling out data forms, and CPAP use may be effective in bringing users back regularly. In addition, the use of progress bars to visualize distance to a future achievement has been shown to encourage user engagement.

Even with the inclusion of such modern retention methodologies, ultimately, MyApnea must benefit its users sleep apnea and overall health. The proposed visualization, alongside the stated methodologies, will help the patients on MyApnea improve their symptoms and quality of life by improving their understanding around the connection between BMI, alcohol, CPAP usage, and their sleep apnea while, hopefully, empowering them to adhere to their treatment plan.

**Conceptual Implementation of Solution**

Our proposal is for a web application to visualize user data on MyApnea.org. The application is divided into three main modules: Visualization (‘Progress’), User Input (‘Update’), and Gamification (‘Medals’).

**Visualization Module**

The first module is for the user-selected visualization; comprised of two time series charts, with the upper time series including biometric and CPAP data sources the lower time series including sleep quality measures. Data filters will be used to allow the user to visualize combinations of these data sources. The data sources that will be displayed include BMI, systolic blood pressure, diastolic blood pressure, heart rate, perceived daytime sleepiness, number of nighttime arousals, and perceived sleep quality. It is expected that, with increased CPAP usage, sleep quality will increase and daytime sleepiness will decrease. Additionally, there should also be an approximately inverse relationship between BMI and sleep quality. Aside the data filters, a data toggle will allow the user to select between only their data or a comparative visualization of their data against site-wide averages. From this, a user will be able to assess how they are doing in respect to all the users across the site, encouraging a personal goal of ‘beating the averages’. Finally, panning and zooming of the data will allow the user to hone in on points of interest, enabling a more granular examination of patterns in the data and, more generally, their progress.

**User Input Module:**

The middle module will be for users to enter their ‘daily’ data. It has input fields for weight, CPAP usage hours, systolic blood pressure (SBP), diastolic blood pressure (DBP), heart rate, perceived daytime sleepiness (1, i.e. very poor – 10, i.e. excellent), perceived sleep quality (1, i.e. very poor – 10, i.e. excellent), and the number of nighttime arousals. BMI is computed from the height provided in the surveys and the weight provided each time a user submits data. For best utility, the user should enter data daily. In the future implementation of this application, a user’s CPAP may be able to upload data and fill in several of the fields directly via a data card or USB cable.

**Gamification Module**

The bottom module will show the user’s achievements through points and star badges. Achievements will be given for the completion of milestones relating to community participation on MyApnea.org or for healthy behaviors, as indicated through data submitted through the input module. Each achievement will give the user a certain star badge, notifying them with a small pop-up notification. There will be progress bars below the stars to indicate progress toward the next milestone. For instance, responding to another user’s forum post earns a bronze badge for the category “Forum Friend”, while posting 10 times...
earns a silver badge. Similarly, to become a earn a gold star as a “CPAP Warrior”, one must submit CPAP usage data every day for 6 months. Other achievements include “Survey Samurai” for survey completion, “Data Dignitary” for daily data submission streaks, and “Thought Leader” for receiving up-votes for a research question posted using the Rank the Research tool, with many other possible titles to encourage user goals. These badges will be visible to other users on the forums, and will be able to be shared via a variety of social media platforms: when one earns a badge, a dialogue will prompt the user to share the achievement via Facebook, Twitter, or Instagram.

Survey Module

It should also be noted that we are currently engaged in an ongoing exploration of other visualization possibilities for the survey data. It is likely that if such a visualization is created, it will be done with a new Survey module.

Software Architecture

The underlying implementation will be a modified model-view-controller architecture (Figure 1.) Data entered will be posted to the server through a REST API using SSL encryption, ultimately updating a database of all the user data. The visualization module will be rendered using data requested from the server via the REST API, with the server making the appropriate query to the database. Currently, MyApnea.org is built on an Apache server using the Ruby on Rails framework, coupled with a PostgreSQL database. The front-end of the application will be implemented in MyApnea.org’s current responsive CSS framework.

Prototype Implementation and Evaluation Plan

The current prototype is a simplified, standalone version of the conceptual dashboard application. It is an illustrative example of the dashboard concept articulated above with the purpose of facilitating communication of the dashboard concept to the MyApnea team and participating patient cohort. At the time of writing, we are engaged in discussions with the MyApnea team regarding the possibility of integrating the dashboard concept into the MyApnea.org web application. Here is a link to the current iteration of the prototype.

Visualization Module

The primary difference between the prototype and the conceptual implementation described above, in regards to the data visualization module, is the absence of data source toggling; social data is not available in the prototype. In addition, the prototype is currently operating on mock data generated within the application. This mock data is generated on a ‘per patient’ basis and illustrates relationships within the data commonly seen in the real-world: systolic blood pressure is higher than diastolic blood pressure, BMI is a function of a person’s weight and height, increased CPAP usage results generally (with some noise) improves sleep quality, decreases daytime sleepiness, and decreases the number of nighttime arousals.

User Input Module

The prototype includes a simple UI mockup of the user input module with a web form containing data input fields and a submission button. With the current implementation, the user can fill out the data input fields of the form and click the submission button, however, no data will be sent to the server or saved to the database. Front-end validation of the input data has yet to be implemented, however, such validation will be implemented on any deployment of this module on the MyApnea.org website.

Gamification Module

While the user interface for this module is mostly functional, it is not data driven. Instead, alterations to the underlying code have been made to illustrate how the conceptual implementation might look once a user has achieved a number of medals. The social media component has yet to be implemented, too.
Survey Module

For the prototype, no survey module was developed. Exploration of possible uses for the survey data in the context of user engagement is ongoing.

Additional Technical Details

The server environment has been written in JavaScript using Node.js and the Express server framework for rapid prototyping. The software has been deployed using Heroku, a cloud-based platform-as-a-service (PaaS) host. The prototype is not responsive to browser and device screen dimensions, however, a live iteration would involve leveraging the pre-existing responsive CSS framework on MyApnea.org.

Evaluation

Evaluation will focus on garnering feedback from the stakeholders working on the MyApnea.org website. Feedback from the researchers and software developers building MyApnea has been, and will continue to be, critical to the dashboards success and upcoming integration with MyApnea.org, however, perhaps more importantly, a dialogue with the MyApnea patient cohort has begun regarding the prototypes usability, objectives, and the addition of features that users would like to see in upcoming iterations. Given the modular and extensible layout of the dashboard interface and underlying software architecture, it is possible that, from this feedback, this engagement may grow to include new modules that further encourage user engagement, retention, and perhaps an improved quality of life for its users.

Conclusion and Further Work

The proposed interactive web application will increase patient engagement, adherence, and retention. It will accomplish this through providing patients with a way to view their progress and compare themselves to site-wide averages, rewarding them for good health behaviors and adherence to their treatment plans using achievement badges. At the time of writing, a live, full-featured implementation has yet to be deployed to patients and undergo feedback-based development. Such iterations will likely be necessary to develop a tool that truly accomplished the outlined goals.

Currently, the conceptual dashboard only incorporates survey and patient-entered data sources, however, in the future, the MyApnea team anticipates collecting quantitative data through each user’s CPAP directly, which would likely prove an invaluable data source. As patients acclimate to the dashboard, they may appreciate having a means of easily uploading their sleep and CPAP usage data. Such an ability would lessen the time commitment when entering data and provide a quantitative, less bias confirmation that their behaviors are indeed improving their sleep health. Furthermore, the dashboard concept illustrated here has the potential to be expanded and adapted to data relevant to other health conditions, thereby making it a tool for any health website that wishes to increase patient engagement.
Figures

Figure 1. A representation of the dashboard concept’s underlying architecture. When the application is loaded, an initial request is made to the server using a custom REST API to retrieve the user data that drives the visualization and gamification modules. This data is created through user submissions using the Input module. After the user fills out the Input module’s form and clicks the submit button, the data is sent to the server layer. The data is then validated and processed into a record object that is representative of the database schema. The record object is then submitted to the database. It is from these records that data is pulled for the Visualization and Gamification modules.

3Association of Schools and Programs of Public Health (ASPPH), Washington, DC

1. Problem Definition
Public health and informatics practitioners are often required to apply and conduct a research that involves knowledge outside their expertise. Epidemiologists, for example, could be assigned a task to analyze the seasonal trend of influenza by studying Electronic Health Records(EHR), which requires certain information processing knowledge such as data structure, programming language(e.g. Python), and database management. There are various ways to acquire new knowledge: traditional methods such as taking lectures or reading books and papers, taking advantage of the information technology by searching the Web. Recently, thanks to the high-speed Internet, massive online open courses (MOOC) such as Coursera has gained much popularity. Such methods, however, assume that the user knows what to look for, as they all require a certain searching phase (e.g. need to search for the appropriate lecture, need to use the appropriate search keyword).

But what if the user does not know what to look for? It is very likely that the epidemiologist from the above example is not familiar with the terms such as Natural Language Processing, Python or NoSQL Database Management. Researchers from the medical/health field often face this problem these days, especially now that computing, statistical and analytic methods are actively being exploited. Effectively addressing this knowledge gap will help many interdisciplinary studies to be conducted with a smoother learning curve. This problem can be significantly alleviated by involving human interaction in the search process. For example, by describing his/her given task, the researcher can guide the machine to look for relevant learning materials. Also, the machine can take feedbacks from the user so that it can improve its performance as it repeats the search. Teaching relations between various concepts (or knowledge) to the machine can also help the user to navigate through the recommended learning materials, as opposed to scrolling through the list of results.

In this paper, we present I-SMILE, a project lead by the students of Georgia Institute of Technology in collaboration with the Centers for Disease Control and Prevention (CDC). I-SMILE is a similarity-based recommendation system that understands the task described by the user, and recommends relevant books, papers, online courses, and even human experts. The system utilizes the project description and also considers the expertise and learning profile of the user, what he/she searched for in the past, so as to better recommend the most relevant learning material to the user. The user can also search through concept taxonomy such as MeSH Tree to get a high-level understanding of relevant concepts and navigate through the recommended learning materials.

![Figure 1. System Architecture](image-url)
2. System Description

Figure 1 depicts the overall architecture of I-SMILE, grouped by high-level components. We will go over each component to describe the functionality and the design choices.

Data Collection & Indexing

I-SMILE takes advantage of various forms of learning materials that can be collected from the Internet. We have collected the course list and course descriptions from Coursera and Udacity, two popular MOOCs. Book descriptions were collected from Google Books, where MeSH terms were used as search keywords. Abstracts of papers and journals were collected from PubMed and PubMed central, again using the MeSH terms as search keywords. Additional educational materials and lectures were provided by the CDC. All collected learning materials are then processed using basic natural language processing (NLP) techniques such as lemmatization, and indexed into a traditional vector-space model information retrieval (IR) system.

User Profile

Users must create a user account in order to use I-SMILE service. Figure 2 (a) is the main page of the current version of I-SMILE. At the top is the Sign Up link, where the new user can create an account.

When first creating their accounts, users can also enter their skill sets and the level of proficiency for each skill. This information will be used in combination with the user feedback, which will be described later, to search for learning materials that specifically suit each user’s need. Specifically, the user profile and the user feedback is leveraged by collaborative filtering, a well-known recommendation algorithm. We plan to implement collaborative filtering module in the next development phase. The collaborative filtering module will play an important role in scoring the learning materials in the searching phase.
**Task Description Analysis (Problem Narrative Search)**

One of the key features of I-SMILE that involves human interaction is its ability to support narrative search. In the text box in Figure 2 (a), the user can provide a text that describes the task he/she needs to fulfill, and the machine will analyze it to extract important keywords. I-SMILE uses a part-of-speech (POS) tagger and a dependency parser from Stanford NLP group’s CoreNLP package. Given a text, the system analyzes the text to extract only noun phrases. Then, using a list of stop words, it removes/transforms the extracted noun phrases to produce only the most relevant, distinguished noun phrases, which are in turn used as search keywords. An example can be seen in Figure 2 (b), where extracted words are highlighted and added to the list on the right. The user can check the list and remove/add new keywords. We are currently adding a feature to use MeSH terms and document frequency of each word to improve the performance of keyword extraction.

Additionally, the system provides a list of MeSH terms that are most similar to each extracted noun phrase in order to help the user decide if he/she needs more search keywords. In Figure 2 (c), the system is suggesting MeSH terms that are most relevant to the word **natural**. You can see that **Natural Language Processing** placed on the top of the list.

**Social Networking (People and Resource Finder)**

I-SMILE differs from other recommendation/search engine in that it can find users who are working with, or worked with similar tasks. The motivation behind this feature is to promote collaboration and knowledge sharing between fellows working on similar projects. When the user performs a narrative search, the system stores the analyzed result of the user-given task description in its database. Then, when another user performs a narrative search, I-SMILE compares the analyzed result of the newly given task description with its stored results. The comparison is based on the Jaccard coefficient of the nouns extracted from task descriptions. If there is a certain level of similarity, the system generates a list of users who searched for that similar task description in the past. This feature involves exposing personal information such as user’s affiliation and user’s email address. Therefore, when first creating a user account, the user can opt-out to become unsearchable by other users.

**Search & Combine**

Using the phrases and words extracted from the Task Description Analysis phase, I-SMILE retrieves the relevant learning materials from its database based on the standard vector space model. The list of phrases and words are aggregated into an “or” search operation. In the next development phase, I-SMILE will also retrieve the recommended learning materials from the collaborative filtering module. Combining the results from the both modules, I-SMILE will return to the user the learning materials that are both relevant to the task description and suited to each user.

**Result Presentation & Navigation**

The combined results are by default presented in a traditional ranked list fashion, as can be seen in Figure 2 (d). The user can use the filter features on the left of the result page to selectively view the learning materials from specific sources. The list of users who searched for similar task descriptions is listed on the right side of the result page. By clicking the username, the current user can check the target user’s contact information and the task descriptions he/she searched for in the past.

If the user is not familiar with what he/she is searching for, then simply listing the retrieved learning materials in a relevancy order might not be very effective. Therefore, we plan to update I-SMILE so that it can import external concept taxonomy such as MeSH Tree. Once the system is given the taxonomy, it will link the documents in its database to each node of the taxonomy. After the search is performed and the system returns the learning materials to the user, he/she will be able to expand the taxonomy from left side of the search result page. Nodes that are relevant to the current search will be highlighted. By looking at the parent and child nodes of the highlighted nodes, the user can get an overview of the knowledge structure. The user will also be able select or de-select the nodes of the taxonomy, and the search result will change accordingly. Each time the user highlights or de-highlights a node, the previous search keywords will be modified, and the new search will be performed to match the current state of the taxonomy tree.

**User Feedback**

The user can give explicit feedback to the system by using the star-rating system, as can be seen in Figure 2 (d). If he/she finds a certain learning material useful/useless, he/she can give a rating to that specific learning material. I-
SMILE, however, can also take advantage of implicit user feedback, namely the click-through data. Although not as obvious as the star-rating system, a user clicking a certain learning material is also a form of feedback. I-SMILE stores this click-through information and uses this in combination with the user profile to perform recommendation based on collaborative filtering. Explicit feedback based on the star-rating system is utilized as a measure of evaluation, which will be discussed later. Click-through data can also be used as a measure for evaluation as well.

3. Comparison with Alternative Solutions

I-SMILE provides an interactive experience for the user. The important features of this system can be better understood in comparison with currently available alternatives for learning new knowledge.

Google Search

Google returns the search result as a list of links to articles/pictures/videos. Google search expect short phrases as query and does not work with long queries such as project description as in our case. Google search does not differentiate the sources of the results since everything is presented in a single ranked list.

I-SMILE periodically collects high quality learning materials from chosen sources, and makes them available to the user by combining both content-based vector space model and personalized collaborative filtering. This enables I-SMILE to provide new learning materials readily to users while considering the characteristic of each user.

The most important distinction between I-SMILE and Google search, however, is that the user can perform the search based on his/her task description, which does not force the user to be familiar with what he/she wants to learn.

MOOC Courses

Another way of learning new knowledge is to search for courses on MOOC sites such as Coursera or Udacity. A great feature of this learning method is that in some cases, the user might be able to network with his peers who are taking similar courses and help each other learn through collaboration, which motivated us to implement a networking feature of I-SMILE as described above.

Searching for online courses, however, also requires the user to know the proper search keywords in advance. Furthermore, typical MOOC websites only provide lecture videos, which are not always the best method to learn. Videos cannot be searched by its content, forcing the user to search lectures by their descriptions. I-SMILE provides multiple forms of high quality learning materials, including videos from two popular MOOC sites. Such availability enables the user to choose the learning medium with which he/she is comfortable.

Limitation

I-SMILE requires advanced NLP techniques to extract important keywords from the task description. Currently, the system uses Stanford CoreNLP package, which provides the state-of-the-art NLP modules such as a POS tagger and a dependency parser. These are, however, developed for general use cases, and therefore are vulnerable to very domain-specific text. For example, if the user-provided task description contains a lot of domain-specific acronyms or jargons, the NLP module will not be able to recognize them properly, leading to suboptimal results. The user can still modify the extracted keywords, but it will not be very effective without the domain knowledge.

This problem can be resolved if there are available training data to re-train the NLP modules for the target domain. Such training data, however, require considerable amount of time and money to build. In future, we plan to explore the recent neural network word representation models, which can be trained in an unsupervised fashion. Incorporating the word representations as features to the traditional NLP methods has proven to be quite effective. Word representations can also be utilized in other ways such query expansion or automatic construction of concept taxonomy.

4. Implementation and Dissemination

I-SMILE is an active ongoing project, being developed and tested on Amazon Web Service (AWS) cloud computing environment. Our system is exposed as a web application and the user can access the service by a web browser, without having to install any additional software. The back-end of the system is implemented mostly in Python, and the front-end in standard HTML and Javascript for web browser compatibility. We chose MongoDB to store the raw descriptions of the learning materials, and ElasticSearch to serve as the standard IR system. Both MongoDB and ElasticSearch are designed to be highly scalable and lightweight, which makes it very easy to expand I-SMILE to hold enormous amount of learning materials and serve the user in real-time. Furthermore, thanks to the flexible and
efficient cloud-based environment, large-scale deployment is as simple as adding more machines to the current cluster.

In the future, we plan to create VM images of the machine instances in our deployment environment for services providers who need a customized system. A new I-SMILE instance can be easily launched using the images we provide. Within minutes, they will have their own system running in their own infrastructure. We believe this feature will facilitate the adoption of I-SMILE. For example, organizations that manage sensitive data, such as research institutes will be able to safely operate the system by launching the image on their infrastructure and importing their internal documents and user profiles into the system without exposure to external users.

5. Evaluation Strategy

By regarding I-SMILE as a vertical search engine, conventional evaluation metrics for IR systems can be applied to evaluate I-SMILE. We plan to evaluate the system based-on both explicit and implicit user feedback with 50 informatics fellow from CDC (note that two fellows participated in this project from the start)

Evaluation with explicit feedback

We can construct an evaluation dataset by collecting the star-rating feedback by the user. For each recommended document \( d \), we associate it with the input task description \( q \) and the rating score \( s \) from user \( u \). Initially, we will ask the CDC fellows to carefully evaluate top 30 results for each of the 20 task descriptions and at least 3 different users should have a consensus in terms of result rating to give us reliable data for evaluation. Then we could measure the performance of our system with below metrics.

1. Precision measures the percentage of relevant document in a ranked list. We are interested in precision@1, precision@5, prediction@10, where precision@k is defined as below.

\[
\text{precision}@k = \frac{\#\text{relevant document in top-}k}{k}
\]

2. Discounted cumulative gain will take the score into consideration. The \( s_i \) in below equation is the rating of the material at position \( i \). Clearly, DCG gives more importance to higher-ranked documents. This is important because the user is unlikely to scroll down or even move to the next page to find interesting learning material if they can’t find one in the top ranks.

\[
\text{DCG}@k = s_1 + \sum_{i=2}^{k} \frac{s_i}{\log_2 i}
\]

Evaluation with implicit feedback

Though explicit feedbacks provide more accurate and reliable data for evaluation, collecting them requires considerable resources, which makes them inappropriate for a constantly changing project such as I-SMILE. We also plan to evaluate the system with implicit feedbacks, namely click-through data. The assumption behind this evaluation is that higher-ranked documents that are not clicked are less relevant than lower-ranked ones that are clicked. For example, given a list of learning materials \( (d_1, d_2, d_3, d_4) \), if only \( d_3 \) is clicked, it is believed that \( d_3 \) is more relevant than \( d_1, d_2 \). We maintain a database to record the click information of the user to leverage them in the future as a dataset for evaluation.

6. Conclusion

In this paper, we presented I-SMILE, a novel recommendation system that facilitates learning new knowledge for users who are unfamiliar with the target domain. I-SMILE employs various strategies based on NLP techniques to provide description-based search, social networking, customized search results, and taxonomy based result navigation. In the future, we plan to apply more advanced method such Deep Learning to improve the system’s capability to understand domain-specific task descriptions.

Learning from the Data: Exploring a Hepatocellular Carcinoma Registry Using Visual Analytics to Improve Multidisciplinary Clinical Decision-Making

Michelle Hribar PhD, L. Nelson Sanchez-Pinto MD, Kate Fultz Hollis MS, Gene Ren, Deborah Woodcock MBA
Department of Medical Informatics & Clinical Epidemiology
Oregon Health & Science University, Portland, OR

Summary

Collaboration among cancer care providers -- often done in multidisciplinary conferences -- can improve patient care. However, managing the data associated with these conferences is difficult and there is often limited access to national level data for treatment decisions (e.g., national cancer registries). We propose a novel method for developing data visualizations and visual analytic tools to explore hepatocellular carcinoma (HCC) data from a national registry and implement them in the clinical workflow of multidisciplinary conferences. The HCC Data Visualization Repository and Clinical Tool will allow clinicians to extract complex information from HCC data using custom-designed visualizations. This solution would be extensible to other cancers and disease groups, and could significantly improve patient care. An interactive prototype of the repository may be accessed at http://hccviz.azurewebsites.net/.

Background

Problem definition. Since the early 1990s, cancer care became more complex due to increased specialization among disciplines and more sophisticated treatments, as well as greater access to clinical practice data in electronic health records (EHRs) and other biomedical “Big Data.” As a result, patient care is no longer provided by a single specialist; rather it is delivered by multidisciplinary teams (MDTs) working in conferences, commonly referred to as tumor boards. A recent systematic review of oncology MDTs and patient outcomes suggests that providing multidisciplinary care improved patient outcomes with regard to diagnosis and/or treatment planning, survival, patient satisfaction, and clinician satisfaction¹.

Tumor boards take many forms (e.g., in-person or virtual round tables, clinics) and may include oncologists, radiologists, surgeons, pathologists, nurses, social workers, dieticians, physiotherapists, and occupational therapists. Their goal is to not only improve patient care through collaborative decision-making, but also foster learning within the team that may lead to future care improvements. In the latter sense, tumor boards have the potential to function as “rapid-learning health care” laboratories within their own institutions. A rapid-learning health system is one in which EHRs, big data (data with high variety, volume, and velocity), computers, and learning networks are used to accelerate evidence-based medicine. Using this data for rapid learning will require tools including mathematical approaches, software systems, visualization platforms, and education². Despite their aspiration to learn rapidly, tumor boards have limited resources to make the rapid-learning process a working reality.

Toward rapid learning in cancer care. At Oregon Health & Science University (OHSU), the team caring for patients with hepatocellular carcinoma (HCC) meets weekly to formulate and refine treatment plans for 12-15 patients. A nurse coordinator prepares patient summaries, which are presented in paper form. As each case is orally presented at the multidisciplinary liver tumor conference, a team member navigates through the patient’s electronic medical record (EMR), projecting additional information (e.g., imaging studies) on the conference room screen (Supplemental Materials, Exhibits 3 and 4) (Observation at Multidisciplinary Liver Tumor Conference. 2015 Apr 14, 21, 28).

The OHSU liver tumor conference encounters several challenges. The first is inefficiency: much extra time is spent preparing summaries before the conference and hunting for relevant data within the patient’s EMR during the conference. The second is temporality: the difficulty in analyzing patient data over time (as a patient may be discussed on multiple occasions as their disease progresses). The third is limited access to relevant and potentially helpful data: the lack of a tool that enables HCC MDT members to compare their patient data with similar patients in a way that supports evidence-based care.
In response to these challenges, the OHSU liver tumor board is developing the Multidisciplinary Bioinformatics Data (MDBD) Tool, a software application to capture and store the rich knowledge generated from their tumor board meetings in a more structured way. Other institutions are collaborating with OHSU in a data-sharing network to develop a national HCC database for clinical care and rapid healthcare learning. The MDBD development team has not yet determined how providers will access the national level data; we propose that interactive data visualizations have the potential to present information so that trends and insights can be quickly identified.

Visualizing complex clinical data is difficult. In their systematic review of data visualizations of EHR data, West et al. found few EHR visualization techniques before 2014 that could process huge amounts of clinical and other data. “Although most studies recognize the importance of the growing amount of clinical data, we found few innovative EHR visualization techniques that lend themselves to the large amount of data available electronically.”

The AMIA challenge. Our team therefore chose to focus on the design of a platform for the development of data visualizations and visual analytic tools to interact with complex cancer patient data. Using the OHSU liver tumor board as our test case, we propose an application that will allow providers to explore the MDBD database with intuitive, powerful data visualizations developed in collaboration with HCC providers. This application will allow clinicians to identify national cohorts of patients with phenotypes (and eventually genotypes) similar to the patients they are treating, and to use the experience of many other medical teams to inform the decisions they are making; in short, to support an evidence-based rapid-learning system for HCC care.

**Solution Design and Development**

**Design process.** To determine the best approach for clinicians to interact with a national HCC database, we performed a needs assessment through interviews with members of the MDT liver tumor board and stakeholders of the Multidisciplinary Bioinformatics Data (MDBD) tool currently in development. Dr. Willscott Naugler, a gastroenterologist and lead Principal Investigator of the MDBD project, provided us with the workflow for the conference (Supplemental materials, Exhibit 3) as well as the vision for the MDBD project. The goal of the MDBD project is to improve the MDT conference workflow by streamlining data collection and presentation and ensuring data is structured and accessible to all MDT members. Further, all data collected by the tool will be de-identified and sent to a national HCC database. Participating institutions will have access to the detailed data about their own patients as well as data from other HCC patients in the national database.

Discussions with the head of MDBD development (Justin Ramsdill) provided us with the data dictionary for the tool. In addition, we discussed the needs for data interaction among members of the OHSU liver tumor board (Supplemental Materials, Exhibit 5). Since interacting with national HCC data isn’t currently possible, the liver tumor board members were not sure of the best approach. However, all expressed interest in seeing data about different strategies and sequences of treatment, particularly for patients clinically similar to those discussed at conference. They were interested in seeing the prevalence of certain treatment protocols as well as the outcomes for the protocols. They weren’t sure of the best way to view this data, but they wanted to be able to compare specific treatments and protocols quickly.

**Solution description.** Our proposed solution is a data visualization and visual analytics platform. This platform will have two main components: 1) an online visualization development and evaluation repository and forum; and 2) a data visualization and visual analytics tool integrated with the MDBD tool to aid with clinical decision-making during MDT tumor board meetings. This solution will take advantage of the human ability for pattern recognition and the capacity to easily extract relevant information from visualizations in order to improve care based on complex clinical data.

The online visualization development and evaluation repository is a key component of our proposed solution. The repository will become a forum for data visualization experts, informaticians, data scientists, and clinicians where visualizations and visual analytics solutions are conceptualized, developed, and improved through an iterative process. The workflow for this platform starts with a need or a question, such as: “What is the laboratory profile of patients who respond to a specific HCC therapy a month after their treatment?” Through a requirements-gathering process, clinicians’ needs are further refined and additional visualizations and visual analytics solutions are developed using the de-identified HCC sample data.

These visualizations are posted in the online repository, where feedback is gathered from users (both clinicians and non-clinicians) and used to make further quality improvements to the visual solutions. High-interest visualizations will be formally evaluated with a select group of HCC clinicians and beta-tested by all users of the MDBD tool. This online visualization development platform will provide a constructive solution to the uncertainty of the providers’
needs for data interaction. For illustration purposes, a prototype visualization repository along with three prototype visualizations have been developed and posted online (http://hccviz.azurewebsites.net/) (Supplemental Materials, Exhibit 1).

The clinical data visualization and visual analytics tool is the second component of the proposed solution and will be integrated with the MDBD application. The visualization and visual analytics tool will act as the interface between clinicians in the MDT meetings and the national HCC database. This application will allow clinicians to explore therapeutic and outcomes data of HCC patients on a national level using data visualization and visual analytics tools previously validated through the online repository as described above. Clinicians will be able to use this program as an additional tool to inform the decisions they make about their patients during the MDT tumor board meetings.

**Alternative Solutions**

Currently the OHSU Liver Tumor Board MDT reviews and discusses each patient’s case to come to a consensus about staging (liver and cancer) and a treatment plan. Staging and treatment decisions are currently informed by the Barcelona Clinic Liver Cancer (BCLC) Staging System (Supplemental Materials, Exhibit 2). The BCLC staging system provides rough guidelines, but not exact recommendations, particularly for non-surgical patients. Consequently, there is considerable variation in care, especially across institutions. Having access to national data about treatments and outcomes would help inform HCC treatment decisions; visualizing this data would help clinicians quickly gain insight.

There are few visual analytics tools currently used for comparing individual patient data with national databases. Searches on PubMed using terms like "Registries"[MeSH] AND visualization[All Fields] and "Medical Record Linkage/methods"[MAJR] AND visualization[All Fields] brought little recent references relevant to the use of data visualization with either internal registry data or national databases like SEER (Surveillance, Epidemiology and End Results). Maier et al. used the U.S. SEER cancer registry dataset with a digital breast cancer tumor board at a German university hospital to determine the dataset’s utility in the clinical settings. They noted that few studies in the literature specifically linked patient data with a cancer registry database. Other large databases with cancer data include CancerLinQ, the American Society of Clinical Oncology (ASCO) health information technology initiative whose first elements will debut by early 2015. Currently, though, there is no significant use of CancerLinQ in the clinical setting.

The MDT could interact with the national HCC database directly by using pre-existing business intelligence software such as Tableau (www.tableau.com) or QlikView (www.qlik.com). However, choosing a program and creating visualizations is time consuming and not the top priority for busy care providers. In addition, while some providers may prefer the freedom of creating their own visualizations, many would be overwhelmed by it.

**Solutions Comparison**

Making clinical decisions for HCC patients is a complex, difficult task. Table 1 summarizes the possible strategies for tackling this problem, along with the strengths and weaknesses for each approach. The current method of MDT discussions of patient data and BCLC staging guidelines is not prescriptive for all patients, nor are there opportunities for determining better guidelines, because data is unavailable. The MDBD tool currently in development at OHSU will collect HCC-specific data on a national scale, but it is still unclear how clinicians will best interact with this data for treatment decisions. Using existing business intelligence software such as Tableau or QlikView with the MDBD data will be too overwhelming and time-consuming for most care providers and its portability to other institutions might be limited. Therefore, clinical visualizations and visual analytics tools developed by informaticians and data analytics experts and informed by clinicians will provide the best opportunities for data interaction with the MDBD data.
Table 1. Comparison of approaches for HCC treatment decision making (Hribar et al. solution highlighted)

Implementation and Dissemination

Initial development of the MDBD tool is underway within the Oregon Clinical & Translational Research Institute (OCTRI). Five regional medical centers will participate in this pilot program and will use the web browser-based MDBD tool in their liver tumor board meetings. Our proposed clinical data visualization and visual analytics tool will be implemented as a feature of the MDBD tool in a future version of the software. In parallel, our online visualization development and evaluation repository and forum will be made accessible to users. Members of the participating MDTs, clinical informaticians, and data analysts will be encouraged to participate in visualization development projects led by our group. The visualization development projects will include a pilot testing of the methodology as well as team member use of the data visualization and visual analytics tools in live MDT meetings.

After this initial implementation, we will invite other national and international HCC MDTs, as well as other disease-oriented MDTs, to participate in the visualization repository. In order to achieve wider dissemination, our solution will be presented to the medical community through scientific publications, presentations at national conferences, and other outreach venues.

Evaluation

Our proposed solution will be evaluated in four different stages: (a) user feedback regarding the data visualization prototypes in the online repository; (b) formal evaluation of the visualization solution using usability methodologies with clinician-users; (c) evaluation of the effect of the visualizations and visual analytic tools in the clinical decision-making, including clinician perception and satisfaction; and (d) evaluation of patient outcomes (Supplemental Materials, Exhibit 6).

Methods used for formal evaluation of the visualizations will include creating user-centered design principles, testing the visualizations in context, and evaluating information search strategy performance with real users⁶. Evaluation methods to assess the user’s analysis and reasoning capabilities⁷, as well as insight-based methodologies⁸ will evaluate usefulness of the visualizations. It will be important to measure the effects of a visualization on decision-making; we propose using an MDT teamwork measurement scale before and after using the visualization to measure this effect⁹. Finally, the evaluation of different patient outcomes (survival, remission, quality of life, time-to-therapy, etc.) will be performed with pre/post-intervention study methodology.
Conclusion

While demand is rapidly growing for visualization tools and techniques able to handle the complexity of clinical and biomedical “Big Data,” novel approaches to making these data easily accessible to and actionable by providers are in short supply. We believe applications like the HCC Data Visualization Repository and Clinical Tool have the potential to enable clinical insights at institutional and national levels, improve patient care, and support the development of a rapid-learning healthcare system.

Accelerating Biomedical Informatics Research with Interactive Multidimensional Data Fusion Platforms

Satyajeet Raje, MS\textsuperscript{1,2}
\textsuperscript{1}Dept. of Computer Science and Engineering, \textsuperscript{2}Dept. of Biomedical Informatics, The Ohio State University, Columbus, OH

Abstract

A prototype data fusion platform is presented that enables users to perform automated interpretation and ad-hoc integration of multiple datasets in real-time. It is designed to cut down data pre-processing time significantly. The prototype platform design illustrates interactive features that are highly visual and intuitive and do not require programming expertise. The demo is available at http://52.25.231.52:8080/dataFusionPlatform/.

Introduction

Data-driven research and analytics is at the core of clinical and translational informatics\textsuperscript{1}. A growing number of datasets are becoming publicly available in the current biomedical and healthcare research landscape. This, abundance of data has made large-scale data-driven biomedical research a real possibility. However, due to the lack of researcher-friendly tools for handling multi-dimensional datasets, data availability has not yet been effectively translated to its meaningful use.

Problem Description: Closer inspection of the current data-driven research process reveals that researchers spend more time in pre-processing and curating of data rather than the actual analysis itself. The amount of time and resources required to complete this pre-processing often limits the usefulness of the remaining research process. Moreover, the completely manual process renders handling of large and complex datasets or interpretation of multiple datasets in parallel nearly impossible for researchers. This has severely 'choked' the pace of research.

Quantitative data analysis involves several unavoidable pre-processing activities such as data exploration, collection, cleaning, curation, interpretation, etc. across diverse multi-dimensional datasets\textsuperscript{2}. These can be broadly classified into three steps of data discovery, interpretation and integration. The activities involved are as follows:

• **Dataset discovery** involves locating and selecting the required datasets and perform initial validity of the data contained within. This validation is based on its relevance to previous research and on provenance and quality information of the data.

• **Data interpretation** involves understanding what the data looks like at a highly granular (column) level and how it may be integrated with the other datasets that the researcher might be interested in. After finding a suitable dataset, researchers have to manually relate the columns from the different public and private datasets.

• **Data integration** involves combining selected datasets and tables based on the researchers’ interpretation. Currently, researchers perform this manually every time a new dataset is to be integrated. The task is finding possible “matches” across datasets and then performing the “join”. In database terminology a “join” can be defined as a point (usually a column) where data is integrated whereas a “match” is a possible join\textsuperscript{3}.

Informal interviews of biomedical informatics researchers revealed that most of these tasks are performed manually and thus are very time-consuming\textsuperscript{4}. The researchers also identified that though there are several data analysis tools readily accessible, there are very few automated tools to aid researchers in the pre-processing tasks. The difficulty and effort is amplified due to multiple iterations often needed in research.

Proposed Solution: Data Fusion Platform

For this submission, a proof-of-concept implementation of a data fusion platform is presented, designed to provide automated, end-to-end, real-time and ad hoc functionality across the data pre-processing tasks\textsuperscript{5}. The hypothesis is that such an automated “plug-and-play” solution would drastically reduce the pre-processing time, which, in turn would greatly accelerate the pace of biomedical and healthcare research.

The platform leverages reusable, semantically coherent annotations across datasets using standard reference ontologies in order to provide automated features for pre-processing needs of the researchers. This allows individual researchers, working independently to effectively crowd source dataset collections. Through the proposed platform, the researchers should be able to easily navigate through the dataset collection, interpret and integrate the relevant
datasets and obtain data in a format that is ready to be processed by various analysis tools (such as SPSS, Stata and R). The platform provides an intuitive and researcher friendly interface, without necessity of programming.

**Review of Comparable Existing Tools**

Several tools supporting data analytics activities in business environments are available. However, we argue that these are not suitable for academic environments. Let us consider why in detail. First, researchers working independently and do not share an integrated data store, as is the norm in large-scale business data analytics. So tools designed around centralized data structure and schema would not work in a research environment, which would benefit from a more distributed, crowd-sourced approach. Rather than pushing datasets into a unified predetermined schema, the researchers need a tool that performs quick, automated and interactive mapping and matching for ad-hoc interpretation and integration of datasets as needed.

Second, researchers often lack the resources of dedicated technological expertise that is available within enterprise data warehousing contexts. Thus, they might not have dedicated programmers, often required to work with commercial tools. Moreover, such tools are generally expensive and, thus, not accessible to individual academic researchers with limited research budgets.

From this understanding of the research process, it is clear that lightweight tools specifically designed for researchers that work with crowd sourced datasets are critical in order to accelerate the pace of data-driven research. Three types of tools are predominantly accessible to and used in data preprocessing by researchers, as identified by the interviews. These are data discovery tools, scientific workflow management systems and data integration platforms. In this section, a summary of the survey of the existing tools available for data preprocessing performed is presented.

*Data Discovery Tools:* These are often dataset collections or “knowledge stores” with search capability to query for relevant datasets. They tend to be domain specific, for example, the NCBI Entrez collection of biomedical datasets. Collections such as data.gov and census.gov for publicly available government datasets are especially interesting as they contain environmental and socio-economic datasets, crucial for cross-domain research. Thus, even though these tools are effective for discovery of topical datasets, the tasks of interpretation and integration are still manual.

*Workflow Management Tools:* Workflow-based data platforms, such as Taverna and Galaxy Workflow allow researchers to create and share common tasks that need to be performed on data in the form of series of repeatable steps in a single workflow. For example, the process of converting raw genetic data to a usable tabular format is a standard workflow. Such tools are useful to record common preprocessing steps such as transformations and cleaning on popularly used datasets and formats that are very domain specific. Thus, interpretation and integration of new datasets is still problematic.

*Data Integration Platforms:* As mentioned earlier, the commercially available data integration platforms are designed for large-scale shared business needs and not for the individual researcher. Traditionally, data integration follows the Extract-Transform-Load (ETL) process relying on schema mapping and matching. Even though automated matching techniques have been studied for long, they are still time-consuming and show moderate accuracies. Thus, they are not suitable for interactive real-time features and lack the ad-hoc integration functionality. So even though large-scale data integration platforms, such as Informatica and IBM’s Infosphere may be ideal for data analytics in a business environment, such an approach is not suitable for researchers’ needs.

**Design Methodology**

This section discusses the methodology followed while designing the data fusion platform in detail. An enterprise modeling approach was adopted. The steps involved are summarized below:

1. **Identification of purpose and scope:** Researchers working in the biomedical informatics and biostatistics domain were interviewed to understand the typical preprocessing workflow in quantitative data analysis. Much of this is discussed in the previous section. This allowed us to identify the specific problem that the data fusion platform should solve and define the scope.

2. **Identification of requirements:** They were then asked to identify functional as well as non-functional expectations from a hypothetical fully automated data fusion platform that aids in the preprocessing tasks. A grounded theory approach was applied to narrow down the requirements around the tasks of data discovery, integration and interpretation.

3. **Use case specification:** From the requirements identified above, use cases around the various data preprocessing tasks could be derived. These serve as the functional requirements of the platform. The data fusion platform implementation is expected to functionally address all of these use cases.
4. **Implementation**: The scope and use cases provide specifications for the prototype implementation. An agile methodology for rapid software development was adopted, which can accommodate changing requirements.

5. **Evaluation**: The platform is to be evaluated for both its functionality and usability. Functional evaluation involves task-based assessment of the system. The usability evaluation is designed using human computer interaction principles.

**Scope of the Data Fusion Platform**

Based on the responses of researchers, the scope of the platform can be defined as:

- Support bottom-up build up of crowd-sourced datasets, interconnected using semantic annotations that connect individual dataset schema to reference ontologies (such as MeSH, SNOMED, UMLS, dbpedia, etc.). This would enable moving away from predetermined centralized database schemas and promote efficient data sharing and reuse.
- The coverage of classes, entities, relationships, etc. by the reference ontology used for annotations is beyond the scope of the platform implementation.
- Provide a lightweight solution to handle research needs by replacing the overhead of schema matching and mapping and support automated interpretation and ad-hoc integration tasks for multiple / changing hypothesis.
- Aid automated and real time execution data preprocessing tasks with limited requirement of technical resources or programming expertise. The platform should be capable of accelerating data-driven research with an intuitive and interactive researcher friendly (and not programmer-oriented) interface.

**Functional Requirements Specification using Use Cases**

The interviewed researchers were asked to identify the expectations and specific functionality from a hypothetical data fusion platform for leveraging crowd-sourced datasets. These requirements were then narrowed down into specific motivating scenarios around the tasks of data discovery, integration and interpretation, illustrated below. These use cases serve as the functional design requirements for the data fusion platform.

**Discover relevant datasets and conduct initial assessment of suitability**

**Use Case 1**: "Find available datasets that can be integrated with given dataset"

Search for relational datasets of topical interest using existing data discovery tools like data.gov, census.gov, geodata, NCBI Entrez datasets, etc.

**Use Case 2**: "Get quality information about the dataset"

Assess provenance data (publishers, version, etc.) as well as quality information (e.g. number of data entries, analysis of missing values, etc.) of the datasets.

**Real-time Interpretation**

**Use Case 3**: "Find all possible matches between given datasets"

Automatically find "matches" between multiple local and public datasets using explicit table / column level annotations.

**Use Case 4**: "Suggest intermediate datasets for integration"

Automatically find intermediate datasets required to integrate given two datasets with no direct "match".

**Perform ad-hoc integration of data**

**Use Case 5**: "Suggest the best possible join for me to integrate given datasets"

Compare multiple datasets “matches” for relevance and integration possibilities in a real-time environment using heuristics of data quality / retention / loss. For example, datasets A and B can be joined on column X or can be joined using P, an intermediate dataset with a different set of columns. The number of data rows (observations) retained after the join can be a simple heuristic measure to compare which “match” is suitable for integration.

**Use Case 6**: Export the “joins” and data in format ready for analysis

Perform ad-hoc, real-time “joins” across identified datasets and deliver them in relational (tabular) format for use in various analysis tools like SPSS, Stata, etc.

**Non-functional Requirements**

The interviewed researchers also identified the following non-functional requirements for the data fusion platform:

- **Visual query interface**: An intuitive visual / graphical user environment that cuts across datasets, is not programmer oriented, and capable of delivering above functionalities.
- **Semi-automated annotation**: The platform should provide some degree of automation in the annotation process of a particular dataset. This would reduce the cost of annotation and improve heir precision.
- **Low query latency**: The query time for the automated interpretation tasks should be reasonably low to allow smooth operation in real-time.
• **Scalable Architecture:** The platform should be able to support a large number of datasets without losing the above requirements of intuitive interface and low latency.

**Implementation Details**

We have successfully implemented a prototype platform that fits the defined scope and addresses most of the stated requirements. It can perform automated interpretation across datasets and can identify “joins” for data integration using user-defined semantic annotations. The key design elements that help address the requirements are:

• **Data Fusion Ontology (DFO):** The internal storage ontology is key to the implementation of the platform. It defines the structure of the data and annotations stored within the platform. It is represented in an ontological format (OWL) that allows automated reasoning and extreme portability of the annotations.

• **Persistent data store:** A persistent data store is key to scalability of the platform. The annotations are stored in an ontological format (OWL / N-triples) using the DFO specifications. They can then be easily translated to any required database, for instance the Neo4j format for this implementation.

• **Graph-based exploration of datasets:** The interface allows an intuitive graph-based exploration of the datasets. The automated interpretation and ad-hoc integration can also be performed within the same interface.

The components of the platform are shown in figure 1. The dataset is input using the annotation interface, which interacts with the annotation engine. The user can annotate the tables and columns of the dataset using classes and properties from the reference ontologies. Note that in the above platform design the cost of annotation of a particular dataset is incurred only once. The annotation engine then verifies these annotations for completeness and validates it against the reference ontologies and the internal reference ontology, called the data fusion ontology (DFO). They are then translated into a Neo4j schema and loaded into the Neo4j graph database. These can now be reused by the query interface to perform the various preprocessing tasks as discussed in the use cases.

![Figure 1. Data Fusion Platform components](image)

For this design challenge, we are showcasing only the query interface with the assumption is that the datasets are already annotated and loaded into the Neo4j database. This is done in order to save the evaluators the time and effort of annotating new datasets. The demo interface is implemented as a web application using javascript and the D3 visualization library on the frontend and a Neo4j graph database at the backend. The database is queried using the cypher query language based on the user interactions at the front end. The interface allows users to browse the annotated datasets and perform real-time interpretation and ad-hoc integration. Currently, the platform can record and export the “joins” made by the users in the interface. This record can, in turn, be used to perform the actual integration. Please refer to the supplemental material (s1) for detailed walkthrough and screenshots of the demo design implementation.

**Large-scale implementation and Future development**

*Automated annotation process:* The annotation process is a major challenge in the large-scale implementation. The current implemented annotation process is completely manual. As part of future work, more automated techniques to aid the annotation process as shown in figure 1. These techniques would apply NLP methods as well as previous user annotations for automated classification of columns based on the reference ontology. Such a semi-automated annotation process should improve precision and drastically reduce the overhead of manual annotation.
Scaling the platform: There are two ways in which the platform is expected to scale. The most important consideration is how the platform will scale as more datasets are added expanding the size of the dataset collection. The current technology stack (viz. Neo4j, Cypher and D3) should be sufficient to handle this scaling. Another important consideration is allowing multiple users. Currently, the platform treats each session independently and all the changes and modifications are limited to the client-side only. Eventually, there would be need of storing user information and create profiles. This would provide better security through access control for the platform. It would enable advanced functionality such as user-specific collections, sharing, collaboration, etc.

End-to-end solution: The platform is expected to evolve as an end-to-end solution for data preprocessing. This would need inclusion of data discovery through search functionality. It would also require connecting to the actual data. We hope to expand on parallel research at OSU, such as ResearchIQ\textsuperscript{10}, in order to achieve this.

Evaluation Plan
As mentioned earlier, the data fusion platform will be evaluated for functionality as well as usability. We propose three different types of evaluation methods:

- **Task-based evaluation:** A task-based evaluation method involves identifying specific tasks to be performed by the system. In this case, the tasks will be designed around the use cases specified above. The platform will first be evaluated for the functionality by checking if it is actually capable of performing the tasks. A successful platform should be able to perform all the above use cases to be functionally complete.

- **Cognitive walkthrough:** The cognitive walkthrough can be considered as an extension of the task-based evaluation. An optimal workflow to perform each task is preredcorded. In the next stage of evaluation, a set of test users will be asked to perform the same tasks. The eyeball tracking and think-aloud protocols will be used as users are performing the tasks. An evaluator would also note various aspects of the process, such as whether the user could actually finish the task, the deviation from the optimal flow, time required to complete etc. Both the user actions and the responses will be recorded and analyzed to evaluate the user interface.

- **Heuristic evaluation:** The heuristic evaluation will be performed in two parts. First, the interface is to be evaluated by UI experts based on the HCI principles\textsuperscript{11}. Next, we would design a questionnaire based on these principles and to survey the naïve users of the system. The platform will be evaluated as a combination of the expert comments and the user responses.

Conclusion
The data fusion platform design presented here provides researcher with an intuitive interface to perform several preprocessing tasks. The implementation allows users to automatically interpret to find “matches” across datasets as well as perform ad-hoc “joins” to integrate datasets in a real-time environment. The platform is expected to evolve into an end-to-end solution for all data preprocessing tasks.

Acknowledgements
I would like to thank Justin Dano, Tyler Kuhn, Marques Mayoras and Bradley Myers who were instrumental in development of the prototype system. I would also like to extend a special thank you to my advisors Dr. Jayashree Ramanathan and Dr. Philip Payne. The demo is available at \url{http://52.25.231.52:8080/dataFusionPlatform/}

Three-dimensional Content-Based Cardiac Image Retrieval using global and local descriptors

Leila C. C. Bergamasco¹, MSc, Fátima L. S. Nunes, PhD²

Abstract

The increase in volume of medical images generated and stored has created difficulties in accurate image retrieval. An alternative is to generate three-dimensional (3D) models from such medical images and use them in the search. Some of the main cardiac illnesses, such as Congestive Heart Failure (CHF), have deformation in the heart’s shape as one of the main symptoms, which can be identified faster in a 3D object than in slices. This article presents techniques developed to retrieve 3D cardiac models using global and local descriptors within a content-based image retrieval system. These techniques were applied in pre-classified 3D models with and without the CHF disease and they were evaluated by using Precision vs. Recall metric. We observed that local descriptors achieved better results than a global descriptor, reaching 85% of accuracy. The results confirmed the potential of using 3D models retrieval in the medical context to aid in the diagnosis.

1. Introduction

Technology has entered in all sectors of society over the last years, changing the way people work and interact. Medicine, in particular, is one of the areas that has most benefited from the technological advent and often leads the way in the use of existing advances.

Computer-Aided Diagnosis (CAD) schemes provide assistance on diagnosis, using patient data and medical image data. These systems highlight suspicious areas in a medical image, in order to provide detailed data from an anomaly to the health professional¹. Recently, Content-Based Image Retrieval (CBIR) has emerged as an important technology to aid diagnosis, since it allows retrieving from a database those images that are most similar to an image provided as an input.

Parallel to the technological advancement cited, the area of graphics processing, including image processing, computer graphics, virtual reality and related fields has also evolved over the years. One of the causes is because the hardware utilized by these areas has become more efficient and cheaper.

In this scenario, techniques have been developed for the reconstruction of three-dimensional (3D) models. One of the main reasons for the increasing use of 3D models in health is that they provide additional information when compared with two-dimensional (2D) images. Besides the information about depth and volume, it is possible to condense color, contrast and resolution characteristics from 2D slices³.

Because of these characteristics, many complex medical exams use 3D models in the diagnosis. Magnetic Resonance Imaging (MRI) and Computerized Tomography (CT) are examples of medical image modalities that allow experts to identify abnormalities such as aneurysms, coronary artery diseases and tumors in several internal organs of the body without the need for invasive methods³. However, each exam from these modalities can generate hundreds of 2D slices and a high volume of data to be examined by physicians in order to perform their diagnoses.

Cardiology can be greatly benefited by CBIR systems using these images. Through MRI and CT exams, computational aid can be provided for the analysis of different diseases such as cardiac ischemia, heart attacks and cardiac insufficiency. A possible solution to overcome the large data volume problem to be analyzed is to generate a 3D model from the 2D slices and use this model to aid the diagnosis. In the Information Retrieval area, the same approach can be used: the system uses the 3D model for extracting the features instead of hundreds of 2D slices. This solution can be faster and more accurate than the approach using 2D image², ³, ⁵. However, this approach also
has limitations, since the volume or the surface needs to be available. Obtaining this kind of object is not a simple process, since the slices need to be segmented and reconstructed.

In the health area the use of 3D models can be particularly useful for detecting shape alterations in the reconstructed structure. The shape deformation is an important symptom of many diseases, such as Congestive Heart Failure (CHF) which is characterized by the inability of the heart to pump blood at an adequate rate for the metabolic requirements of the body.

CHF can be discussed from two perspectives: Left-sided Heart Failure and Right-sided Heart Failure. CHF can affect only one side of the heart, and as it is a closed circuit, it is common that this insufficiency on one side makes the other side work harder, resulting in excessive strain, hence producing global CHF. This excessive strain produced in the ventricles can deform this structure in the mid- and long-term. Weight gain or thickness of the ventricle indicates hypertrophy, while increase of the chamber size indicates dilation.

In this context, a CAD system using CBIR concepts to assist the specialists in finding similar cases based on the 3D model of the structure analyzed can be quite useful both for the diagnosis and for medical education. Despite the large amount of retrieval systems for content-based 2D medical images, the research on 3D models is still incipient in the literature. It is therefore important to develop more specific techniques that take into account the particularities of medical models.

This article contributes to fill this gap by presenting the definition, implementation and validation of one global and three local shape feature descriptors, applied in reconstructed heart left ventricle models. These models were previously classified by an expert as cases with anomaly (CHF disease) and without anomaly. The aim of this research report is verify how different descriptors techniques behave on this specific scenario and which strategy is more precise.

This article is organized as follows: Section 2 presents some works related to the work theme; Section 3 describes the methodology used in the tests and describes the descriptors used; Section 4 discusses the results and Section 5 presents the final conclusion.

2. Background

Research on 3D CBIR is relatively recent, with the main articles of the area published over the last ten years. The components of a CBIR system, both in 2D and 3D domains, are descriptors, similarity function and indexation structures. Descriptors are algorithms that extract some feature from the images. A set of features forms a features vector. Similarity function is an algorithm (usually a distance function) used to measure how similar two images are. There are different metrics for calculating distances, such as Euclidean and Manhattan Distance. Indexation structures are data structures developed to make faster the retrieval.

In 2D CBIR the descriptors can be classified as global or local, and they are usually divided into three categories: shape, color and texture. Shape descriptors are predominantly developed in 3D domain, and there are numerous different subcategories that vary from author to author. Yubin et al. propose categorizing shape descriptors based on geometry, statistics or projection. The geometry category considers as basic features of the 3D model, such as vertices and volume. Descriptors that use quantitative analysis tools such as histograms to define the features and create descriptors are in the statistics category, and descriptors based on projection are those that extract 2D images from the 3D models and also analyze them by using 2D descriptors. We found only a study that performs the retrieval of 3D models based on their colors, which presented a limitation of retrieving 3D models with completely different shapes as being alike.

In relation to the difference between global and local descriptors, the former analyzes the 3D model as a whole, and the feature vector includes information from all regions of the 3D structure. Local descriptors analyze parts of the models individually. According to Qin et al., global descriptors are easier to implement and have shown robust results taking into account that the 3D models analyzed are simple models. However, for more complex and detailed models, using a local descriptor approach can be preferable. Although it can require more processing, retrieval is more accurate and makes the retrieval system more flexible, since it can select regions of interest to be compared.

The similarity functions applied to features vectors of the 3D CBIR systems analyzed are the same used by 2D CBIR systems, with a prevailing use of Euclidean and Manhattan distances. Since the features vectors are still a similar data structure, the type of similarity function used remains the same.
3D models of 3D CBIR systems cited in the literature are generally representations of domestic objects such as chairs, vases, bottles and cars. Benchmarks for 3D CBIR, as for instance the Princeton and McGill Benchmarks, also used generic models to evaluate their descriptor\(^5\). With this type of benchmarks global descriptors have presented good results, since these models have very distinct shape differences.

In the medical context, few works have focused on 3D CBIR. Glatard et al.\(^8\), for example, obtained a 3D volume of the myocardium, and use this object to identify the cardiac cycle phase (systole or diastole) a given query image was in and find slices similar to the query image. A projection-based descriptor that uses 2D images extracted from a 3D object was used.

In Wu et al.\(^9\) different volume descriptors were combined to analyze brain models from PET (Positron Emission Tomography) exams. According to the categorization of Yubin et al.\(^3\) these descriptors can be considered as geometry-based descriptors, since they analyze primitive information of the 3D model, such as the volume and number of voxels. Finally, Aman, Yao and Summers\(^10\) used the SIFT descriptor and Bag of Words to retrieve Colonography CT Scans. The authors applied the Normalized Discount Gain metric to evaluate their results\(^10\).

The development of CBIR systems based on 3D models, in order to aid the diagnosis, requires knowing the anatomical structure of the organ in the images and the anomaly under study. Often, the global shape descriptors have limitations, requiring local descriptors, as described in this present work.

### 3. Methodology

To achieve the proposed objectives one global and three local descriptors were defined and implemented. To calculate the similarity among the models the Euclidean Distance was used, as shown in Equation 1, where \(x\) and \(y\) are two feature vectors with \(n\) size and \(i\) indicates the \(i\)-th position at each feature vector. In the next sections each of the descriptors implemented will be detailed.

\[
\text{Euclidean Distance} = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2} \quad (1)
\]

#### 3.1. Descriptors

**3.1.1. Distance Histogram Descriptor (DHD)**

The Distance Histogram Descriptor (DHD)\(^12\) considers the surface and the geometry of the 3D model analyzed. The algorithm computes the distance between the centroid of the model and its surface considering random points. Next, the distance is divided into ranges that form the bins of a Distance Histogram.

Figure 1 shows the DHD adaptation for the context of this work. From a reconstructed model provided as query, the distance between the centroid of this model and the random points on the surface is calculated. This distance is normalized, and the frequency of occurrence of each distance value in the model is computed to compose a histogram. This histogram is transformed into a feature vector and compared with other vectors stored in the database. To compute the similarity between two vectors the Euclidean distance is applied and the models are classified according to the value obtained. The lower the value, the more similar the model stored in the database and in relation to the query provided\(^13\).

**3.1.2. Local Distance Histogram Descriptor (LDHD)**

As mentioned earlier, CHF may cause ventricle deformations, especially in the lower regions of the structure. This descriptor takes in account this information and analyzes specific parts of the model based on their octants.

First, the 3D model is divided into eight octants and then the Distance Histogram of each part is calculated. For each Distance Histogram created, its respective area is computed, as given by Equation 2, where \(f_i\) is the \(i\)-th value of frequency, \(d_i\) is its respective value of distance, and \(n\) is the number of histogram bins. In other words, each of the eight positions of the distance vector stores the area of the \(i\)-th octant (Figure 2).

\[
\text{area} = \sum_{i=1}^{n} f_i d_i \quad (2)
\]

Figure 2 shows an example of each step of the LDHD. From a model reconstructed and used as query, the Distance Histogram is calculated for each of the octants, considering the centroid of the model as the point of origin for all of them. The area of each histogram is calculated and stored in a vector. This vector is compared with other vectors in the database using a similarity function. If the result is less than a threshold value, the result for this comparison is
zero, otherwise it is 1. The sum of the end positions of this vector indicates the degree of similarity between the two models.

![Figure 1](image1.png)

**Figure 1.** Steps performed by Distance Histogram Descriptor.

The problem of using common similarity functions directly into features vectors in this case is the loss of information about the octant reference. Most of the similarity functions cited in the literature do not consider the positioning of each feature in the vector; all features have the same weight and if one of them has a bad result all the 

![Figure 2](image2.png)

**Figure 2.** Steps of the Local Distance Histogram Descriptor.

The problem of using common similarity functions directly into features vectors in this case is the loss of information about the octant reference. Most of the similarity functions cited in the literature do not consider the positioning of each feature in the vector; all features have the same weight and if one of them has a bad result all the
feature vector can be compromised. Thus, the main advantage of this descriptor regards allowing the end result of the descriptor to reflect the local differences of the model analyzed. This type of approach in the 3D scenario is new, because it allows applying a global solution at specific points in the model.

3.1.1. 3D Hough Transform Descriptor (3DHTD) - Frequency

The Hough Transform is an effective technique for detection of curves and objects in 2D and 3D domain from a set of points. An important characteristic of this technique is how it discretizes the spatial information of the image in order to identify which points belong to the same set of interest\(^4\).

R-Table is a reference table in which the indexed curve is represented by the angle of the gradient and which is widely used in 2D Hough transform\(^4\). In the 3D domain, R-Table can be used to organize information about the normal vector, which indicates the positioning of a given surface, in addition to the distance of this surface related to the origin. Compared to other descriptors that only take into consideration the distance, there is a major gain for spatial problems that require detecting shape alterations at specific locations.

In the 3D Hough Transform Descriptor (3DHTD) descriptor, the discretization of spatial information occurs by using a Cubic Matrix, a 3D extension of R-Table, where the values of the rows and columns are measured according to a predetermined degree of resolution based on spherical coordinates \((\theta, \varphi)\). This degree of resolution indicates the range value on cubic matrix that the information will be grouped. Thus, lower resolution values indicate a larger area to be analyzed. The normalized Euclidean distance between the centroid and surface is computed to measure the depth of the Cubic Matrix. Finally, the content of each cell is defined by the frequency that this triple \((\theta, \varphi \text{ and distance})\) occurs in the model.

The set of triples of a model, along with its respective frequency of occurrence \((\text{freq})\), is stored in the database as a position in the feature vector of the model, as shown in Equation 3, where \(a_i\) is the \(i\)-th Cubic Matrix set \(\{\theta, \varphi, \text{distance, freq}\}\).

\[
\text{FeatureVector} = \{a_1, a_2, ..., a_n\} \quad (3)
\]

The similarity between two models is obtained by comparing the frequency of each cell of the Cubic Matrix. Figure 3 shows how this descriptor works: from a 3D model given as query the information is extracted using 3DHTD – Frequency, and the Cubic Matrix generated (mRquery) is compared by Euclidean Distance with another Cubic Matrix stored on Database (mRDatabase).

![Figure 3](image_url)
3.1.3. 3D Hough Transform Descriptor (3DHTD) – Standard deviation

This descriptor is a second approach of 3DHTD presented in the previous section, which analyzes the distance variations of the surface up to the origin point of the model in the spatial intervals defined by a given degree of resolution.

To reduce the dimensionality of the Cubic Matrix in order to find the standard deviation values, the mean distance for each pair of angles \((\phi, \theta)\) is computed. Next, the standard deviation of a set of frequencies using Equation 4 is calculated, where \(f_i\) is the \(i\)-th frequency of the pair of angles \((\phi, \theta)\), \(\mu\) is the average of the values found (in this case it is the distance), \(x\) is the cell value and \(n\) is the total of occurrences within the range of each pair of angles \((\phi, \theta)\).

\[
DP = \sqrt{\frac{\sum (f_i(x-\mu)^2)}{n}} \quad (4)
\]

Afterwards, Euclidean distance is applied, which verifies the entire matrix by comparing the values of the standard deviation, as shown in Figure 4. Similar to 3DHTD – Frequency, the feature vector is created from a 3D model given as query and a matrix based on Standard Deviation (matrixSDQ) is generated. This matrix is compared with another matrices stored on database (matrixSDR) by using the Euclidean Distance.

![Diagram of 3D Hough Transform Descriptor using standard deviation](image)

**Figure 4.** Implementation of the 3D Hough Transform Descriptor using standard deviation.

3.1. Experiments

The descriptors presented in the previous sections were applied in models of the left ventricle reconstructed from MRI images. Each MRI exam was composed by 45 heart slices obtained during diastole. These slices have spatial resolution of 256x256 pixels and contrast resolution of 16 bits per pixel. Besides the Precision versus Recall curve, the response time of each of these descriptors was also analyzed.

To test the descriptors in medical images, 30 sets of MRI exams from Heart Institute (InCor) were used - 53% exhibited the problem of CHF and 47% showed no abnormality. 55% of patients were women and 45% were men.
The frames were segmented focusing on the region of interest in the left ventricle using Seg3D software\textsuperscript{15}. The ImageVis tool was used for the reconstruction\textsuperscript{16}. Figures 5 and 6 show an example of the slices and the reconstructed ventricle, respectively.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{image1.png}
\caption{Example of a slice and the ventricle region segmented (in red).}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{image2.png}
\caption{Examples of reconstructed ventricles.}
\end{figure}

We used the Precision versus Recall metric to evaluate the results of the CBIR system, where Precision indicates the proportion of relevant images retrieved and Recall indicates the proportion of all relevant images that are in the database and that were retrieved\textsuperscript{18}. We also used a Distance Matrix, where the cell color indicates how similar a model is to the model given as query. The matrix was divided into two clusters: one related to patients with CHF (patients 1 to 16), and another related to patients with no anomaly (patients 17 to 30). The color of the cells indicates the order in which they were retrieved: the darker cells indicate lower distances and, therefore, models were retrieved before the models related to the lighter cells.

4. Results and Discussion

Figures 7 and 8 show the Precision versus Recall curve for each descriptor. In both cases, with and without the CHF disease, the 3DHTD using frequency was the best performing descriptor, indicating that spatial information is important for retrieving objects that have specificities at different places of the models. This descriptor reached an average of 85\% of precision for lower values of recall, which means that as the number of models retrieved increased, the precision decreased, since we have fewer models available on database and the shape difference between them becomes more difficult to distinguish.

The 3DHTD descriptor using standard deviation had less satisfactory results. The main limitation of this latter method is that small deformations may not be taken into consideration due to the standard deviation characteristic which considers the average of the range of values to compute the deviations of the data set.

The LDHD, which divides the models into octants and creates an auxiliary vector to compare local distances, presented good performance, about 75\% of precision, showing that it is feasible to use locally the global descriptor Distance Histograms. The Distance Histograms, in turn, showed a somewhat less satisfactory performance, about 60\% of precision, mainly due to the specificities of the models, in which local information is extremely important for composing the diagnosis.
Figure 7: Precision vs. Recall curve comparing all descriptors implemented in the models with CHF.

Figure 8: Precision versus. Recall curve comparing all the descriptors implemented in the models with no anomalies.

The errors observed for the first five models retrieved for each query can be found in the Distance Matrices (Figure 9). The 3DHTD - Frequency and the LDHD descriptors had a better performance that can be realized by comparing the generated clusters. DHD and 3DHTD – Standard Deviation descriptors had many outliers, while 3DHTD - Frequency and the LDHD descriptors generated more uniform clusters, separating into two groups the 3D models with and without the CHF disease.
These results show that the descriptors that take into consideration the spatial location of deformations achieved better performance than the descriptor with a global approach. The local descriptor 3DHTD – Frequency, for example, had a better performance — above 20% to 30% more precise — compared to Distance Histogram that uses a global approach. 3DHTD uses spherical coordinates and the distance of the face to the centroid to extract features from the 3D object. Consequently, it considers spatial location as well as the deformation degree as elements of comparison. Additionally, the 3DHTD – Frequency compare each model according to the deformation pattern. In other words, if two models have the same deformation on the same location but their frequencies are different, this means that they are different because the intensity of the deformation are highlighted by the frequency. The performance was consistent with the theory in which the descriptors were based on. Given that the main problem was to identify local deformations, the descriptors that provided this type of information and that cross-referenced with other data such as the degree of deformation (indicated by the distance from the surface to the center of the model) were more likely to achieve better results.

In this work the Euclidean distance was used, however there is a large set of other functions that can be implemented. Thus, evaluating results using other distance functions and develop more descriptors within this context can also enrich the discussion about 3D CBIR, hence offer a contribution to the actual state of the art. The current studies that we found in the literature usually use the same strategy applied in the 2D domain, commonly distance functions — as Euclidean and Manhattan — that measure the distance between two feature vectors. In this paper, for example, we have a 3D feature vector – the Cubic Matrix, and complex data structure to store the information resultant from the descriptors which we created. This can be considered a new way to store and compare the huge volume of information provided by medical images.

5. Conclusion

The objective of this paper was to define, implement and validate four descriptors and compare their performance for the retrieval of three-dimensional medical models with deformations at specific locations, in order to aid the CHF disease diagnosis. In many medical imaging exams it is common that several slices of a structure have to be analyzed by the expert. The generation of 3D models reconstructed from these slices can be a way to decrease the amount of information to be analyzed by experts. In addition, the development of descriptors that can characterize adequately these models is an important contribution for the computer-aided diagnosis area. As mentioned in the Discussion section, local descriptors achieved better results: they were above 20% to 30% more precise than global descriptors, mainly because we were looking for retrieve 3D models with specific and small changes.

This study has some limitations. The first of them is the low number of cases to test the developed techniques, which became difficult to make a deeper analysis of the results considering, for example, gender and age. Due to this limitation, it was also difficult to identify more specific variations on each group. The second one was the use of only Euclidean distance as similarity function; other metrics and evaluation forms can be explored.

Thus, from this work we show evidences that it is feasible to apply the concepts of 3D CBIR for more specific contexts. In this paper CHF disease was studied, however the descriptors developed in this paper can be applied to solve other problems that include local deformations of 3D convex models. In addition, the application of these descriptors in non-convex models also can contribute to evaluate them in a new context. New topics for study about 3D CBIR system can also include similarity functions for 3D feature vectors and complex structures. For future
work we are working in increase our database with more 3D medical models. We also are planning to apply these descriptors as well as others new techniques to retrieve cases with different cardiac diseases with a high level of precision.

As mentioned, there are currently few studies related to CBIR in the 3D domain and, therefore, this research presents a contribution comparing performance of global and local descriptors facing the recovery of 3D medical models for aiding the diagnosis of CHF disease.

Analyzing Self-Help Forums with Ontology-Based Text Mining: An Exploration in Kidney Space

Philipp Burckhardt, MSc, Rema Padman, PhD
Carnegie Mellon University, Pittsburgh, PA

Abstract

The Internet has emerged as a popular source for health-related information. More than eighty percent of American Internet users have searched for health topics online. Millions of patients use self-help online forums to exchange information and support. In parallel, the increasing prevalence of chronic diseases has become a financial burden for the healthcare system demanding new, cost-effective interventions. To provide such interventions, it is necessary to understand patients’ preferences of treatment options and to gain insights into their experiences as patients. We introduce a text-processing algorithm based on semantic ontologies to allow for finer-grained analyses of online forums compared to standard methods. We have applied our method in an analysis of two major Chronic Kidney Disease (CKD) forums. Our results suggest that the analysis of forums may provide valuable insights on daily issues patients face, their choice of different treatment options and interactions between patients, their relatives and clinicians.

1 Introduction

In recent years, the Internet has emerged as a major source of health-related information, with more than 80% of the US Internet-user population, 113 million adults, having used the Web this way. How health information on the Internet affects decision making has been studied thoroughly as well as the demographics of help seekers, yet another area has received much less scrutiny: The proliferation of online self-help forums for chronic diseases that facilitate a social support network for patients.

The reason for this lack of attention is two-fold: On the one hand, the text amassed in these forums is generally too large to be hand-coded and subjected to a qualitative, human-guided analysis. On the other hand, automated text mining with the goal of discovering knowledge is a very challenging task and an active area of research.

In natural language processing (NLP), there has been a lot of work done in areas such as sentiment analysis, document summarization and topic modeling. Most of the current approaches are unsupervised learning methods, which utilize elaborate statistical methods and require a large amount of training data in order to generate sound results.

Although we are living in the era of ‘Big Data’, the data sets of these specialized self-help forums are much smaller than those of popular social networks. Confronted with this challenge, we opted to create a method for analyzing textual documents that deals with the relative data scarcity. In addition, popular topic modeling algorithms such as Latent Dirichlet Allocation (LDA) are mostly used to cluster documents into broad categories. Yet, our goal is to uncover hidden facts that would otherwise remain unknown.

In our proposed method, we use semantic ontologies to annotate natural language documents and mould them into a machine-readable format, with the goal of encoding the ontological knowledge a human might have. Unlike most statistical methods which use word counts as their atomic units, our representation is based on inter-related semantic concepts, which form an intermediate ontological layer representing a ‘web of meaning’. This ‘web of meaning’, which consists of hierarchically organized conceptual nodes, is then analyzed by statistical means, the results of which can inform and ease content analysis.

Because of aforementioned challenges, not much research has been done in the analysis of self-help forum communication. Existing studies have investigated the impact on attitudes towards healthcare providers running such forums. Others have studied the benefits and challenges arising from the usage of online communities by patients.

Instead of engaging in the debate on the perceived benefits and disadvantages of such forums, we take the view that even erroneous conceptions and misunderstandings on the side of the patients provide valuable insights insofar as they manifest themselves in the minutiae of online discussion forums and can thus inform researchers on how chronic disease patients deal with their conditions. Taking this perspective, Liu et al. study how such patients use video blogs.
to share their stories, and Zhang et al. investigate the intent of people posting on health message boards. There is also a small but growing body of research on how to evaluate the benefits and harms of different treatments and drugs by utilizing comments on online medical forums.

The results of analyzing online forums can lead to a broadened perspective for the healthcare sector. Let us assume a doctor who treats a patient with a chronic disease. Not only has there been a decline in the time doctors can spend with their patients, but due to the nature of the doctor-patient relationship, which is confined to single points in time, the doctor only gets a snapshot and not the whole picture of the patients’ health. Therefore, it would be desirable for a clinician to learn how the patient feels, whether the treatment is successful and what other issues the patient might have. The analysis of forum communication of patients facing similar problems could extend the vision of the attending clinicians and increase their understanding of patients’ needs and preferences.

Discerning communication patterns on self-help networks could also give rise to insights on how patients complement the information received from their doctors. These insights could lead to suggestions to improve the guidelines for doctor-patient communication and to integrate self-help networks into treatment programs.

In 2011, $49.2 billion was spent in the United States on the treatment of End Stage Renal Disease (ESRD), the final stage of CKD. It is estimated that more than 11% of the US adult population have some degree of CKD, with recent projections suggesting that more than 50% of those aged 30 to 64 years will likely develop CKD. In light of these trends, seeking improvement in the care of CKD patients has become a national issue as well as an economic necessity, both in terms of developing new treatments as well as preventive measures. This challenge is not restricted to the US, with CKD being called a “global challenge” requiring concerted action “to avoid a major catastrophe.” Although the gained insights might be very valuable, we are not aware of any studies learning communication patterns and insights from freely available CKD self-help forums - there has been only a small-scale intervention study targeted at adolescents. In this study, which serves also as a use case for our methodology, we report on the results of an analysis of two major CKD self-help forums, DaVita and KidneySpace. The insights we have gained in this area render the pursuit of our methodology a promising endeavor.

2 Data

The basis of our analysis is formed by the communication acts from the following self-help forums about CKD: DaVita, a large forum on kidney disease and dialysis hosted by DaVita, one of the primary kidney care companies in the United States, and KidneySpace, a privately operated kidney support forum that was run by the Renal Support Network until it closed down on January 30, 2015.

Table 1: Example thread from KidneySpace forum in JSON format

```json
{
  "posts": [
    {
      "content": "With all the attention around transplant, UNOS has opened up a number for people to call. (…)",
      "title": "\# to call regarding concerns about your transplant center",
      "user": "OZfan",
      "date": "August 17, 2007, 03:17:18 PM PDT"
    },
    {
      "content": "Hopefully I won’t have to use this number.",
      "title": "Re: \# to call regarding concerns about your transplant center",
      "user": "Purple_Reign",
      "date": "August 23, 2007, 12:57:49 AM PDT"
    }
  ],
  "title": "\# to call regarding concerns about your transplant center",
  "url": "http://www.kidneyspace.com/index.php/topic,40.1"
}
```

For each thread, our data set contains the following features: Its title, URL address as well as a list of posts, which
includes both the content of the posts as well as information on the author and date the post was written. An example thread is displayed in Table 1.

In total, our data set of the Davita forum consists of 6,501 threads with 41,079 posts. The time of the posts ranges from 2004 to the beginning of 2014, for a total of almost ten years. For KidneySpace, we have collected 3,715 online discussions totaling 20,857 posts from August 2007 until the year 2013, with 581 unique users present in the data set. For Davita, 5,603 users are represented in the study. This number is striking insofar as the total number of registered users exceeds 180,000, implying that a very large number of registered users did not write a single post. This trend continues if we look at the distribution of the number of posts per user, which are displayed for both forums in Figure 1. It seems as if most of the users are mere bystanders who do not actively communicate on the discussion forums, but instead are passive readers. This practice of *lurking* is commonly observed and has been studied in the literature.\footnote{23}

\includegraphics[width=0.4\textwidth]{davita.png}
\includegraphics[width=0.4\textwidth]{kidneyspace.png}
\caption{Post frequencies for users of both forums. The number of posts has been censored at a value of 25, with the last bar in both plots denoting users with more than 25 posts.}
\end{figure}

Comparing the two forums, it can be seen that KidneySpace, although a much smaller forum in total, seems to have a more active community: The average number of posts per active user is 2.588 for Davita and 6.196 for KidneySpace.

Before our data analysis, we pre-process the raw forum data and annotate it with ontological information, turning it into a structured, machine-readable and statistically analyzable corpus. The necessary background information and the proposed methodology is presented in the next section.

3 Methods

Traditionally, statistical models for text analysis use word counts as their atomic units. Such a representation, which is devoid of meaning, is ill-suited to the characteristics of languages, which often display *polysemy* and *synonymy* of words.

To illustrate the problem of synonymy, we may use a mundane example: Every native speaker of English knows that the expression “Give me a buck” is equivalent to “Give me a dollar”, which in return is equivalent to “Give me a clam”. Any word-based model will treat the three words buck, dollar and clam as different entities, and there would be no inherent connection between them. A human listener though recognizes that these three words are synonyms and share a common meaning. However, not only can multiple words refer to the same concept, but a word can have different meanings, too. This polysemy may be illustrated by the word ‘lemon’ which denotes a fruit as well as a defective automobile.

When we as human beings assign the proper meaning in a given context, we make use of our ontological knowledge. To train an algorithm to make such an assignment, there is a need for a digital ontology. For this project, we have evaluated three commonly used ontologies: ConceptNet, the UMLS Semantic Network and the WordNet taxonomy.\footnote{24, 25, 26} In order to use these ontologies, we wrote APIs for each of them and made them publicly available under an open-source license\footnote{UMLS: http://bit.ly/1BjRuiM, WordNet: http://bit.ly/1MLW421, ConceptNet: http://bit.ly/1C2tmDD}.

Although our proposed methodology is ontology-agnostic, we have settled on WordNet as it does not have some of the
Figure 2: Synsets of the noun ‘doctor’ and their hypernyms

disadvantages of the other two options. ConceptNet, developed at the MIT Media Lab, aggregates information from various sources, at the cost of structural inconsistencies. The Unified Medical Language System (UMLS) contains a vast dictionary of more than two million biomedical and health related concepts (called the Metathesaurus), but its general ontology is very flat, consisting of merely 133 inter-related entities, whereas WordNet establishes relationships between all of its 117,000 concepts, called synsets, an abbreviation for sets of synonyms. However, a potential issue with WordNet might be its missing specialized medical concepts. Therefore, we thought of enhancing it by UMLS. Since UMLS does not contain colloquial language needed in our context, we considered the Consumer Health Vocabulary\(^2\), which provides a mapping from colloquial terms to the relevant concepts in UMLS. But since we found that approximately 84\% of words could be assigned to a WordNet synset, the marginal benefit from incorporating UMLS information into WordNet seems limited.

The advantage of mapping words to their respective ontological concepts is that the relationships between these concepts enable us to attach background information to our data. We focus on the Is-A relationship between concepts. This results in a taxonomy that can be represented as a tree structure with very general concepts on the higher layers of the tree and very specific concepts as leafs. For two concepts sharing an Is-A relationship, we refer to the broader concept as the hypernym of the more specific concept. In Figure 2, the possible synsets for the noun ‘doctor’ are displayed as well as their hypernyms. Because of this tree of knowledge, we can deal with the linguistic problems of polysemy and synonymy.

**Pre-Processing:** We start by tokenizing each input document and then run a standard Part-Of-Speech (POS) tagger to infer the lexical class of each extracted token. We remove interpunctuation, convert characters to lower case and strip off extra whitespace occurring in the documents. We then exclude all stop words from the analysis. Our system uses a stopword list of 571 words, including conjunctions such as and, auxiliary verbs such as should and pronouns like they. After removal of stop-words, we use a custom-implementation of WordNet’s morphy algorithm for morphological processing in order to map inflected forms back to their base forms. One of the input parameters of the morphy function is the POS tag, which identifies words as a noun, adjective, verb or adverb. Because of this intermediate step, it is possible to associate each word with all candidate synsets from the ontology, i.e. all possible meanings the word could have. Words for which no base form could be inferred are removed from further analysis. The steps of the pre-processing stage are visualized in Figure 3.

**Word Sense Disambiguation:**

The goal of *word sense disambiguation* is to choose the appropriate sense of a word given its context. For each word, we wish to select the correct synset \( c \) from the candidate set \( C \) of possible synsets. For example, when the word

\[\text{See: } \text{http://www.consumerhealthvocab.org/}\]
Figure 3: Pre-Processing Steps

Eating too much protein can strain the kidneys.

Figure 3: Pre-Processing Steps

The figure shows a flowchart of the pre-processing steps for text analysis. It includes steps such as tokenization, part-of-speech tagging, stopword removal, and morphological analysis. The flowchart illustrates the transformation of text into structured data for further analysis.

‘lemon’ occurs in a text about fruits, we would like to choose the synset with the definition *yellow oval fruit with juicy acidic flesh*, whereas in a text about used cars it is highly probable that ‘lemon’ refers to the synset \{lemon, stinker\} denoting an artifact (especially an automobile) that is defective or unsatisfactory.

Similarly to the approach by Fodeh et al.,\textsuperscript{27} for any given word \(w_i\) and its context \(W(i)\) (in our case, the other words in the sentence of the \(i\)-th word), we choose the synset \(c_i\) as

\[
\arg \max_{c_i \in C_i} \sum_{w_j \in W(i)} \max_{c_2 \in C_j} \text{sim}(c_1, c_2),
\]

where \(C_i\) and \(C_j\) are the sets of possible synsets for words \(w_i\) and \(w_j\) and \(\text{sim}(c_1, c_2)\) is some similarity measure between the synsets \(c_1\) and \(c_2\). The idea behind this equation is familiar to anybody: That the narrative context gives each word its special meaning.

In the literature, many different similarity measures have been proposed,\textsuperscript{28} some depend on the taxonomy and deem two synsets to be more semantically similar the closer the two nodes are together in the hyponym tree,\textsuperscript{29} other so-called Information Content metrics take probabilistic information of synset occurrence into account.\textsuperscript{30} Jurafsky and Martin argue\textsuperscript{28} that of the similarity or distance based information measures, the Jiang-Conrath similarity measure\textsuperscript{31} performs most consistently. This measure takes both taxonomic and probabilistic information of synset occurrence into account. Inserting the definition of the Jiang-Conrath similarity measure into Formula (1), we estimate the synset for word \(w_i\) as

\[
\arg \max_{c_i \in C_i} \sum_{w_j \in W(i)} \max_{c_2 \in C_j} \left[-\text{IC}(c_1) - \text{IC}(c_2) + 2 \times \text{IC}(\text{les}(c_1, c_2))\right],
\]

where \(\text{IC}(c)\) denotes the self-information of concept \(c\), a quantity defined as \(\text{IC}(c) = -\log P(c)\), \(P(c)\) being the probability to observe an instance of concept \(c\). We choose the context \(W(i)\) as the sentence in which word \(w_i\) appears.

In the formula, \(\text{les}\) denotes the lowest common subsumer, the lowest node in the hyponym tree which is an ancestor for both \(c_1\) and \(c_2\). This formula reflects two forces: On the one hand, concepts are more likely to be chosen the more frequent they are. On the other hand, the information content of the \(\text{les}\) has the effect of favoring synsets that share a very specific \(\text{les}\): For example \{nurse\} and \{doctor\} have \{medical practitioner\} as \(\text{les}\). Its information content is higher than in the case where the \(\text{les}\) for both synsets would be just \{entity\}. Thus, in co-occurrence with ‘nurse’, we conceive the ‘doctor’ as a \{medical practitioner\} and not as a \{intellectual\}.

In order to compute \(\text{IC}(c)\), we estimate the probabilities \(P\) via their empirical frequencies. Obtaining synset counts of a document corpus is often prohibitively costly, as it would require to manually annotate each word with its correct synset. A common practice is not to insist on obtaining a sense-tagged corpus and instead calculate the empirical frequencies by summing up the number of occurrences of words belonging to synset \(c\).\textsuperscript{30} This method is undesirable for disambiguation, as its only effect will be that synsets with multiple words end up having a higher probability of being chosen. Instead, we make use of the Brown corpus, one of the few corpora for which the occurrence of synsets has been determined by annotating its documents by hand. However, the corpus size is only 500 documents, so the Brown corpus has the drawback that many synsets are assigned a count of zero. To increase disambiguation performance, a straightforward approach is to manually annotate a training set from the domain of interest, in our case
Figure 4: Simplified Illustration of the Merging Process

medical self-help forums on CKD. In order to make this process easier, we have developed a command-line tool where users can manually annotate words in training sentences with their correct synsets. This allowed us to increase the percentage of correctly disambiguated synsets to around 75%.

**Document Merging and Word Propagation:** Each document is now represented as a set of disambiguated synsets. Since we have augmented each synset with ontological knowledge in form of its hypernyms, it has now the form of a document tree. Next, we merge all document trees together into a single corpus tree (see Figure 4). In doing so, we take all words that have occurred in the corpus and attach them not only to their respective synset, but also to all its hypernyms. To make this clear, consider the example of a ‘nurse’ which belongs to the \{nurse\} synset. However, a \{nurse\} \textbf{Is-A} \{health professional, health care provider, caregiver\}, and the word propagation algorithm ensures that the word ‘nurse’ is also attached to the hypernym synset. This allows us to pose questions such as ‘Which words denoting health professionals appear in our corpus?’ and obtain answers that also include all words which belong to children of \{health professional\}.

**Thresholding:** Many synsets appear only once or twice in a document corpus and could be the result of random noise. We want to discard these synsets and only keep those that are reflective of the inherent characteristics of the document collection. As a default choice, we remove all synsets from the tree which appear in less than \(\sqrt{n}\) of the documents, where \(n\) denotes the total number of documents.

**Analysis:** The analysis of the generated synset tree proceeds in three different steps. First, we have a global view on the univariate frequencies of the concepts. From this most distant zoom level, we have a bird’s eye view that allows us to detect the most probable and conspicuous synsets. The ontological tree structure in its visual form allows us to easily explore the corpus, for example by starting from highly abstract concepts drilling down to more specific ones. To give an example, we might encounter the abstract synset \{emotion\}. Looking what kind of emotions appear, we would see that \{cravings\} appears surprisingly often, and that the word most often disambiguated to this synset is ‘appetite’. A likely hypothesis might be that articulated desires are almost exclusively linked to nutrition.

For the identified synsets (in above example, nutrition or cravings), we take a detailed view investigating their Pearson correlation with other synsets. This allows us to identify interaction fields between different synsets and sharpen our hypotheses. Because we are looking for real correlations and not chance occurrences, we have to carry out hypotheses tests. Here, we also have to account for multiple testing since for any given synset, all possible pairwise correlations with other synsets (for which there is no word-overlap) are calculated. We do this by controlling the false discovery rate (FDR), i.e. the expected percentage of correlations wrongly considered significant, at level 5%. Specifically, we use the procedure by Benjamini-Yekutieli as it is applicable even under arbitrary dependencies among tests. In our example, we find to our surprise that the most correlated synset with \{cravings\} is \{nausea,sickness\}, raising the question whether the patients are not actually complaining about a loss of appetite.

In a final step, we check the formulated hypotheses by tracking the proportion of posts in which they can be established.
To do this, we draw a simple random sample from the documents in question (a size of 100 is chosen as a default), in our example documents containing remarks about ‘appetite’. Selecting a random sample helps in eliminating potential biases by giving all documents an equal probability to be selected.

A human judge then goes through automatically generated summaries of the selected documents. This human-guided step is crucial as there are often multiple explanations for the observed frequencies and correlations, and only a look at the actual documents can reveal which of them apply.

4 Results

CKD patients eventually have to face a decision regarding which treatment to undergo. The following options exist: Hemodialysis (HD), peritoneal dialysis (PD) and kidney transplantation. The different treatment options all have their own risks and benefits, so patients might not be sure which suits them best. In addition to that, patients might have to change treatment because a transplant is rejected and has to be replaced by PD or HD. They might also have to switch between dialysis types as a result of of high blood pressure, fluid overload or infections.

Hence, it is no wonder that discussions on all three options make up a considerable amount of our corpus. In the opening posts, the synset {haemodialysis, hemodialysis} is mentioned 785 times, and the synset {organ transplant, transplant, transplantation} even appears in a total of 1,409 documents. Table 2 displays the list of synsets most correlated with the respective treatments. To provide some perspective: the average correlation coefficient of the pairs formed by the 1,876 distinct synsets in the corpus above the threshold level is approximately 0.0435 with a standard deviation of 0.0598.

Table 2: Table displaying synsets correlated with treatment options. CIs are adjusted to control the false coverage-statement rate (FCR) at level 5%. To save space, each synset is identified by one representative synonym, e.g. {dark, night, nighttime} is displayed as {night}.

</table>

Whereas forum members mentioning transplants seem to be most interested in discussing the modalities of receiving a kidney transplant from a donor, a large amount of discussions on PD and HD seem to involve comparisons between the two options, e.g. the most highly correlated synset with {haemodialysis, hemodialysis} is {peritoneal}. And indeed, 10% of discussions on the two treatments mention both HD and PD.

A commonly raised objection concerning HD is the need to visit a dialysis center, with many patients preferring to undergo dialysis at home, either in the form of home HD or PD. {home} frequently co-occurs with both PD and HD. PD patients or those considering it seem to be mostly discussing its practical aspects: Synsets like {catheter}, {exchange}, {bag} and {dark, night, nighttime} all refer to the immediate process of PD. Because of this practical
bias in the results, we assumed that a large proportion of users discussing PD have practical experience. Manually checking a random sample of 100 opening posts mentioning PD, we find that 67 did already undergo PD treatment while 33 did not, so significantly more patients belong to the former group (95%-CI: 0.57, 0.76).

Besides considering the three different treatment options, some of our other observations are the following:

1. We found a disproportionate occurrence of the synset \{hubby, husband, married man\} compared to \{married woman, wife\}, with only 122 first threads mentioning the latter and 433 mentioning husbands.
2. Of all the 3,174 first threads, 617 reference an ancestor, most of the time either mother or father.
3. A very large number of discussions centered around food, with \{food, nutrient\} appearing in 2,623 of 10,216 opening posts. Besides several ingredients, we found \{formula, recipe\} to be highly correlated with the food synset (Corr: 0.195, 95% CI: [0.176, 0.215]).

The first observation could mean that women constitute the majority of forum members or at least of those who care for a significant other. To check this, we manually labelled the gender of 200 users by looking at their opening threads. We positively identified 94 members, of which 67 were women and 27 men. The 95% CI for the percentage of female users is (0.58, 0.76), indicating that significantly more women than men are active in the considered CKD discussion forums. Because of the second observation, we might guess that up to 20% of all opening threads were created by someone caring for a relative. Out of a random sample of 100 threads, we have manually identified 79 posts coming from someone caring for an ancestor, in most cases father or mother, and five threads alluding to a question on the hereditary nature of the disease. 16 threads were of an unspecified nature. This confirms our hypothesis that offspring of patients are concerned about the health of their parents and seek help online. Notice that in both cases, we restricted our view to the first threads created by each user. We decided to do this as it ensures that heavy users do not bias the results when inferring a characteristic of the forum population. The third observation triggered the hypothesis that while patients may in theory know what their diet should look like, they could be missing recipes that can help them to practically adapt to the new dietary requirements. In the documents, \{formula, recipe\} appeared 220 times, and in a random sample of 100 of opening posts containing both food and recipe, 40 posters specifically asked for recipes, 36 shared recipes and 24 discussed some other recipe-related topic. These results suggest that 3% of users who discussed food specifically asked for recipes. (95%-CI: 0.026, 0.042).

5 Discussion

We found Internet self-help forums to be an unique and potentially fruitful medium for learning about the daily issues CKD patients face. Our results indicate that there might be a need for stronger embedding of relatives in the treatment process. We also detected a gender gap, with significantly more women active on the forums than men. Further research might provide insights whether this finding applies only to the two considered forums or generally, and if so, what measures could be taken to increase men’s participation. A bit surprising was our observation that many people seem to discuss alternatives to classical hemodialysis such as home hemodialysis or peritoneal dialysis, even though the percentage of patients on these treatments combined is only around 10% in the US. It is unclear to us whether the clientele opting for these more unpopular treatment options is particularly contracted in the two considered forums or whether in general there exists a much larger demand for PD and home hemodialysis. Another explanation for this might be that patients engaged in these forums are highly motivated and more active in their disease management. Finally, a significant number of patients inquired about the types of food they were still allowed to eat, asking for recipes satisfying their nutrition requirements.

As we have seen, self-help forums accumulate a lot of information over time. This makes the forums data hubs that patients can query to answer their questions. However, not all of the accumulated information is accurate, and the shared first-hand experiences might not be representative. Therefore, it is necessary to investigate the potential biases existing in the opinions and experiences expressed on these forums. In addition, analyzing the differences in patient’s reactions towards first-hand experiences of fellow patients compared to the advice of their doctors might shed further light on how patients’ needs are addressed best.

Analyzing online communication data comes with a lot of challenges, requiring the development of new approaches for text analysis. The results of our proposed methodology are encouraging, but there are several potential improvements.
One of them would be to enhance the disambiguation algorithm, which is an active research topic in itself. One limitation of our current algorithm is that the similarity score for words of different parts of speech is always zero due to the WordNet hierarchy. Hence, if there was only one word of a given part of speech in a context, the most frequent synset is chosen without taking the neighboring words into account. A potential remedy could be to leverage WordNet’s synset definitions in the similarity calculation. This would be similar to the Lesk algorithm\textsuperscript{34} which was adapted to WordNet previously.\textsuperscript{35}

Alternatively, disambiguation could be improved by extending the Brown corpus or by integrating ontologies such as UMLS to compensate WordNet’s deficiencies in the medical domain. Another limitation of our current method is that it does not take syntactic information into account and thus relies on a human-guided final step. If this could be incorporated, one would not only pertain semantic information, but could also identify the interactional relations: Who acts and who is acted upon? However, given the complexity of such a task, this might be a long-term project. From a short-term perspective, it might be more fruitful to develop methods for calculating synset similarity and clustering techniques of synset trees in order to more easily identify discussed topics. Since our methodology is not tied to a single medical domain, one could think of applying it in other areas. In particular, we think of forums where due to the nature of the problem one would expect high veracity (chronic or lethal diseases) or where due to a high social stigma there is a lack of reliable information (e.g. depression).

6 Conclusion

Given the persistent rise in costs related to CKD, developing new preventive measures to curb disease progression has become an economic necessity. In this study, we have developed a process to systematically analyze online self-help forums. We encountered a few surprising phenomena: The large gap in user activity, the gender gap, forums as knowledge hubs and the desire for practical information. The study of online self-help forums broadens the perspective and allows medical practitioners to gain insights into the daily routine of chronic disease patients. Incorporating the insights drawn from such analyses might allow doctors to take a more holistic view of their patients and promote more personalized treatments. Information extraction and analyses of communication of chronic disease patients might therefore play an important role in developing new preventive care approaches.

Dynamic Estimation of the Probability of Patient Readmission to the ICU using Electronic Medical Records

Abstract

In this paper, we propose a framework to dynamically estimate the probability that a patient is readmitted after he is discharged from the ICU and transferred to a lower level care. We model this probability as a latent state which evolves over time using Dynamical Linear Models (DLM). We use as an input a combination of numerical and text features obtained from the patient Electronic Medical Records (EMRs). We process the text from the EMRs to capture different diseases, symptoms and treatments by means of noun phrases and ontologies. We also capture the global context of each text entry using Statistical Topic Models. We fill out the missing values using a Expectation Maximization based method (EM). Experimental results show that our method outperforms other methods in the literature terms of AUC, sensitivity and specificity. In addition, we show that the combination of different features (numerical and text) increases the prediction performance of the proposed approach.

Introduction

Currently, the accurate and opportune prediction of patient readmission to the ICU shortly after he is transferred to a lower level care is of great interest to health providers. Tools that estimate the probability of patient relapse and readmission to the ICU aid physicians and health care providers to determine the possible resources that should be allocated to the patient and to discover the possible causes of relapse that could lead to the patient to be readmitted to the ICU. The timely and accurate estimation of patient’s probability of readmission allows us to successfully trigger a medical alarm before the patient is transferred from the ICU.

This probability estimation also permits the early identification of patients with elevated risk of readmission. As a result health care providers can differentiate those patients from the ones who are stable and less likely to return in order to assign medical resources more effectively.

Most of the existent methods in the literature\(^{1,2}\) rely on the use of static classifiers that do not take into account the evolution of the patient or the dynamic nature of the patient’s features. To overcome these challenges, we propose a dynamic method based on Bayesian Time Series and Dynamic Linear Models (DLM) to estimate the probability of readmission before the patient is discharged to indicate the existence of a possible medical alarm. Our contribution is summarized as follows: We model the probability of patient readmission as an aggregated latent state which is updated each time new features are observed (lab results, vital signals, etc.). Our model is fed with heterogeneous data obtained from his Electronic Medical Records (EMRs) which consists of text and numerical data with both discrete and continuous variables. We incorporate the text information into the model by developing a method which converts the unstructured text information into discriminative features that are later incorporated into the model. Finally, we address the missing values problem by estimating those values using a Regularized Expectation Maximization (EM) based method.

In this context, we find that the dynamic estimation of the probability of patient readmission to the ICU provides a more accurate prediction when compared with other methods in the literature and other static prediction methods.
Background

Prevailing medical practice relies on frameworks such as the Apache III\textsuperscript{3}, and SAPS II\textsuperscript{4} scores. Both methods, widely used to predict patient mortality in the Intensive Care Unit (ICU) are used as proxy to estimate the likelihood that a patient is not ready to be transferred to a lower level care and there is a high probability of being readmitted if he is discharged from the ICU. These methods incorporate temporal information in a limited way by only choosing the worst-case scenario values during the first 24-hour window that a patient is inside the ICU. As a result, they often overestimate the probability of mortality (not readiness to be transferred from the ICU). Moreover, these scores are only estimated once during the entire stay in the ICU, which may not indicate whether the patient would recover and be successfully transferred from the ICU in the future.

Data Mining has been previously used to address the problem of estimating the likelihood that a patient is readmitted to the ICU\textsuperscript{1,2}. Other prediction methods such as Batal et al.\textsuperscript{5} include the dynamic information by collapsing the time series of features, such as blood pressure and heart rate, into static features that are later used in a classification framework. However, this model does not take into account the evolution of the patient in time. Most of the existing solutions rely on training a static classifier with a patient’s observed feature vector. These features are mainly static, such as lab reports produced at a given point of time or the estimated APACHE score at the discharge time.

Furthermore, most of the methods mentioned above assume the availability of all the features at the prediction time. This assumption may not be valid in a real scenario where the data is often incomplete and segmented. Health care data suffers from a large volume of missing data due to the fact that not all the features are collected (lab results, vital signal, etc) for all the patients at all time. One of the most common methods to fill out these missing values is to perform mean imputation. However, this practice has been shown to introduce more noise into the model rather than reduce it\textsuperscript{6}. To tackle this problem, previous approaches segment the patient features according to their age group and then calculate the average value for each segment\textsuperscript{7,8}. Other methods handle missing values by fitting a distribution for each feature with the observed data and sample from the estimated distribution when the value is missing\textsuperscript{9}. Similarly, the use of Multiple Imputation to predict the missing values has been proposed previously. Here regression techniques with the other observed features as covariates are deployed\textsuperscript{6,7}. Overall, these methods do not take into account the temporal aspect of the missing data where current features values are highly dependent on previous values.

Most of the existing prediction models do not use text from the Electronic Medical Record (EMRs) due to its complexity. However, text data contains key information that is potentially useful to better predict the likelihood that a patient is readmitted to the ICU. Examples of text include lab reports, admission, doctors and nurse notes. Ghassemi et. al\textsuperscript{10} combine static numerical features such as SAPS II score with topic modeling features from the text of the EMRs to estimate the probability that a patient die after 30 days of being discharged using Support Vector Machines (SVM).

Our proposed approach combines text and numerical information in a dynamic setting that allows us to predict the patient readmission before the patient is transferred from the ICU to other hospital areas. In addition, our proposed approach takes into account the evolution of the patient health state and temporal aspect of the patient features to predict how likely he will relapse and will be readmitted to the ICU.

Methods

In this section, we describe the method to construct the probability of readmission as a latent state, the methodology we use to extract numerical features and to process the text information to extract the discriminative features. In addition, we outline the framework we use to handle missing values. Finally, we describe the experimental settings and the methodology to validate the proposed approach.

Definition of Probability of Readmission as a Latent State

We define the that a patient \(i\) would be readmitted to the ICU in the next 30 days \(Y_{t,i}\) or not \(Y_{t,i} = -1\) if it is discharged from the ICU at time \(t\) as a binary variable. \(Y_{t,i}\) is 1 with a probability of \(\pi_{t,i}\), which represents the probability that a this patient is readmitted if he is transferred from the ICU at time \(t\). (probability of readmission). This probability is a function of a latent state \(\theta_{t,i} = [\xi_{t,i}, \tilde{\theta}_{t,i}].\) This latent state is formed by the estimation of the log-odds of the probability of readmission in previous steps \(\xi_{t-1,i}\) and the patient features observed at time \(t, \tilde{\theta}_{t,i}\). The value of \(\tilde{\theta}_{t,i}\) is obtained by combining a set of observed features \(X_{t,i}\) obtained from the EMR at time \(t\) and the value
of this combination at previous steps, $\hat{\theta}_{t-1,i}$.

In this framework, we are able to include both the patient’s features and his health context obtained from previous time steps. This is not accounted for in the static classification frameworks. Our proposed model is a special case of the Generalized Dynamic Linear Models (GDLM)\(^{11}\). Here, we employ the logistic transformation to accommodate our specific context. This leads to the following expressions:

\[
Y_{t,i} \sim \text{Bernoulli}(\pi_{t,i}), \quad \pi_{t,i} = \frac{e^{\xi_{t,i}}}{1 + e^{\xi_{t,i}}}, \quad (1)
\]

\[
\xi_{t,i} = \xi_{t-1,i} + \tilde{\theta}_{t,i} + w_{t,i}, \quad w_{t,i} \sim N(0, W_{\xi}) \quad (2)
\]

\[
\tilde{\theta}_{t,i} = \lambda \tilde{\theta}_{t-1,i} + \beta X_{t,i} + w_{t,i}, \quad w_{t,i} \sim N(0, W_{\theta}) \quad (3)
\]

Here $\lambda$ is a decay factor that determines the contribution of previous feature values in the current value of $\tilde{\theta}_{t,i}$. The vector $X_{t,i}$ is constructed from the patient’s observed lab test results, vital signals readings, text notes features, and demographics (features). In this model we assume that most of the values of $X_{t,i}$ are observed. In later subsections of this paper, we explain how we model and estimate the missing values of the feature vector. The vector $\beta$ represents the regression coefficients we use to combine the observed features. The value of $\theta_{t,i}$ can take both positive and negative values. Thus, we are able to increase or decrease the probability of readmission using the observed features $X_{t,i}$. $W_{\xi}$ and $W_{\theta}$ are the evolution variances of $\xi$ and $\theta$ respectively.

The value of $\xi_t$ reflects the log-odds effect on the probability of readmission $\pi_{t,i}$ by previous observed features contained in the state $\theta_{t,i}$. To illustrate this effect, we calculate the impact of the user’s features $X_{t,i}$ observed at time $t$ and then aggregate them into the state $\theta_{t,i}$ after $k$ steps assuming no other values of $[X_{t+1,i} \ldots X_{t+k,i}]$ are observed. This impact is determined by the following forecast function:

\[
\xi_{t+k} = \sum_{r=0}^{k} \lambda^r \tilde{\theta}_r = \tilde{\theta}_t (1 - \lambda^{k+1}) / (1 - \lambda) \quad (4)
\]

As illustrated by the previous equation, the proposed model incorporates knowledge from prior measurements into the current state estimation. This effect representation allows us to predict patient probability of readmission even when no measurements are available at a given time $t+k$. In addition, the effect does not decrease over time, as opposed to $\theta_t$ (observed features). Each time there are new observations available, the value of the effect $\xi_{t,i}$ is updated using equation 4.

**Model Fitting**

Figure 1 shows the graphical model of this framework. The colored circles represent the variables that are observed in the model. The non-colored circles are the latent variables and model parameters that need to be inferred. The learning across multiple users is reflected through the estimated parameters $\Phi$ defined as: $\Phi = \lambda, W_{\theta}, W_{\xi}, \beta$. This representation is flexible enough to expand the model and to incorporate different weighting vectors $\beta$ for different patient groups with a particular disease or age range.

We fit the model using Dynamic Linear Models with Logistic Transformation. This model incorporates the user features into an aggregated patient state that evolves over time, in contrast to static classification models. In addition, we train the model using the entire patient’s stay path as opposed to individual time steps. By performing this, we take into account the uncertainty about the future in the estimation of the probability of readmission.

Our proposed approach allows us to predict future values of the state as more readings become available. Consequently, we are able to dynamically estimate the current patient probability of readmission and predict its evolution using the predictive forecast function of the latent state. Figure 2 describes the fitting steps for the proposed model.

In the following subsections, we describe the process to extract both numerical and text features, as well as the method to fill out missing values. Once we have the time series features for all the patients in the training set, we give an initial value to the model parameters $\Phi$.

We train the model using an iterative method based on Expectation Maximization (EM). This method consists of 2 steps: E and M steps. In the E step, we estimate the latent state of the patient $i$, $\theta_{t,i}$ using the Forward Filtering
Backward Smoothing method (FFBS)\textsuperscript{12}. In this method, we estimate first the latent state $\theta_{t,i}$ using the values of the observed features $X_{t,i}$ and the state value of the previous time step $\theta_{t-1,i}$ (Forward Filtering). Once we have estimated the entire path, we correct the estimated latent state backwards using the estimated state values of future time steps $\theta_{t+1,i}$ (Backward Smoothing). By combining the Forward Filtering (FF) and the Backward Smoothing (BS), we guarantee the construction of a fully dynamic model with feedback where previous values of the path affect the current latent state while accounting for the future uncertainty. One variant of this dynamic model is to train the model with no feedback about the future (open loop feedback). To achieve this, we fit the model using the latent states obtained with the Forward Filtering (FF) step only.

The M-step consists of estimating the values of the parameters $\Phi$ that optimize the latent patient paths (probability of readmission path) previously estimated in the E-step. Then, we repeat the E and the M steps until convergence.

We predict the probability of readmission in the test partition assuming that we do not know the final outcome of the patient. Therefore, we estimate the latent state $\theta_{t,i}$ using the estimated parameters and previous values of the latent state $\theta_{t-1,i}$ using Forward Filtering.

**Numerical Features Extraction**

We extract the numerical features using the events described in the EMR. A patient may be subject to different procedures and events during his stay in the ICU based on his condition. The events that we incorporate into the model are selected by means of the $\chi^2$ test. We estimate then this score for all the events that appear in the corpus and retain those with higher score (the most discriminative ones). We extract 30 features such as blood pressure level, lab procedures, pain level, and heart rate.
We observe that the selected features are a combination of those used by the APACHE III and SAPS II scores. We find that 80% of the Apache III score features and 90% of the SAPS II features are included in our selected features. This selection shows consistency between our proposed approach and these widely used methods of the literature.

We identify that some of the selected features are considered to have a bimodal distribution. For instance, it is equally dangerous to have a really low blood pressure as to have it to be really high. To integrate this knowledge, we assign a weight for each possible range of the event. Those weights are obtained from the those used by the Apache Score III.

We then divide the selected user features into two groups: quasi-static and dynamic. Some of the labs and procedures do not need to be performed at each time step. Therefore, we consider these features as quasi-static (they are updated if there is a new reading). Features such as blood pressure, pain level and heart rate are considered to be dynamic. This division impacts how missing values are treated in these features. The quasi-static features are updated when a new value is observed. Meanwhile, the dynamic features will be filled in using the method to estimate missing values described later in the paper. In addition to these features, we include two demographic features about the patient: gender and age which we treat as static variables. Both features provide us the initial conditions to set the initial probability of readmission. Table 1 shows a summary of the feature extraction process.

Text Feature Extraction

Standard approaches used as proxy to estimate the probability of readmission, such as Apache III and SAPS II scores, do not incorporate text information. One of the main challenges researchers face is to incorporate this type of data effectively and to create discriminative features.

To achieve this, we extract text features to improve the health state prediction, consequently the estimation of the probability of readmission to the ICU. The text entries found in an EMR mainly consist of nurse’s entries, procedures reports, admission and discharge information, among others. Each text entry has an assigned timestamp. Thus we are able to construct a time series for each of the text features we extract. In this subsection, we describe the steps we follow to process the text and extract different features that are later integrated into the model. Figure 3 depicts the text-based feature extraction process.

Noun Phrases Extraction

Given the nature of health care text data, we need to extract meaningful phrases and concepts to successfully represent diseases and treatments (features) which help us to improve our statistical estimates. To achieve this task, we extract noun phrases relevant to the medical domain by annotating a set of discharge summaries using the Clinical Text Analysis and Knowledge Extraction System (cTAKES) and Metamap. With these tools we extract clinical named entities (concepts) such as drugs, diseases/disorders, signs/symptoms, anatomical sites and procedures.

Discharge Summaries provide us a rich data set to explore and to extract noun phrases. These documents often aggregate the patient’s medical history. This includes all the patient’s information collected during his stay in the ICU, treatments and care information that the patient should follow after he is discharged from the ICU.

After extracting all the entities, we select the phrases which describe a disease, a procedure or a medication using the medical ontologies provided by SNOMED (matched concepts). In addition, we also detect which set of noun...
phrases corresponds to stop words (i.e. patient name, doctor name). By means of tf-idf term selection, we select the most important noun phrases and remove those with low score.

Once the phrase selection is completed, we perform standard stop words removal and stemming before indexing the documents. Then, we extract two types of features: term and topic based features which we describe below.

**Term-Based Features**

We incorporate into the model a term-based feature using the obtained noun phrases and word terms from the EMR text entry. This feature is based on the classification of the text entries: $-1$ if the patient is ready to be discharged and $1$ if not. We use the Naive Bayes classifier, which has been shown to provide good predictive performance and it is computationally feasible for the unbalanced classes problem\textsuperscript{16}.

In order to make this classification feasible, we reduce the large vocabulary size of the corpus by extracting the most discriminative terms by means of $\chi^2$ test of the probability of readmission\textsuperscript{17}. We performed this test on the whole corpus. Our goal is to obtain a global estimate from the whole corpus in order to reduce the bias resulting from the term selection. We keep 4000 terms after this step.

**Topic-Based Features**

The second set of text features is based on statistical topic modeling. These models allow us to reduce the dimensionality of the term space to a smaller feature space of latent ”topics”. In addition, we are able to model topics for unseen documents without training the model again, as the method is generative.

In this context, each document is represented as a mixture of topics with a certain probability. Similarly, each topic is represented as a mixture of words. Our hypothesis is that topics capture the global context of the document while this cannot be achieved by selecting text terms alone. By capturing this context, we are able to improve the performance of the prediction of patient readmission.

For this application, we fit a GD-LDA model to extract the topics from the corpus set using 75 topics. The corpus consists in all the processed text entry notes (noun phrases + terms) of all the patients. GD-LDA, which is a generalization of LDA\textsuperscript{18}, allows us to model correlations between topics as opposed to LDA. In addition, this method is fitted in an unsupervised form, and it is computationally efficient, which permits us to train a large number of documents in a single batch contrary to other statistical topic models that model correlations such as Correlated Topic Models (CTM)\textsuperscript{19}.

We then remove the background topics which we define as word mixtures with a high percentage of common words (more than 90% of the terms inside the topic). We define as common words those that do not have healthcare related information by comparing them with the ontologies from the UMLS using MetaMap\textsuperscript{14}. These ontologies provide
information about healthcare treatments, drugs and diseases. We keep 65 topics after this step.

After removing the background topics, we select the 10 most discriminative topics by means of the $\chi^2$ test and include them in the dynamic model as features. Our hypothesis is that patients with certain topics in their EMR are more susceptible to be readmitted to the ICU than those whose EMR does not have them. In order to make the documents comparable, we use the values of \{1, 0\} to show the presence or absence of a topic in the document instead of the probability of the topic in the document (two patients with similar medical history can have the same topics in their EMRs, but in different proportions). Thus, we indicate that a topic is present in a document if it accounts for more than 5% of the total topic mixture inside the document. In addition to the most discriminative topics, we include the classification output of the text entry (patient ready to be discharged or not) using the document topic mixture as features. Here we use Naive Bayes classifier.

**Missing Features Estimation**

The proposed framework mentioned above assumes that most of the patient’s features are observed at each point in time. When feature values are not observed, we indicate they are missing and then we impute their value.

For the current application, the patient’s features have an implicit temporal aspect. The value of features in time $t$ are highly dependent on their value in previous time steps $1..t-1$. Then, standard imputation methods based on the mean value could lead to estimation errors. To overcome this challenge, we impute the missing values by means of a Regularized Expectation Maximization method. This iterative method uses the observed features at a particular time to impute the missing ones using an initial value of the parameters (E-step). Then we choose parameters that minimize the error rate between the observed values and the imputed ones (M-step).

The E-step (expectation) consists of estimating the missing features $\hat{x}_m$ using the values of the available ones $x_a$ inside the record using the following equation:

$$\hat{x}_m = \mu_m + (x_a - \mu_a)\gamma, \quad \gamma \sim N(0, \Sigma) \quad (5)$$

where $\mu_m$ is the mean estimate of the missing features of a record and $\mu_a$ is the mean estimate for the available features in a given record. We define as a record all the observed features of a patient at a given point in time $X_{t,i}$. The value of $\gamma$ is the vector of regression coefficients for the available features. The hypothesis behind this step is to represent the missing record values as a combination of the available values for a given record and an estimated mean of the
missing values of all the records.

After the missing values have been imputed, we perform the M-step. In this step, we estimate the mean and variance of the observed features and coefficient weights of how these are combined to impute a missing value. We repeat both steps until a certain error rate is achieved (around 5%). More details of the algorithm can be found in the work of Schneider.20

Experimental Settings and Validation

We test our approach by estimating the probability that a patient discharged from the ICU and transferred to other areas of the hospital would be readmitted in the near future. This prediction is critically important in the accurate prognosis of patient health state (we want to avoid health complications in the patient by discharging him before time). In addition, this prediction is very important to assign medical resources effectively.

For the situation which we are modeling, we predict the probability that the patient would be readmitted if he is discharged at time \( t \) using the information available in his EMR before he is discharged. The EMRs are obtained from the MIMIC II data set.21 This dataset contains text and numerical information that describes procedures, medications and vital signs readings from a given patient during his stay in the ICU. MIMIC II is composed of medical records from over 30,000 patients admitted to the ICU during a 7 year window of hospitals from Boston Area.

We validate our method using the EMRs of 15,000 patients selected randomly. In order to compare our approach with other methods from the literature, we only study the adult patients (over 18 years of age) without excluding patients due to a specific illness; this data consists of 11,648 people. We report our results using five-fold cross validation, taking 80% of the patients as training set and the remaining 20% as test set. We construct the time series of each patient by aggregating the patient information every 3 hours.

We report the probability of patient readmission after \( t = 24 \) and 48 hours and at the time of discharge. Our goal is to test the prediction capability of the proposed approach at different time steps. We compare our method with related methods of the literature used as proxy to estimate the probability of readmission such as Apache Score3 and SAPS II4. In addition to these methods, we compare the proposed approach with static classification methods such as Naive Bayes and Random Forests with 50 trees with a sliding window for \( t = 24, 48 \) and before patient discharge as in our proposed method.

Results

When analyzing the time series of the patients, we detect that the 57% of the patients stayed 24 hours of less. Thus common practices used as proxy to detect the probability of patient readmission such as Apache Score and SAPS II are not applicable for those patients. We also detect that after dividing the features in quasi-static and dynamic features 34% of the features are not observed. Therefore, the method to fill out missing values would have high impact in the estimation of the results.

Figure 4 shows the obtained topics after constructing noun phrases and removing background topics. Note that by performing these steps we are able to obtain cleaner topics, each one related to a particular disease describing symptoms and body parts than those provided by Ghassemi et al10. In addition to the quality of the topics, we also evaluate the quality of the topic-based classification output using the document topic mixture as features. Here we observe that 72% of the notes from the discharged patients that were readmitted were classified correctly and 52% of the notes from the patients that were not readmitted to the ICU were classified correctly using topic-based features. In addition, we evaluate the performance of the classification using term-based features. Here we observe that 53% of the notes from readmitted patients were predicted correctly and 10% of the notes from patients non readmitted were classified correctly. When comparing both features, we observe that topic-based classification is more accurate than term-based classification. In this context, we corroborate our hypothesis that topics capture the global context of the of the text notes and improve the classification performance when compared with term-based classification.

Table 2 shows the AUC, sensitivity and specificity for the proposed method and other methods proposed in the literature. Here we observe that our proposed framework outperforms the other reported methods in the three reported

\(^1\)K-fold cross validation provides a more robust prediction evaluation than leave-one-patient-out-method because K-fold cross validation uses less training data
measures and the time steps reported. We notice that in the other methods their prediction performance decreases after 24 hours. Compared to these methods, our proposed approach does not decrease the performance significantly after 24 hours of patient admission. The reason behind this fact is that the evolution of the latent state and the compilation of the feature data from previous time steps into the current one.

In addition, our proposed approach has a good balance between sensitivity and specificity. A high specificity value implies the existence of a small number of false alarms. In a real scenario, this measure has a high impact due to the limited medical resources that health providers have. Physicians do not want to be overloaded with false alarms at the time a true alarm arrives. But at the same time, they need to be predicting accurately the existence of a true alarm. Detecting all true alarms correctly is desirable since the cost of not detecting a patient who is not ready to be discharged who is very ill and dies outside the ICU is very high.

In table 2, we also observe that mortality prediction models such as Apache III and SAPS II provide a good proxy to estimate the probability of readmission. However the main limitation of these methods is that they tend to overestimate the probability of readmission as we can observe in the specificity measure. The best static prediction method is based on Random Forests at $t = 24$ hours.

Note that the combination of topic, text based and numerical features provide the best prediction performance. Therefore, we corroborate our hypothesis that text data provides complementary information to numerical features and increases the performance in the prediction of patient readmission. When analyzing the average probability of readmission, in our model with all the features, we notice that this probability increases from 0.69 in $t = 24$ hours to 0.89 in before patient discharge to those who were not readmitted compared to 0.90 in $t = 24$ hours to 0.92 before the patient is discharged from those who were readmitted to the ICU. This shows that the stay length affects the estimation of the probability of patient readmission. This phenomenon can also explain the performance decrease of the other prediction methods.

**Discussion**

In this paper we have proposed a dynamic model that combines heterogeneous data form the patient Electronic Medical Records to predict the patient readmission to the ICU. The accurate prediction of patient readmission would lead to an good allocation of resources that potentially could reduce cost in the transfer and patient care.

The use of an aggregated patient state which combines current features with previously observed ones allows us to predict the probability of readmission even if not new features are observed. The results of the proposed model depend on the quality and quantity of the patient observed features. The more features values are observed for a given patient in his EMR and the more diverse patient pool data is, the more accurate readmission prediction would be.

The current model provides a single aggregated latent state. Future work includes expanding the model to create of different latent states, one latent state for each body subsystem. Our final goal is to obtain a global prediction estimate.

| Table 2: Performance of the 3 variations of our model, 2 different methods used in the literature and 2 static classification methods in terms of Sensitivity, Specificity and AUC |

In 24 hours compared to these methods, our proposed approach does not decrease the performance significantly after 24 hours of patient admission. W e notice that in the other methods their prediction performance decreases after 24 hours. Compared to these methods, our proposed approach does not decrease the performance significantly after 24 hours of patient admission. The reason behind this fact is that the evolution of the latent state and the compilation of the feature data from previous time steps into the current one.
which results from the combination of the subsystems latent states. In the same manner, we plan to expand the model to accommodate different feature weight vectors, one for each disease group. Our hypothesis is that feature values are different across multiple diseases.

Abstract
Cardio-respiratory instability (CRI) occurs frequently in acutely ill. If not identified and treated early, it leads to significant morbidity and mortality. Current practice primarily relies on vigilance of the clinical personnel for early recognition of CRI. Given limited monitoring resources available in critical care environment, it can be suboptimal. Thus, an “Early Warning Scoring” mechanism is desirable to alert medical team when a patient is approaching instability. It is widely recognized that critically ill may show subtle changes prior to the onset of CRI, but it is not well known how their risk evolves before the onset. Using large amounts of physiological data routinely gathered from continuous noninvasive monitoring of Step-Down Unit patients, we demonstrate a data-driven approach that: (1) Characterizes patient’s individual CRI risk process; (2) Identifies groups of patients that progress along similar risk evolution trajectories; (3) Utilizes grouping information to help forecast the emergence of CRI.

Introduction
Cardio-respiratory instability (CRI) is commonly observed in critically ill patients. If not caught early, CRI may escalate and require costly interventions and result in poor outcomes1. In current practice, prompt recognition of CRI often heavily relies on the vigilance and experience of the clinical staff2, which presents a challenge especially in environments where case load is high and experienced staff is in shortage3. The study by Hravnak et al.2 shows that about 25% of the patients may develop at least one episode of CRI during their Step-Down Unit(SDU) stay, however, about 83% of CRI episodes occurred without being noticed, and among those that were actually recognized, the average latency of detection may be as long as 6.3 hours.

Given that a large amount of multi-parameter continuous vital sign measurements are readily available from existing bedside monitors commonly used in critical and post-operative care, it is not only desirable, but also possible to develop “Early Warning Scoring” (EWS) systems and incorporate them into the current monitoring process that is primarily driven by human judgment. In our previous work4, we developed such a scoring model to predict CRI. Similarly to other EWS frameworks, it can estimate with some accuracy “if” and “when” a patient might deteriorate, however, it offers little insight into “how rapidly” it could happen. Knowing the likely rate of crisis escalation in individual patients would be tremendously valuable for clinical resource allocation and it could substantially improve medical outcomes.

We propose a data-driven approach that builds upon physiologic monitoring data to discover phenotypes of CRI risk evolution during periods before its onset. It takes a “bottom-up” approach to paint a microscopic view of each individual patient’s risk process towards CRI by explicitly modeling its dynamics as well as the heterogeneity observed between the individuals. To estimate the instantaneous risk score, it uses a popular supervised classification approach. Temporal sequences of the estimated risk scores are then used to learn a finite mixture model of risk score trajectories that are approximated as third order polynomials. The mixture model groups the individual risk trajectories into a parsimonious number of equivalence classes: the risk trajectory groups. Patients who are grouped together share similar apparent dynamics of their risk evolution in the period preceding the onset of CRI, while the risk evolution patterns differ between distinct groups.

In the first part of the paper we describe the approach we take to model risk of CRI and its evolution, and how the individual risk trajectories are grouped into phenotypic equivalence classes. We then proceed to demonstrate how the ability to identify assignment of a patient to its most likely phenotype group could help forecast the onset of CRI, especially in patients whose risk escalation is rapid and who are therefore at the highest chance of being missed under the current critical care practice until their condition substantially deteriorates. We illustrate our proposed modeling methodology with empirical evaluation on real-world bed-side monitoring data collected in a Step-Down Unit (SDU) of a hospital that includes 532 annotated monitoring episodes that escalated to a real CRI episode, combined with 370 controls.
This work has relevance to some of the EWS literature. There are basically two categories of EWS. The first type is the triage EWS. Often computed just once, at the time of admission, triage risk scores are static and designed to communicate the patient’s long-term risk in general (such as e.g. mortality) without specifying a time horizon of the possible occurrence of any particular future adverse events. Example of a triage EWS is the well-known APACHE score\(^5\) or its newer alternatives that use advanced machine learning models\(^6\). Our work however is more closely related to the second type of EWS that is designed for continuous monitoring purposes. Rothman Index\(^7\) is an example. This index is computed from 26 variables extracted from the electronic health record that include vital signs, nursing assessments, laboratory test results and cardiac rhythms, and it communicates the risk of mortality within the next 24 hours, among other outcomes. Rothman Index can be updated at regular intervals (most typically hourly) or when new information about the patient’s status becomes available. Though not part of its design, if sufficiently informative data is available, scores like Rothman Index could potentially be used to model trajectories of risk evolution. In that sense, our work can be thought of as a “meta-analysis” of a particular continuous updated bedside monitoring score.

In the setting of continuously monitored patients, our modeling framework is similar to what Guiza et al.\(^10\) developed for Neuro-ICU patients to predict the Increased Intracranial Pressure (ICP) which is a risk factor for poor outcome. They built a single model to predict the ICP events to occur in 30 minutes based on dynamic features extracted from a 4-hour period of observation in a mixed cohort of positive and control patients. In our previous work\(^4\), we instead built 30 independent models to predict CRI at subsequent one-minute intervals starting 30 minutes before the hypothetical onset of the event. This makes it possible to reason about the temporal trends in CRI predictions using the data available at any given point in time, which laid the basis for our current investigation.

Our approach is also related to the concept of dynamic risk process. Wiens et al.\(^11\) estimated daily risk of C.diff colonization in hospitalized patients through a classifier that contrasted positive patients (who eventually tested positive) and control patients (those who never tested positive, or have never been tested) using a large number of features extracted from electronic health records as inputs. They reported a time series of Area Under the Receiver Operating Characteristic Curve (AUC) scores within days before the C.diff events to characterize the temporal pattern of the overall model performance. We have explored a similar approach to modeling temporal patterns of model performance for CRI events in our previous work.\(^4\) In this paper, however, we take a step further to analyze the underlying longitudinal risk process for each event for each individual patient. This allows us to have a detailed view of the risk evolution trajectories beyond what can be obtained by using the cross-sectional aggregated temporal AUC scores.

**Methods**

**Data**

Non-invasive continuous vital signals were collected from bedside monitors for patients in a 24 bed surgical/medical trauma Step-Down Units in a large urban teaching hospital during a three month period. Heart rate (HR), respiratory rate (RR) and peripheral oxygen saturation (SpO\(_2\)) were recorded at frequency of 1/20 Hz (3 readings per minute), blood pressures measurement (SysBP, DiaBP) were recorded intermittently with the minimum frequency of once every 2 hours.

**Identification of CRI events**

CRI events often occur in patients who show obviously abnormal vital signs for an extended period of time, the onset of CRI may signify the switch of patient’s state from being relatively “stable” to “unstable” and thus require clinical intervention. In order to identify real CRI events, and separate them from clinically irrelevant artifact often present in bed-side monitoring data, we first identify vital sign events (VSEs) which are the individual instances of any of the vital signs exceeding a predefined threshold\(^8\). We then apply temporal persistence criterias to filter out VSEs that last less than 3 minutes and/or the duty cycle of the observed exceedance is lower than 80%. Guided by the CRI event annotation protocol\(^9\), a committee of 6 clinical experts adjudicated the resultant sets of events in order to discriminate true CRI events from the artifacts. The artifact events refer to the events manifesting in data that have no relevance to patient’s physiological state, such as side effects of body movement, monitoring hardware or software malfunctions, etc. We only used the events adjudicated as true CRI in our analysis described below.

**Inclusion and exclusion criteria**

We have included all patients with least one CRI episode during their SDU stay in our analysis. If one patient had multiple events, all could be included, with the exception of the events that occurred within one hour of admission
(for the first CRI event of a given patient) or if they occurred within one hour after the ending of a prior event (for subsequent CRI events recorded during the particular hospital stay). Since the goal of our work is to model the patient’s risk of progression towards a CRI from their currently stable state, these data filtering criteria ensure that the pre-event periods are indeed “event free” and that the patients during these time periods can be considered clinically stable.

The patients who have never experienced any CRI during their stay became our control group. For them, we identified hypothetical event onset timestamps during their first 6 hours of the SDU stay. The timestamps were spaced evenly 45 minutes apart unless there were no sufficient data available. To be more conservative about our control set, we opted to use only the data from the initial periods of SDU stay, since most patients tend to stabilize further as their stay at SDU extends.

Feature extraction

In order to analyze the dynamics of the risk processes, for each event, either positive CRI or control, we identified 30 reference timestamps, equally spaced at 1-minute intervals ending at the onset and starting up to 30 minutes before the CRI onset time. Together with the onset time (lag=0), each patient/event combination had 31 sets of observations at those subsequent timestamps, or less if no sufficient data was available. For each observation, a set of numerical features was derived from the vital signs during the time windows of 5, 10, and 15 minutes, ending at the particular timestamp. Simple statistical features of vital sign time-series were derived separately for each vital (HR, RR, SpO2, SysBP, DiaBP), including mean, variance, min, max, range, linear slope, and fraction of valid readings, for each of the three window-width settings. This resulted in a total of 105 (3 window sizes x 5 vitals x 7 statistics) features for each observation (i.e. a patient/event/timestamp combination). Fig. 1 illustrates the feature extraction process.

![Feature extraction framework](image)

Figure 1. Feature extraction framework.

Modeling the risk process of as related to an individual event

We derived the risk process for each patient/event combination using a supervised machine-learning framework. We first constructed a training set of observations from positive and control data described above, with each observation represented by an array of 105 features derived from the interval of 15 minutes immediately preceding the onset of the events (i.e. lag=0), either true CRI or a control non-event, and we assigned a binary label as either positive or negative, accordingly to the output dimension of each such data point. We then trained a random forest classification model from this data. We chose the random forest approach for illustrative purposes only. It is likely other popular classification models could be used in its stead with comparable success. Our choice was partially motivated by positive personal experience with this type of classifier in various application domains and due to the ability of the particular implementation used to gracefully handle missing data.

The trained random forest model was then used to score the data observed during periods preceding the onset of CRI or control non-events, separately and independently for each of the 30 reference timestamps, and for each of the patient/event combination from a held out data set that was not used to train the classifier to mitigate the risk of over-fitting.

The predictions made by the trained classifier on the held-out data served as the estimated risk scores. Their values range from 0.0 to 1.0, with the higher values reflective of a greater similarity of the currently observed vital signs
features to those of patients going into an episode of CRI, and conversely, lower values suggest resemblance to the non-events obtained from control patients. Computing these scores over time at one-minute intervals, we obtained time series of scores that can be used to reflect the risk process as it is leading towards the event of interest.

We conducted our experiments using a 10-fold cross validation protocol, where the complete set of patients was split into 10 disjoint subsets. In each of 10 iterations, one of these subsets was used as a test set and the concatenation of the remaining nine subsets as the training sets. We split the data in a particular way to make sure that (1) the same patient’s data would belong to either training or a test set, but never to both in the same cross-validation iteration; (2) the proportion of positive and negative observations stayed relatively similar across all cross-validation iterations.

Group models of risk processes

We then analyzed the collection of the individual risk processes derived in the previous step, using the Group Based Modeling (GBM) approach13. In this approach, temporal patterns of patients’ risk processes are modeled as a mixture of polynomial functions with timestamps as the covariates. For a given risk trajectory of length T, assuming K groups, and the likelihood function of the trajectory is provided as follows:

$$\sum_{i=1}^{K} \pi_i \prod_{j=1}^{T} P_i(Y_j | X_j)$$

in which \(\pi_i\) and \(P_i\) is the prior probability and probability function respectively for group indexed by \(i\). \(Y_j\) is the response variable value at timestamp indexed at \(j\), in our case it is the estimated risk score from random forest classifier; \(X_j\) is the covariate, in our case it is the timestamp value (i.e. \(X_j = j\)).

Given the assumed number of distinct groups of risk trajectories (K) and the chosen order of the polynomials, the model estimates smooth trajectories for each of the groups characterized by the shape of the polynomial functions. The probability function form is determined by the response variable, in our case, since the response variable is a risk score bounded between 0 and 1, we used the truncated normal distribution. The model also estimates the prior distribution of the group membership across modeled data. The model parameters are inferred using Maximum Likelihood method through a numerical optimization procedure. We used the SAS procedure “traj” described in this paper14 and available from this website15.

After the GBM model is trained, posterior group membership for a currently observed risk process trajectory of an individual can be computed on-the-fly. Knowing the likely membership of a patient to one of the previously identified risk trajectory classes, we can inform the medical personnel of the likely near-term evolution of this patient’s status towards a possible CRI episode. The posterior membership is computed as follows:

$$P(group = i | Y, X) = \frac{\hat{\pi}_i \prod_{j=1}^{T} \hat{P}_i(Y_j | X_j)}{\sum_{i=1}^{K} \hat{\pi}_i \prod_{j=1}^{T} \hat{P}_i(Y_j | X_j)}$$

Prediction algorithm

We used the trained group model above as a part of the prediction algorithm designed to estimate the expected patient’s risk status \(t\) minutes in the future from now. In order to study the utility of the risk process grouping information for forecasting CRI, we set up two alternative protocols that took the grouping information into consideration.

In the first of these protocols, the feature set of a random forest classifier included the previously described 105 statistical features of the vital signs, but also the maximum posterior group membership indicator as an additional discrete feature. In the training phase, group membership is obtained from the fully observed individual risk process (i.e. “now casting” trajectories), while in test phase it is estimated from an online prediction of the group membership based on the currently observed vital sign features and the resulting estimated risk scores. We call these current snippets of risk score time series “trajets” since they are smallish segments of a longer risk trajectory.

The second risk-process-group aware protocol also used the current 105 statistical vital sign features, but each risk trajectory class was treated with a separate random forest risk estimation model trained using only the data of patients who have been assigned to the particular group. This was equivalent to enforcing that each decision tree in
the random forest predictor used the group label as the root node feature, while the former approach allowed the grouping information to be leveraged anywhere in the decision tree hierarchies.

As a baseline, we included the third protocol that did not use estimated groupings to forecast CRI at all. It however used the 105 time series features only, consistently with what we have been doing in our previous work.

In testing, the current patient’s data is processed using the trained risk score estimation models to obtain a “trajlet”: a short time-series of estimated risk scores. The trajlet is then processed by the trained GBM model to predict the risk process group category this trajlet most likely belongs to. The group information is then combined with the 105 features extracted to make a prediction. In the third, baseline protocol, the prediction is simply obtained by feeding the 105 features together with the group information into the single trained random forest classifier. The second protocol follows that but including predicted trajectory membership information as the additional input feature. In the third protocol, since separate models are built for each group, we only make the prediction for the most likely group assignment, and to that we use the model trained for that group and the 105 statistical features.

We empirically evaluated performance of those algorithms at predicting CRI to set on in 20 minutes. We used AUC as the performance metric. Figure 2 depicts the information flow for the first and the second protocol.

Figure 2. Information flow for the first and second protocol used to forecast CRI.

**Results**

**Data for experiments**

Subject to the inclusion/exclusion criteria described above, we included 158 positive patients and 71 control patients in our analysis, from which 532 positive events and 370 non-events were identified. The average number of events is 3.4 for each positive patient (CRI) and 5.2 for each control patient (non-events). For each event, 31 observations were generated at timestamps of 0, 1, 2,… and up to 30 minutes before the CRI onset time. This amounted to 25,983 observations. Demographic information of the positive and negative cohorts is presented in Table 1. The right hand side of the table lists the prevalence of admission diagnosis category and medical history conditions deemed to have possible relevance to CRI occurrences. As expected, control patients had significantly shorter lengths of SDU stay than the target group; however they did not reveal significant differences in any other observed characteristic.

**Estimating risk process trajectories and risk process grouping**

A total of 902 individual risk evolution sequences (532 positives and 370 negatives) were generated using the supervised learning method described above. We present here the result from a 10-fold cross validation experiment in which the risk estimates are pooled from 10 disjoint test sets in the 10-fold setup. A finite mixture model of truncated normal distribution was used with the GBM approach. We chose to use K=5 groups, each modeled with a polynomial of third order.

Figure 3 presents the 5 groups of risk process trajectories learned from our data. Each summarizes CRI risk progression for the cross validated set of patients during 30 minutes before the onset of their CRI event (or non-event for the controls). Solid lines in Figure 3 show the representative risk process trajectories for each group aggregated over the individual risk trajectories underlying the particular group, where the group assignment is based on their maximum posterior probability of group membership given full length of trajectories. Dotted lines depict means and confidence intervals estimated from the trajectory group models. On the horizontal axis, timestamp 0 indicates the onset of CRI. Vertical axis scale shows the risk scores. The graph also includes group size information (with count on left and proportion in parenthesis) obtained from the GBM model. Table 2 presents the distribution of labels and types of CRI events (stratified by the type of vital sign that was first to cross the control limits) for each group. Figure 4 shows the most likely trajectories for each of the group based risk process models, overlaid with the corresponding individual risk processes, each smoothed with third order polynomials.

As can be seen, those trajectories reveal five distinct CRI risk trends. The largest group is group 2 (trajectory plotted in yellow, “persistently low risk”), including 43% of the test cases with about 2/3 of them coming from control patients. The characteristic of this group is a flat trend of low risk over time. As can be noticed in Figure 4, individual patient trajectories that belong to this group also include some positive cases with very late (that is, rapid) onset of CRI. Most of the time these patients look stable, but then they suddenly develop CRI without leaving much lead time for the early warning system to recognize the change. With these exceptions aside, patients who could be classified as members of this group are not likely to require medical attention in the near future.

Group 5 (pink, “persistently high risk”) includes about 18% of all cases, with about 94% of them associated with positive events. This group is characterized by a persistently high risk of CRI. These patients have been in poor
condition before our observation started and they remain in it throughout. Medical personnel is likely already aware of their need for close scrutiny, and early warnings are of little use in these cases.

Group 1 (red, “late onset”) and group 4 (blue, “early onset”) contain mostly positives cases (82% positives for group 1 and 90% for group 4). Different from the other groups, they exhibit gradually increasing trends of risk, though at different lead times of the onset of the patient’s status change. Group 4 picks up the risk escalation trend as early as about 25 minutes before the CRI event, while group 1’s trend looks very similar to that of group 2 (which has a negative majority) until about 10 minutes before CRI onset. These groups are very interesting from the clinical perspective. If we could establish for a patient with the apparently low risk at the moment, that their likelihood of becoming unstable would escalate in the near term, and in addition to that we could establish with some certainty how rapid will the escalation be, this would provide medical personnel with very valuable information about the outlook of all individuals under their care so that they could prepare, prioritize, and take preemptive actions if possible, to mitigate the consequences of the imminent health status deteriorations.

Lastly, group 3 (green, “transient”) is comprised of about equal number of positive and negative cases, and it is the hardest to classify apart from others. Unless a patient can be confidently assigned to the “persistently low risk” group, they will require close monitoring, so do patients belonging to this particular group.

These results show potential utility of the proposed approach to modeling evolution of risk in managing critical care resource allocation. It also has a potential to favorably impact patient outcomes by characterizing the likely rate of escalation of the imminent crisis in a particular patient, prompting medical personnel to act with a desired urgency.

In column (B) of Table 2, we show the fraction of all positive cases can be reliably identified at various lead times as members of groups 1, 4 or 5. The combined recall of patients who will eventually become unstable across these three groups is about 59% with a specificity of 92% (false positive rate of 8%). In columns (C) and (D) of Table 2, we show the true positive (TP) and true negative (TN) counts that would be produced if we were to accurately predict group membership which can be used to predict the outcome (CRI vs. non-event) using the class majority vote rule. The recall rate of such system would be 77% at a specificity of 72% (false positive rate of 28%).

Considering the distribution of data and results according to which vital sign was first exceeded during an episode of CRI, we notice a relatively small portion of BP and HR events, and when they occur they often seem to be hard to separate from negative cases. About half of RR events belong to the “persistently high risk” group, while 17% of them belong to the “late onset” group and about 16% to the “early onset” group. For SpO2 events, 30% are mixed with negatives in the “persistently low risk” group but they are most likely the cases with the late sudden onset. Additional 27% of SpO2 events group with “late onset” class and 12% with the “early onset” class, while 17% belong to the “persistently high risk” group.

Forecasting future occurrences of instability

In this section, we report preliminary experimental results of an attempt to use risk trajectory group estimation to support forecasting of CRI. So in this case, we only observe a portion of the full risk trajectory (a “trajlet”), from which we can make online determination of the group membership. Then, we can leverage the predicted grouping to predict expected patient’s CRI risk changes in the near time.

In this experiment, we set the current time to 20 minutes before the event. This leaves us with the 10 initial minutes of observations to form a “trajlet” that becomes the input for group classification algorithm. This can be done on-the-fly using the group model learned from training data. In Figure 5, AUC scores of three risk estimation models described above split by the estimated group label. Model #1 (red) is the single random forest model with an additional discrete feature encoding predicted group membership; Model #2 (green) uses five independent random forest models, one for each risk trajectory group, and Model #3 (blue) is the baseline single random forest model with no group information incorporated. In Figure 6, we present ROC curves for each of these models, separately for each CRI risk evolution trajectory group.

Figure 4. Group trajectories overlaid with smoothed individual risk process trajectories participating in these groups.

We observe some divergence of performance between the baseline model and group based models, primarily in the context of group 1. This is the “late onset” group. It is interesting to see that group classification information available at 20 minutes before the onset of CRI, when the current risk score of group 1 does not differ much from the risk score of the “persistently low risk” group 2, is helping boost forecasting ability about the eventual outcome when compared to the model that does not use group assignment information. This suggests that group information carries some predictive value which is not captured effectively by the numeric features used by the baseline random forest model. This opens possibility for effective use of group information to inform clinical personnel of imminent health crises even before the moment when momentary online risk scores begin to escalate (20 minutes before the onset vs. approximately 10 minutes for group 1).

For group 2 (“persistently low risk”), all three models show very similar performance. This is not surprising since these patients often show consistency throughout the period of observation and their risk trends can be easily captured by random forest classifier even without using the group information. In case of group 4 (“early onset”), the risk trend is about to pick up around the time of making the prediction (20 minutes before the event), and it seems that the baseline model was already able to capture the information needed for forecasting, hence group information also does not help much here. It should be noted that it should be possible to repeat the interesting result discussed in the context of group 1 above, if we moved the time of observation further back. Group 5 (“persistently high risk”) is primarily composed of positive cases, with very limited representation of negatives, and the lack of
class balance makes ROC characteristics look unimpressive for either of the three considered models. It is also noted that the integrated performance (five groups combined) compared across three models shows no significant difference. This is understandable since this result is driven by the differences in performance between groups and the relative group sizes. In our case, groups 2, 3 and 4 where performance variation is small, account for over 80% of the cases in data. Given the integrated performance that is similar across the three models, at the false positive rate of 30%, sensitivity is 69%, positive predictive value is 76% and specificity is 70%.

Figure 5. AUC scores compared among three models for each group as well as for all 5 groups combined, showing 95% empirical bootstrap confidence intervals.

Conclusion

We described a framework designed to model evolution of risk as a heterogeneous process with the application to tracking emergence of Cardio-Respiratory Instability using continuous vital signal available from bedside monitors. We have evaluated this framework empirically using representative cohort of step-down unit patients. The presented framework is intuitive and it allows us to model explicitly the dynamics of risk changes for individual episode for individual patient. This new capability has a potentially useful clinical application in helping to understand how the patients deteriorate and not only if they will, and if so, when.

Using a group based modeling approach we discovered distinct types of risk evolution processes. Some patients exhibit persistently high-risk status, some show persistently low risk status, and some fit models that follow particular trajectories of risk escalation. The former type of patients either already receive attention of the clinical personnel, or they are not in urgent need to receive it, but patients who could be reliably identified as one of those who are on a rapid trajectory leading towards a crisis, could be flagged by the presented method for immediate attention of clinical personnel. These quickly escalating instances are particularly hard to capture by the current monitoring protocols.

Our framework establishes a linkage between the risk process and the predictive performance of the models. The distinct types of trend patterns suggest various degrees of predictability in terms of lead time and reliability. Assuming the trend patterns reflect the true underlying risk progress of the patient group, then the predictability revealed from the grouping represents an upper bound of the performance that an early warning score algorithm may achieve. It helps explaining variations of performance at various lead times and among different cohorts drawn from the population. The common practice of reporting an aggregated model performance for entire population at a fixed
point of time may mask the rich underlying dynamics and heterogeneity across the individual patients and their phenotypic equivalence classes that could be informative and clinically relevant. In this aspect, our framework is general and it can be directly adapted to any other modeling scenario involving temporal escalations or de-escalations towards or away from adverse or favorable events in healthcare and beyond.

In the context of clinical care, our method reside in between of the population-level analysis where a universal model is built for the whole population of interest, and a personalized approach where individual characteristics of the individual patient are the only source of predictive information. Both these approaches have their limitations, most prominently the risk of over-generalization in the population-level modeling case, and the risk of over-specification and the perils of low data supply in the personalized modeling case. Our framework lies in between of those two extremes allowing for heterogeneity between the individuals but also providing data support to make reliable predictions possible by drawing the required evidence from the patient’s group peers.

Additional utility of our work is in providing explanatory capability by visualizing current and expected future risk trajectory and updating it dynamically at frequent intervals, in order to provide salient and timely information to the medical personnel in an intuitive and understandable fashion.

Abstract

Parkinson’s disease (PD) is a severe neurodegenerative disorder without effective treatments. Here, we present a novel drug repositioning approach to predict new drugs for PD leveraging both disease genetics and large amounts of mouse model phenotypes. First, we identified PD-specific mouse phenotypes using well-studied human disease genes. Then we searched all FDA-approved drugs for candidates that share similar mouse phenotype profiles with PD. We demonstrated the validity of our approach using drugs that have been approved for PD: 10 approved PD drugs were ranked within top 10% among 1197 candidates. In predicting novel PD drugs, our approach achieved a mean average precision of 0.24, which is significantly higher (p<e-11) than 0.16 for a state-of-art drug discovery approach based on mouse phenotype data. Comparison of gene expression profiles between PD and top-ranked drug candidates indicates that quetiapine has the potential to treat PD.

Introduction

Parkinson’s disease (PD) is the second most common neurodegenerative disorder and affects 5 million people throughout the world¹. The prevalence of PD is expected to grow significantly with the aging of population². Current pharmacological treatment options are primarily dopamine replacement strategies³,⁴. Among them, levodopa remains the most effective agent in treating PD³, but may cause serious adverse events, such as motor and neuropsychiatric complications⁵. In addition, the dopaminergic therapies usually fail in reversing the progressive neuronal loss and controlling non-dopaminergic features of PD, such as sleep impairment, dementia, and sensory disturbances, which have become a major source of disability for most patients²,³,⁴. Therefore, new drugs are desired to improve the treatment of PD.

Computational drug repositioning approaches lead to rapid drug discovery. Most current repositioning strategies can be categorized as drug-based, disease-based, and profile-based (Figure 1). Drug-based (Figure 1(a)) and disease-based (Figure 1(b)) approaches exploit drug-drug or disease-disease similarity and existing drug-treatment knowledge to infer new disease-drug associations⁶,⁷,⁸. Drug similarities are based on pharmacological data, such as drug chemical structure⁹ and drug side effects¹⁰. Disease similarities are calculated using disease phenotype⁷, disease genetic and genomic data¹¹. Recently, profile-based repositioning strategies (Figure 1(c)) have successfully found new drugs for inflammatory bowel disease¹², small cell lung cancer¹³, and lung adenocarcinoma¹⁴. These approaches do not rely on the knowledge of existing drug treatments, and have increased ability to discover new drug-disease pairs compared with drug-based and disease-based strategies.

Current profile-based drug repositioning approaches mainly exploit the gene expression profiles of drugs and diseases¹²,¹³,¹⁴, and have an inherent challenge: the lower-level genomics profile similarities between drugs and diseases do not necessarily translate into higher-level drug treatment efficacy in diseases. Recently, the Mouse Genome Informatics (MGI) has made available large amounts of phenotypic descriptions for mouse genetic mutations based on systematic gene knockouts¹⁵, which are impossible on human. These causal gene-phenotype associations in mice have been demonstrated useful in discovering of new disease genes¹⁶,¹⁷ and drug targets¹⁸, and also have the potential to overcome the challenge in profile-based drug repositioning approaches. Hoehndorf and colleagues have used mouse phenotypes in their drug repositioning approach¹⁹. They first predict disease genes through comparing human and animal phenotype ontologies, and then link the predicted disease-gene associations with the drug-target data to suggest new drug indications. In this study, we present a novel profile-based drug repositioning strategy to exploit both lower-level disease and drug genetics and higher-level mouse phenotypes. We apply the approach for PD drug discovery and compare with Hoehndorf’s approach.
Our approach leverages disease-gene associations, drug-target relationships, and mouse phenotype data to predict new drugs for PD. We first identified PD-specific mouse phenotypes using human disease genes in OMIM, and then screened all the FDA-approved drugs for candidates that share similar mouse phenotype profiles with PD. Recent studies have demonstrated that disease-associated genes have potential to guide drug discovery. Mendelian genetics in Online Mendelian Inheritance in Man (OMIM) has been underappreciated in drug target identification, but in fact provides invaluable opportunities for drug repurposing. To date, OMIM has included 15 high-penetrance PD genes that are likely to cause the PD symptoms in the mice carrying their mutations. Though these genes are mostly associated with familial PD, clinical studies have shown that the familial and sporadic forms of PD usually share the same molecular pathways. We compared our approach with the pure genetics-based approaches and demonstrated the importance of mouse phenotypes in improving the performance of PD drug detection. We also compared with Hoehndorf’s approach and show that combining disease genetics with mouse phenotypes using our novel approach achieves significantly better precision. Finally, we analyzed the gene expression profiles for top-ranked candidate drugs and the result suggests that quetiapine has the potential treat PD.

Figure 1. Computational drug repositioning strategies: (a) disease-based methods, (b) drug-based methods, and (c) profile-based methods.

Figure 2. Drug discovery approach for Parkinson’s disease combining human disease genetics and mouse mutation phenotypes.
Methods

Our hypothesis is that a drug has the potential to treat PD if the drug target genes are associated with PD phenotypes in mice. Gene-phenotype associations based on systematic mouse gene knockouts provide rich information to link drugs and their new indications. Figure 2 shows that our drug repositioning approach based on mouse phenotypes contains two steps. In the first step, we searched for the mouse phenotypes associated with PD using the well-studied disease genes. In the second step, we extracted a set of mouse phenotype features for each candidate drug and systematically calculated the semantic similarities (using mammalian phenotype ontology) of the phenotype profiles between PD and candidate drugs. Using the mouse phenotype similarity between the drugs and disease, we predicted how likely the drugs can be used to treat PD.

A. Identify mouse model phenotypes for PD using disease genetics in OMIM

We searched for mouse model phenotypes for PD using 15 genes associated with 20 subtypes of PD in OMIM. The mutations of these genes highly increase the risk for PD and are likely to cause PD phenotypes. All these human genes have homologies among mice. We downloaded the phenotype annotations for mouse genes from MGI, and extracted 358 phenotypes that are linked to the 15 PD genes. Different PD genes may share common phenotype annotations. For example, 7 out of 15 PD genes point to the phenotype of neurodegeneration. We weighted each phenotype with the number of its associated PD genes. The weights intuitively represent the confidence that the phenotype is related with PD.

We ranked the PD-specific mouse model phenotypes by their weights, and investigated the category of the top-ranked phenotypes. The mammalian phenotype ontology classifies mouse phenotypes into 30 categories. We first mapped each PD phenotype to its categories by tracing the isa relationship in the mammalian phenotype ontology. The 358 phenotypes were mapped into 24 categories. Then we calculated a score for each category by summing the weights of all the phenotypes in it. We ranked the categories based on these scores and examined the top five categories.

B. Prioritize candidate PD drugs based on the similarities of mouse phenotype profiles between disease and drugs

We collected a set of candidate drugs from DrugBank. The drug-target database in DrugBank contains information for 1427 FDA-approved (for any indication) drugs. We extracted 1197 drugs that target on human/mouse orthologous genes, and included them into the candidate drug set. Then we combined the drug-target relationships and phenotype annotations for the target genes to link each candidate drug to a set of mouse model phenotypes through the drug target genes. We constructed a vector of mouse phenotypes for each drug, and weighted each phenotype by the number of its associated target genes.

We calculated the semantic similarity between the vector of mouse phenotypes associated with PD and each candidate drug to determine how likely the drug can be used to treat PD. A similar calculation of semantic similarity between ontology concept vectors was used in a previous study. We first quantified the information content for each phenotype term as \(- \log p(t)\), in which \(p(t)\) represents the frequency among phenotype annotations to all the 7568 mouse genes. In calculating the information content, if a gene is annotated by one phenotype term, we assumed that it is also annotated by the ancestors of this term in the hierarchy of mammalian phenotype ontology. Hence, a phenotype term has higher information content than its ancestors, which lie on higher levels in the ontology. Then we defined the semantic distance as:

\[
sim(t_1, t_2) = \max_{a \in A(t_1, t_2)} \log p(a),
\]

where \(A(t_1, t_2)\) is the set of common ancestors for \(t_1\) and \(t_2\). To calculate the distance from the phenotype vector \(p_1\) to \(p_2\), we matched each phenotype term in \(p_1\) to the most similar term in \(p_2\) and took the average:

\[
sim(p_1 \rightarrow p_2) = \frac{1}{|A(t_1, t_2)|} \sum_{t_2 \in p_2} \max_{t_1 \in p_1} \sim(t_1, t_2).
\]

The matching similarity was weighted by the product of weights for phenotype term \(t_1\) and \(t_2\). The similarity between \(p_1\) and \(p_2\) was defined as the average of semantic similarities in both directions:

\[
sim(p_1, p_2) = \frac{1}{2} \sim(p_1 \rightarrow p_2) + \frac{1}{2} \sim(p_2 \rightarrow p_1).
\]

C. De novo evaluation in prioritizing FDA-approved PD drugs

We investigated if our method can prioritize approved PD drugs. We ranked the 1197 candidate drugs using the semantic similarities of the mouse phenotype profiles between the drugs and PD. Then we extracted FDA-approved
PD drugs from FDA drug labels. Our drug ranking algorithm does not use any information of the approved PD drugs. In the de novo evaluation, we calculated the distribution of approved PD drugs among our ranks by plotting a 10-bin histogram. Specifically, we divided the ranks into 10 ranges, and counted the number of approved PD drugs within each range. In addition, we investigated the target genes for the top 10% candidate drugs. We ranked these drug target genes by the number of drugs (ranked within top 10%) that target on each gene. We also calculated the distribution of genes targeted by the FDA-approved drugs among all the drug target genes using histogram.

We demonstrated the importance of using mouse phenotypes to predict drugs for PD. Recent studies have shown that disease-associated genes can guide the detection of existing drug therapies and promising candidate drugs.22,23 We compared our approach with two genetics-based drug discovery methods (figure 3). The first method directly matches the disease genes in OMIM with the drug target genes to repositioning existing drugs for new indications. The second method extends the disease-associated genes with their functionally related genes based on protein-protein interactions (PPIs), and matched the extended gene set with the drug target genes for drug repositioning. We downloaded the PPIs from the STRING database, and used the experiment data source, which contains PPI databases such as HPRD, BIND, and GRID. We evaluated if the two methods have the ability to identify approved PD drugs without using mouse phenotypes, and compared the result with our approach.

![Figure 3](image)

**Figure 3.** Our approach compared the mouse phenotype features between disease and drugs. We compared with genetics-based drug discovery methods, which directly match the disease genes and their interacting genes with the drug target genes. The comparison aims at demonstrating the importance of using mouse phenotypes.

D. Evaluation in ranking novel PD drugs and comparison with an existing drug repositioning approach

We investigated if our approach has the ability to prioritize novel PD drugs. In our recent studies, we constructed large-scale drug-disease treatment knowledge bases from multiple data resources using techniques including natural language processing, text mining and data mining.22,33,34 The databases included 9,216 drug-disease treatment pairs extracted from FDA drug labels, 34,306 pairs extracted from 22 million published biomedical literature abstracts, and 69,724 pairs extracted from 171,805 clinical trials. Based on these knowledge bases, we constructed two evaluation sets as the proxy of novel PD drugs: the first set consists of the drugs that have been tested for PD in clinical trials and the second set consists of PD drugs extracted from literature abstracts in Medline. We removed the FDA-approved PD drugs from both sets. We used histogram to investigate the distribution of drugs in each set among our rank. We also generated a precision-recall curve and calculated the mean average precision to evaluate the ranking of drugs in the union of the two sets.

We compared the performance of our approach with a recent drug discovery approach proposed by Hoehndorf.49 In their approach, the human diseases were linked to mouse phenotypes through phenotype ontology comparison, and then associated with orthologous genes based on the gene-phenotype relationships in animal models. After that, they linked the predicted disease genes with the drug-target data to suggest candidate drugs for a given disease. We compared the histograms that represent the distributions of evaluation drugs as well as the precision-recall curves for the two methods.

E. Test the top-ranked drugs using gene expression data analysis

We further examined the top-ranked drugs by comparing their gene expression profiles in Gene Expression Omnibus (GEO)51 with that of PD. For the drugs, we extracted data sets that contain gene expression levels before and after adding the drugs to human or animal brain tissues. For PD, we downloaded the data sets that compared the
PD patients and healthy controls. We used the GEO2R software to identify the significantly differential expressed genes (adjusted $p$ value $< 0.05$) for the disease and drugs, respectively. Then we investigated if common significant genes exist between PD and the drug, and if these common genes have opposite directions of regulation.

Results

A. Our disease genetics-based phenotype prioritization algorithm identified PD-specific mouse model phenotypes

We ranked and classified the mouse model phenotypes detected using PD genes in OMIM. The top ranked phenotype categories are nervous system and behavior/neurological phenotypes as expected (Table 1). Examples of nervous system phenotypes with the highest weights include neurodegeneration and alpha-synuclein inclusion body, which characterize the pathology of PD. In addition, top-ranked behavior/neurological phenotypes, such as impaired coordination and abnormal gait, mostly include typical motor symptoms of PD. Interestingly, the rest top-ranked phenotype categories show that the pathology of PD is complex and involves not only the nervous system, but also immune system, homeostasis and other aspects.

Table 1. The top-ranked categories of mouse phenotypes extracted using PD genes in OMIM.

B. Our approach prioritized FDA-approved PD drugs

We extracted 22 FDA-approved drugs for PD and 474 genes targeted by these drugs. The median rank of the 22 drugs is 125 (top 10% among 1197 drugs). The histogram in figure 4 shows that our approach prioritized 10 approved PD drugs within top 10%. The table in figure 4 shows the rank and percentile of the top 10 approved PD drugs. Among them, the most effective dopamine replacement agent, levodopa, was ranked within top 5%. Figure 5 shows that the drugs prioritized by our approach frequently target on the drug target genes for approved PD drugs. In figure 5(a), nine in the top ten drug target genes (except GABRA1) are target genes for approved PD drugs. Figure 5(b) shows that half of the top 10% genes have been targeted by approved PD drugs, while the other half are new drug targets and may lead to novel candidate PD drugs.

Figure 4. Our approach ranked the approved PD drugs in the top. A total of 10 among 22 approved PD drugs were ranked within top 10% among all the 1197 drugs.

</tbody>
</table>
Figure 5. The drug target genes that are most frequently targeted by our top 10% drugs. (a) The top 10 drug target genes for our prioritized drugs. (b) The distribution of target genes for approved PD drugs among all the drug target genes.

Approved PD drugs and their target genes cannot be easily detected through matching disease genes and drug target genes. We compared the performance in identifying approved PD drugs with two genetics-based drug discovery methods. Using the first method, none of the 15 PD genes directly matches the target genes for approved PD drugs and we detected zero approved drug. Using the second method, we detected one approved PD drug, rasagiline, through its target gene BCL2, which interacts with the PD gene PARK2. Though the disease genes for PD and their interacting genes do not directly provide information on the drug target genes, our approach prioritized 10 out of 22 approved PD drugs by exploiting the gene-phenotype associations in mouse models.

C. Our approach outperformed an existing approach in prioritizing novel PD drugs

The top ranked drugs generated by our approach are enriched for the novel PD drugs in the two evaluation sets (figure 6). We extracted 81 drugs from clinical trials to construct the first set, and the candidate drugs in our approach contain 69 of them. Our approach ranked a total of 22 drugs in the top 10% (3.2-fold enrichment comparing to the random cases, \( p < e^{-4} \)), and this number is 450% higher than 4 drugs in the bottom 10%. Most testing drugs (68%) in the clinical trial set were ranked within top 30%. The evaluation set based on Medline contains 102 drugs, and our candidate drugs included 85 among them. We ranked 26 within top 10% (3.0-fold enrichment comparing to the random cases, \( p < e^{-4} \)), which is a 760% increase comparing with 3 drugs in the bottom 10%. In contrast, figure 7 shows that the evaluation drugs spread out in different rank ranges when using the existing drug discovery approach based on mouse model phenotypes. Comparison between figure 6 and 7 show that our approach performed better than Hoehndorf’s approach in ranking novel PD drugs in the two evaluation sets.

Figure 6. The distribution of our ranks for two sets of novel PD drugs extracted from clinical trials and Medline texts.
Figure 7. The distribution of evaluation sets based on clinical trials and Medline texts among the ranks generated by the baseline approach based on mouse phenotypes.

The precision-recall curves in figure 8 further shows that our performance is significantly better than the previous approach. The mean average precision for our approach is 0.24, which is significantly higher than 0.16 for the Hoehndorf’s approach (p<e-11). The result means that our approach achieved higher precision averagely at all recall levels, and mostly ranked the novel PD drugs higher than the previous approach.

Figure 8. Precision-recall curves in ranking the novel PD drugs for our approach and Hoehndorf’s approach based on PhenomeNet.

D. Gene expression analysis suggests quetiapine as a potential PD drug

Among the top 10 candidate drugs, we found a set of gene expression samples available for quetiapine in GEO. We identified 61 significant genes for quetiapine from GEO series GSE45229 and 1650 significant genes for PD from GSE8397. Table 2 lists the common significantly differential genes between PD and quetiapine, as well as the direction of regulation for each gene and the logarithm of fold change. Among these genes, MAOA regulates the metabolism of neurotransmitters such as dopamine and is closely associated with PD. In addition, MAOA is not a drug target gene for quetiapine based on the drug-target data in DrugBank. The gene expression analysis suggests that quetiapine, one of the top ranked drugs, has the potential to treat PD.

**Discussion**

Our study has several limitations that may be addressed in the future. Currently, we used the disease genetics knowledge in OMIM as the seeds to detect PD mouse phenotypes. We have demonstrated in several recent works that disease genes predicted by analyzing human disease phenotype networks and genetic functional relationship networks also have the translational potential in drug discovery. In the future, we will develop approaches to integrate disease associated genes in OMIM, GWAS and prediction results from computational approaches in the drug repositioning approach.

In addition, other information including human disease phenotypes, disease similarities and drug similarities may also contribute in further prioritize strong candidate drugs. In the future, we will develop approaches to seamlessly integrate these data, and investigate the candidate drugs from different angles.

Finally, our experiments tested the ranks of drugs in three evaluation sets: approved PD drugs, drugs that are tested for PD in clinical trials, and PD drug treatments extracted from biomedical literature. These evaluations tested the performance of our approach in retrieving the most successful PD drugs, and approximated its ability of detecting novel PD drugs. In the future, biomedical experiments and clinical studies are required to further demonstrate the effectiveness of the candidate drugs in treating PD.

**Conclusions**

In this study, we developed a novel drug repositioning approach to predict new drugs for Parkinson’s disease using both disease genetics knowledge and mouse model phenotypes. Our approach can identify FDA-approved PD drugs and prioritize novel PD drugs. A comparison with pure genetics-based drug repositioning approaches shows the importance of using mouse model phenotypes in identifying PD drugs. In addition, our approach outperformed a recently proposed mouse phenotype based drug discovery method through combining disease genetics with mouse model phenotypes using a novel computational approach. Further gene expression analysis on top-ranked candidate drugs suggested quetiapine as a potential PD therapy.

Automated Classification of Consumer Health Information Needs in Patient Portal Messages

Robert M. Cronin, M.D., Daniel Fabbri, Ph.D., Joshua C. Denny, M.D., M.S., and Gretchen Purcell Jackson, M.D., Ph.D.
Vanderbilt University Medical Center, Nashville, Tennessee

Abstract

Patients have diverse health information needs, and secure messaging through patient portals is an emerging means by which such needs are expressed and met. As patient portal adoption increases, growing volumes of secure messages may burden healthcare providers. Automated classification could expedite portal message triage and answering. We created four automated classifiers based on word content and natural language processing techniques to identify health information needs in 1000 patient-generated portal messages. Logistic regression and random forest classifiers detected single information needs well, with area under the curves of 0.804-0.914. A logistic regression classifier accurately found the set of needs within a message, with a Jaccard index of 0.859 (95% Confidence Interval: (0.847, 0.871)). Automated classification of consumer health information needs expressed in patient portal messages is feasible and may allow direct linking to relevant resources or creation of institutional resources for commonly expressed needs.

Introduction

Patients have health information needs about a variety of topics including symptom management, medication side effects, prognosis, coping, where and from whom to get treatment, and financial assistance1-10. In 2000, Jones described the multitude of ways patients would attempt to answer their questions with informatics tools during the next decade11, such as consumer sites on the world wide web and electronic mail messages between patients and physicians as well as among patients with similar conditions. These predictions have largely proven true1, 12-16. Recently, newer tools, such as patient portals, have emerged as another means of addressing consumer health information needs. Patient portals are web-based applications that enable patients to interact with their health information, healthcare systems, and providers17-19. Secure patient-provider messaging is one of the most popular functions of patient portals20-23. Several studies exploring the types of communication that occur through portal messaging have demonstrated the expression of important health and information needs involving prescription refills, interpretation of laboratory values, and requests for appointments20, 21, 24, 25. Other research has shown that clinical care can be delivered through portal messages24, 25. Patients may report new health problems, and these messages may result in further evaluation or treatment26.

Previous studies of the content of portal messages are limited in several ways. First, prior studies have analyzed only small numbers of messages almost exclusively in the primary care setting. Patient portals are now being widely deployed across specialties in many healthcare institutions27, 28. Second, most prior work has only described the communications with a narrow range of categories such as tests, appointments, symptoms, referrals, and general medical questions. Finally, previous research has employed manual analysis to characterize these messages. With millions of secure messages exchanged between patients and providers each year, better techniques are needed to understand fully the information needs expressed and health care delivered through patient portals.

Automated detection of concepts in consumer generated documents has been studied using natural language processing (NLP) techniques with standardized terminologies. Vocabularies have been developed to classify clinical and consumer generated documents including the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) and the Consumer Health Vocabulary (CHV) vocabularies in the Unified Medical Language System (UMLS)29, 30. These vocabularies have been used in studies analyzing clinical text as well as patient-generated text on social media31-34. Previous work has shown that adding semantic types (STYs) to clinical questions leads to improved classification35. NLP techniques using standardized vocabularies and semantic types have not been studied in automated classification of patient portal messaging.

This prior research suggests that identification of consumer health information needs in portal messages should be possible, but to date, these techniques have not been applied to analyze portal communications. In this paper, we
describe the development and evaluation of an automated classifier that employs NLP techniques and machine learning algorithms on patient-generated secure messaging text to identify types of consumer health information needs within a patient portal.

Methods

Setting

This study was conducted at Vanderbilt University Medical Center (VUMC), a private, non-profit institution that provides primary and regional referral care to over 500,000 patients annually. VUMC is located in middle Tennessee and serves both adults and children with over 900 inpatient beds, 50,000 inpatient admissions, and over 1 million outpatient visits per year. VUMC launched a patient portal called My Health at Vanderbilt (MHAV) in 2005 and completed deployment of the portal throughout the clinical enterprise by 2008. MHAV patient portal is available to all patients who receive medical care at VUMC. MHAV provides a suite of common patient portal functions including access to selected portions of the electronic medical record, appointment scheduling, secure messaging, bill management, and delivery of personalized health information46, 37. MHAV currently has over 293,000 registered users, including more than 19,000 pediatric accounts, with over 255,000 logins per month.

Portal Messages

We collected the content of all patient-generated secure messages sent through the MHAV portal from the launch of the portal in 2005 through 2014. De-identified messages were extracted from the VUMC Synthetic Derivative (SD), a database containing a de-identified copy of all hospital medical records created for research purposes. Over 2.5 million patient-generated messages were present in the SD. One thousand individual messages were randomly selected from an equal distribution over the 10-year period of this data set for analysis in this study.

Taxonomy

Our research team developed a taxonomy of consumer health information needs and communications shown in Figure 1. This taxonomy provides a comprehensive model of the semantic types of consumer health communications. Previous literature describes classification of clinical and other healthcare provider needs38-41. Classifying consumer health information needs has been an ongoing research question1, 2, 4-10, 42-44, and some studies have examined patient and caregiver needs in selected diseases45, 46. However, existing taxonomies have been incomplete or difficult to use.

Our taxonomy divides information needs and communications into five main categories: clinical information, medical, logistical, social, and other. We use the taxonomy to describe both needs and communications because it can be employed to categorize both questions and the answers to these questions. This taxonomy has evolved from a model of clinical information needs that express questions that require medical knowledge, such as those which could be answered by a consumer health information resource40. This component of the model is the most well developed as it has been employed to structure medical textbooks and evaluated on a diverse set of communications including patient journals and questions from patient and caregiver interviews40, 47. The model was then expanded to add the medical, logistical, and social needs that are expressed in other types of communications, such as portal messages. Medical needs are requests for delivery of medical care, such as the expression of a new symptom requiring management or an inquiry about a test result. Logistical needs are requests for pragmatic information, such as the location of a clinic or the copy of a medical record. The social category includes personal communications such as an expression of gratitude or a complaint. The other category covers communications that are incomplete or unintelligible. Portal messages can contain more than one type of communication. Components of the taxonomy have been validated with inter-rater reliability studies of classification of consumer questions.47

Gold Standard

A gold standard was developed by manual analysis of the types of needs and communications that were present in the selected 1000 messages. Two to three individuals reviewed the content of all 1000 messages and assigned all relevant categories to each message. Discrepancies were discussed and consensus achieved to produce this gold standard.

Our 1000 patient generated messages contained 721 medical needs, 234 social needs, 121 clinical information needs, and 222 logistical needs (Table 1). Thirty-one of the patient-generated messages were categorized as other, which consisted of error messages, incomplete messages, or messages that were incomprehensible. The number of
different major categories in each of the remaining messages included 676 with one major category, 260 with two major categories, 30 messages with three major categories, and three messages with all four major categories. We used a co-occurrence matrix (Table 1) to represent how often information needs from multiple categories are expressed in a single message (the value in each cell represents the number of messages that have category x and y over those messages that have category x).

**Figure 1.** The taxonomy of consumer health information needs.

Automated Classifiers

Automated classifiers utilized message contents to learn the major categories of consumer health information needs present using the taxonomy described above. We built four classifiers to identify consumer health information need categories in portal messages: basic, Naïve Bayes, logistic regression, and random forest. The basic classifier used regular expressions to detect whether a few words for each consumer health need category appeared in the messages (Table 2). The three other classifiers used the following machine learning techniques to predict if health information need categories were present in the message: Naïve Bayes, logistic regression, and random forests. To create the classifiers, we used python’s Scikit Learn package. We used Bernoulli Naïve Bayes with an alpha of 0.1 and random forests with 500 trees. The inputs to the machine learning classifiers consisted of Bag of Words (BoW), concept unique identifiers (CUIs), and semantic types (STYs). BoW is a representation of messages as a bag (or set) of its words represented as a vector for each message representing the number of times a word appears in the message. CUIs are unique concepts or meanings of words and STYs are broad categories of concepts represented in the Unified Medical Language System (UMLS). All features were represented as matrices with the messages representing the rows, the different features representing the columns. For the BoW, the numbers of occurrences of each word in each message make up the cells in a row. CUIs and STYs were binary features, which were zero or one depending on whether the CUI or STY was present in the message. Common stop words were removed from messages for the BoW representation. To determine CUIs and STYs, we used Knowledge Map Concept Indexer (KMCI), a validated tool designed at Vanderbilt, to pull concepts from the text within these messages using NLP and UMLS. The machine learning classifiers were trained and tested on a gold standard corpus of 1000 documents with 5-fold cross validation.

Evaluation and Statistical Analysis

We wanted to determine the ability for classifiers to predict a single category of need in a message and to predict all of the major categories of needs within a message. We evaluated the ability to predict a single major category in the machine learning classifiers with area under the receiver operator curves (AUCs). AUCs can measure the predictive...
ability of each classifier to learn whether a single category is present in a given patient generated message. For our basic classifier, we determined the ability to identify an information need category through the presence of several typical words found in those categories within the message.

We used the Jaccard index\(^{51}\) to predict how well the classifiers are able to learn the set of information needs that are in a single message, since multiple categories of information needs may be present in a single message. The Jaccard index is a measure of the similarity between two sets:

\[
J(A, B) = \frac{|A \cap B|}{|A \cup B|}
\]

The Jaccard Index was chosen for its ability to determine similarities between two sets of binary outcomes. It has similar performance in text classification tasks as other similarity metrics such as Pearson’s correlation coefficient\(^{52}\). A Jaccard Index of 1 indicates that the sets A and B have all elements in both sets, and a Jaccard Index of 0 means the sets A and B have no common elements. In our study, the gold standard annotated set represents A and the predicted set from the different classifiers represents B. We averaged the Jaccard indices for each message to give an overall estimation of the ability to predict the set of information needs across the entire corpus of messages. This study was approved as non-human subjects research by the VUMC Institutional Review Board.

### Results

The AUCs for the classifiers had different values depending on what type of input was used (Tables 4-7). The basic classifier’s AUCs ranged from 0.674 to 0.848. AUCs for Naïve Bayes ranged from 0.557 to 0.796, with medical needs having the highest AUC when using BoW and STYs (AUC: 0.796; 95% Confidence Interval (CI): (0.779, 0.813)). Logistic regression’s AUCs ranged from 0.814 to 0.883, with logistical needs using BoW, CUIs, and STYs having the highest AUC (AUC: 0.883; 95% CI: (0.863, 0.903)). Random forest’s AUCs ranged from 0.804 to 0.914 with logistical communication using BoW, CUIs and STYs having the highest AUC (AUC: 0.914; 95% CI: (0.883, 0.945)). The highest AUC for clinical information needs was the basic classifier (AUC: 0.848; 95% CI: (0.843, 0.853)); logistical needs was random forest with BoW and STYs (AUC: 0.914; 95% CI: (0.883, 0.945)); social needs was random forest with BoW, CUIs, and STYs (AUC: 0.839; 95% CI: 0.822, 0.855)); and medical needs was logistic regression with BoW and CUIs (AUC: 0.870; 95% CI: (0.842, 0.897)).

The Jaccard index for the basic classifier averaged over all 1000 documents was 0.674 (95% CI: (0.663, 0.684)). The average Jaccard indices for the different machine learning classifiers also were different depending on the inputs (Table 7). Logistic regression’s highest Jaccard index was 0.859 (95% CI: (0.847, 0.871)) when using BoW and CUIs with or without STYs, while random forest’s highest Jaccard index was for BoW and STYs: 0.858 (95% CI: (0.847, 0.870)). Naïve Bayes’ highest Jaccard index was 0.776 (95% CI: (0.763, 0.790) with BoW and STYs.

Discussion

We examined the ability to classify automatically the content of patient generated messages from patient portals into consumer health information need categories. Our developed classifiers showed promise in identification of the types of consumer health information needs expressed in portal messages, but different types of needs were best identified by different approaches to automated classification. The best classifiers for each major category of information needs had high predictive ability and were able to determine which major categories are present in a single message. As adoption of patient portals increases, automated techniques may be needed to assist in managing growing volumes of secure messages. Automated classification of health information needs may aid in connecting patients to needed resources and in triaging portal messages. In addition, automated classifiers could support consumer health informatics research to understand the nature of communications and care delivered within patient portals. Such work could lead to better resources for commonly expressed information needs and might support compensation for care delivered online.

In this study, our gold standard had a majority of medical needs among messages. This finding supports previous literature demonstrating the delivery of care through patient portals. However, we did notice between 10-20% of messages discussed other content such as clinical information needs about conditions or interventions, logistical issues having to do with billing and navigating the health care system, and social needs such as acknowledgements of care. Therefore, a patient portal can be used for many different health information needs beyond those previously reported. Our classifiers had different levels of performance for each category of information needs. Certain categories, such as clinical information needs could be identified based on a few words with a basic classifier. The observed clinical information needs expressed in portal messages were typically questions about test results and procedures that have a characteristic phrasing, which could be easily identified by a few common terms. The other categories needed more sophisticated machine learning techniques as their expressions were more diverse. Multiple words appearing together in certain needs and not others would require more complex methods to identify needs. Finally, meanings of words (concepts) or categories that words fit under (semantic types) may be important in determining if a need is present. More complex methods like Naïve Bayes, logistic regression and random forests with NLP performed better in larger and more complex parts of the taxonomy.

Logistic regression and random forests performed similarly, and both outperformed Naïve Bayes. Logistic regression performed better in clinical information and medical needs, but poorer than random forests for the other categories. Each classifier performed better with different inputs. Social needs performed best when using BoW and STYs for Naïve Bayes, but BoW, CUIs, and STYs for logistic regression and random forest. BoW and STYs worked the best when determining logistical needs for random forests, but BoW, CUIs, and STYs were best for Naïve Bayes and logistic regression in the messages. However, the gains in AUCs when adding NLP CUIs and STYs over just BoW were modest in most cases. These findings likely represent the fact that NLP tools may not add
very much, and it is the combination of words that predict information needs categories. Several factors may influence this observation. Patient generated text is likely to have less formal biomedical content and thus may have fewer concepts than medical texts. Higher order NLP methods, such as negation, also likely have little impact on content type. Thus, current results do not necessarily support a significant need for NLP, but more research into NLP of patient generated messages is needed. Logistic regression identified all of the health information needs categories in a single message better than other methods based on the Jaccard index, but random forest had a similar Jaccard index. As each classifier performed better for different information needs categories, a hybrid of information needs classifiers might best determine which categories are in a single message.

The performance of these classifiers may be limited by several factors. First, patient generated messages are more likely to include misspellings which may adversely affect information need identification. These messages may also contain abbreviations not commonly used and different abbreviations for the same word. Second, automatic derivation of meaning from patient-generated texts using computers is an ongoing challenge. Our classifiers may not be able to understand the meaning of the text, and therefore cannot determine the category of information need. Third, we utilized a standardized vocabulary for our classifiers; however standardized vocabularies may not capture different ways of expressing concepts.

Automatic classification of health information needs in patient portals has several potentially important applications. First, it could allow triaging of patient generated messages to different members of the health care team or information resources. For example, logistical needs are more likely to be answerable by an administrative assistant, whereas medical needs may require a nurse or physician to respond. Clinical information needs can be answered by an information resource such as an educational module or trusted web application. Therefore, automatic classification might enable routing of these messages appropriately without human intervention. Second, classifiers might be used to detect levels of urgency in messages. North et al. showed that occasionally patients will send potentially life-threatening symptoms through patient portals21. Utilizing automated classifiers to detect urgent messages could prevent adverse events by prioritizing responses or alerting a provider through an alternative means of communication. Finally, these classifiers could be used to determine health information needs that are frequently expressed in select patient populations, drive appropriate resource development, and potentially automatically respond to messages with links to appropriate resources.

This study has several limitations. First, this study was conducted at a single institution with a locally developed patient portal. Although the information needs seen in these messages are common needs that have been seen in other papers about patient portal messaging20, 21, our results may be limited by the unique policies and procedures developed for MHAV. Second, this study employed a small data set. Therefore, all information needs and the full breadth of their expression may not be adequately represented. Third, this study has older data including the years 2005-2014, and some of the content of messages may have become antiquated based on secular trends. Our ongoing research projects will evaluate these methodologies on larger data sets, and explore the performance of automated classifiers across clinical specialties were vocabularies and needs may differ.

Conclusions
We have created automated classifiers that show promising results in identifying the types of consumer health information needs expressed in secure messages sent through a patient portal. Certain classifiers were able to determine different semantic categories of information needs better than others. Basic classifiers were better at identifying logistical needs while logistic regression and random forests were better for clinical information, social, and medical needs. NLP techniques can improve the ability to identify the types of information needs in patient-generated messages, but the improvements were modest. Additional research is needed to improve the performance of these classifiers to support applications such as message triage, question answering, resource development for common questions, and research on consumer health communications.

Acknowledgements
We are grateful to Shilo Anders, Ebone Ingram, and Jared Shenson for their assistance in creation of the manually annotated set of portal messages used as the gold standard for this research project. The portal message content used for the analyses was obtained from VUMC’s Synthetic Derivative, which is supported by institutional funding and

Health Literacy, Education Levels, and Patient Portal Usage During Hospitalizations

Sharon E. Davis, MStat1, Chandra Y. Osborn, PhD, MPH1, Sunil Kripalani, MD, MSc1, Kathryn M. Goggins, MPH1, Gretchen Purcell Jackson, MD, PhD1

Abstract

Patient portal adoption has rapidly increased, and portal usage has been associated with patients’ sociodemographics, health literacy, and education. Research on patient portals has primarily focused on the outpatient setting. We explored whether health literacy and education were associated with portal usage in an inpatient population. Among 60,159 admissions in 2012-2013, 23.3% of patients reported limited health literacy; 50.4% reported some post-secondary education; 34.4% were registered for the portal; and 23.4% of registered patients used the portal during hospitalization. Probability of registration and inpatient portal use increased with educational attainment. Health literacy was associated with registration but not inpatient use. Among admissions with inpatient use, educational attainment was associated with viewing health record data, and health literacy was associated use of appointment and health education tools. The inpatient setting may provide an opportunity to overcome barriers to patient portal adoption and reduce disparities in use of health information technologies.

Introduction

Patient portals are online tools allowing patients and their families to interact with health care systems, health care providers, and portions of the patient’s electronic health record1,2. Over the last several decades, many health care organizations have adopted patient portals in response to consumer demands and regulatory pressures3-17. Patient portals have been shown to increase patient satisfaction, promote adherence to preventative and treatment recommendations, and improve clinical outcomes in the management of chronic diseases such as diabetes, hypertension, and depression12,14,17-22. There have been well-documented associations among health literacy, education levels, and the use of technology, including patient portals. In a large outpatient study of patients with diabetes, individuals with limited health literacy were less likely to use electronic health portals, a difference that persisted after adjustment for internet access23. Patients with a high school education or less were also less likely to use health portals24. Indeed, when asked about their preferences, patients with low health literacy and those with lower educational attainment expressed a preference for self-management support to be delivered in person or by phone, rather than via internet25. Complementary research shows related relationships, for example, between socioeconomic status or race and portal use26,27. However, not all have found a relationship between health literacy and the use of internet portals or mobile health tools28,29.

Nearly all patient portal research has been conducted in the outpatient setting in either primary care or medical specialty practices7,9,10. The inpatient setting, however, may represent an opportunity to explore barriers to patient portal adoption and to promote portal use30,31. The Vanderbilt University Medical Center (VUMC) has a well-established patient portal, My Health at Vanderbilt (MHAV), which has been deployed throughout all adult and pediatric specialties16. MHAV was designed and promoted for outpatient use, and some of the patient portal policies, such as a delay in availability of test results or a two to three business day expectation for secure message responses, might discourage portal usage in the acute hospital setting16. However, in recent years, both clinicians and the portal development team have observed an increase in the number patients using MHAV not only while remote from the health care system, but also when admitted to the hospital. In addition to a widely adopted portal, VUMC routinely collects health literacy data on adult patients during hospital admission intake. Integrating these data, we examined whether health literacy and educational attainment were associated with patient portal registration and portal usage in the inpatient setting.
Methods

Admission data

This study was conducted at VUMC, a comprehensive, academic health care facility in middle Tennessee and a major referral center for the Southeastern United States. We collected data on all admissions to Vanderbilt University Hospital (VUH) between January 1, 2012 and December 31, 2013. The VUMC Institutional Review Board approved this study.

Data on patient sociodemographics and clinical characteristics for all admissions were extracted from VUMC’s clinical data warehouse. We extracted information on patient age (date of birth), gender, race, date of admission, date of discharge, length of stay, chief complaint, and admitting service for each admission. Patients with “unknown” or “declined” race responses were coded as “unknown.” Anesthesiology, ophthalmology, psychiatry, research, dermatology, radiology, and radiation oncology, each of which had <100 admissions during the study period, were grouped into an “other” category. An emergency medicine category included patients who were admitted to inpatient services, but never physically left the emergency department prior to discharge. Admissions to pediatric services reflected adult patients admitted to pediatric providers at the adult hospital, which sometimes occurs for selected cases such as adult patients with pediatric cancers.

Patient portal usage

MHAV was launched in 2005 and has been implemented throughout the clinical enterprise since 2008. MHAV provides patients with electronic access to components of their health record, supports secure messaging with health care providers, allows for appointment management, and delivers personalized health education information based on patients’ diagnoses. All VUMC patients are eligible for a MHAV account, and MHAV users may grant account access to their caregivers and/or family members as delegate users. After implementation, MHAV was rolled out incrementally through the VUMC outpatient clinics. Physician champions encouraged provider use of MHAV, and technical support staff was available to patients, physicians, and staff as the portal was brought to individual clinics. Patients initially register for the portal online, with full access to electronic health record information being provided only after in-person user identity verification.

We extracted data on patient MHAV registration and use for all patients admitted to the hospital during the study period. Dates of MHAV registration were compared with dates of inpatient stay to determine whether patients had portal accounts during hospitalization. Patients were considered registered with a portal account during an admission if they were registered prior to discharge. From MHAV usage logs, we determined the functions accessed within the portal and user status (i.e., the patient or his/her delegate) during each admission. Admissions were classified as having inpatient portal use if any activity by the patient or his/her delegate occurred between the time of admission and the time of discharge. Portal activity during hospitalization was grouped into major functions: account management (e.g., assigning a delegate), appointment management, secure messaging with health care providers, viewing portions of the electronic health record (i.e., laboratory test results, radiology reports, clinical visit summaries, medication lists, immunization history), accessing health educational materials, and other (e.g., viewing website help).

Health literacy and educational attainment

Since 2010, nursing intake forms for adult admissions to VUH have included questions on educational attainment and health literacy. Years of educational attainment was collected as a continuous variable in the electronic health records by nurses, and was later categorized as less than high school, completed high school, some post-secondary education, and a 4-year college degree or more education. Health literacy was assessed using the Brief Health Literacy Screen (BHLS), a 3-item survey tool designed to identify patients with limited health literacy, which has been validated in research settings and as administered by nurses in our medical center. The three questions of the BHLS survey ask patients: 1) “How confident are you filling out medical forms by yourself?”; 2) “How often do you have someone help you read hospital materials?”; and 3) “How often do you have problems learning about your medical condition because of difficulty understanding written information?”. Patients responded to each question using a 5-point Likert scale, with the question regarding confidence filling out forms reverse coded. Responses were summed, and higher scores indicate higher levels of literacy. We operationalized health literacy as a continuous score and a binary indicator of adequate versus limited health literacy. Patients with scores ≤9 were classified as having limited health literacy.
Statistical analysis

We restricted our analysis dataset to admissions of adult patients (age ≥18 years) with known gender, documented educational attainment, complete BHLS responses reported during admission, and discharge date no later than March 31, 2014, which was the end of our follow-up period.

Unadjusted and adjusted logistic regression models examined the relationships between patient characteristics, including sociodemographics and health literacy, and 1) MHAV registration status, 2) inpatient use during admissions of registered patients, and 3) portal functions accessed during admissions with inpatient use. For the fully adjusted models, we included age, gender, race, length of stay, month of admission, and admitting service. Educational attainment and health literacy were both included in multivariable models. Continuous variables – BHLS score, educational attainment in years, age in years, length of stay in days, and month of admission – were fit with 4-knot restricted cubic splines. In all models, we applied the Huber-White method to correct standard errors for correlation among multiple admissions to the same patient. Our analyses were conducted in R 3.1.2.

a Limited health literacy defined as score ≤9.  

b Admissions excluded due to missing education or health literacy data.  

c median and interquartile range (25th percentile / median / 75th percentile) included for continuous variables.
Results

Between January 1, 2012 and December 31, 2013, there were 84,185 admissions to VUH. We excluded 7 admissions with discharge dates after our follow-up period, 638 admissions of patients with age <18 years, and 5 admissions for which patient gender was not available. Of the 83,535 remaining admissions, the BHLS was not completed in 21,903 admissions (26.2%) and educational attainment was missing in another 1,473 admissions, restricting our analysis to 60,159 admissions and 41,176 unique patients. Whether health literacy and education data were record was associated with sociodemographics and clinical characteristics (see Table 1). Compared to patients with health literacy and education data, those excluded due to missing health literacy or education data were more likely to be younger, female, and Asian/Pacific Islander or unknown race (p<0.05). Patients without health literacy or education data also had shorter length of stays than patients with these data (p<0.05). Admissions to Obstetrics/Gynecology were least likely to have health literacy or education data available.

A description of the study population is presented in Table 1. The study population was predominantly Caucasian (81.1%), with a median age at admission of 55 years (interquartile range 41–66 years). Half of all hospitalizations were admitted by Medicine (51.4%) and the median length of stay was three days (interquartile range 2–5 days). Patients were registered for MHAV during 34.4% of admissions and used MHAV during inpatient stay in 8.0% of all admissions. Among admissions involving patient registered for MHAV, inpatient portal use occurred in 23.4%.

Across all admissions, 23.3% of patients reported limited health literacy (Table 2), with reading hospital materials being the most challenging question. Half of admissions involved patients with some post-secondary education (50.4%), while 13.6% involved patients with less than a high school education. Literacy levels and educational attainment differed by demographics (p<0.05). Correlation between continuous BHLS scores and educational attainment in completed years was 0.32.

a Limited health literacy defined as score ≤9.

Portal registration

Health literacy and educational attainment were higher for admissions of patients registered for MHAV compared to admissions of patients not registered for MHAV (Table 2). Two-thirds (67.6%) of registered patients reported some post-secondary education, while only 41.3% of unregistered patients reported similar educational attainment. In unadjusted and adjusted models, the probability of portal registration increased across the range of educational attainment (p<0.05; Figure 1). The largest increase in the probability of registration occurred between 10 and 15 years of education (roughly between high school and college degrees).

Health literacy was limited in 16.1% and 27.1% of admissions of registered and unregistered patients, respectively. In both unadjusted and adjusted models for portal registration, patients with limited health literacy were less likely to be registered than patient with adequate health literacy (p<0.05). For BHLS scores above 10, the predicted probability of registration increased with BHLS score; a clear and significant pattern of association within lower ranges of health literacy was not observed (Figure 1).
Inpatient portal use

Among admissions of registered patients, admissions with and without inpatient use had similar levels of health literacy and educational attainment. For both registered patients using the portal during their inpatient stay and those registered patients not using the portal during their inpatient stay, two-thirds reported education beyond the high school level and approximately 5% reported never attending high school. After adjustment for sociodemographics, clinical characteristics, and health literacy, educational attainment remained significantly associated with inpatient portal use (p<0.05). For MHAV registered patients with approximately 15 or more years of education, the predicted probability of inpatient portal use increased with additional years of education, although confidence intervals became wide due to small sample sizes for the highest educational levels reported (Figure 2).
Limited health literacy was reported for 18.1% of admissions with inpatient portal use and 15.5% of admissions of registered without inpatient portal use; mean BHLS scores were not different between the two groups (12.6 for users and 12.9 for non-users). With adjustment for sociodemographics and clinical characteristics, we did not observe an association between health literacy and the inpatient portal use (Figure 2).

**Portal functions accessed during inpatient stay**

During the 4,829 admissions with inpatient portal use, patients viewed their health record information in 71.8% of admissions, used secure messaging in 57.2% of admissions, managed medical appointments in 21.0% of admissions, viewed health education materials in 20.1% of admissions, conducted portal account management activities in 4.5% of admissions, and used other functions in 8.0% of admissions. In adjusted models, educational attainment was associated with whether data from the electronic health record was viewed through the portal during admission (p<0.05). The predicted probability of viewing health record information through the portal steadily increased with years of education (Figure 3). We also observed, in adjusted models, associations between health literacy and whether appointment management tools and health education materials were accessed through the portal during admission (p<0.05). The predicted probability of using either function increased over the lower ranges of BHLS, peaking around scores of 10-11 and then declining somewhat (Figure 4).

![Figure 3](image.png)

**Figure 3.** Among admissions with inpatient portal use, predicted probability of viewing health record data through the portal by educational attainment, after adjustment for sociodemographics and clinical characteristics.

**Discussion**

This study is one of the first to examine patient portal usage during hospitalizations and the relationships between patient characteristics, including sociodemographics, health literacy, and education. In a large population of adult patients with diverse health care needs and diagnoses, we found that both health literacy and educational attainment appeared to have a significant effect on the likelihood of being registered for a patient portal. Probability of registration and inpatient portal use increased with educational attainment. As educational attainment increased, portal users were more likely to access health record information within the patient portal. While health literacy was associated with registration, it was not associated with whether patients accessed the portal during admission. Among inpatient portal users, however, health literacy was associated with use of appointment management and targeted health education tools. Similar to our results, Mayberry et al did not observe an association between health literacy and portal use. In contrast, Sarkar et al observed lower levels of portal use among patients with limited health literacy. Both studies were conducted in outpatient populations limited to patients with diabetes.
Figure 4. Among admissions with inpatient portal use, predicted probability of accessing appointment management tools and viewing health education materials through the portal by health literacy, after adjustment for sociodemographic and clinical characteristics.

There are several possible explanations for our findings. First, registration for the portal may be a formidable barrier that prohibits patients with limited levels of health literacy and educational attainment from becoming portal users. Prior research has also observed lower portal registration rates among patients with lower educational attainment and limited health literacy.23, 24 Once patients have overcome the registration barrier, education and health literacy may no longer affect portal usage. If this explanation were true, we expect to see similar trends in both the inpatient and outpatient settings. Studies of outpatient populations, however, report inconsistent findings regarding associations between portal use and literacy.23, 28 Alternatively, while admitted to the hospital, patients may receive encouragement and support in using the patient portal from hospital staff or family members, as well as contextual support such as continuous computer and internet access. This assistance may help patients overcome barriers resulting from limited health literacy or education. For example, during inpatient stay, all VUH patients may have access to the internet through computers available in patient rooms. Nurse may assist patients with use of in-room technologies, allowing patients to access the portal. If limited health literacy and education are associated with more limited computer or internet access in patients’ daily lives, then equity in computer access during an inpatient stay may have a clear connection to our results. For patients with limited access to technology in the outpatient setting, portal registration may be more difficult, or even limited to times during which patients interact with the health system, leading to associations such as those we observed between education, health literacy, and registration. During hospitalizations at VUMC, however, this technology access barrier is eliminated, which may explain the lack of an association we observed between health literacy and inpatient portal use. Whether registration serves as the prohibitive barrier to portal adoption or the presence of additional portal support during an inpatient stay is responsible for the observed associations, the inpatient setting may provide an opportunity to promote patient portals and reduce disparities in adoption of patient engagement technologies.

This study is strengthened by leveraging routinely-collected health literacy data obtained on a large cohort of adult patients; exploring adoption of a well-established patient portal with a large user community; and including patients treated by all clinical specialties rather than limiting to patients with particular diseases. However, the study is not without limitations. MHAV is a locally-developed patient portal deployed at a single institution and designed to support outpatient use cases. The findings for our portal may not necessarily translate to other portals with different registration processes and user interfaces, variations that may result in different barriers and associations between education, health literacy, and portal adoption. A number of other factors not examined in this study influence portal use, including socioeconomic status and whether or not the patient was an existing VUMC patient at admission. VUMC is a large referral center in the region, and thus patients who are transferred here might not have a portal account since they are unfamiliar with the medical center and most likely do not plan to return. Additionally, we
were not able to ascertain how patients accessed the portal. During the study period, VUMC did not provide dedicated computers for patient use in patient rooms, and thus patients wanting to access the portal during hospitalization would have needed access to a personal web-enabled device. More recently, VUMC has implemented an interactive television system that provides patients with in-room web access to the MHAV portal. Follow-up studies will examine whether this increase in technology access is associated with increased inpatient portal use. Additionally, we did not account for severity of admitting diagnoses or affected systems, which may limit patient physical and mental ability to use the patient portal during a hospital stay.

While we can distinguish portal activity conducted through patient and delegate user accounts, we do not have health literacy or educational information for delegates. For the inpatient portal use models, we associated delegate activity during each admission with the admitted patient’s education or health literacy information, which may or may not be a reflection of the delegate’s traits. We observed delegate use in 4.2% of admissions with inpatient use, and 2.9% of admissions with inpatient use solely involved delegate activity and no portal access through the patient’s account. While the delegate account policy is designed to avoid multiple users accessing the patient account, we cannot be certain whether patients used the portal themselves or logged in to allow family members access to their health information, in which case the recorded education and health literacy information may not be representative of the individual interacting with the patient portal.

Additionally, almost one fourth of patients were missing health literacy or education data. Although this limited our sample size, the remaining cohort of patients was still large. As we continue to administer health literacy measures to patients, we will be able to add health literacy and education data for patients from previous admissions. Finally, these measures are beginning to be administered in the clinics at VUH, making clinic intake forms another valuable resource of health literacy and education data for patients.

Conclusion

Patient portals engage patients in their health care, increase patient self-efficacy, and improve the quality of care. While studies of portal adoption have focused on outpatient primary care settings, patient portals may provide valuable benefits to hospitalized patients. Leveraging data from a patient portal with a large population of registered users treated across inpatient clinical specialties and data from a health literacy assessment widely implemented throughout the adult inpatient setting, we sought to understand associations between patients’ characteristics, including sociodemographics and health literacy, and portal registration and inpatient portal use. In our diverse adult inpatient population, lower education and limited health literacy were independently associated with a reduced probability of being registered for a portal account. Among patients registered for the portal, however, health literacy was not associated with whether patients accessed the portal during a hospital stay. The inpatient setting may serve as an opportunity to promote patient portal adoption and increase patient confidence with portal tools, increasing patient engagement during admission and potentially maintaining this engagement as patients transition to outpatient care. A deeper understanding of how education and health literacy act as barriers to portal registration more so than portal use is necessary for designing and implementing successful patient portal promotion activities.

Abstract
Modern EHR systems are complex, and end-user behavior and training are highly variable. The need for clinicians to access key clinical data is a critical patient safety issue. This study used a mixed methods approach employing a high-fidelity EHR simulation environment, eye and screen tracking, surveys, and semi-structured interviews to characterize typical EHR usage by hospital physicians (hospitalists) as they encounter a new patient. The main findings were: 1) There were strong similarities across the groups in the information types the physicians looked at most frequently, 2) While there was no overall difference in case duration between the groups, we observed two distinct workflow types between the groups with respect to gathering information in the EHR and creating a note, and 3) A majority of the case time was devoted to note composition in both groups. This has implications for EHR interface design and raises further questions about what individual user workflows exist in the EHR.

Introduction
Electronic health records (EHRs) have become a central component of the modern clinical workflow, serving as a central documentation repository, an ordering mechanism, and a provider communication tool. EHRs have been promoted as a mechanism for improving quality of healthcare delivery, patient safety and provider efficiency. Widespread adoption has been driven in part by substantial governmental incentives through the Centers for Medicare and Medicaid Services (CMS) Meaningful Use program, with 59% of U.S. hospitals and 48% of office-based providers using EHRs as of 2014.

Implementations of EHRs have been shown to dramatically influence clinical workflows. End-user behaviors and training approaches are highly variable. Adaptive end-user behaviors such as excessive use of copy-paste/copy forward, “overdocumentation”, and “upcoding” may compromise health care quality and patient safety; training and standardization may help reduce these practices. Beginning efforts have been made to establish standard practices among EHR end users. However, these efforts have largely focused on documentation and not on information review.

The challenges facing consistency in EHR training and use are diverse. Though back end databases are fairly consistent across instances of an EHR, user interfaces and workflows can be substantially different depending upon the institution and clinical environment in which the EHR is used. Within an institution or practice group, the physician-level characteristics in usage of EHR features and usage intensity have been found to be highly variable and personalized.

The strong influence of personal experiences and preferences is thought to partly explain this variance. Assessment of end-user EHR behaviors has often been conducted via self-reports and surveys, direct observation, and meaningful use measure reporting. Survey and reporting methods can provide a high-level perspective of provider behavior, but do not capture individual workflows. Direct observation may lack the accuracy required to quantitatively evaluate differences between individuals or groups of individuals. Real-time eye tracking technology has been shown to successfully capture user behavior in online website searching, website interface design, visual attention and video games. Within the realm of medicine, it has been employed to study radiologic and electrocardiography interpretation, note reading, and medication administration. The purpose of this study is to address this gap in knowledge by characterizing the workflow patterns of physicians using the EHR. This is done using a mixed methods approach employing a high-fidelity EHR simulation environment equipped with eye and screen tracking, surveys, and semi-structured interviews to characterize the typical EHR usage by a group of hospital physicians (hospitalists) as they encounter a new patient.
Methods

This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU; Portland, OR). Subjects signed a consent form prior to participation.

Development of Simulation Cases

An instance of our EHR environment (EpicCare, Epic Systems Inc., Verona, WI) was created to house simulated patient cases. This simulation environment imports all end-user customizations from the actual EHR environment, so the interface looked exactly as it would for each subject. Simulated cases were based upon real patient cases with common principal diagnoses (i.e., among the top 10 most common ICD-9 diagnoses for adults upon hospital discharge). Two patient cases (Cases A and B) were created and independently reviewed for medical accuracy and clinical realism by domain experts in accordance with previously published recommendations for high-fidelity case creation. Both patients had previously established care at our institution, but were now presenting to the emergency department (ED) for evaluation of a new set of symptoms. Each case contained historical data in each of the categories listed in Table 1; the current ED visit contained vitals, intake/output, laboratory data, EKG, chest roentgenogram, and a half-completed ED resident note stating the history of present illness, physical exam findings, and review of systems.

Recruitment and Testing of Subjects

Attending physicians from the OHSU Division of Hospital Medicine comprised the study population. Simulations were conducted on a representative active patient ward to mimic external distractions encountered by physicians as they use an EHR. Subjects were asked to act as the admitting hospitalist, review both patient charts, and create a history and physical (H&P) note complete with assessment and plan for each patient. Simulation time was not limited. Case order was held constant for all subjects throughout the study. After completing the cases, subjects were asked to verbally describe their typical workflow for admitting a patient. Semi-structured interview questions were used to elicit details about when they use the EHR during that process, their principal sources of information, note writing strategies, and the nature of the patient interaction. Lastly, subjects were asked to complete a questionnaire regarding demographic information, EHR experience, and general computer experience.

Eye and screen tracking were conducted using a Tobii X2 60 Eye Tracker (Tobii Systems, Danderyd Municipality, Sweden), a non-invasive tracker mounted below the computer monitor. All testing was conducted using a standardized computer station with consistent and static screen and chair height. Before each simulation, the eye tracker was calibrated to each subject using a 1-minute 9-point calibration algorithm provided by the manufacturer. Upon commencement of the simulation the screen tracking software (Tobii Studio, Tobii Systems, Danderyd Municipality, Sweden) captured screen video, keystrokes, mouse clicks, ocular saccades, and eye fixations. A velocity threshold identification filter was used to identify sets of fixations (gazes), using the standard definition of a fixation as lasting a minimum of 100 ms. Each video was coded manually by a member of the research team (JD). Videos were coded by recording the information type upon which the gaze was situated at each second of the case.

Data Analysis

Simulation gaze data were divided into two major categories: informational and navigational. Informational gazes pertained to any kind of clinical data (all entries in Table 1 except 14); navigational gazes were defined as lacking clinical data, and frequently occurred on toolbars, menus, and up/down scrolling arrows. Documentation was considered a subset of the informational gaze category. Comparisons between group means were conducted using two-sided t-tests.

Table 1. Twenty-one information types used in video coding
Several metrics were used to evaluate the data. First, we measured the average duration of each participant’s gaze on each information type (Table 1), calculated by their total duration of gazes on that information type divided by the number of gazes on that information type during the case. Next, we calculated the total number of transitions between information types for each patient case, and the total number of informational gazes for each case.

Equations used in DTMC analysis

\[
P_{ij} = \Pr(X_1 = s_j|X_0 = s_i) \quad (1)
\]

\[
P = \begin{bmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{bmatrix}. \quad (2)
\]

Figure 1. Equations used in DTMC analysis

We used first-order Discrete Time Markov Chains (DTMCs) to model transitions between information types. A Markov Chain consists of a series of successive state-to-state transitions (Equation 1, Figure 1), which form a transition matrix. Equation 2 illustrates an example of a transition matrix, which has three states. The row i (i = 1,2,3) shows the transition probability distribution from information-type i to other information-types j. For example, \( p_{13} \) is the probability that a subject transitions from information-type 1 to 3. Higher probabilities in the matrices indicate the information-type pairs that are more likely.

Results

Subject characteristics

From a total of 23 eligible subjects, 17 (74%) subjects completed a total of 33 patient cases. Fifty-nine percent of subjects were male; the mean length of time since medical school graduation was 13.3 years. One hundred percent of subjects described themselves as “somewhat” or “very experienced” with computers. The mean length of time using the study EHR (EpicCare) was 6.5 years.

Simulation characteristics

The subjects were divided into two groups based upon how long into the case it took them to begin composing a note. This division was based upon a natural grouping observed in average note start times per subject (Figure 2). Subjects in Group 1 (n=8) began composing a note on average less than 2 minutes into the case; subjects in Group 2 (n=9) began composing a note on average more than 2 minutes into the case.

Table 2. Demographic and simulation characteristics

The proportion of men in Group 1 (87.5%) was significantly greater than the proportion of men in Group 2 (33.3%, p=0.02) (Table 2). Using a Likert-type scale to assess self-rated computer experience (1, less experienced; 2, somewhat experienced; 3, very experienced), Group 1 reported a higher mean experience score compared to Group 2 (2.5 and 2, respectively; p=0.03). Time since medical school graduation and length of EpicCare experience did not differ significantly between the groups.

The average time for Case A was significantly longer than Case B (mean±SD, 28:12±8:05 and 21:56±6:35 respectively, p=0.02). To evaluate a potential learning effect, the note start times were normalized to total case times and compared among the groups from Case A to Case B. There was a slight difference in the decrement in note start time ratio between the groups, with Group 2’s note start ratio dropping more in Case B, but this was not significant.
Number of transitions per second was evaluated as well. Whereas the transitions per second for Group 1 decreased slightly from Case A to Case B, the transitions per second for Group 2 increased slightly, but the difference between the two was not statistically significant (G1 = 0.006, G2 = -0.005; p = 0.14).

Group 1 had significantly more gazes (G1=81.7, G2=62.3; p=0.04) and transitions (G1=75.5, G2=57.5; p=0.04) over the course of each case. There was no difference between the groups in average case time, navigation time, and average number of unique information types accessed within each case.

Semi-structured interviews

Self-described workflows elicited from the semi-structured interviews were consistent with categorization into Group 1 and Group 2. Representative quotations are shown in Table 3.

Clinical content

The information types with the longest total gaze durations are shown in Figure 3. For both Groups 1 and 2, total duration of gazes for documentation (composition of the H&P note) was much higher than all non-documentation information. G1=851 seconds, G2=745 seconds. The non-documentation information types with the greatest average and total duration of gazes (greater 10 seconds) were imaging results, inpatient progress notes, lab values, medications, and ambulatory clinic notes. These five information types were also the most often visited throughout the simulations. Group 1 gazed at laboratory values significantly more often than Group 2 (G1=13.3, G2=8.2, p=0.02). Differences were observed in less frequently visited information types as well. Past medical history (G1=0.75, G2=1.6, p=0.06), problem list (G1=1.4, G2=2.9, p=0.08), family history (G1=0.7, G2=0.2, p=0.04) and other information types (G1=3.88, G2=2.53, p=0.04) all showed slight differences in visitation frequency between groups. These trends in frequency remained consistent when the gaze values were normalized by the total number of visits to all information types.

Figure 2. Distribution of note start times

Table 3. Representative quotations from semi-structured interviews

**Group 1**

Early note composition, greater frequency of transitions between information types

- “I often start my note right away as I go about my chart review.”
- “I tend to be linear… I jump around.”
- “I usually start with a note because it autopopulates with the information I need.”

**Group 2**

Information review with longer duration per screen and less transitions, followed by note composition

- “I review all the current data, labs, and imaging. Then look at last clinic note, meds, and clinical history. I start writing a note after that.”
- “I look at the meds, prior notes and imaging, then start putting a note skeleton together.”
- “I do a quick review of the chart before I go see the patient. Then I build my problem list and when I create the note, it auto-imports the information I’ve collected.”
Transition visualizations

Figures 4a and 4b show circle visualizations of normalized Markov Chain frequencies of information types for both groups. Nodes situated around the rim of the circle represent the various information types, ordered by size moving counter-clockwise. The sizes of the nodes are proportional to their gaze number distribution frequencies, and the thickness of the lines connecting nodes indicate the normalized frequencies of transitions (transition probability) between the two information types. For clarity, only the top 80% of total transitions are depicted here.

The general patterns are the same between the two groups: most of the transitions are centered around documentation, which is also the most frequently visited information type. We can identify the top 5 most frequently visited information types, which are consistent between the two groups: documentation, lab values, inpatient progress note, vital signs and imaging results. In addition, because documentation played a larger role in group 1 than it did in group 2, there were fewer high frequency transitions compared with group 2.

One important observation from the visualization is which information types were closely related. For example, the social history, past medical history, family history, and past surgical history nodes are co-located because they were similar in visitation frequencies. In Group 1, there are more bold lines from documentation to other information types, capturing the notion that Group 1 transitioned more frequently between documentation and other information types.

Discussion

This study assessed characteristics of physicians’ information search patterns in an EHR as they created a note for a new patient. There were two discrete types of
users based upon information review and documentation tasks. The key findings from our analyses are: 1) There were strong similarities across the groups in the information types the physicians looked at most frequently; 2) While there was no overall difference in case duration between the groups, we observed two distinct workflow types between the groups with respect to gathering information in the EHR and creating a note; and 3) A majority of the case time was devoted to note composition in both groups.

Both groups showed the same preferences for a small subset of information types, in terms of how long they looked at each information type (Figure 3). Imaging results, progress notes, laboratory values, medications, and prior clinic notes were looked at longest. The total number of unique information types also did not differ between groups. This suggests some uniformity in clinical reasoning that may be explained by their mutual medical specialty, common clinical environment, and/or similarities in medical training. Differences between groups were only found in lower-frequency information types; members of Group 1 spent less time reviewing past medical history and problem lists, and more time reviewing the family history.

Groups 1 and 2 exhibited significantly different workflow types, despite no overall difference in case completion time. Group 1, characterized by early note creation, transitioned frequently between information types in the EHR after starting the note (Figure 4). Group 2 physicians, characterized by later note creation, tended to dwell on information longer before starting to compose the note. Group 1 showed a markedly higher number of transitions and gazes compared to Group 2, confirming a higher rate of switching from one information type to another. We found significant differences between the groups in how the simulation time was used. Overall, Group 1 spent substantially longer time in the documentation phase of the simulation. Subjects’ self-described workflows (Table 3) supported a dichotomy between early and note creation. Subjects in Group 1 mentioned starting a note as one of their first activities prior to information gathering (and “jumping around” in the EHR when gathering information) whereas Group 2 members described reviewing a variety of information prior to note creation.

Both groups spent a much higher amount of time on note composition than any other task, including reviewing clinical information (Figure 3). The time and burden associated with documentation is noted in the literature. What this study highlights is the finding that documentation time may overshadow all other tasks, including time to read or review the clinical data. This raises the question of whether the time and burden of documentation relates to the untoward effects of EHR implementation on patient care that have been observed. Further research is needed to elucidate the interplay between EHR documentation burden, clinical reasoning, and patient care.

This research raises several questions about the nature of EHR information seeking and patterns in end-user behavior. Several models have been proposed to describe this process. Traditionally information seeking is viewed as a sense-making process in which the user formulates a personal perspective through finding meaning. A common thread shared by most proposed models of information seeking is that it is a dynamic process, where the users move non-linearly through levels of certainty based upon information encountered and judgments of relevancy and specificity. The resultant perspective or decision is not necessarily the same among individuals and is dependent upon the effectiveness of the user’s information retrieval. This becomes problematic in the realm of clinical medicine, where standard of care dictates that there be some baseline level of uniformity in clinical reasoning to ensure patient safety. Ensuring some baseline level of competency in information retrieval becomes crucial when considering the complexity of modern EHR systems, where it has already been demonstrated that end-user behavior is highly variable. This research suggests that users take different pathways to arrive at a common endpoint. The information used and the time to complete the task may not differ, but the order in which the end product (clinical note) is created may differ depending on the user. Of Nielson’s five criteria for usability is affordance. The different workflows described in this study support the need for interfaces to afford for 1) fluctuation between varying levels of certainty in the meaning-finding process and 2) a variety of approaches in clinical documentation.

Of note, significant differences were observed in the gender composition and self-rated computer experience level between Group 1 and Group 2. With respect to the gender difference, though the sample size of the current study is too small to draw firm conclusions from this observation, our results raise the question of whether different genders may approach the tasks of EHR information gathering and documentation differently. Gender differences in clinical reasoning and information processing have been explored previously. Myers-Levy’s theory of selectivity and information-processing research in other disciplines suggest that women are more likely to employ elaborative information processing strategies regardless of the task complexity, whereas men are more likely to utilize heuristic processing strategies, only switching to elaborative strategies on more complex tasks. Conversely, in the medical literature no significant gender-related difference has been found in diagnostic reasoning. With the insertion of the EHR into clinical workflows we must consider the electronic interface as an additional layer of complexity. Research
conducted on website audiences has shown that differences in perception and satisfaction can vary greatly among gender groups\textsuperscript{51}. Females have demonstrated greater proficiency in computer display navigation and optical cue responsiveness on the screen\textsuperscript{52}. Taken together, prior research suggests that there may be several factors that contribute to gender differences in EHR usage; further research is needed. With respect to the difference in self-rated computer experience, it is unclear whether this outcome is independent of the strong gender differences between the groups. Conflicting research exists on gender differences in perceptions of self-efficacy and attitudes toward computers\textsuperscript{48,53}. If it is an independent outcome, it is not clear that the higher level of computer experience in Group 1 translated into better performance in the simulation task.

There are several important limitations to this study. First, though simulations were conducted in a high-fidelity environment, subjects were aware that the cases were fictional patients. There were no actual patients to interact with and subjects relied upon the content of the history of present illness, review of systems, and physical exam as it was documented in the EHR. Though this may have diminished the realism of the cases, it is expected that it would exert a uniform effect on the subjects. Cases were made to be slightly less complicated than the “average” patient seen at our institution, a tertiary care facility, for the purposes of simulation time. Second, interpretation of the eye tracking gaze data is still in its infancy in clinical informatics research, and it is unclear how well gazes and transitions represent clinical reasoning processes. Third, the notes created during the simulations were not evaluated for accuracy and completeness, thus we cannot comment on whether differences in search patterns affect clinical reasoning and medical decision making. Lastly, the study was conducted among one specialty of physicians at one institution.

Conclusion

This study demonstrates the presence of two information-gathering and documentation workflows among hospitalists using the EHR to admit a new patient. This has important implications for EHR interface design, specifically with respect to affordances for multiple information-gathering pathways. Future studies must continue to examine the workflow differences among individuals, specifically pertaining to note quality, clinical accuracy, and efficiency.

Learning a Severity Score for Sepsis: A Novel Approach based on Clinical Comparisons

Kirill Dyagilev, PhD\(^1\), Suchi Saria, PhD\(^{1,2}\)

\(^1\)Dept. of Computer Science, Johns Hopkins University, Baltimore, MD
\(^2\)Dept. of Health Policy & Mgmt., Johns Hopkins University, Baltimore, MD

Abstract
Sepsis is one of the leading causes of death in the United States. Early administration of treatment has been shown to decrease sepsis-related mortality and morbidity. Existing scoring systems such as the Acute Physiology and Chronic Health Evaluation (APACHE II) and Sequential Organ Failure Assessment scores (SOFA) achieve poor sensitivity in distinguishing between the different stages of sepsis. Recently, we proposed the Disease Severity Score Learning (DSSL) framework that automatically derives a severity score from data based on clinical comparisons — pairs of disease states ordered by their severity. In this paper, we test the feasibility of using DSSL to develop a sepsis severity score. We show that the learned score significantly outperforms APACHE-II and SOFA in distinguishing between the different stages of sepsis. Additionally, the learned score is sensitive to changes in severity leading up to septic shock and post treatment administration.

Introduction
Sepsis — a whole-body inflammatory response to infection — is one of the leading causes of death in the inpatient setting and is associated with significantly higher costs of care\(^1\). The risk of sepsis-related adverse outcomes can be reduced by early treatment\(^2\). Thus, changes in a patient’s health status is regularly assessed by the caregiver (clinicians and nurses) to plan timely interventions. This requires the caregiver to interpret a diverse array of markers (e.g., heart rate, respiratory rate, blood counts, and serum measurements) that measure the underlying physiologic and metabolic state. Such clinical assessments are time-consuming, require extensive experience, and more importantly, are prone to missing signs of decline that may be only subtly visible in the observed markers.

In this paper, we address the problem of quantifying (scoring) the latent sepsis severity of a patient at a given time. That is, we derive a mapping from the high-dimensional observed marker data to a numeric score that tracks changes in sepsis severity over time — as health worsens, the score increases, and as the individual’s health improves, the score declines. More generally, a means for accurate estimation and tracking of an individual’s health status can enable clinicians to detect critical decline such as decompensations, and acute adverse events in a timely manner. Additional potential benefits include assessment for whether an individual is being responsive to therapy, stratification of patients for resource management, and risk adjustment for clinical research\(^3\).

Background: Qualitatively, the concept of disease severity score has been described as the total effect of disease on the body; the irreversible effect is referred to as damage, while the reversible component is referred to as activity\(^4\). The precise interpretation of concepts of damage and activity are typically based on the application at hand. Desirable properties of a severity scale include: 1) face and content validity i.e., the variables included are important and clinically credible, and 2) construct validity i.e., the scoring system parallels an independently ascertained severity measurement\(^4\).

Historically, severity scores have been defined and derived in a number of different ways\(^5\). One approach is to have clinical experts fully specify the score. Namely, using the existing clinical literature, a panel of experts identifies factors that are most indicative of severity of the target disease. These factors are weighted by their relative contribution to the severity and summed together to yield the total resulting score. For example, the Acute Physiology And Chronic Health conditions score\(^6\) (APACHE II), which assesses the overall health state in an inpatient setting, uses factors that are most predictive of mortality. For instance, a heart rate between 110 and 139 beats per minute adds 2 points to the final score while a heart rate higher than 180 beats per minute adds 4 points. Similarly, mean arterial blood pressure between 70 and 109 mm Hg adds no points while a value between 50 and 69 mm Hg adds 2 points. A number of additional widely used scoring systems have been designed in this way, including the Multiple Organ Dysfunction Score\(^7\) (MODS), the Sequential Organ Failure Assessment\(^8\) (SOFA), and the Medsger’s scoring system\(^4\).

A second approach commonly taken is to characterize severity as a predictive score that is associated with the risk of experiencing a target downstream event. That is, high severity states are more likely to be associated with adverse
events and higher mortality rates. To train such a score, supervised learning is used with the presence or absence of the downstream adverse event (e.g., septic shock or mortality) as the labels. For example, the pneumonia severity index (PSI) uses this approach to combine 19 factors including age, vitals and laboratory test results, to calculate severity as the probability of morbidity and mortality among patients with community acquired pneumonia. The relative weight of each factor in the resulting score was derived by training a logistic regression function that predicts risk of death in the following 30-hour window. Others have similarly used downstream adverse events such as development of c.diff infection, septic shock, morbidity, and mortality as surrogates for severity scores. Yet other approaches use probabilistic state estimation techniques.

However, the above-mentioned approaches for the derivation of disease severity scores have their limitations. The expert-based approach captures known clinical expertise well, but it does not extend to populations where current clinical knowledge is incomplete. The approach of regressing against the risk of downstream adverse event yields scores that suffer from bias due to treatment-related censoring. Specifically, scores learned from data assuming one standard of care, when used under a different standard of care may lead to erroneous conclusions about the individual disease severity state. Say, we have data from a unit where children with temperature of 102°F are frequently prescribed treatment for the flu. This intervention subsequently cures the patients and they do not experience any associated adverse events (e.g., sepsis or septic shock) or death. However, it is also known that a child with temperature of 102°F, if left untreated, is likely to die. Thus, a temperature of 102°F is clinically considered to be a high severity state which in this unit is frequently treated in a timely manner. Since the learning algorithm uses the presence of a downstream adverse event as a surrogate marker for severity, rare occurrence of adverse events following 102°F causes the learning algorithm to score the temperature of 102°F as benign. This is problematic for two reasons. First, it is not consistent with how severity is interpreted clinically. Moreover, if such a score were to be used to guide interventions, it might erroneously cause the clinician to undertreat children with temperature of 102°F, thus likely worsening outcomes. See Dyagilev and Saria for a numerical example.

In recent work, we proposed an alternative Disease Severity Score Learning (DSSL) framework for learning severity scores. The DSSL framework leverages this key observation that, while requesting experts to quantify disease severity at a given time is challenging, acquiring clinical comparisons – clinical assessments that order the disease severity at two different times – is often easy. From these clinical comparisons, DSSL learns a function that maps the patients observed feature vectors to a scalar severity score. With some abuse of terminology, we refer to this mapping function as the DSS function. We showed empirically that the generalization performance of DSSL is less sensitive to variations in treatment administration patterns compared to the supervised learning approach described above.

In this paper, we test the feasibility of using DSSL to develop a sepsis severity score. We use the MIMIC-II dataset containing electronic health record data from patients admitted to the Beth Israel Deaconess Intensive Care Units between 2001 and 2008. Clinical comparisons required for training the score are generated automatically using the Surviving Sepsis Campaign (SSC) guidelines. We show that the learned score significantly outperforms APACHE-II and SOFA in distinguishing between the different stages of sepsis. Additionally, the learned score is sensitive to changes in severity leading up to septic shock and post treatment administration. We also show that only a small number of clinical comparisons are needed to obtain a high quality score. Thus, by not having to rely on needing a large number of clinical comparisons, the use of DSSL in domains where guidelines are unavailable for generating clinical comparisons in an automated manner (as we do in this paper) becomes feasible.

Methods
In this section, we describe the DSSL framework and the L-DSS method for learning linear DSS functions.

General DSSL Framework We consider longitudinal data routinely collected in a hospital setting. These include co-variates obtained at the time of admission such as age, gender, and clinical history; time-varying measurements such as heart rate and respiratory rate; and text notes summarizing the patients evolving health status. These data are processed and transformed into tuples \( < x_i^p, t_i^p > \) where \( x_i^p \in \mathbb{R}^d \) is a \( d \)-dimensional feature vector associated with patient \( p \in P \) at time \( t_i^p \) for \( i \in \{1, \ldots, T_p\} \) and \( T_p \) is the total number of tuples for patient \( p \). A feature vector \( x_i^p \) contains raw measurements (e.g., last measured heart rate or last measured white blood cell count) and features derived from one or more measurements (e.g., the mean and variance of the measured heart rate over the last six hours or the total urine output in the last six hours per kilogram of weight). Let \( D \) denote the set of tuples across all patients in the study. The problem of learning a DSS function is defined by the sets \( O \) and \( S \) of pairs of tuples from the set \( D \) of all tuples, and by the set \( G \) of permissible DSS functions. The set \( O \) contains pairs of tuples \( (< x_i^p, t_i^p >, < x_j^q, t_j^q >) \) that
are ordered by severity based on clinical assessments, i.e., $x_{1}^{p}$ corresponds to a more severe state than $x_{2}^{q}$. We refer to each of these paired tuples as a *clinical comparison* and the set $O$ as the set of all available clinical comparisons. These clinical comparisons can be obtained by presenting clinicians with data $x_{i}^{p}$ for patient $p$ at time $t_{i}^{p}$ and data $x_{i}^{q}$ for patient $q$ at time $t_{i}^{q}$. For each such pair of feature vectors, the clinical expert identifies which of these correspond to a more severe health state; the expert can choose not to provide a comparison for a pair where the severity ordering is ambiguous. These pairs can also be generated in an automated fashion by leveraging existing clinical guidelines. In the Experimental Methods section, we describe how we use an existing guideline in the task of learning sepsis severity.

Below, we describe the L-DSS algorithm for learning linear DSS functions. This algorithm builds on the widely-used soft max-margin training technique that seeks to maximize the distance between the pairs that are at different severity levels. We briefly review the key concepts of soft max-margin ranking before we describe these are adapted to the task of learning a linear DSS function.

**Soft Max-Margin Ranking**: Consider the toy example shown in Figure 1. In this example, we assume that all feature vectors are taken on same patient and the time at which these feature vectors are taken is irrelevant. We simplify the notation accordingly. Let $D$ contain the three feature vectors $\{x_{1}, x_{2}, x_{3}\}$ where $x_{i} \in \mathbb{R}^{2}$, and $O$ contain the pairs $(x_{2}, x_{1})$ and $(x_{3}, x_{2})$, i.e., feature vectors $x_{2}$ and $x_{3}$ have higher disease severity than $x_{1}$ and $x_{2}$ respectively.

Max-margin ranking seeks to find a vector $w$ such that the *margin* between pairs of different severity levels is maximized. In our example, we show parameter vectors $w_{1}$, $w_{2}$ and $w_{3}$ for three candidate ranking functions in Figure 1. For each feature vector $x$, the assigned (severity) score for a given ranking function parameter $w_{i}$ is computed as the projection, $g_{w_{i}}(x)$, of $x$ on $w_{i}$. The induced ranking between two vectors $x_{1}$ and $x_{2}$ is computed based on the margin which is defined as the difference in their projections. In the example shown, the rankings induced by both $g_{w_{1}}$ and $g_{w_{3}}$ correctly order all pairs in $O$, i.e., $g_{w_{1}}(x_{3}) > g_{w_{1}}(x_{2}) > g_{w_{1}}(x_{1})$ and $g_{w_{3}}(x_{3}) > g_{w_{3}}(x_{2}) > g_{w_{3}}(x_{1})$, while the rankings induced by $w_{2}$ do not. Furthermore, $w_{3}$ also induces an ordering with a larger margin between the pairs in $O$. Margin-maximization leads to an ordering that is more robust with respect to noise in $x$. Finally, the set $G$ contains a parameterized family of candidate DSS functions $g$ that map feature vectors $x$ to a scalar severity score. In this paper we focus on linear DSS function alone, however, the DSSL framework extends to non-linear DSS functions as well.

In the DSSL framework, our goal is to learn parameters of the function $g \in G$ that quantifies the severity of the disease state represented by a feature vector $x$. This is done using an empirical risk minimization approach, i.e., an objective function is constructed that maps functions $g \in G$ to their empirical risk. This function objective contains two key terms. The first term penalizes $g$ for pairs of tuples ($< x_{i}^{p}, t_{i}^{p} >$, $< x_{j}^{q}, t_{j}^{q} >$) $\in O$ for which the severity ordering induced by $g$ on vectors $x_{i}^{p}$ and $x_{j}^{q}$ is inconsistent with the ground truth clinical assessment. The second term imposes penalty of high rates of temporal changes of the DSS value, thus encouraging selection of a temporally smooth DSS function. The smoothness requirement allows to learn severity scores that mimic the natural inertia exhibited by biological systems. In what follows we present the formal definition of this objective function for learning a linear DSS.
More formally, for each pair of feature vectors \((x_i, x_j) \in O\), we define the margin of their separation by the function \(g_w(x)\) as \(\mu_{ij}^w = g_w(x_i) - g_w(x_j)\). The maximum-margin approach suggests that we can improve generalization and robustness of the learned separator by selecting \(w\) that maximizes the number of tuples that are ordered correctly (i.e., \(\mu_{ij}^w > 0\)) while simultaneously maximizing the minimal normalized margin \(\frac{\mu_{ij}^w}{\|w\|}\). Using the standard soft margin framework, the SVMRank algorithm\(^{21}\) approximates the above-mentioned problem as the following convex optimization program:

\[
\min_{w, \zeta_{i,j}} \left[ \frac{1}{2} \|w\|^2 + \frac{\lambda_0}{|O|} \sum_{(x_i, x_j) \in O} \zeta_{i,j} \right], \quad \text{subject to the ordering constraints:}
\]

\[
\forall(x_i, x_j) \in O: \quad g_w(x_i) - g_w(x_j) = w^T(x_i - x_j) \geq 1 - \zeta_{i,j} \quad \text{and} \quad \zeta_{i,j} \geq 0
\]

Joachims et al.\(^{21}\) solved this optimization program in the dual formulation\(^{21}\). Chapelle et al.\(^{22,23}\) proposed to transform the problem in (1) into a twice differentiable unconstrained convex problem and solve it in its primal form. To this end, we observe that for every value of \(w\), the optimal values of \(\zeta_{i,j}\) are given by \(\zeta_{i,j}^* = \max\{0, 1 - w^T(x_i - x_j)\}\). Substituting to (1), we obtain the following unconstrained convex optimization problem:

\[
\min_{w} \left[ \frac{1}{2} \|w\|^2 + \frac{\lambda_0}{|O|} \sum_{(x_i, x_j) \in O} \max\{0, 1 - w^T(x_i - x_j)\} \right].
\]

The terms of the form \(\max\{0, a\}\), also called the hinge loss, are not differentiable at \(a = 0\). We approximate these terms with the Huber loss \(L_h\) for \(0 < h < 1\) given by

\[
L_h(a) = \begin{cases} 
0 & \text{if } a < -h \\
(a + h^2)/(4h) & \text{if } |a| \leq h \\
a & \text{if } a > h
\end{cases}
\]

It can be seen that \(L_h(a)\) is identical to hinge loss for \(a < -h\) and \(a > h\). This approximation yields the following unconstrained, convex, twice-differentiable optimization problem:

\[
\min_{w} \left[ \frac{1}{2} \|w\|^2 + \frac{\lambda_0}{|O|} \sum_{(x_i, x_j) \in O} L_h(1 - w^T(x_i - x_j)) \right].
\]

The L-DSS Objective and Optimization Algorithm: We now describe the L-DSS algorithm for learning linear DSS functions. We return to our original setting, where we are given sets \(O\) and \(S\) which contain feature vectors belong to more than one patients at varying times.

The L-DSS objective function is obtained by augmenting the Eq. (2) with the following term:

\[
\sum_{(x_i^p, t_i^p), (x_{i+1}^p, t_{i+1}^p) \in S} \left[ \frac{w^T(x_{i+1}^p - x_i^p)}{t_{i+1}^p - t_i^p} \right]^2.
\]

This term penalizes DSS functions that exhibit large changes in the severity score over short durations, hence encouraging selection of temporally smooth DSS functions. Substitution of this term yields the following L-DSS objection function:

\[
\min_{w} \left[ \frac{1}{2} \|w\|^2 + \frac{\lambda_0}{|O|} \sum_{(x_i^p, t_i^p), (x_{i+1}^p, t_{i+1}^p) \in O} L_h(1 - w^T(x_i^p - x_j^p)) \right],
\]

\[
+ \frac{\lambda_8}{|S|} \sum_{(x_i^p, t_i^p), (x_{i+1}^p, t_{i+1}^p) \in S} \left[ \frac{w^T(x_{i+1}^p - x_i^p)}{t_{i+1}^p - t_i^p} \right]^2
\]

1893
This optimization program is solved using the Newton-Raphson algorithm.

**Experimental Methods**

In this section we derive a sepsis severity score by applying the L-DSS method to the large scale MIMIC-II dataset\(^{19}\). With some abuse of terminology, we refer to the resulting sepsis severity score as the L-DSS-Sepsis score. We assess the quality of the obtained L-DSS-Sepsis score by testing its sensitivity to severity changes of different granularity. In our first experiment, we test whether the L-DSS-Sepsis score is sensitive to significant changes severity. Specifically, we test whether the L-DSS-Sepsis score can accurately distinguish and order correctly by their severity different stages of sepsis. We show that the L-DSS-Sepsis score outperforms on this task two clinical scores that are widely used in the ICU setting. In two additional experiments, we analyze the sensitivity of the L-DSS-Sepsis score to a finer-grained changes in sepsis severity. In particular, in the second experiment, we show that the L-DSS-Sepsis score is sensitive to changes in severity state leading up to septic shock. This suggests that the L-DSS-Sepsis score can potentially be used for early detection of this adverse event. In the third experiment, we show that the L-DSS-Sepsis score is sensitive to post-therapy changes in severity and hence could potentially be used to assess patient’s treatment response.

The rest of this section proceeds as follows. We begin with the brief overview of MIMIC-II, the dataset used for learning the sepsis severity score. We then describe the clinical guideline for coarse grading of sepsis severity and show how this coarse grading can be used for automatic generation of clinical comparison pairs. Next, we describe how to choose the values of free parameters for the L-DSS algorithm. We conclude with the detailed description of the three experiments that are used to assess the quality of the learned L-DSS-Sepsis score.

**Dataset:** We use MIMIC-II, a publicly available dataset containing electronic health record data from patients admitted to the ICUs at the Beth Israel Deaconess Medical Center from 2001 to 2008\(^{19}\). We only include adults (> 15 years old) in our study \((N = 16,234)\). We compute 42 different features that are derived from vital sign measurements, clinical history variables, and laboratory test results.

**Sepsis Severity Grading and Automatic Generation of the Clinical Comparison Pairs:** One of the inputs required by the L-DSS algorithm is the set \(O\) of clinical comparisons. For sepsis, these pairs can be created automatically by leveraging the coarse severity grading of sepsis proposed in the Surviving Sepsis Campaign (SSC)\(^{20}\). SSC classifies sepsis development into the following four stages with decreasing levels of severity: septic shock, severe sepsis, SIRS, and “none” (i.e., none of the above). For each of these stages, the guideline defines criteria as combination of 1) thresholds for individual measurements that capture deviation of this measurement from its normal range, and 2) presence of specific diagnosis codes or diagnoses noted in their clinical notes. However, not all measurements needed for implementing the SSC criteria may be available at the given time. We thus relax the definition of the SSC guidelines so it uses measurements made within a short time window prior to the given time. For instance, for fast changing signals (e.g., blood pressure) we use a two hour window, and for slower changing signals (e.g., creatinine), we use an eight hour window. If no measurements were taken in the designated time window, we consider sepsis stage to be unknown. We implement these criteria and automatically identify tuples in the dataset where these SSC definitions are met.

We leverage the SSC grading of sepsis severity to automatically generate clinical comparisons in the following manner. First, we randomly assign the 16,234 patients in the MIMIC dataset to training (60%) and testing sets (40%). Within the training set, we assign two thirds of the patients to the development set and the remaining third to the validation set. For each of the development, validation and testing sets of patients we generate a separate set \(O\) of clinical comparison pairs. This is done by randomly sampling an equal number of pairs of feature vectors \((x_p^i, x_q^j)\) for each of six combinations of different sepsis stages according to SSC, i.e., shock-severe, shock-SIRS, shock-none, severe-SIRS, severe-none, and SIRS-none. These pairs include feature vectors that are taken from the same patient (i.e., \(p = q\)) or from different patients (i.e., \(p \neq q\)). Overall, we extracted 30,000 clinical comparison pairs for the validation set, and 60,000 clinical comparison pairs for the testing set. For the development set, we extracted several sets \(O\) of different sizes, ranging from 120 pairs to 60,000 pairs. We construct the set \(S\) of smoothness pairs to contain 80,000 randomly sampled pairs \((x_p^i, x_{p+1}^i)\) of consecutive feature vectors.

When generating clinical comparisons by automating clinical rules, a natural question that one might ask is whether the learned scores simply recover these clinical rules and thus yield no generalization beyond the SSC grading. This is not the case for two reasons. First, the guideline criteria rely on information captured in notes and diagnosis codes that are not available to the L-DSS method. Second, the temporal smoothness term constrains the learned scores to be smooth and to generalize beyond grading for the coarse severity stages. This issue is covered in greater detail in
In addition to sets \( \mathcal{O} \) and \( \mathcal{S} \), the required input of the L-DSS algorithm includes the values of free parameters \( \lambda_0 \) and \( \lambda_5 \). To specify these values, we follow the two-step procedure proposed in Dyagilev and Saria\(^{18} \). First, with \( \lambda_5 \) set to 0, we select the value of \( \lambda_0 \) that maximizes the accuracy of ordering of clinical comparison pairs for the validation set of patients. That is, we count the fraction of clinical comparison pairs in the set \( \mathcal{O} \) that are ordered by L-DSS in concordance with the ordering prescribed by the SSC. We refer to this quantity as the severity ordering accuracy or \text{SOA}. For a given \( \lambda_0 \), we choose the value of \( \lambda_5 \) that maximizes the SOA of the resulting score. When there are several such values, we pick to the largest \( \lambda_5 \) among these maximizers. Namely, when there are multiple scores that achieve the maximal SOA, we give preference to the smoothest one.

**Missing data imputation:** Following Hug\(^{24} \), we used a modified Last Observation Carried Forward (LOCF) method to impute missing data in given feature vectors. Specifically, within a given time window \( w \), the last value of the observed signal was used. The window length \( w \) for each signal was set to be the typical sampling frequency of this signal. Specifically, the value of \( w \) was determined by combining clinical knowledge regarding signal’s typical rate of change and manual inspection of the distribution of duration between consecutive measurements of this signal. If no measurements were taken within the specified window, the missing value was replaced with the population mean.

### Experiment 1: Distinguishing between the Severity Stages of Sepsis

In our first experiment, we evaluate whether L-DSS-Sepsis can distinguish and correctly order the different stages of sepsis severity. We consider L-DSS-Sepsis scores learned from a different number of training clinical comparison pairs. For each size of the training set, we report the SOA on the testing set of the obtained L-DSS-Sepsis score. As a baseline for our assessment, we use the severity ordering accuracy of existing clinical scores that are widely used in ICU\(^{1} \). There exists several general purpose severity scores that have been validated to assess illness severity and risk of mortality among septic patients\(^{5,23–27} \). In this paper we focus on two of them. The first one is the Acute Physiology and Chronic Health Evaluation\(^{2} \) (APACHE II) score, which is a widely used scoring system for assessing general (not necessarily sepsis-related) disease severity in hospitalized individuals. The second one is based on the Sequential Organ Failure Assessment (SOFA) score\(^{6} \), which was originally designed to assess per-organ sepsis-related damage severity. Specifically, we use the total SOFA score which is the sum of SOFA scores of all organ systems.

### Experiment 2: Is L-DSS-Sepsis sensitive to changes in severity leading up to adverse events?

In the second experiment, we assess whether L-DSS-Sepsis is sensitive enough to capture changes in severity that can occur over the time period leading up to an adverse event. To this end, we examine the behavior of L-DSS-Sepsis in the 18 hour period prior to septic shock. We consider all patients with septic shock in our data with at least 18 hours of data prior to septic shock onset (\( N = 684 \)). On these patients, we define three time intervals of interest: 1) 6 hours prior to the onset of septic shock; 2) 6–12 hours prior to the onset of the septic shock; 3) 12–18 hours prior to the onset of septic shock. We denote the average values of the learned scores in these intervals by \( \bar{s}_{6-0}, \bar{s}_{6-12}, \) and \( \bar{s}_{12-18} \), respectively. We calculate values of \( \Delta_1 = \bar{s}_{6-0} - \bar{s}_{6-12} \) and \( \Delta_2 = (\bar{s}_{6-0} - \bar{s}_{6-12}) - (\bar{s}_{12-12} - \bar{s}_{12-18}) \) for each patient. Using the standard one-tailed t-test, we assess the p-value \( p_{\text{trend-up}} \) for whether the obtained \( \Delta_1 \) can be observed by chance under the null hypothesis that \( \Delta_1 \) are drawn from a zero mean distribution. Similarly, we assess the p-value \( p_{\text{rate acceleration}} \) for whether the obtained \( \Delta_2 \) can be observed by chance under the null hypothesis that \( \Delta_2 \) are drawn from a zero mean distribution.

### Experiment 3: Is L-DSS-Sepsis sensitive to post-therapy changes in severity?

We now evaluate whether L-DSS-Sepsis is sensitive to changes in severity due to administration of fluid bolus – a treatment used for septic shock\(^{20} \). Towards this, we use the self-controlled case series method. We compare trends exhibited by L-DSS-Sepsis values over the five hour intervals prior to and post administration of fluid bolus. We refer to the trends over these intervals as \( \Delta_{\text{prior}} \) and \( \Delta_{\text{post}} \). The value of \( \Delta_{\text{prior}} \) is computed as the difference between the value of the L-DSS-Sepsis at the time of treatment administration and the mean value of L-DSS-Sepsis over the five hour interval prior to treatment administration. Similarly, the value of \( \Delta_{\text{post}} \) is calculated as the difference between the mean value of L-DSS-Sepsis over the five hour interval after treatment administration and the value of L-DSS-Sepsis at the moment of treatment administration. If the patient is responsive to fluid therapy, then \( \Delta_{\text{treat}} = \Delta_{\text{post}} - \Delta_{\text{prior}} < 0 \), that is, if the L-DSS-Sepsis was trending up prior to treatment administration, we expect this trend to be attenuated or even reversed by the treatment.

We identify cases of fluid administration events related to sepsis using the following criteria: 1) the patient is experiencing SIRS, severe sepsis or septic shock at the time of treatment administration, and 2) the patient is hypotensive (has systolic blood pressure below 100 mm Hg), a commonly used criteria for prescribing fluids in sepsis. To avoid
confounding due to multiple administration of fluids, we restrict our attention to treatment administrations that were not preceded or followed by another fluid bolus administration within a five hour window. This yielded a total of 81 fluid bolus administration events. Employing the one-tailed t-test, we assess the p-value \( p_{\text{treatment response}} \) for whether the observed values of \( \Delta_{\text{treat}} = \Delta_{\text{post}} - \Delta_{\text{prior}} \) can be observed by chance under the null hypothesis that \( \Delta_{\text{treat}} \) are drawn from a zero mean distribution.

Results and Discussion

In our first experiment we assess the ability of the L-DSS-Sepsis score to distinguish and correctly order the different stages of sepsis severity. Specifically, we train the L-DSS-Sepsis score on clinical comparisons sets \( O \) of different sizes and measure the corresponding values of severity ordering accuracy (SOA). We present the results of this experiment in Figure 2(a). As expected, the SOA is an increasing function of the number of training clinical comparisons. We note that the L-DSS algorithm yields highly accurate scores even with relatively small amount of training examples. In particular, the maximal SOA equals 0.855 and is obtained by L-DSS-Sepsis scores trained on 30,000 clinical comparisons or more. The SOA of 0.847, which is 99\% of the maximal SOA, is obtained for 1200 clinical comparisons or more. The routinely used clinical scores — APACHE-II and Total SOFA — yield SOA of 0.654 and 0.601, respectively. They are thus outperformed by all L-DSS-Sepsis scores that are trained on 120 clinical comparisons or more. This performance achieved by the L-DSS-Sepsis is significant from a clinical standpoint as it orders severity states more accurately than the two widely used clinical scores. Moreover, it suggests that the L-DSS algorithm yields high quality severity scores even when trained on a small number of clinical comparisons. Hence, it can be applied to diseases where clinical comparisons need to be manually created by experts, thus their number should be minimal.

![Figure 2](image_url)

**Figure 2:** (a) Severity ordering accuracy (SOA) of the L-DSS-Sepsis scores on the testing set for number of training clinical comparisons. Vertical line marks 1200 training clinical comparisons. (b) Distribution of the L-DSS-Sepsis values for different stages of sepsis. (c) Temporal trajectory of a severity score over the time period leading up to septic shock. The vertical line marks the onset of septic shock. (d) Temporal trajectory of a severity score before and after administration of fluid bolus. The solid vertical line marks the administration of fluid bolus.

Hereafter, we use the L-DSS-Sepsis score trained on 1200 clinical comparisons. In Figure 2(b) we plot the probability density of the L-DSS values at different sepsis severity stages. We observe that, on average, the value of L-DSS score during septic shock is higher than in other less severe stages of sepsis. Since the L-DSS score is temporally smooth, this suggest that the L-DSS trajectory should trend up over the time period leading up to septic shock, i.e, should be sensitive to changes in severity leading up to adverse events. In our second experiment, we verify this hypothesis. Overall, over 67\% (95% confidence interval: 63\% - 70\%) out of 684 observed values of \( \Delta_1 \) and 57\% (95\% confidence interval: 53\%-60\%) out of 684 observed values of \( \Delta_2 \) were positive. The obtained p-values \( p_{\text{trend-up}} < 10^{-21} \) and \( p_{\text{rate acceleration}} < 2.25 \cdot 10^{-2} \) rule out the null hypothesis in favor of the stated hypothesis, that is, the learned scores trend up significantly prior to a septic shock and this trend accelerates over time. As an illustration, in Figure 2(c), we show the L-DSS trajectory on an example patient leading up to the onset of shock. It can be seen that the severity score of this patient exhibits a clear upward trend prior to the septic shock. Early identification of this trend can potentially alert the caregiver about a need for a medical intervention and prevent the impending adverse event.
In our last experiment, we addressed the question of whether the L-DSS score is sensitive to post-therapy changes in severity. Overall, the change of trend $\Delta_{\text{treat}}$ is negative in at least 77% (95% confidence interval: 68% - 86%) out of 81 recorded values of $\Delta_{\text{treat}}$. The obtained p-value $p_{\text{treatment response}} < 5 \cdot 10^{-8}$ rules out the null hypothesis in favor of the stated hypothesis, that is, that L-DSS shows significant response to therapy. As an illustration, in Figure 2(d), we show the L-DSS trajectory on an example patient 10 hours before and after administration of fluid bolus. It can be seen that the severity score of this patient trends up prior to treatment and trends down post-treatment.

**Conclusion**

In this paper we evaluated the feasibility of automatically learning a score (L-DSS-Sepsis) that tracks the severity of sepsis over time. We validated the learned sepsis severity score using electronic health record data obtained from patients admitted to four different ICUs at an academic medical center over a period of eight years. Compared to existing illness severity scores of APACHE-II and SOFA, the L-DSS-Sepsis score was significantly more accurate in distinguishing between the different stages of sepsis. The L-DSS-Sepsis score also showed face validity: its trajectories were temporally smooth and tended to trend upwards in individuals that progressed to septic shock. Furthermore, the L-DSS-Sepsis score also behaved as expected after fluid administration–as the patient’s health improved, the value of the L-DSS-Sepsis score decreased. These experiments suggest that an automated severity tracking score such as L-DSS-Sepsis may enable early interventions and monitor a patient’s responsiveness to therapy.

Our study has several limitations. While the L-DSS-Sepsis score showed desirable behavior in tracking changes in illness severity, additional studies are needed to validate whether it identifies at-risk patients before the caregiver has identified them as such. Similarly, whether the L-DSS-Sepsis score can be used to develop a tool for measuring fluid responsive remains to be studied. Finally, the key advantage of the DSSL framework is that it is less prone to practice pattern variations. Data from more than hospital using on a similar population of patients is needed to further test this hypothesis.

Overall, the discussed results are promising. The DSSL framework is general purpose and can be applied to other disease domains and populations. Furthermore, we are encouraged by the fact that the DSSL framework yields high quality sepsis severity scores even when given as few as 120 clinical comparisons. This suggests that it can be successfully applied to diseases for which coarse severity grading guidelines are not available and thus clinical comparisons need to be obtained from asking experts to annotate.

Automated Grading of Gliomas using Deep Learning in Digital Pathology Images: A modular approach with ensemble of convolutional neural networks

Mehmet Günhan Ertosun, PhD¹ and Daniel L. Rubin, MS, MD¹,²
¹Department of Radiology, Stanford University, Stanford, CA, USA

Abstract

Brain glioma is the most common primary malignant brain tumors in adults with different pathologic subtypes: Lower Grade Glioma (LGG) Grade II, Lower Grade Glioma (LGG) Grade III, and Glioblastoma Multiforme (GBM) Grade IV. The survival and treatment options are highly dependent of this glioma grade. We propose a deep learning-based, modular classification pipeline for automated grading of gliomas using digital pathology images. Whole tissue digitized images of pathology slides obtained from The Cancer Genome Atlas (TCGA) were used to train our deep learning modules. Our modular pipeline provides diagnostic quality statistics, such as precision, sensitivity and specificity, of the individual deep learning modules, and (1) facilitates training given the limited and variable data in this domain, (2) enables exploration of different deep learning structures for each module, (3) leads to developing less complex modules that are simpler to analyze, and (4) provides flexibility, permitting use of single modules within the framework or use of other modeling or machine learning applications, such as probabilistic graphical models or support vector machines. Our modular approach helps us meet the requirements of minimum accuracy levels that are demanded by the context of different decision points within a multi-class classification scheme. Convolutional Neural Networks are trained for each module for each sub-task with more than 90% classification accuracies on validation data set, and achieved classification accuracy of 96% for the task of GBM vs LGG classification, 71% for further identifying the grade of LGG into Grade II or Grade III on independent data set coming from new patients from the multi-institutional repository.

Introduction

Gliomas are the most common primary malignant brain tumors in adults ¹. They can occur anywhere in the central nervous system, but primarily occur in the brain and arise in the glial tissue ². While these tumors are typically malignant, some types do not behave consistently in a malignant fashion. Gliomas can be WHO grades I–IV based on malignant behavior ¹.

These tumors are differentiated by pathologists through visual inspection of histopathology slides. There are three histological types of glioma: astrocytoma, oligodendroglioma, and oligoastrocytoma. The nuclei of these histological types have distinct characteristics that pathologists use for morphology-based classification. For instance, nuclei in oligodendrogliomas typically are round in shape, small in size, and have negligible cell-to-cell variability with uniform nuclear texture whereas, whereas nuclei in astrocytomas are elongated and irregular in shape, with an uneven, rough nuclear texture due to the clumping of chromatin ¹¹. Many gliomas contain either mixtures of these nuclei or have intermediate forms. Nuclei with either variable combinations of oligodendroglioma and astrocytoma components or with morphologically ambiguous forms make the accurate and reproducible histopathology classification of gliomas challenging ¹¹.

Beyond histopathology determination, another key task for the pathologist is to determine the grade of the tumor (I to IV). For this task, the pathologist considers morphological features of the tumor in the histopathology slides, including mitosis, nuclear atypia, microvascular proliferation, and necrosis. Grade I tumors have a low proliferative potential, and therefore they are usually cured by surgical resection. Grade II tumors are infiltrative and tend to recur, with patient survival from 5 to 15 years. They have a low level of proliferative activity and usually progress to higher grades of malignancy. Grade III tumors have histological evidence of malignancy, and these tumors exhibit nuclear atypia and brisk mitotic activity. Grade IV gliomas, also known as glioblastoma multiforme (GBM), are the most aggressive cancer subtype, and they are characterized by the presence of microvascular proliferation and pseudopalisading necrosis ⁴.

1899
Histopathology tumor grading is a crucial activity, since Grade I has the highest overall survival \(^2,5\) and Grade IV (GBM) has the poorest overall survival. The Cancer Genome Atlas (TCGA) database includes grades II and III tumors as a set of lower grade glioma (LGG), and higher grade brain tumors in set of glioblastoma multiforme (GBM). Survival probabilities calculated from TCGA data for GBM and LGG are shown in Figure 1, showing that survival is strongly dependent on the tumor grade. Hence, it is very important to differentiate between different grades of glioma in considering the treatment options. A major challenge in determining the grade of these tumors is that there is high inter-reader variability in determining the tumor grade \(^9\). This may be due to the fact that the image features that are used to classify these tumors into grades are not always clear or difficult to reliably determine by different observers. Computerized image analysis can partially overcome these shortcomings, due to its capacity to quantitatively and reproducibly measure histologic structures on a large-scale \(^10\).

A workflow for analysis of quantitative nuclear features in glioblastoma (GBM) was previously described,\(^10,11\) wherein individual nuclei are segmented, and then nuclear features are computed to characterize the segmented nuclei. Each individual nucleus is described using features from four categories which are nuclear morphometry, region texture, intensity, and gradient statistic. Those features are then used to assign a score to each nucleus, and a correlative analysis of the morphological score with treatment response and patient survival is carried out. When the computerized analysis results were compared to a panel of neuropathologists, the computerized analysis provided better discrimination between GBMs with differing degrees of an oligo-component, at least with regard to predicting response to therapy. This suggests that nuclear morphology analysis is a promising approach to facilitating a better understanding and diagnosis of glioma and predicting response to therapy and survival \(^11\).

Deep learning has various closely related definitions or high-level descriptions, one of which is: “A class of machine learning techniques, where many layers of information processing stages in hierarchical supervised architectures are exploited for unsupervised feature learning and for pattern analysis/classification.” \(^13\) The essence of deep learning is to compute hierarchical features or representations of the observational data, where the higher-level features or factors are defined from lower-level ones. The family of deep learning methods have been growing increasingly richer, encompassing those of neural networks, hierarchical probabilistic models, and a variety of unsupervised and supervised feature learning algorithms \(^13\).

Convolutional Neural Networks (CNNs or ConvNets), are a type of discriminative deep architecture in which layers consisting of a convolutional layer and a pooling layer are often stacked up with one on top of another to form a deep model \(^14\). The convolutional layer shares many weights, and the pooling layer subsamples the output of the convolutional layer and reduces the data rate from the layer below. The weight sharing in the convolutional layer, together with appropriately chosen pooling schemes, endows the CNN with some “invariance” properties (e.g., translation invariance). CNNs have been found highly effective and been commonly used in computer vision and image recognition \(^13\). CNNs have the advantage of automatically learning the appropriate features, as opposed to traditional machine learning approaches that use hand-crafted features.

In this work, we study not only GBM (Grade IV), but also LGG (Grade II and Grade III), and we create a classification pipeline to grade histopathological images of glioma. Our work is significant in that this is a basic, yet very strong sub-typing that is strongly associated with patient survival. Our approach does not analyze single nuclei individually with classical hand-crafted machine learning features, but instead it analyzes the nuclei within the image tiles using deep learning and automatically learns the appropriate features. Best to our knowledge, deep learning has not yet been applied to pathology image analysis for glioma.
**Figure 1.** Survival probabilities for GBM (Grade IV), LGG – Grade II, and LGG – Grade II calculated from data from TCGA database

**Materials and Methods**

**Dataset**

We obtained publicly available digital diagnostic whole-slide hematoxylin and eosin (H&E) stained histopathology images (WSI) from The Cancer Genome Atlas (TCGA), which included two types of brain cancer: glioblastoma multiforme (GBM) and lower grade glioma (LGG). The LGG dataset contains Grade II and Grade III tumors.

**Preprocessing**

Each WSI included in the TCGA dataset can exceed 2GB in size\(^{11}\). In order to process these images and resulting data structures, we partitioned these images into tiles. Tiling was also useful to enable parallel processing of the image to further accelerate the preprocessing.

The tile size was 1024x1024 pixels in size at the 20x resolution which is the same size and resolution used for tissue microarrays (TMAs), which can be used by a trained pathologist to make informed opinions about a whole tumor. Tiling the entire slide produces some tiles that contain little or no tissue, and only tiles that contained tissue occupying at least 90% of the tile area were chosen for further analysis\(^{12}\). Tissue is distinguished by hysteresis thresholding on the grayscale and 8-bit depth complemented image, and nuclei are segmented using morphological top-hat filtering and hysteresis thresholding\(^{12}\).

Due to the success of the prior nuclear morphology-based studies of GBM,\(^{10,11}\) we selected to work on images in which we segment the nuclei during the preprocessing stage, but do not crop the individual nuclei, instead leave them within their original positions within the tile to not to lose the nuclei distribution map within that specific tile.

The tiles, on which we segmented the nuclei, are then further tiled to reduce in size to form samples, which we call “e-microbiopsy (electronic micro biopsy) samples,” as shown in Figure 2. This is done to reduce the sample sizes to a scale so that the deep learning networks can be trained on the GPU. Despite the attractive qualities of CNNs, and despite the relative efficiency of their local architecture, they have still been prohibitively expensive to apply in large scale to high-resolution images, and in the end, the network’s size is limited mainly by the amount of memory available on current GPUs and by the amount of training time that we are willing to tolerate\(^{21}\). For this work, we have decided for the size of the input images to the network to be 256x256 by considering the factors of GPU memory capacity, and the training time it would take for the deep learning networks.
Figure 2. Image preprocessing (a) Whole tissue slide, (b) A single tile taken from the original image, (c) one of several electronic microbiopsy samples that are input into the deep learning pipeline, where the nuclei are segmented yet left at their original positions to preserve their inter-nuclei interaction and distributional properties.

Convolutional Neural Networks (CNNs)

CNNs are representatives of the multi-stage Hubel-Wiesel architecture, which extract local features at a high resolution and successively combine these into more complex features at lower resolutions. CNNs consist of two kinds of layers: convolutional layers (C layers), which resemble the simple cells, and pooling layers (P layers), which model the behavior of complex cells. Each convolutional layer performs a discrete 2D convolution operation on its source image with a filter kernel and applies a non-linear transfer function. The pooling layers reduce the size of the input by summarizing neurons from a small spatial neighborhood.

The standard way to model a neuron’s output \( f \) as a function of its input \( x \) is with \( f(x) = \tanh(x) \) or \( f(x) = (1 + e^{-x})^{-1} \). In terms of training time with gradient descent, these saturating nonlinearities are much slower than the non-saturating nonlinearity \( f(x) = \max(0;x) \). The neurons with this nonlinearity are referred as Rectified Linear Units (ReLUs). Deep convolutional neural networks with ReLUs train several times faster than their equivalents with tanh units, hence we are using rectified linear units in this work.

The final layer of the CNN is fully connected to the preceding layer, which is a loss layer. The loss layer drives learning by comparing an output to a target and assigning a cost to be minimized. We use a softmax-loss as the loss layer, so the output of the fully-connected layer acts as input for the softmax classifier. The softmax loss layer computes the multinomial logistic loss of the softmax of its inputs, and it is conceptually identical to a softmax layer followed by a multinomial logistic loss layer, but provides a more numerically stable gradient.

Implementing and Training the CNNs

The CNNs are trained with the back-propagation algorithm. We are using Caffe for implementing and training the CNNs. Caffe trains models by the standard stochastic gradient descent algorithm. The CNNs are discriminatively trained via back-propagation through layers of convolutional filters and other operations such as rectification and pooling. Layers have two key responsibilities for the operation of the network as a whole: a forward pass that takes the inputs and produces the outputs, and a backward pass that takes the gradient with respect to the output, and computes the gradients with respect to the parameters and to the inputs, which are, in turn, back-propagated to earlier layers.

Evaluation

We tested our pipeline on independent set of data from TCGA patients who were held out during development of our method and that were not used during training and validation (our CNNs did not previously see any portion of tissue samples from these patients).

Results

Modular Deep Learning Classification Pipeline

We built a modular deep learning pipeline comprising an ensemble of Convolutional Neural Networks (CNN). We created an ensemble of two CNNs, as shown in Figure 3. The first CNN classifies a histological slide to GBM vs LGG, and the second CNN determines the tumor grade (grade II, grade III) for the LGG cases. By definition, GBM
is a grade IV glial tumor, hence the output of pipeline yields possible grade of Grade II, Grade III or Grade IV.

Figure 3. Modular deep learning pipeline for grading glioma using an ensemble of Convolutional Neural Networks.

Figure 4 (left) shows the structure of the first CNN that is used for GBM vs LGG classification. This CNN has a LeNet-like architecture \(^{14}\) and consists of 8 layers, comprising convolution, pooling, rectified linear unit (ReLU), a fully connected (FC) layer, and finally a softmax layer. The second CNN that is used for LGG grade classification is shown on the Figure 4 (right). This network consists of 19 layers, and it is deeper compared to first CNN, but the deeper layers have a fewer number of kernels. The largest bottleneck to be aware of when selecting a CNN architecture is the available graphics processing unit (GPU) memory.

Figure 4. (Left) The structure of the first CNN that is used for GBM vs LGG classification. (Right) The structure of the second CNN that is used for determination of LGG grade classification.

At the moment, it is still difficult to design a theoretically optimal CNN architecture for a particular image classification task \(^{24}\). Hence, a common practice is evaluating several CNNs with different layer architectures (independently to the later evaluations) in order to find a suitable CNN architecture for that particular classification task. \(^{25}\)

We trained the each individual CNN separately. When it comes to deep learning, since it could easily take several days or even weeks to train a network and there are at least thousands, sometimes millions, of data samples, it is not practical to use methods like leave-one-out cross-validation. A common practice is to have 80%-20% or 70%-30%, sometimes even 50%-50%, split of data \(^{21}\) into training and validation sets, and use the training set to train the network and then validation set for validation and parameter optimization purposes.

For training the first CNN we used a total of 8750 e-microbiopsy samples coming from 22 whole tissue slides coming from 4 different tissue source sites, with a training subset of 6998 and validation subset of 1752 samples (80%-20% split). For training the second CNN module we used a total of 7066 e-microbiopsy samples coming from 22 whole tissue slides coming from 3 different tissue source sites, with a training subset of 5671 and validation subset of 1395 samples. We stop the parameter optimization and training process once we reach a point where training error is less than or equal to 2%, and validation error is less than or equal to 10%. The factors that are taken into account for choosing these numbers include implementing early-stopping, as it is known to combat overfitting and acts as a regularization technique. Figure 5 shows the accuracy plot during the training and validation of this first CNN module for the task of GBM vs LGG classification.
Figure 5. The accuracy curve for training and validation of the first CNN module that is used for GBM vs LGG classification.

Figure 6 shows the outputs of 1st, 3rd and 5th layers of the first CNN module, illustrating how the scale of information extracted changes in different layers of the network. The first layers extract features at a low-level scale, (such as intra-nuclei or single-nuclei level features); as the sample progresses through deeper layers of the network, coarser features are extracted, such as inter-nuclei and distributional properties.

Figure 6. Visualizing an e-microbiopsy sample at different layers of processing in the first CNN: The outputs of 1st, 3rd and 5th layers are shown. Image features that are extracted vary in terms of spatial scale within different layers of the CNN.

Figure 7 shows the training and validation accuracies for the second module for the task of determining the grade of an LGG case.

Figure 7. The accuracy curve for training and validation of the second CNN module that is used for grade classification of an LGG sample.
Figure 8 shows the weights learned by the first layer kernels of second CNN module. This shows that the CNN has learned low-level morphological features, such as edge and arc like structures, as well as colors belonging to the nuclear stains and their opposing colors on the color wheel. Some of these features could recognize the nuclei and parts of nuclei, and some of them could recognize the inter-nuclear space, or the inter-nuclear boundaries.

![Image of CNN weights](image)

**Figure 8.** The weights learned by first twenty four of the first layer kernels of the second CNN module

Figure 9 shows the visualization of the second CNN module when an e-microbiopsy sample is fed into the network. Outputs of the first, fourth, seventh and tenth layers are shown. Low level features are more local, and deeper layers reveal coarser image features through the network’s hierarchy in which higher-level features are learned from lower level features.

![Visualizations of CNN outputs](image)

**Figure 9.** Visualizing an e-microbiopsy sample input to the second CNN: The outputs of 1st, 4th, 7th and 10th layers are shown.

**Testing on Independent Data**

In our evaluation of the first CNN module, in which 100 e-microbiopsy samples were randomly selected from 10 independent test slides that had not been used during training and validation of our models, we obtained a classification accuracy of 96% for the task of GBM vs LGG classification. For the second CNN module, wherein we randomly selected 100 e-microbiopsy samples from 7 independent LGG test slides not used previously, we obtained classification accuracy of 71% for the task of Grade II vs Grade III classification for LGG. Figure 10 shows the confusion matrices and individual diagnostic qualities of these two modules and their respective tasks.

![Confusion matrices](image)

**Figure 10.** Confusion matrices and diagnostic qualities of the modules

**Discussion**

In this work, we developed and applied a deep learning approach to the problem of automated classification of LGG vs. GBM and determination of tumor grade. We did this through the assembly of two modular CNN components, each specialized to the two different classification tasks. Our preliminary results appear to be promising, showing 96% accuracy for distinguishing LGG and GBM and 71% accuracy for distinguishing Grade II and Grade III LGG.
The task of classifying the type and grade of glioma using image features is not unlike other types of automated image feature machine learning problems in which a set of pre-defined features is used to characterize the image and predict the classification label, and our current work could have been approached using pre-defined features, such as nuclear shape, texture, etc. However, a substantial disadvantage of pre-defined features is the need to know those which are most informative in the classification task. Often the best features are not known, and a method of unsupervised feature learning could be advantageous, particularly if abundant data are available.

By not segmenting the individual nuclei into individual images as it was done in previous studies \(^{10,11}\), but keeping the locality and distributional properties of them through the tissue image, our deep learning networks are extracting not only intra-nuclei and single nuclei features, but also inter-nuclei features, such as their density, distribution and interactions. Deep learning methods “let the data speak,” and they discover the relevant features in the data itself, rather than imposing pre-defined features. It could take a long time to train a CNN; however, once CNNs are trained, it is very fast to perform the classification. This is a benefit of using CNNs, as the conventional machine learning approaches with hundreds of pre-defined features could take a much longer time to classify images, compared to a CNN. Also, if the already trained networks are wanted to be updated for some reason, such as accumulation of new data that is to be included for training, the methods of transfer learning and fine tuning would enable the faster updating of the already trained networks without the need of starting a new training session from scratch which would take longer time.

We proposed and explored using an ensemble of Convolutional Neural Networks to form a modular decision pipeline. There are various reasons that we chose to have an ensemble of modular and rather simpler CNNs, as opposed to using a single, but more complex monolithic CNN. First, we would like to be able to gauge measures of the diagnostic quality and statistical measures of the performance of the test, when it comes to decision making in biomedical field. Having such a modular structure enables us to analyze the diagnostic quality of each individual decision step. Second, we opted for having a pipeline with modular units at each decision step, as this would make it easier to analyze each smaller unit independently and help to obtain features that are more intuitive or interpretable, compared to having a single yet very complex unit which could make it difficult to gain intuition regarding its operation. Third, the size of image datasets are generally smaller in the medical domain due to challenges of acquiring many images, and CNNs are difficult to train using small datasets. \(^{15}\) Hence, in this work, we opted for training smaller networks with fewer output classes compared to a single, very deep and complex one, with the outputs representing all possible cases in which we are interested. As the number of output classes increases, the more samples might be needed to train a network well. Fourth, by having modular CNN units, we could explore different network architectures. For example, in our case, in one unit we had a shallower network with higher number of kernels per layer, and another network was deeper with fewer number of kernels per layer. Finally, having such a modular structure could enable users to be able to selectively use specific paths or units along the pipeline. Such modularity would allow us to integrate our single units to probabilistic graphical models, such as Bayesian networks and Markov decision processes, or to combine with other machine learning approaches such as Support Vector Machines (SVM).

The results of our evaluation of accuracy for LGG Grade classification on independent data (71%) is a reasonable preliminary result, but leaves room for improvement. There are several potential reasons for this performance. First, TCGA data vary in terms of coming from multiple centers, each of which processes the tissues with non-uniform protocols for tissue slicing, staining, image acquisition, and timing of the steps. Differences in slide preparation, microscope, and digitizing device between two batches of data may lead to differences in image properties between the two batches, and these differences, called “batch effects,” can bias the performance estimates of predictive models. \(^{16}\) The quality of WSI is also affected by artifacts introduced during image acquisition and batch effects, resulting from variations in experimental protocol. Data quality is especially challenging in collaborative repositories, such as TCGA, where a large amount of high-throughput data is collected from multiple institutions. \(^{16}\) Apart from artifacts introduced during tissue processing and image acquisition, there are variations within the tissue slides, and portions of pathology images could contain non tumor tissue which may or may not be relevant to the diagnosis, so classification accuracy can be further improved by considering a set of e-microbiopsy samples from a slide and making the decision via a majority voting like scheme. Future work in which our methods are applied to more homogenous data (e.g., that from a single instruction) would be interesting to establish the magnitude of these confounding aspects on the accuracy of our results. Such future work could also motivate research efforts to reduce the impact of such variations on methods such as ours.

Another factor that could impair the accuracy of our method in classifying LGG grade is that the distinction between a Grade II vs Grade III glioma is more subtle compared to distinguishing Grade IV from Grades II and Grade III. It
has been noted that significant problems relate to the interpretation of histologic criteria used to classify and grade gliomas.\textsuperscript{17,18} Problems with tumor grading are most significant for intermediate grade tumors, for which patient survival broadly overlaps that associated with lower and higher grade tumors.\textsuperscript{9} Our results also agree with these prior observations.

![Graph showing survival probabilities for GBM (Grade IV), LGG Grade II, and LGG Grade III](image)

**Figure 11.** Survival probabilities for GBM (Grade IV), LGG Grade II, and LGG Grade III, shown alongside the respective CNN modules that perform the classification

In terms of survival, if we look at the plot calculated from the survival data of all samples in TCGA (Figure 11), GBM cases are clearly distinct, with a very low probability of survival. For LGG Grade II and LGG Grade III, even though the main rate curves are separated, the %95 confidence intervals are overlapping. So, from the survival point of view, the accuracies of CNN modules also share similar behavior, similar to previous observations from others that there are challenges in tumor grading in intermediate grade tumors, for which patient survival broadly overlaps.\textsuperscript{9} On the other hand, our modular pipeline has advantages, because each unit can be executed individually (i.e., classifying GBM vs LGG). Though pathologists can likely distinguish LGG and GBM with similar accuracy as our approach, our methods could be useful in quality improvement initiatives, as a “second look,” or teaching applications. Our modular approach lets us meet the requirements of minimum accuracy levels that are demanded by the context of different decision points within a multi-class (i.e. more than 2 classes) classification scheme.

Moreover, to our knowledge, our work is the first to apply deep learning methods to the task of pathology image diagnosis and classification of tumor grade. There are many facets of CNN architectural optimization that we have not yet explored which we plan on pursuing in future work. We will also work on ways to improve our accuracy by exploring extra steps during the preprocessing stage, and also including information from the tissue stroma.

**Conclusion**

We developed a deep learning-based modular pipeline with ensemble of CNNs for the problem of classification and grading of glioma from digital pathology images. Our modular classification pipeline approach has the advantages of having diagnostic quality statistics of individual modules, making it easier to train these models given limited data availability and being able to explore different CNN structures for each module, facilitating relatively smaller hence easier to analyze CNNs, and giving flexibility to be used as single modules or within the framework of other modeling or machine learning applications. Our deep learning based classification modules achieved more than 90% accuracies on validation data set, and our approach produced 96% accuracy for GBM vs LGG classification, and 71% accuracy for LGG Grade I vs LGG Grade II discrimination on an independent data set coming from new patients from a collaborative repository where data is collected from multiple institutions. These results may be improved in future by leveraging our modular approach enabling us to address and optimize the different components of the task (diagnosis of GBM vs LGG, and determination of tumor grade) separately.

Introduction
Electronic health records (EHRs) have potential to improve the quality, efficiency, and cost of health care.¹⁻⁶ The transition from traditional paper-based care to EHRs within both hospitals and ambulatory practices has been aggressively promoted by federal initiatives⁷⁻⁸ and is rapidly transforming the process of health care delivery throughout the United States.⁹⁻¹¹ However, clinicians have raised concerns that EHR implementation has negatively impacted their real-world clinical productivity.¹²⁻¹⁶ For example, at Oregon Health & Science University (OHSU), we have one of the leading biomedical informatics departments in the world and completed a successful EHR implementation in 2006 that received national publicity. Yet we have published studies showing that OHSU ophthalmologists currently see 3-5% fewer patients than before EHR implementation and require >40% additional time for each patient encounter.¹⁷

Approaches toward improving the efficiency of clinical workflow using EHRs would have significant real-world impact. Clinicians are pressured to see more patients in less time for less reimbursement due to persistent concerns about the accessibility and cost of health care.¹⁸,¹⁹ Providers today are facing increased patient loads along with increased encounter times due to EHR use, but do not have guidance or information about how to meet these demands. For example, ophthalmologists typically see 15-30 patients or more in a half-day session, utilize multiple exam rooms simultaneously, work with ancillary staff (e.g., technicians, ophthalmic photographers), and examine patients in multiple stages (e.g., before and after dilation of eyes, before and after ophthalmic imaging studies). This creates enormous challenges in workflow and scheduling, and large variability in operational approaches.²⁰

Patient wait time is a result of pressure on provider time as well as clinic inefficiency; wait time has been shown to affect patient satisfaction as well as create barriers to health care.²¹²². Mathematics, specifically queueing theory, explains waiting by the mismatch of arrival times and service times (time with a physician).²³ This mismatch can be increased by ad-hoc scheduling protocols that artificially increase patient wait time.²⁴,²⁵ Addressing this mismatch using smarter scheduling strategies has potential for improving patient wait time.²⁶ Studying and evaluating appointment scheduling strategies in clinical settings is impractical, however, since patient and provider time is too valuable for experimentation. Empirical models of clinical processes using discrete event simulation (DES) can evaluate potential scheduling strategies effectively before implementing them in clinical settings. DES requires large amounts of workflow timing data—much more than can reasonably be collected using traditional time-motion studies. We believe that data to address these problems is currently available within EHR. One major benefit of EHR systems is that clinical data can be applied for “secondary use” beyond direct provision of clinical care; current efforts have focused on areas such as clinical research, public health, adverse event reporting, and quality assurance.²⁷⁻²⁹ Data mining the EHR data has been used to determine patient no-shows with success, grouping patients in emergency departments (ED)³¹, and for quality assurance in the ED.³²,³³ DES has been used for quality improvement in healthcare, but not for evaluating scheduling strategies based on secondary use EHR data and detailed workflow data.³⁰,³¹,³⁴,³⁵

In this paper, we present the results of using secondary EHR data for modeling clinical workflow in 3 outpatient ophthalmology clinics at OHSU. Ophthalmology is an ideal domain for these studies because it is a high-volume, high-complexity field that combines both medical and surgical practice. Our results show that the secondary use of EHR data for workflow data shows promise; it matches the trends of observed clinic workflows and is available for thousands of patient encounters. Further, workflow data can be used to build simulation models for evaluating scheduling strategies based on patient classification.
Methods

This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU).

Study Environment

OHSU is a large academic medical center in Portland, Oregon. The ophthalmology department includes over 50 faculty providers, who perform over 90,000 annual outpatient examinations. The department provides primary eye care, and serves as a major referral center in Pacific Northwest and nationally. We selected 3 outpatient clinics to study: 1) pediatric ophthalmology (LR), 2) comprehensive eye care (LL), and 3) glaucoma (MP). These 3 clinics represent the diversity of outpatient care in ophthalmology at OHSU.

Over several years, an institution-wide EHR system (EpicCare; Epic Systems, Madison, WI) was implemented throughout OHSU. This vendor develops software for mid-size and large medical practices, is a market share leader among large hospitals, and has implemented its EHR systems at over 200 hospital systems in the United States. In 2006, all ophthalmologists at OHSU began using this EHR. All ambulatory practice management, clinical documentation, order entry, medication prescribing, and billing tasks are performed using components of the EHR.

Workflow Modeling and Reference Data Collection

Interviews with staff and observations of each of the three clinics were performed to determine the basic patient flow. For the three outpatient ophthalmology clinics we studied, this flow consists of interactions with ancillary staff and the physicians, along with possible dilation time between interactions. Once the workflow was understood, we performed time-motion studies for 3 - 6 half-days at each of the clinics. One to two observers recorded timestamps of physicians and staff as they entered and exited exam rooms; these timestamps were then processed later to determine the duration of time spent in exam rooms with patients. This observational timing data served as our reference data for validation of the EHR timestamp data.

Collection of EHR Timestamp Data

Through preliminary iterative data collection and analysis, we identified a set of EHR timestamp data that represents the different steps of the patient flow for each clinic. The source for this data is the clinical data warehouse for our EHR (EpicCare; Epic Systems, Madison, WI). While these timestamps are specific to OHSU’s implementation in ophthalmology, comparable timestamps are available for other vendors, installations and specialties.

1. **Start and End of Patient Visit: Check-in, check-out and after visit summary printing timestamps.** For some clinics, the check-out process happens after the patient leaves; in this case, the timestamp of the after visit summary printing better represents the end of the exam.

2. **Start and End of Each Provider Interaction: Audit log timestamps.** Timestamps from the audit log can be used to represent the beginning and ending of individual provider interactions during the course of the office visit. In addition to timestamp data, this required data about providers (user IDs), exam rooms (workstation IDs) and patient encounters (encounter IDs) to select the proper context for the timestamps.

3. **Time of Dilation: Structured ophthalmology documentation form.** Eye dilation information is entered in the structured ophthalmology documentation form of our EHR. From this data, we can determine if a patient’s eyes were dilated and at what time.

After obtaining the data through queries, we processed the data and computed the workflow timings from EHR timestamps using R programming language scripts.³⁶

Data Analysis

For each clinic, we compared the timing data collected through observation to the timings computed from the EHR timestamps. We looked at the difference in interaction lengths with staff and physicians, as well as differences in overall summary statistics using the reference timings we observed and the time estimates computed from the EHR timestamps. We also included one year of EHR timing data from each of the 3 ophthalmology physicians to compare trends with the observed clinic days, because the longer-term goal of using EHR data for workflow timings is to generate a large validated dataset.
Simulation Models
We used Arena simulation software to build a model of one clinic’s workflow—the pediatric clinic (LR)—using one year of EHR timestamp data. In this model, we focused on the steps of the exam: the initial exam by ancillary staff, eye dilation, and the ophthalmology physician exam. We evaluated scheduling strategies based on patient classification; we studied the best time to schedule new patients to minimize average patient wait time.

Results
Clinic Workflow Modeling and Reference Data Collection
To collect time-motion workflow data, we observed each of the 3 clinics for 3-6 half-days (162 clinical encounters, 263 interactions between staff and patients or between ophthalmologists and patients). For the clinics we observed, 15-20 patients were typically seen during the half-day clinic session but ophthalmologists at OHSU may see up to 30 patients per half-day. Figure 1 summarizes the workflow of the clinics. Patients have an initial exam with an ancillary staff member—either a certified ophthalmic technician (tech) or an orthoptist. The pediatric clinic (LR) uses both types of ancillary staff; the other clinics use only techs. After the initial exam, patients’ eyes may be dilated before the physician examines them.

Validation of EHR Timestamp Data for Workflow Timing
After extracting EHR timestamps and computing provider interaction lengths, we compared them to those from observations as shown in Tables 1-3. Overall, the time differences at all 3 clinics were similar: 65–69% of the total EHR interaction estimates for each clinic were ≤3 minutes from the observed reference timings, with only 17–24% of the EHR interaction estimates >5 minutes from the observed reference timings. For the comprehensive eye care (LL) and glaucoma (MP) clinics, the EHR timings for physician exams were particularly close to the observed ones, but the tech exams were not. In these clinics, we observed that techs occasionally charted in exam rooms before and after seeing patients.

Tables 1-3: Time Difference between EHR Timestamps and Observed Data. For each clinic, we calculated the difference between the observed interaction time and the EHR estimates. For all the clinics, 65–69% of all EHR estimates were within 3 minutes of the observed times; at least 76% of the EHR estimates at each clinic were within 5 minutes.
which resulted in EHR timings that inaccurately overestimated the actual interaction times. Conversely, we observed providers interacting with patients before and after using the EHR, which resulted in EHR timings that inaccurately underestimated the actual interaction times.

To validate the use of large amounts of EHR data, we looked at summary statistics for the observed timings, the EHR timings for the observed days and the EHR data for one year for each of the 3 clinics as shown in Figure 2. While there was often significant variance between observed data and EHR timestamp data, the general trends matched closely. The EHR estimates tended to be high for ancillary staff and low for physicians. We presume that this is due to techs performing documentation before and after exams, and due to physicians interacting with patients before and after using the EHR.

We then performed a statistical analysis comparing the EHR timestamps to the observed ones; the results are given in Table 4. Using a Wilcoxon signed rank test, we compared the observed data to their associated EHR timestamps to determine if they were different. The results are given in the “Obs” position for the median difference and the p

Table 4: Results of statistical analysis of differences between EHR timestamps for observed days and 1 yr. EHR timestamps are significantly different for ancillary staff when observed days are compared to 1 year of EHR data.
values in Table 4. Only two sets of timings were statistically significantly different: the tech for Glaucoma (MP) and the physician for Pediatrics (LR). Since we’re interested in using the EHR timings to generate a large dataset, we want to compare the observed timings to one year of EHR timing data. We used the Wilcoxon rank sum test to determine if the 1 year of EHR timing data was significantly different from our observed timings (given in the “1 yr” position for the median difference and p values in Table 4). In this case, the test shows that all ancillary staff’s 1 year of EHR timings are significantly different than the observed timings, but the physicians’ EHR timings were not. This is consistent with the graph shown in Figure 2: the physician’s average 1 year EHR timings are similar to the observed, but the ancillary staff’s are not. We presumed the difference was due to EHR timings including staff documentation time. However, because documentation is part of the workflow, including it in the timing data may still accurately reflect the workflow in simulation models.

Development of Computer Based Models

To investigate the utility of the EHR timing data, we started with creating simulation models for one clinic, the pediatric ophthalmology clinic (LR). Using the 1 year EHR dataset, we built a simulation model of the clinic workflow, ran the simulation 100 times and measured the average total exam time (the amount of time spent with a provider) and the average wait time (Table 5). As shown, the average exam and wait times in the simulated model are similar to those we observed and those we calculated using the EHR timestamps. This suggests simulation models that use EHR timing data provide a reasonable approximation of workflows, even though they didn’t match the observed ancillary staff interactions. We presume that this is because the EHR timings include documentation, which is a part of the clinic workflow.

To better schedule patients, we have performed preliminary studies based on patient classification using the relationship between clinical and demographic factors and visit length using timing data from the EHR. Table 6 shows the mean exam time as determined by EHR timestamps for a simple patient classification: new and returning patients at the pediatric clinic (LR). When we further break these classifications down into child and adult patients, we see that the means and standard deviations change. The pediatric clinic treats adult strabismus patients who weren’t diagnosed or treated as children. The adult patients’ means and standard deviations are considerably larger than those of children. For example, a returning adult patient takes about as long as a new child patient; therefore, classifying patients and representing them accurately in our model is key for meaningful analysis.

We have also studied a scheduling strategy based on patient classification: testing the ideal time to schedule new patients. As we see in Table 6, new patient exams are longer than returning patients and have greater variability.

We compared different ways of scheduling new patients and compared the resulting wait times and clinic length. For each test, we scheduled 15 patients in a 4 hour half day of clinic, 3 of whom were new patients (1 adult, 2 child). This is consistent with the mix of patients normally seen in the pediatric clinic (LR). The “New First” strategy scheduled the new patients first, while the “New Last” strategy scheduled the new patients last. The “New Near Last” strategy scheduled the new patients in the 11th, 12th and 13th slots with two returning patients in the last two slots. The results are summarized in Table 7, suggesting that scheduling the new patients last reduces wait times for the returning patients.

Table 6: Total exam times for different patient classifications for pediatric clinic (LR). From the EHR timestamps, we calculated the total exam times for different patients. As the classification becomes more specific, the means and standard deviation change. For example, the adult patients take more time and have a greater standard deviation than children, which can skew classifications that do not consider age.
time and variability (but also increases the length of the clinic), and that scheduling the new patients near the end of the clinic is the best strategy for minimizing both the average patient wait and clinic length. We note that scheduling the new patients first results in dramatically longer patient wait times. These wait times are longer than when the schedules don’t take into account patient classification, as is the case in Table 5 for our observed data. EHR timing data and initial simulation models. Our later simulation models predict that scheduling new patients last or near to last will drastically improve the wait time over what we observed.

</table>

Table 7: Average wait times and clinic lengths for different scheduling strategies. This was based on scheduling 15 patients in a half-day clinic session, with 3 new patients (1 adult, 2 child). Scheduling new patients last results in less average wait time than scheduling them first, but it also causes the clinic to be longer. Scheduling them near the end (2 returning patients after) balances wait time and clinic length.

Typically, secondary uses of EHR data have been for clinical research, quality assurance, and public health, rather than for operational purposes. While emergency departments have used EHR timing data for tracking patients and quality assurance, our study focuses on using EHR data for modeling outpatient workflows and studying scheduling strategies. Our study shows that the data needed to study workflow can be mined from the EHR and that it represents general trends of clinic workflow. Patient flow is a concern for all areas of healthcare, in both inpatient and outpatient settings. As patients move through the stages of their care, bottlenecks occur at points where demand for resources (providers, beds, etc.) exceeds availability. Obtaining workflow data using time-motion studies is not feasible for the large amounts of observations necessary for determining variability, and using EHR large-scale timestamp data may be an alternative approach.

2. Timestamp data are less reflective of patient interaction length when EHR use does not coincide with actual clinical workflow. Data from this study show that EHR data contain information about provider interaction time, but only when the systems are being used in a predictable workflow. It is impossible to discern whether the remaining time is spent with a patient or not. We found that the EHR timestamps overestimated interaction lengths with ancillary staff when they charted in the EHR before and after the patient exam. Of the 31 ancillary staff interactions where the difference was greater than 5 minutes (Tables 1–3), 22 of them (71%) were overestimated by the EHR timestamps. Similarly, we found that EHR timestamps underestimated provider exam times when physicians interacted with patients before and after using the EHR during the exam. Of the 10 physician interactions that were more than 5 minutes different, 9 of them were underestimated by the EHR timestamps. Similarly, statistical analysis shows that the ancillary staff’s 1 year EHR timings are different when compared to the observed timing data; this is due to EHR documentation done prior to and following the patient interaction. Since this documentation time is a part of the workflow, the EHR timing data may still be used successfully in simulation models. In addition, we are currently investigating other automated methods for gathering workflow timing data, such as combining EHR data with timing and location tracking data gathered from indoor location services (i.e. iBeacons). These methods have the potential for generating more complete and accurate timing data than EHR timestamps alone.

3. These data may be used for novel activities such as developing simulation models for alternative clinical scheduling and workflow strategies. Extracting workflow timing data from the EHR for large amounts of patient encounters allows us to determine trends for average times and variability, determine probability distributions for the workflow timings and build simulation models based on these distributions. Our initial simulation model accurately predicts the wait time resulting from the variability and patterns of patient arrival and provider exam times. In addition, the EHR data allows us to classify patients; in this case, looking at adult vs. child patients as well as new vs. returning patients for a pediatric ophthalmology clinic. We found that adult patients and new patients had exam times that were longer and had greater variability. The simulation models suggest that scheduling these

Discussion
This study has the following key findings: 1) secondary use of EHR timestamp data is generally accurate for measuring patient interaction length, 2) timestamp data are less reflective of patient interaction length when EHR use does not coincide with actual clinical workflow, and 3) these data may be used for novel activities such as developing simulation models for alternative clinical scheduling and workflow strategies.

1. Secondary use of EHR timestamp data is generally accurate for measuring patient interaction length.

2. Timestamp data are less reflective of patient interaction length when EHR use does not coincide with actual clinical workflow. Data from this study show that EHR data contain information about provider interaction time, but only when the systems are being used in a predictable workflow. It is impossible to discern whether the remaining time is spent with a patient or not. We found that the EHR timestamps overestimated interaction lengths with ancillary staff when they charted in the EHR before and after the patient exam. Of the 31 ancillary staff interactions where the difference was greater than 5 minutes (Tables 1–3), 22 of them (71%) were overestimated by the EHR timestamps. Similarly, we found that EHR timestamps underestimated provider exam times when physicians interacted with patients before and after using the EHR during the exam. Of the 10 physician interactions that were more than 5 minutes different, 9 of them were underestimated by the EHR timestamps. Similarly, statistical analysis shows that the ancillary staff’s 1 year EHR timings are different when compared to the observed timing data; this is due to EHR documentation done prior to and following the patient interaction. Since this documentation time is a part of the workflow, the EHR timing data may still be used successfully in simulation models. In addition, we are currently investigating other automated methods for gathering workflow timing data, such as combining EHR data with timing and location tracking data gathered from indoor location services (i.e. iBeacons). These methods have the potential for generating more complete and accurate timing data than EHR timestamps alone.

3. These data may be used for novel activities such as developing simulation models for alternative clinical scheduling and workflow strategies. Extracting workflow timing data from the EHR for large amounts of patient encounters allows us to determine trends for average times and variability, determine probability distributions for the workflow timings and build simulation models based on these distributions. Our initial simulation model accurately predicts the wait time resulting from the variability and patterns of patient arrival and provider exam times. In addition, the EHR data allows us to classify patients; in this case, looking at adult vs. child patients as well as new vs. returning patients for a pediatric ophthalmology clinic. We found that adult patients and new patients had exam times that were longer and had greater variability. The simulation models suggest that scheduling these
patients later in the clinic helps to minimize the average patient wait time; this is consistent with previous studies that found that high variability patients are better scheduled at the end of the clinic.43

Limitations
There are several limitations to our study. First, in order to find the necessary data in the EHR, we had to discern when the provider was using the EHR during a patient interaction. At OHSU, we have uniquely named workstations in each exam room, which makes identifying patient interactions easier. If laptops were used, it would be much more difficult to determine when a provider was with a patient versus charting in an office. Second, the EHR timestamps do not always capture time spent with patients when the provider is not using the EHR. While we can determine what times the providers are not using the EHR, we cannot pinpoint what they are doing at those times.

Conclusion and Future Directions
The secondary use of EHR data for workflow models and optimization is promising. We have shown that EHR timestamps represent the trends of workflow timing data even if they do not capture all the details of the workflow. Having workflow timing data available for all patient encounters allows for creating simulation models for testing different clinic scheduling strategies. However, because EHR data does not accurately capture the entire workflow, we are looking at ways to automatically collect complete workflow data using tracking devices and indoor location services (e.g. iBeacons45). From this complete data, we hope to build more accurate simulation models for evaluating scheduling strategies for all of the 3 clinics as well as generalize these models for other outpatient clinics. We plan to validate our simulation results by implementing the new scheduling strategies in the clinics and monitoring the effects on patient wait time. Larger studies are needed to validate this approach for general use, but the secondary use of EHR timestamp data has implications for broadening the use of EHRs from a repository of clinical data toward a holistic tool for managing clinical workflow.

Abstract

Post-liver transplant patients require lifelong immunosuppressive care and monitoring. Computerized alerts can aid laboratory monitoring, but it is unknown how the distribution of alerts changes over time. We describe the changes over time of the distribution of computerized alerts for laboratory monitoring of post-liver transplant immunosuppressive care. Data were collected for post-liver transplant patients transplanted and managed at Intermountain Healthcare between 2005 and 2012. Alerts were analyzed based on year triggered, time since transplantation, hospitalization status, alert type, action taken (accepted or rejected), reason given for the action taken, and narrative comments. Alerts for overdue laboratory testing became more prevalent as time since transplantation increased. There is an increased need to support monitoring for overdue laboratory testing as the time since transplantation increases. Alerts should support providers as they monitor the evolving needs of post-transplant patients over time. We identify opportunities for improving laboratory monitoring of post-liver transplant patients.

Introduction

More than 65,000 liver transplant patients are currently living in the United States.¹ These patients require lifelong immunosuppressive care and monitoring to prevent organ rejection, toxicity, and death following this costly and complex procedure. A capitated model may be used to reimburse providers for the lifelong care of post-transplant patients, incentivizing transplant centers to minimize costs.² Achieving higher quality care at lower cost is the daunting challenge facing the United States in the era of the Patient Protection and Affordable Care Act and advancing Meaningful Use legislation.³,⁴ Computerized decision support aids have demonstrated potential to support higher quality health care. Their effectiveness has been shown in areas of relatively simple logic, such as checking for medication interactions or recognizing laboratory tests with out-of-range results.⁵,⁶ When appropriately applied, such clinical decision support (CDS) has been shown to reduce errors, decrease costs, and encourage best practice.⁷,⁸ The Office of the National Coordinator for Health Information Technology (ONC) has emphasized the importance of CDS to optimize health care outcomes and the need for its widespread adoption.⁹ CDS has the potential to improve laboratory monitoring for post-transplant immunosuppressive care.¹⁰

In 2004, a computerized alerting system was implemented at Intermountain Healthcare (IH) to support the laboratory monitoring of post-liver transplant patients.¹¹ While internal laboratory results were already available, a data entry program was created to input information regarding laboratory results from external laboratories as structured data in the EHR.¹² The availability of structured data for all laboratory results allowed alerts to be generated for all post-transplant patients regardless of laboratory used for testing. Alerts were generated for new, out-of-range, or overdue immunosuppression-related laboratory testing using automated rules developed by experts in transplant management. The automated rules employed the same logic found in the protocols used by nurse transplant coordinators for routine laboratory monitoring. Alerts were delivered to an electronic inbox within the EHR and remained until accepted or rejected. Nurse transplant coordinators could view the alert message along with information useful for decision making (e.g. date and value of the laboratory result that triggered the alert, date of and time since liver transplantation, and hospitalization status). Coordinators could accept or reject the alert, select the reason for the action taken, and leave a narrative comment. As of 2015, the liver transplant team at IH has continued to use the data entry system and the CDS alerts developed in 2004 to manage their growing population of over 500 active liver transplant patients. A previous study showed that this system led to significant improvements in the completeness, timeliness, and reduced redundancy of laboratory result reporting.¹¹ A more detailed description of the infrastructure, logic, and alerts delivered are available in previous publications.¹¹,¹³
We found one other study that used CDS to support post-transplant laboratory monitoring. Researchers found evidence that CDS improved clinical outcomes and decreased costs during the first year of post-transplant care. Other transplant centers have expressed an interest in implementing CDS to support the lifelong management of their post-transplant patient population. Yet there are studies indicating that CDS may be disruptive or no longer used by target users after initial implementation. While the initial study at IH analyzed alerts over the first five-month period after implementation, there is a gap in the understanding of how alerts are used by nurse transplant coordinators for laboratory monitoring of post-liver transplant patients over time, particularly as time since transplantation increases.

**Objectives**

In this study, we aimed to describe alerts delivered to nurse transplant coordinators from 2005 to 2012. Our objectives were to a) describe the alerts delivered to nurse transplant coordinators to manage patients after liver transplantation over an eight-year period, b) describe the distribution of the alerts and the time to respond to alerts as time since transplantation increased, and c) identify opportunities for improving alerts in order to improve the management of post-transplant immunosuppressive care.

**Methods**

The liver transplant program at IH performed 776 liver transplant surgeries from January 1, 1988, to December 31, 2012. The study population included patients who received a liver transplant at IH and who were monitored for post-transplant laboratory testing of immunosuppressive care by IH nurse transplant coordinators. We included alerts generated between January 1, 2005, and December 31, 2012, for this study. Since individual patient outcomes were not reported for this study, each transplantation was included for patients who received multiple liver transplants (n=15). We classified patients as lost to follow-up during a time period when there was a gap of 365 days or greater between an alert for overdue tacrolimus laboratory testing and an alert for a new tacrolimus laboratory result. We excluded overdue alerts for patients during the time they were classified as lost to follow-up. Patients became active once an alert for a new laboratory result was received. All alerts were triggered by either new (including out-of-range) or overdue laboratory testing.

Data were extracted from the IH enterprise data warehouse (EDW) with the help of EDW experts and a transplant center data manager. Data included immunosuppression and related laboratory results, triggered alerts, and hospital admission and discharge dates and times.

We analyzed alerts based on the year an alert was triggered, time since transplantation, hospitalization status, alert type, action taken (accepted or rejected), reason given for the action taken, and narrative comments. Correlations among data elements were identified. We described the response time between alert generation and action taken, stratified by time since transplantation. We also described the time between an alert for an overdue laboratory test and an alert for a subsequent new laboratory result (including only the first in a series of alerts for overdue testing), stratified by time since transplantation. Time-based results were summarized using a box-and-whisker plot with the ends of the whiskers representing the lowest value within 1.5 times the interquartile range of the first quartile and the highest value within 1.5 times the interquartile range of the third quartile. Outliers (values outside the whiskers) were not shown.

Institutional Review Boards from Intermountain Healthcare and the University of Utah approved this study.

**Results**

Nurse transplant coordinators received alerts for 564 post-liver transplant patients from January 1, 2005, to December 31, 2012. The number of active patients who received laboratory monitoring grew from 338 in 2005 to 418 in 2012 (Table 1).

From January 1, 2005, to December 31, 2012, there were 124,082 computerized alerts delivered to nurse transplant coordinators for laboratory monitoring of post-liver transplant patients. Coordinators received an average of 42.5 alerts per day over this time period, and all alerts were either accepted or rejected. Nearly all (98.0%) alerts were accepted, and 22.8% of alerts were received while the patient was hospitalized. The most common alerts were triggered by new results for creatinine (41.5%) or tacrolimus (30.4%) or when patients were overdue for tacrolimus (12.1%) or creatinine (9.8%) laboratory testing (Table 2).

While the number of alerts per patient remained fairly stable, the number of alerts per day gradually increased over time (39.0 in 2005, 45.6 in 2012) (Table 1). This paralleled an increase in the number of active patients over the
same period (338 in 2005, 418 in 2012), even though the number of transplantations declined. Alerts for overdue laboratory testing constituted a growing proportion of all alerts over time, increasing from 19.6% in 2005 to 29.3% in 2012. There was not a constant change over time in the proportion of alerts generated while patients were hospitalized. The proportion of alerts that were rejected decreased from 7.0% in 2005 to 0.6% in 2008 and remained below 0.6% per year through 2012 (Table 1).

Among alerts for overdue laboratory testing, few (<1%) alerts were generated while patients were hospitalized but up to half of these were rejected (Table 2). When patients were not hospitalized, 8.3% of overdue creatinine alerts and 8.5% of overdue tacrolimus alerts were rejected. The most common reason for rejecting an alert was due to external laboratory results that were available but had not yet been entered into the EHR (Table 3). For accepted alerts, coordinators most frequently sent a notification letter or indicated that they had previously sought to notify the patient. No single patient constituted more than 1% of alerts for overdue laboratory testing.

Conversely, the proportions of alerts generated for hospitalized patients were greater among alerts for new laboratory results (range: 13.8-64.5%) than among alerts for overdue laboratory testing (Table 2). Whether for hospitalized patients or not, few (range: 0-2.2%) alerts for new laboratory results were rejected. Among actions taken for accepted alerts, 100% required no additional action and 48% indicated that the coordinator reviewed the results if the patient was hospitalized, but for non-hospitalized patients, coordinators responded to accepted alerts in a variety of ways, such as reviewing laboratory results, contacting the patient, consulting the physician, or indicating that no action was required (Table 3).

Among alerts received when patients were not hospitalized, the number of alerts per day and the proportion of overdue alerts increased over time (Table 4), similar to the pattern observed overall in Table 1. However, while the proportion of alerts for low tacrolimus laboratory results remained stable, the proportions for normal and high tacrolimus laboratory results declined over time (normal: 8.9% in 2005, 3.8% in 2012; high: 5.3% in 2005, 1.2% in 2012). Likewise, the proportions of alerts for high creatinine laboratory results remained stable while the proportion for normal creatinine laboratory results decreased (35.3% in 2005, 29.8% in 2012). The rejection rate for overdue laboratory testing decreased from 25% or higher during 2005-2007 (range: 25.0-29.4%) to below 3% during 2008-2012 (range: 0.3-2.5%). The rejection rate for alerts of new laboratory results was 2.0% or lower throughout the study.

As time since transplantation increased, the number of alerts per patient declined from 95 to 21 (excluding 10+ years post-transplant) (Table 5). Likewise, the proportion of alerts received while patients were hospitalized decreased from 53.6% during the first period to 13.5% in the last period. Alerts for overdue laboratory testing constituted a growing proportion of alerts as time since transplantation increased from 2.0% for 0-3 months post-transplant to 44.1% for 10+ years post-transplant. In contrast, the proportion of patients with one or more overdue alerts appeared bimodal, with peaks at 3-4 years post-transplant and at 10+ years post-transplant. The proportion of alerts that were rejected ranged from 0.8% to 4.0% with no pattern as time since transplantation increased.

The response time between alert generation and the action taken for non-hospitalized patients increased with time since transplantation. For alerts of new laboratory results, the median response time increased from 6 to 17 hours...
For alerts of overdue laboratory testing, the median response time increased from 6 to 23 hours (Figure 2) but peaked at 39 hours for patients 1-2 years post-transplant. The median response time for alerts of both new and overdue laboratory testing remained fairly stable from 2-3 years post-transplant and beyond.

</table>
The time between an alert for overdue tacrolimus laboratory testing and the next alert for a new tacrolimus laboratory result for non-hospitalized patients increased with time since transplantation (Figure 3). The median interval increased from 5.8 to 41.2 days from 0-3 months to 10+ years post-transplant.
Discussion

While a few studies have explored how computerized alerts support laboratory monitoring of patients within the first year after transplantation, no studies have analyzed how these alerts are used by nurse transplant coordinators as time since transplantation increases for patients beyond the first year. Our study shows that the distribution of alerts generated to support the laboratory monitoring of post-liver transplant patients changes over time. As time since transplantation increases, there is a greater need to support the process of monitoring patients who are overdue for laboratory testing. In addition, even though the active patient population continued to grow, there was a decline in the number of new post-liver transplant patients at IH. This shift in the population means that a greater proportion of time must be devoted to monitoring patients who are more prone to overdue laboratory testing. Liver transplantation graft failure rates have continued to improve and patients are surviving longer, further increasing the need to monitor immunosuppressive care, particularly for overdue laboratory testing. Transplant coordinators must juggle the contrasting needs of recently transplanted patients, who require frequent new laboratory testing, and the needs of patients who are several years post-transplant and who receive less frequent laboratory testing but are more prone to being overdue for testing. Thus, computerized alerts should be implemented in a way that supports the evolving needs of managing this patient population.

There was a dramatic decrease in rejected alerts for overdue laboratory testing of non-hospitalized patients from 25% or greater during 2005-2007 to less than 3% during 2008-2012. During the study, 73% of these overdue alerts were rejected due to the availability of laboratory results from external laboratories that had not yet been entered into the EHR. The increasing number of overdue alerts generated over time and the substantial decrease in the proportion that were rejected after 2007 may indicate that additional time dedicated to data entry or implementation of electronic laboratory interfaces were used to improve the integration of laboratory results from external laboratories. A nurse transplant coordinator confirmed that an additional employee had been hired in early 2008, in part to focus on data entry of external laboratory results. The challenge of integrating external laboratory results as structured data into the EHR is a significant barrier to the widespread use of CDS. Considerable effort, both in financial cost and in standards development, continues to be spent to overcome this barrier.

By the end of the study period, the proportion of overdue tacrolimus alerts increased while the proportion of new tacrolimus alerts decreased. In addition, the distribution of specific tacrolimus alerts differed: alerts for low tacrolimus results remained stable, but alerts for normal and high tacrolimus results decreased. Overall, the proportion of alerts for low (20.4%) or high (2.9%) tacrolimus laboratory results readily outnumbered the alerts for
normal (6.9%) tacrolimus results. This is particularly unexpected when there was a decline in the number of new patients and an increase in the proportion of patients who have likely had sufficient time post-transplant for providers to maintain patients within the target range. Patient non-compliance is a possible but unlikely explanation. These unexpected differences may also be explained by a mismatch between the unaltered logic of automated rules that trigger the alerts and revised clinical practice. The protocol for immunosuppression had been revised since the automated rules had been implemented, with a downward shift in the target range. Under the revised protocol, nurse transplant coordinators were receiving alerts for low tacrolimus results that were no longer considered below the target range. The automated rules triggering computerized alerts should be updated when the laboratory monitoring protocol is revised.

When the automated rules were implemented, time since transplantation was the main determinant of the desired target range for immunosuppression. In practice, however, nurse transplant coordinators may also adjust this target range based on certain conditions (e.g. Hepatitis C positive status). The target range for tacrolimus is manually decreased for post-liver transplant patients with these conditions. Coordinators must determine whether a patient is positive for these conditions before knowing whether the alert is valid or should be adjusted. Alerts may be improved by further personalizing the logic based on these conditions.

Alert fatigue among physicians is a well-known unintended consequence of alerting systems. While methods for reducing alert fatigue have been demonstrated, the problem persists. One recommendation to minimize alert fatigue is to provide alerts that are non-interruptive. The alerting system analyzed in this study used non-interruptive alerts, or "notifications," that nurse transplant coordinators viewed in an electronic inbox. This may have contributed to the 100% response rate and the 98% acceptance rate for the alerts received by nurse transplant coordinators. In addition, alerts were delivered in a team-based environment to support transplant patient management and were designed specifically to support this workflow. After ten years of experience with the alerting system, nurse transplant coordinators continue to use the system for patient management.

This observational study has limitations. First, the study included only patients who were transplanted at one institution and who received monitoring of immunosuppressive care from the same institution. This population may not be representative of patients at other transplant centers. Second, our definition of patients who were lost to follow-up may have excluded patients who otherwise would have been included in the study.

Conclusion

As patients progress after liver transplantation, overdue laboratory testing becomes more prevalent. Alerts should be capable of supporting providers as they monitor the evolving needs of post-transplant patients over time. Opportunities exist to further improve computerized alerts by maintaining the logic used by existing alerts and by including additional parameters as transplant clinical management practices advance. Implementation of automated laboratory reporting for a greater proportion of reported laboratory results may further reduce cost and the number of erroneous alerts for overdue laboratory testing.

Examining the Distribution, Modularity, and Community Structure in Article Networks for Systematic Reviews

Abstract
Systematic reviews (SRs) provide high quality evidence for clinical practice, but the article screening process is time and labor intensive. As SRs aim to identify relevant articles with a specific scope, we propose that a pre-defined article relationship, using similarity metrics, could accelerate this process. In this study, we established the article relationship using MEDLINE element similarities and visualized the article network with the Force Atlas layout. We also analyzed the article networks with graph diameter, closeness centrality, and module classes. The results revealed the distribution of articles and found that included articles tended to aggregate together in some module classes, providing further evidence of the existence of strong relationships among included articles. This approach can be utilized to facilitate the articles selection process through early identification of these dominant module classes. We are optimistic that the use of article network visualization can help better SR work prioritization.

Introduction
Systematic reviews (SR) provide a summary of evidence from high quality studies for a specific research question. They are regularly used in health care and for health policy making. Evidence-based Medicine (EBM) relies heavily on the use of synthesized, up-to-date research evidence to make decisions. SRs are considered the highest quality source of evidence for EBM.

SR is commonly conducted by domain experts who are able to draft SR scopes, retrieve relevant citations, assess study quality, and synthesize evidence. Expert researchers first identify the SR scope and research questions, and then generate search strategies to explore related databases (e.g. MEDLINE). The search result is a list of citations, which are usually organized in reference management software (e.g. Endnote, Ref-Works). Before synthesizing relevant evidences, expert researchers need to classify articles based on the title and abstract. Then through the triage (or article selection) process, included articles will proceed to the full-text level. In most SRs, expert researchers include only 2% to 30% of citations at the title and abstract level triage, and 1.6% to 27% gets to be included at the full-text level. In other words, expert researchers spend most of their effort excluding non-relevant or low quality studies. As the classification of articles is one of the most resource and time intensive steps, such workload and resource challenges can limit the tractability of an individual review, the ability to fund a review, and also the ability to respond to new evidence that may require an update to an existing review. To accelerate this process, several machine learning (ML) approaches (i.e. Naïve Bayes and Support Vector Machine) were proposed to facilitate and enhance the title and abstract level triage, abstracts screening, or “article selection”.

As SRs aim to identify, appraise, select and synthesize high quality research evidence relevant to the research questions with a well-designed SR scope, we propose a new approach to pre-define the article relationship with similarity metrics in SR reports. The similarity metric is calculated using several MEDLINE elements, such as title, abstract, MeSH, author, and publication type. We hypothesized that relevant (or included) articles should be more similar to each other than to the excluded ones. We could illustrate such an article relationship as an article network. Each article represents as a node and the relationship (similarity) between two articles represents as an edge connecting them. We hypothesize that with article network visualization, we could detect groups or clusters in the article network, especially for relevant (included) articles in a SR report.

Through our research, we have demonstrated the visualization of article relationships using similarity metrics, and discovered community structures for article networks using 20 completed SR reports. Communities are densely connected groups of vertices, with only sparser connections between groups. Communities reveal a non-trivial internal organization of the network, and allow people to infer special relationships among nodes. Communities have been shown to have significant real-world meaning.

We visualized article networks using a force-directed graph algorithm, which is commonly used for generating network graph where pair-wise geometric distances between the drawn vertices match graph theoretic pairwise
distances. Because of the SR article screening process, articles can be classified into three categories: excluded, half-included (articles included at the title/abstract level, but excluded at the full-text level) and included (articles included at both the title/abstract level and the full-text level). We evaluated the distributions of articles from these three categories (excluded, half-included, and included) using graph diameter, closeness centrality, and module classes (communities). Our research questions included: (1) do included articles tend to aggregate together? (2) with a community detection algorithm, do included articles cluster in the same communities (module classes)?

**Methods**

We used 20 completed SRs: 15 SR reports were produced by the Drug Effectiveness Review Project team (DERP; www.ohsu.edu/drugeffectiveness), the data was made publicly available from Cohen, and 5 SR reports were produced by the Cochrane Collaboration. These 20 SRs were completed by experienced and knowledgeable human expert researchers, with inclusion and exclusion decisions made by at least two expert researchers. Table 1 shows the number and percentage of articles included at 1) abstract level decision and 2) full-text level decision. For instance, the review for ACE Inhibitors has a total of 2544 citations. Based on the abstracts, 183 (7.19%) were included; after full-text reading, 41 (1.61%) were included in the ACE Inhibitor SR report. The final inclusion rates range from 0.55% to 27.04%.

Please note that for SRs from DERP (the first 15 SRs in Table 1), full references in MEDLINE format were downloaded using explicit PubMed Identifiers (PMID). For SRs from Cochrane library (The last 5 SRs in Table 1), references in MEDLINE format were retrieved using the established search strategy on PubMed, references from other databases (i.e. EMBASE/Ovid) were not used.

Again, based on the SR article screening process, articles were classified into three categories: excluded, half-included (articles included at the title/abstract level, but excluded at the full-text level) and included (articles included at both the title/abstract level and the full-text level).

### MEDLINE Elements

In order to establish the relationship among articles, we used MEDLINE elements to create the similarity metrics. MEDLINE elements are the fields in the MEDLINE format, that document the major pieces of information of a publication (article). The MEDLINE display format is used in PubMed MEDLINE records. As the most informative elements, title (TI), abstract (AB) and MeSH (MH) elements are widely used in related work to build feature spaces for ML algorithms. Publication type (PT) is also selected by some studies as it may be a key factor for inclusion or exclusion decisions. In our preliminary work, we found that author information also had some predictive value in the article selection process. Therefore, in this study, we used TI, AB, MH, PT and author (AU) element in our experiments.

### Similarity Score

We calculated the similarity using Cosine similarity. Cosine similarity is widely applied to text mining and measures the cosine of the angle between a pair of vectors. It is a common and efficient measure for text comparison, especially for large datasets. Cosine similarity reflects the degree of similarity based on the presence and frequency of words or terms in each text. For every pair of AUs, PTs and MHs, we simply compared

| Table 1. Twenty SR reports’ total article numbers and rate of inclusion |
|---------------------------------|----------------|----------------|
| **Total** | **Abstract** | **Full-text** |
| **ACE Inhibitors** | 2544 | 183 (7.19%) | 41 (1.61%) |
| **ADHD** | 1051 | 92 (9.68%) | 16 (1.56%) |

them by exact string matching, because a minor difference may completely alter the outcome. For example, even if two authors’ names are very similar, they may be two different people. However, TI and AB are free text. To calculate the similarity between two TIs and between two ABs, we pre-processed TIs and ABs by removing some common words (such as "the", "is", "are", etc.) that appear frequently in text, stemming each word by the classic Porter Stemmer algorithm. This approach, named alphabetic features, also has been verified to be an effective method to represent an article. The resulting similarity score ranges from 0 to 1 for each element, where 0 indicates independence and 1 means exactly the same. In summary, the similarity score is the equally weighted sum of the MEDLINE element(s) similarity, ranging from 0 to 5.

Network Visualization

Force-directed graph drawing algorithms assign forces among the set of edges and the set of nodes of a graph drawing. Spring-like attractive forces are typically used to attract pairs of endpoints of the graph's edges towards each other, while simultaneously electrical repulsive force are used to separate each pair of nodes. In balanced states, the edges tend to have uniform length, and nodes that are not connected by an edge tend to be drawn further apart. Graphs drawn with these algorithms tend to be aesthetically pleasing, exhibit symmetries, and tend to produce crossing-free layouts for planar graphs.

We used Force Atlas layout to visualize article networks. In this graphic layout, each article was represented as a node and the edge connecting a pair of nodes had an edge weight, which was the similarity score of any paired articles. The initial article network was a complete network with edges. Large complete networks are usually complex and unreadable. To provide a more readable network, we filtered edges with lower similarity scores (in this study, the threshold was 1.0). After the filtering, the largest connected network was generated to represent the relationships among most articles. In the Force Atlas algorithm model, the pair-wise geometric distances between the drawn vertices match the graph theoretic pairwise distances. In our results, similar nodes (articles) tended to aggregate together after implementing the algorithm. Adjacent nodes represented articles with more similarities.

Evaluation Measures

**Graph Diameter and Closeness Centrality**

To mathematically represent the distribution of articles in the force atlas layout and then topologically study the aggregation/clustering of the included articles, we took graph diameter and closeness centrality as the evaluation measures.

In connected graphs, there is a natural distance metric between all pairs of nodes, defined by the length of their shortest paths. Graph diameter is the length of the shortest path between the most distanced nodes. In other words, a graph's diameter is the largest number of vertices needed to travel from one vertex to another when paths which backtrack, detour, or loop are excluded from consideration. A disconnected graph has infinite diameter. As the graph diameter is the maximum eccentricity of any vertex in the graph, it is widely used to measure the topology and concentration/centralization of a graph. A more concentrated graph comes with a smaller diameter. In this study, we examined the graph diameter of the largest connected network as well as the sub-graphs from the subsets of articles (included, half-included, and excluded).

Closeness centrality measures the farness from one node to all other nodes. The more central a node, the lower its total distance to all other nodes. Closeness can be considered as a measure of how long it will take to spread information from a node to all other nodes sequentially. In our study, each node had a closeness centrality value. We used the distribution of closeness centrality as a measure to evaluate the network centralization.

**Modularity**

Modularity (community detection) is a measure of network structure. It was designed to measure the strength of division of a network into modules. Networks with high modularity have dense connections between the nodes within modules but sparse connections between nodes in different modules. Although a diversity of community detection algorithms have been proposed, the quality of community detection is usually measured by modularity and also some benchmark graphs.

We used modularity to examine resulted communities (also called module classes) in article networks. In this study, the implemented community detection algorithm was a modularity optimization based heuristic method for fast
uncovering of communities in large networks. It was first published in Blondel 2008. This algorithm (also called Louvain method) has several advantages, such as easy implementation, fast computation speed, and the capability to handle large and weighted networks. More importantly, comparing to other methods, Blondel’s algorithm has demonstrated to provide higher quality results for community detection.

While working on several commonly used test-case networks with size ranges from 34 to 118 million, Blondel’s algorithm performs the best in modularity and efficiency while compared to three other algorithms. In addition, this algorithm has also been successfully tested on the commonly applied Girvan and Newman (GN) benchmarks and Lancichinetti and Fortunato and Radicchi (LFR) benchmarks. The performance of Blondel’s algorithm is among the best when considering more than 10 popular community detection algorithms, including Rosvall 2008 and Newman’s works. Blondel’s algorithm has also been applied to some popular social networks with millions of nodes like LinkedIn and Twitter. Therefore, we implemented the Blondel’s algorithm, available in Gephi, to examine the article networks in the SR reports.

Networks Implementation in Gephi

Gephi is an open source software for graph and network analysis. It provides an interactive visualization and exploration platform for all kinds of networks and complex systems, dynamic and hierarchical graphs. It supports Blondel’s algorithm as the modularity function. We used Gephi version 0.8.2 to examine our article networks. There are three parameters for this modularity function, including resolution, randomization, and weight. We used the original modularity function in Blondel’s algorithm. In Gephi, the parameters were adjusted to use “resolution=1.0” and “randomize”. This is also resulted from the nature of Blondel’s algorithm that a random node order is selected for iteration rather than an unnecessarily fixed order. Although different runs might bring slightly different results, the differences are trivial and the overall structure remains the same. In addition, our article networks used article similarities as edge weights, so the “use weight” option was applied.

Result

We examined 20 SR reports, evaluated their graph diameter, closeness centrality, and modularity, and visualized article networks using Force Atlas layout. To provide a readable article network visualization, edges with a weight less than 1.0 were filtered. After filtering, the largest connected network was generated to represent the relationships among most articles, averaging 92.07% of all articles.

To illustrate the article network graph, we used ADHD report as an example to demonstrate the graphical topology and corresponding evaluation measures. Figure 1 shows the article network graphs for ADHD report. The ADHD report had a total of 851 articles; among which, 84 articles were included at the title/abstract level and 20 articles were included at the full-text level. In Figure 1, nodes were colored by inclusion/exclusion classes. Therefore, 20 nodes (included articles) were labeled in green, 64 nodes (half-included articles) were labeled in yellow, and 767 nodes (excluded articles) were labeled in red. To examine the article distribution, we measured the graph diameter of the largest connected network, which was 10; the graph diameter of the sub-network for included articles (green nodes) was 2; the graph diameter of the sub-network for half-included articles (yellow) was 4; and the graph diameter of the sub-network for excluded articles (red) was 9. The graph diameter demonstrated that included articles were similar to each other.

The distribution of closeness centrality for the largest connected network and sub-networks are shown in Figure 2. The closeness centrality of the largest connected network ranges from 1 to 7 (Figure 2a); but the closeness centrality of the sub-network for included articles, ranges from 1 to 2 (Figure 2b). The higher the closeness centrality score is, the more distance the node is to other nodes (less similar). Only if a node was isolated because of the filtering process (edges weighted <1 were eliminated), the closeness centrality score is 0.

In summary, the sub-network of included articles had a smaller graph diameter and relatively smaller closeness centrality values than the largest connected network. We can conclude that included articles tend to have strong relationships (high similarities in MEDLINE elements). Similarly, the sub-network of the included articles also had a smaller graph diameter and closeness centrality values comparing to the sub-network of the half-included articles.
**Figure 1.** Sample article network graphs from ADHD report. Nodes colored by inclusion/exclusion classes (green= included articles; yellow= half-included articles; red= excluded articles).

**Figure 2.** The distribution of closeness centrality for ADHD report

Vertical axis - Closeness centrality
Horizontal axis - Index of articles

**Figure 2.** The distribution of closeness centrality for ADHD report
In Figure 3, it shows the same network graph as Figure 1, but with a different coloring scheme. Here, nodes are colored based on module classes using Blondel’s algorithm. A total of 73 module classes were found. Eight out of 73 modules contain more than 17 nodes, which is 2% of all articles in the ADHD report. The rest of 65 modules were considered minor communities with only a small amount of nodes or even one single node inside. The top three modules, which contain 31.02%, 18.21% and 17.04% of all articles, were colored in red, green, and yellow (in Figure 3) respectively. With this partition, we observed that 18 out of 20 included articles tended to aggregate in the green module class, with the exception of two articles. In other words, the green module class in Figure 3 covers 90% of included articles. The included articles in this green module class (18/155=11.61%), are much higher than those in the entire network (20/851=2.35%). The findings again confirmed our hypothesis that included articles tend to cluster together because of their high similarities to each other. With this scenario, if the article screening process can begin with this community, we could rapidly identify 90% (18 out of 20) relevant articles.

Figure 3. Sample article network graphs from ADHD report. Nodes colored by module classes. A total of 73 module classes were found.

Graph diameter and closeness centrality

To evaluate the graph centralization of the sub-network for included articles, we calculated its graph diameter and closeness centrality range and compared them with the largest connected network (Table 2). Because Skeletal Muscle Relaxants report has the graph diameter of 1, which is not meaningful for calculation, it was not included in the following analysis due to its fracture network. For the remaining 19 SR reports, the average value of largest connected networks’ diameter was 8.26 (SD = 1.76), while the average graph diameter value of the sub-network for included articles was only 3.84 (SD = 1.54). The results show that the graph diameter of the sub-network of included articles was significantly smaller than that of the largest connected network (paired-t test, p<0.001). And for the closeness centrality range of the largest connected network, the largest one was 1~9 while the smallest one was 1~4. The largest closeness centrality range of the sub-network for included articles was 1~5 while the smallest one was only 1~2.

In summary, the graph diameter of the sub-network for included articles was smaller than the graph diameter of the largest connected network. More than half of the SR reports even have less than a half size of the graph diameter. Besides, the closeness centrality range also shows a smaller value and tighter distribution in the sub-network of included articles comparing to the largest connected network, (1~3 vs. 1~6). The results confirmed that included articles tend to aggregate into a few small areas, and these generate “communities” cover 93.75% included articles in average from 19 SR reports in our study.
Module Classes

Table 3 shows modularity results on module classes after the implementation of modularity function (community detection function) for the 20 SRs. We used the number of modules (M), the number of modules with included articles (Mi), and the number of dominant modules with more than 10% included articles (DMi). We also reported the top two modules, which contain most included articles.

Although a large number of modules are detected for the largest connected network (average M = 86), included articles were only found in a few modules (average Mi = 4), and even less were classified into the dominant modules (average DMi = 2). This implies that included articles have strong similarity which tends to cluster in the same module classes. Moreover, the number of included articles found in Module1 (the top module for each report) provides additional aggregation evidence. In average, Module1 covers 25.5% articles overall, but 67.81% included articles. With Module1 and Module2 together, they total cover 89.03% (67.81% + 21.24% = 89.03%) included articles. Due to the space limitation, we only report the top two modules in Table 3. However, other modules except dominant modules contain very few included articles. In many cases, there was only one included article in a module.

Discussion

The use of article network visualization for SR

In this study, we used the visualization approach to demonstrate article relationships. While article networks bring a more intuitive view of article distribution, the use of graph measures also provides mathematical support for our hypotheses. The aggregation of included articles confirms the feasibility of utilizing article relationships (similarity) to facilitate the article selection process for SR. We believe the visualization approach can be a powerful tool in assisting SR researchers for article screening. Taking the ADHD report as an example (Figure 3), we can rapidly identify included articles if we start the article screening in the green module. 90% (18 out of 20) included articles could be found earlier before screening in other areas, thus significant workload would likely to be saved.

The article network visualization can be applied to (1) identify multiple key communities when the topic of articles is diversified; (2) assign high priority to communities with relevant articles and screen articles from the closet neighbors; (3) assign low priority to communities that contain several known irrelevant articles to save unnecessary workload; (4) customize the network structure with different similarity calculation for edge weights that align to specific sub-aims of a SR scope, e.g. authorship, publication type, keywords; (5) provide potential knowledge discovery from unexpected module classes. Our future work has planned to develop such an article network visualization application to assist SR.

The limitation of force-directed algorithm

Although the basic force-directed approach performs well for small graphs, the results are poor for graphs with more than one or two thousands vertices. This is mainly resulted from the obstacles to scalability and resolution. To be specific, the minimum vertex separation tends to be very small for large graphs, which leads to unreadable drawings. In addition, the typical force-directed algorithms are considered to have a time complexity equivalent to O(n^3), thus the running time could be very long for large graphs. Due to this limitation, the SRs we applied in our study had no more than 4000 articles. Algorithms and layouts like T-SNE which supports implicit structure and dimensionality reductions could be considered for larger SRs in future works.

Future direction

As most included articles exhibiting a tendency to aggregate to a specific graphic region, we demonstrated the existence of such dominant module classes that cover a high percentage of included articles. Screening articles within these module classes first will likely accelerate the speed of discovering relevant articles. For our future work, we plan to work on early identification of the dominant module classes by integrating SR expert researchers’ knowledge on SR scopes and research questions. With the external information, we are able to generate virtual article(s) representing ideal articles for inclusion. Virtual article(s) are likely to be located in the dominant module classes in the article network.

Conclusion

We demonstrated visualizing article relationships for SR with MEDLINE similarity in force layout. We used measures: graph diameter, closeness centrality, and module classes from the perspective of graph theory, to evaluate the centrality and communities of generated article networks. The sub-networks of included articles have a significantly smaller graph diameter than those of the largest connected network (3.84 vs. 8.26, p<0.001), and a
smaller distribution in closeness centrality (1~3 vs. 1~6). Although a large number of modules were detected for the largest connected network (n=86) after the implementation of modularity function, included articles only cluster into a few communities (n=4), and are found in even fewer dominant communities (n=2). More importantly, the top two modules covered 89.03% included articles.

Since most included articles in our research cohort exhibited a tendency to aggregate to specific regions, early identifying and exploring of these regions will likely accelerate the discovery of relevant articles for a SR. We conclude that while relevant articles in SRs share common features and strong relationships (similarities), the article similarity can be utilized to facilitate the article selection process thus shortening and facilitating the most labor intensive aspect of the SR, which is the most intensive job in SR. Besides, through the visualization of article networks, we demonstrated viewing article relationships in a more intuitive way. We also discovered other advantages of visualizing article networks that are infeasible from the common text comparison approach. For example, if there are multiple major aggregated regions in an article network, a branching of SR scopes may be needed. Integrating article network visualization as a decision support tool in the SR process will enable SR researchers to discover particular patterns or communities; thus accelerating the SR production.

A Data Quality Ontology for the Secondary Use of EHR Data

Abstract

The secondary use of EHR data for research is expected to improve health outcomes for patients, but the benefits will only be realized if the data in the EHR is of sufficient quality to support these uses. A data quality (DQ) ontology was developed to rigorously define concepts and enable automated computation of data quality measures. The healthcare data quality literature was mined for the important terms used to describe data quality concepts and harmonized into an ontology. Four high-level data quality dimensions (“correctness”, “consistency”, “completeness” and “currency”) categorize 19 lower level measures. The ontology serves as an unambiguous vocabulary, which defines concepts more precisely than natural language; it provides a mechanism to automatically compute data quality measures; and is reusable across domains and use cases. A detailed example is presented to demonstrate its utility. The DQ ontology can make data validation more common and reproducible.

Introduction and Background

The healthcare system in the United States continues to adopt electronic health records (EHR) at a rapid pace.1 The EHR is designed to replace a paper chart and to document and facilitate the delivery of care. Since this electronic data is now much more easily accessed than abstracting from paper charts, it is frequently used for other purposes such as clinical effectiveness research, predictive modeling, population health management and healthcare quality improvement. Secondary use of EHR data is expected to improve health outcomes for patients, but the benefits will only be realized if the data that is captured in the EHR is of sufficient quality to support these secondary uses.2 Investigators have shown that EHR data often contain errors that can impact research results, yet only 24% of clinical studies that use EHR data had a data validation section.3 In order to measure the quality of data there must be an understanding of how the data will be used.4

There is no generally accepted quantitative measure of data quality, but Juran gives an often cited qualitative definition as “…high-quality data are data that are fit for use in their intended operational, decision-making, planning, and strategic roles.”5(p.34-8) Data quality may be adequate when used for one task, but not for another. For example, a higher level of data quality is needed to count the number of diabetic patients with controlled HgA1C than to just count the number of patients. A task refers to concepts in a clinical domain and those concepts are represented by the data. For each task, a set of data quality measures must be developed that determine if the data are adequate to perform the task. The healthcare data quality literature provides terminology and definitions and attempts to organize data quality measures, but there is no general agreement on what these measures should be.6 This terminology-based approach defines measures using natural language, which does not adequately represent the relationships between concepts and is too loosely defined to yield a quantifiable measure of data quality. A better approach is to use an ontology which provides a sufficiently rigorous foundation for concept definitions that enable automated methods for calculating data quality measures.

An ontology is a formal, explicit specification of a shared conceptualization.7 Each concept (also called a “class”) in the ontology has a name, attributes, properties (relations to other concepts) and constraints that must always be true for a concept. The key benefits of defining data quality measures in terms of an ontology are that an ontology is: 1) a specification, written in a formal language and able to represent semantics, 2) a shared vocabulary...
that everyone can use to precisely refer to an aspect of the world, and 3) a sufficiently rigorous specification that can be used for logical inference and computation. An ontology is a logical theory about a part of the world and it defines interrelationships between concepts and axioms that should be true about that world. Automated reasoning can be applied to check internal consistency and make inferences beyond what was explicitly stated in the ontology. This automation eliminates the need for redefining the data quality measures for every task in every domain.

No formal healthcare data quality ontology currently exists, but there is research that examines core data quality concepts. Wang and Strong proposed a framework that consolidates 118 different general data quality characteristics into 20 categories. Kahn proposed a healthcare specific framework using a “fit-for-use” data quality model in which he proposes five high-level dimensions. Liaw performed an extensive literature review looking for commonalities on data quality dimensions. He found consensus on the five most common occurring dimensions were “accuracy”, “completeness”, “consistency”, “correctness” and “timeliness”. While there is some agreement among investigators on these high-level dimensions, there is little agreement or consistency in definitions of more granular data quality concepts such as “validity”, “reliability” and “believability”. In a 2012 paper, Weiskopf defined five high-level dimensions of data quality and listed synonyms for each (Table 1).

<table>

<td>Accuracy, Believability, Trustworthiness, Validity</td>
</tr>
<tr>
<td>Currency</td>
<td>Recency, Timeliness</td>
</tr>
</tbody>
</table>

Table 1: Weiskopf Five Dimensions of Data Quality with Synonyms

While these dimensions capture orthogonal aspects of data quality, they are defined using natural language descriptions and synonyms. As can be seen from Weiskopf’s descriptions, the same terms may be used multiple times to mean different things (i.e. “Accuracy” occurs 3 times), introducing confusion regarding what aspect of data quality is being described. To provide better conceptual clarity and precision, an ontology is needed.

This paper describes the development of a healthcare data quality ontology (DQ ontology) which provides rigorous definitions and can automate the computation of data quality measures. Given formal ontologies for a clinical domain and for a task, the DQ ontology enables measures to be reused without having to reinvent new data quality assessments for every research project. Ontologies for some clinical domains and tasks already exist and researchers can focus on creating additional ontologies that can be used by the DQ ontology to yield quantified measures. This can make it easier to incorporate data quality validation as a standard component of research results. The DQ ontology was developed from a comprehensive list of data quality terms present in the literature. The terms were organized into an ontology and constraints were defined that precisely describe a data quality measure better than natural language and enable quantification of the measure. It makes explicit which data quality concepts depend on the use of the data and which depend on the clinical domain. A detailed example demonstrates the utility of this ontology for quantifying measures and for discussing aspects of data quality.

Materials and Methods

There are a number of methodologies for developing an ontology, but the method described by Noy and McGuiness was selected due to its simplicity and effectiveness. This methodology advocates a seven-step process that takes a list of terms and definitions and turns them into a formal ontology. The first step is to define the scope of the ontology. For this study, the scope is a shared vocabulary of data quality concepts with formal definitions that are automatically computable to quantify data quality. The software development community has had success adopting the approach of a common vocabulary to allow researchers to spend less time defining concepts and more time applying it in research. Next, the reuse of existing ontologies was considered. No formal healthcare data quality ontology exists; but ontologies that describe clinical domains and tasks do exist and will be reused and referenced by the DQ ontology.

In order to enumerate the important terms in the ontology, an extensive PubMed search for articles published between January 1995 and January 2015 was performed to obtain a comprehensive list of terms and definitions that are used to describe healthcare data quality. The goal was to find literature reviews and meta-analyses of papers about healthcare data quality to identify as many core concepts as possible. Also, all articles about informal...
healthcare data quality frameworks or ontologies were examined for key terms and definitions. Keywords included in the query were: (“data quality”) and (“health” or EHR) and (“literature review” or framework or ontology or assessment or model) and (dimensions or accuracy or consistency or completeness or correctness).

There were 181 articles identified, which were manually reviewed by the first author and narrowed to five meta-analyses from Liaw6, Weiskopf34, Kahn11, Chen18, and Lima19. These papers were either reviews of other papers about healthcare data quality or they proposed an informal data quality framework. They all attempted to categorize data quality concepts into semi-orthogonal dimensions. The references from these papers were also reviewed, which yielded an additional five sources: Wang10, Wand29, Chan11, CIHI22, Stvilia23. Collectively, these 10 meta-analyses reviewed 412 papers looking for common aspects of healthcare data quality. There was similarity on high-level concepts such as “correctness”, “consistency” and “completeness”, but there were limited definitions for important terms such as “dataset”, “data”, “measurement”, “metric” and “measure”. Additional papers from the information science literature were found to further define these important concepts24–26.

Ontologies can be specified using a number of methods including OWL27, first order logic, or as UML28. For this paper, the ontology is documented using a UML diagram and a table that lists constraints. A bottom-up approach was taken in which terms and definitions from the meta-analyses were matched and harmonized into equivalent concepts and these concepts where grouped into higher-level categories. Each concept has properties and relationships with other concepts that were discerned from reading the description in the articles. The cardinality of relationships was also defined. Cardinality indicates whether an associated concept is optional, must always occur, or can occur multiple times. For example, a patient must always have a gender, but a blood pressure reading is an optional observation. Constraints were also defined for each concept, describing what should always be true for a concept. The constraints evaluate to a Boolean (true/false) result and can be written in a number of languages including, Object Constraint Language (OCL), first order predicate logic (FOPL), pseudo-code or openEHR constraint language.8,29 For this study, pseudo-code was chosen because it succinctly captures the important aspects of the constraint without introducing a specific, complex syntax.

Results

There were 96 terms and definitions extracted from the literature as a basis for the data quality measures of the ontology. Terms that described the same concept were matched based on their definition and use within the articles. Concepts that appeared in less than three of the articles were deemed non-core and were left out of this version of the DQ ontology. The resulting data quality ontology is shown in Figure 1 as a UML diagram depicting the relationships, attributes, and cardinality of the concepts. For readability, the 19 lower-level Measures were not included in the diagram and are listed in Table 2, which also provides a definition of the measure and a reference to equivalent terms from the meta-analyses. A bold font is used to indicate that a term refers to a concept from an ontology.

The meta-analyses articles make pervasive reference to concepts such as “data”, “information” and “value”. In the DQ ontology, a more precise concept, Representation, defines the lowest level, atomic piece of information that exists in the data being assessed (synonyms for this concept are data field, observation, value, etc). Representations have a DataValue (the part that is stored somewhere) as well as a ValueType that specifies a format to which the DataValue must conform (i.e. numeric quantity, string, choice field, etc). ValueTypes put constraints on the DataValue of the Representation, and can only refer to intrinsic information about the value itself and not to relationships with other Representations. Formal semantics about concepts represented in the data are defined in a separate Domain ontology. Representations have an attribute, DomainConcept, which maps data to a concept in the clinical Domain ontology. There can be multiple Representations for each concept in the Domain. For example, a systolic blood pressure value can be represented as a single number (i.e. 123) or it can be encoded as the first part of a string (i.e. “123/92”). DomainConcepts can also have multiple synonyms in the Domain ontology (i.e. “BP” and “Blood Pressure”), but for the purpose of assessing data quality, they can all be mapped to a single primary DomainConcept (i.e. ‘Blood Pressure’). The Task designates the context or the specific use of the data and is necessary for assessing fitness-for-purpose. The Domain and Task are separate, formal ontologies to which the DQ ontology refers. A Dataset is an arbitrary grouping of Representations of interest. For example, a Dataset can be all of the Representations in the entire EHR.

One of the key concepts in the DQ ontology is the Measure, which is defined as “a quantity that characterizes a quality of the data”. Other possible terms considered were “dimension”, “aspect”, “measurement”, “metric”. Measure was chosen because it captured the notion of quantifying an aspect of interest. The word is used as a noun, not a verb. A Measure is quantified using a MeasurementMethod. A Measurement is a process that performs a MeasurementMethod on a specific Representation (or Dataset) at a point in time that yields a MeasurementResult which is a quantity, usually numeric (but possibly a boolean or text value). A Metric is a
statistic about a series of MeasurementResults along a dimension such as time or across patients. For example, a MeasurementResult could indicate that there were 72 data format errors in a Dataset. But a Metric for that situation would be that there were an average of 5.5 data format errors per day or per patient. This part of the DQ ontology was based in part on core concepts from the Ontology for Software Measurement\textsuperscript{24}.

Four high-level data quality dimensions (CorrectnessMeasure, ConsistencyMeasure, CompletenessMeasure and CurrencyMeasure) categorize 19 lower level Measures. “Accuracy” is one of the terms that had many definitions in the literature. In Weiskopf\textsuperscript{13}, she lists at least 3 different ways that the term is used. It sometimes means only correctness but it is also used to represent completeness or plausibility. For that reason, the term “accuracy” has been avoided in the DQ ontology because it is too overloaded. Instead, the term “correctness” was selected to represent this core concept.

| DomainComplete                | The extent to which information is present or absent as expected.         | Appropriate amount of data: Data are present or absent as expected\(^6\), Optionality\(^1\), Content\(^20\) |
| RelativeCompleteness          | The extent to which a truth about the world is represented in the data. This is computed as sensitivity relative to another Dataset. | Completeness: Is a truth...in the EHR?\(^13\), Accessibility\(^10\,13\,15\), Accuracy\(^3\), Availability\(^13\), Missingness\(^13\), Omission\(^13\), Presence\(^13\), Quality\(^13\), Rate of Recording\(^13\), Sensitivity\(^13\), Validity\(^13\) |
| Sufficiency                   | The data has sufficient Representations along a given dimension (i.e. time, patient, encounter) to perform the Task. | Completeness: ...sufficient breadth and depth for the task\(^11\), Appropriate amount of data\(^11\), Representativeness\(^10\), Sufficiency\(^20\), Accuracy: Coverage\(^22\), Granularity\(^11\,18\), Continuity\(^1\), Level of Detail\(^20\), Completeness\(^1\), Precision\(^13\) |
| DomainCoverage                | The data can represent the values and concepts required by the Domain.     | Completeness: ...represent every meaningful state of the [...] real world\(^9\), Completeness: All values for a variable are recorded\(^3\), Coverage\(^19\), Completeness\(^20\) |
| TaskCoverage                  | The data contains all of the information required by the Task.             | Completeness: ...depict every possible state of the task\(^11\), Usability\(^13\), Usability\(^1\), Utility\(^16\), Importance\(^23\), Usefulness\(^23\), Value-added\(^23\) |
| Flexibility                   | The extent to which the data is sufficient to be used by many Tasks.      | Consistency: ...information...applies to different tasks\(^6\), Flexibility\(^1\), Relevance: Adaptability\(^22\) |
| Relevance                     | The data is sufficient for the Task and conforms to the Domain.           | Relevance\(^6\,18\,20\,23\), Relevance: Value\(^22\), Relevancy\(^10\) |
| CurrencyMeasure               |                                                                           |                                        |
| RepresentationCurrent         | Calculation for time difference between when an observation was made and when it was entered into the system. | Timeliness: delay between a change of the real-world state and...the information system\(^3\), Currency\(^1\), Completeness\(^1\), Time Completeness\(^1\), Up-datedness\(^1\), Recency\(^2\) |
| DatasetCurrent                | Time difference between when a Dataset was updated and when it was made available. For example, periodic updates to a repository. | Timeliness: ...availability of output is on time\(^3\), Opportunity\(^19\), Periodicity\(^18\), Currency\(^1\), Timeliness: Data currency\(^23\), Timeliness\(^11\) |
| TaskCurrency                  | The Data is sufficiently up-to-date for the requirements of the Task.      | Timeliness: ...information is up to date for task\(^11\), Timeliness: ...age of the data is appropriate for the task\(^11\), Timeliness (external)\(^10\) |

Table 2: Data Quality Ontology - Measure Detail
**Illustrative Example of Using the DQ Ontology**

In what follows, an example is provided to illustrate the utility of the DQ ontology concepts. Table 3 lists constraints (using pseudo-code) for some of the **Measures**. These will be used to show how data quality measures can be computed for a sample **Dataset** (Table 4) with respect to the task of calculating an eMeasure. An eMeasure is a ratio for a health outcome of interest. For example, NQF 0018, “Controlling High Blood Pressure”, is defined to be “The percentage of patients 18-85 years of age who had a diagnosis of hypertension and whose blood pressure was adequately controlled (<140/90mmHg) during the measurement period.”

Table 3: Examples of Data Quality Measure Constraints

For the DQ ontology to be applicable, a **Domain** and a **Task** need to be defined. In this case, the **Task** is to calculate the eMeasure defined above and the **Domain** consists of concepts related to blood pressure as well as some information about the patient and the encounter. To make the example more concrete, a minimalist (and incomplete) **Domain** and **Task** ontology will be defined. A portion of a blood pressure (**Domain**) ontology is shown below (patterned after the openEHR blood pressure clinical model):

**BloodPressureDomain** (portion) is an instance of a **Domain** ontology consisting of:
- Patient is a Structure and has 1 MRN, [0 or more] Encounter, 1 Age
  - Age is a Quantity with a constraint of “Age > 0 and < 120”
- Encounter is a Structure with [0 or more] Diagnosis, [0 or more] BloodPressureObservation
- BloodPressureObservation has [0 or 1] Systolic, [0 or 1] Diastolic
- Systolic is a Quantity with a constraint of “value > 0 and < 1000, Systolic > Diastolic”
- Diastolic is a Quantity with a constraint of “value > 0 and < 1000, Systolic > Diastolic”

The **Task** usually has a formal ontology, but for simplicity’s sake a task definition serves to illustrate how concepts in the **Domain** are referenced to specify the criteria for the patient population of interest. It defines the semantics of “diagnosis of hypertension” which, in this example, is a value set of codes from the ICD9 terminology. A portion of an example **Task** instance, TaskNQF0018 is shown below. It is patterned after the eMeasure Quality Data Model (QDM):

**TaskNQF0018** (portion) is an instance of a **Task** ontology consisting of:
- PatientPopulation refers to Patients Age and Diagnosis:
  - InclusionCriteria: Diagnosis in \{401.0, 401.1, 401.9\} and Age \(\geq 18\) and Age \(\leq 85\)
  - SufficiencyConstraint: At least 1 BloodPressureObservation per Encounter
  - Numerator refers to the most recent BloodPressureObservation: Formula is count( BloodPressureObservation.Systolic > 140 and BloodPressureObservation.Diastolic > 90 )
  - Denominator refers to PatientPopulation: Formula is count( PatientPopulation )

Sample patient data is shown in Table 4. Each of the cells in the table shows the value of an instance of a **Representation**. The topmost column headers indicate the **DomainConcept** to which each of the cells map. The lower column headers show the **DataValueType** for the cells in the column. For brevity, other **Representation** information (entryTime, observedTime, etc.) is not shown.
Table 4: Example Patient Data

To assess the quality of the sample data, Measurements that quantify some of the Measures were performed. For this example, the MeasurementMethod evaluates the class constraint of a Measure for all of the Representations in a Dataset and produces a MeasurementResult, which is the proportion of constraints that were satisfied. These results are shown in Table 5. The quantity in the table cell is a fraction where the numerator is the number of constraints that are satisfied and the denominator is the number of Representations for each concept. The cell also shows the decimal equivalent for the fraction. As an example, to compute RepresentationConsistency for the Diastolic DomainConcept, the three Representations in the last column of Table 4 are examined. It can be seen that these Representations have a DataValueType of numeric. But the value for Patient2 is not valid. Therefore, only two of the three Representations have RepresentationConsistency. The rest of the MeasurementResults are shown in the table.

Table 5: Measurement Process Summary for Some Measures

1943
This example shows how the DQ ontology enables a meaningful discussion of data quality characteristics required for computing an eMeasure. It also illustrates a method for quantifying each Measure by evaluating the proportion of constraints satisfied by the Representations.

Discussion

The DQ ontology presented in this study harmonized data quality concepts from the literature and provides a practical framework to evaluate data quality in health care through explicit definitions using constraints and relationships between concepts. The ontological approach provides more precise definitions of concepts than simply relying on natural language, it enables computation of a quantity for a Measure (MeasurementResult) and it makes explicit the relationship between the DQ ontology and the Task and Domain ontologies. This allows the DQ ontology to be reused for different Domains and for different Tasks without having to devise new Measures. The benefit of specifying these as separate ontologies was demonstrated in the previous section. For example, when calculating the DomainConsistency Measure, constraints from the Domain ontology (i.e. “Systolic > Diastolic”) can be referenced when computing MeasurementResults without having to change the definition of the MeasurementMethod (or the computer program that implements it). The same benefit is true when calculating the Sufficiency Measure. A SufficiencyConstraint can be evaluated for different Task ontologies to yield a MeasurementResult without having to change how Measures are defined. Not having to invent a new data quality framework for every research project should make validating data quality more common and reproducible.

Precisely defining both the Domain and Task ontology are very important in accurately describing what each data quality Measure means. Some of the Measures have constraints that reference the Task; these are clearly context dependent. Other Measures reference only the Representation or the Domain and are task independent. The constraints make clear exactly how aspects of each are related and help sharpen definitions. An example will illustrate this. DomainConsistency and RepresentationConsistency often get intertwined in definitions found in the literature. Liaw6 listed a number of sub-meanings under his “Consistency” dimension. One sub-definition (“Consistency: Representation of data values is same in all cases”) is equivalent to RepresentationConsistency, but he did not list an exact equivalent to the concept of DomainConsistency. The closest mapping is “Accuracy: Refers to values and representation of output data”. On the other hand, Weiskopf32 separated and clearly defined these differences. The concept of RepresentationConsistency is embodied as “Concordance: Is there agreement between elements in the EHR, or between the EHR and another data source?” and the concept of DomainConsistency is well defined as “Plausibility: Does an element in the EHR makes sense in light of other knowledge about what that element is measuring?” But there is an issue in the “Concordance” definition in that the last part of her definition “…or between the EHR and another data source” includes reference to another Measure (RelativeCorrectness). A Representation can have RepresentationConsistency without having DomainConsistency, but the reverse is not true. This is reflected in the constraint for DomainConsistency by explicitly referring to RepresentationConsistency as part of the definition. This also highlights the usefulness of a shared vocabulary for data quality. It makes it possible to discuss nuances of data quality characteristics.

Another issue that occurs frequently in the literature is the term “accuracy;” there is an assumption that it is possible to know what is absolutely true about the world. For EHR data, there are no true gold standards for comparison. There are only other sets of data whose “accuracy” is unknown which can be referred to as relative gold standards.31 Comparing one dataset to another to yield a positive predictive value (PPV) and sensitivity measure are a useful way to characterize the data.32 The concept of RelativeCorrectness measures whether data is likely correct by matching a Representation to its counterpart in another Dataset. The matches are considered true positives and are divided by the number of Representations in the Dataset to yield a PPV as a CorrectnessMeasure. Similarly, RelativeCompleteness looks to see which “truths” of the world are captured in the EHR data. If a Representation is present in one Dataset and is also present in the other “relative gold standard”, then these true positives are divided by the number of Representations in the other Dataset to yield sensitivity as a measure of how complete the first Dataset is.

There are a number of limitations to the current research. Data quality concepts described in the meta-analyses were harmonized and mapped to concepts in the DQ ontology. Care was taken to map based on meaning or context of use, but since the meaning was from an interpretation of a definition (or sometimes, a single term), the mapping might not represent what the author of the meta-analyses intended. This research depended heavily on the core data quality concepts contained in the meta-analyses. The literature search may not have been exhaustive in finding all of the meta-analyses or there may be important data quality concepts that were not discussed in those papers. Since many data quality concepts are repeated amongst the papers, it is likely that the most important ones were captured. It is expected that additional data quality concepts will be added to the DQ ontology as the need for having a formal definition for the concept arises. Concepts that did not appear in at least three of the papers were not included in the
DQ ontology. This includes concepts such as objectivity, non-duplication, security and privacy. Future work is needed to incorporate these into the DQ ontology. The concept of DomainComplete is currently too simplistic. It will need to be expanded to better define types of missing data as missing completely at random (MCAR), missing at random (MAR) and missing not at random (MNAR).

The DQ ontology is applicable to structured EHR data. Additional research is needed to extend the DQ ontology to notes and other unstructured data present in EHRs. Natural language processing (NLP) techniques may be used to parse relevant DomainConcepts from the unstructured information. In that case, the DQ assessment techniques described in this paper could be used to characterize that portion of the data.

The next phase of this research is to use the DQ ontology to perform data quality Measurements on actual EHR data. A Domain ontology for a clinical area will be developed in full and mapped through Representations to EHR DataTypes. Similarly, a formal Task ontology will be created and referenced by the data quality Measures. The constraints for the DQ ontology Measures will be written in a formal language, which can then directly be used to compute MeasurementResults and Metrics for a real-world Dataset.

Conclusion

The healthcare data quality literature was mined for the important terms used to describe data quality concepts. These terms were harmonized into a DQ ontology that represents core data quality concepts. Four high-level data quality dimensions (CorrectnessMeasure, ConsistencyMeasure, CompletenessMeasure and CurrencyMeasure) categorize 19 lower level Measures. These concepts serve as an unambiguous vocabulary when discussing healthcare data quality. The class constraints precisely define concepts better than using natural language and provide a mechanism to automatically compute MeasurementResults to quantify data quality. The DQ ontology can be reused with different clinical Domain and Task ontologies to make validating data quality more common and reproducible.

Evaluating Consumer m-Health Services for Promoting Healthy Eating: A Randomized Field Experiment

Yi-Chin Kato-Lin, MS1, Rema Padman, PhD1, Julie Downs, PhD1, Vibhanshu Abhishek, PhD1

1Carnegie Mellon University, Pittsburgh, PA

Abstract

Mobile apps have great potential to deliver promising interventions to engage consumers and change their health-related behaviors, such as healthy eating. Currently, the interventions for promoting healthy eating are either too onerous to keep consumers engaged or too restrictive to keep consumers connected with healthcare professionals. In addition, while social media allows individuals to receive information from many sources, it is unclear how peer support interacts with professional support in the context of such interventions. This study proposes and evaluates three mobile-enabled interventions to address these challenges. We examine their effects on user engagement and food choices via a 4-month randomized field experiment. Mixed models provide strong evidence of the positive effect of image-based dietitian support and negative effects of peer support, and moderate evidence of the positive effects of mobile-based visual diary, highlighting the value of mobile apps for delivering advanced interventions to engage users and facilitate behavior change.

Introduction

The ubiquitous presence of the Internet offers a cost-effective alternative for information processing and communication. The potential of the Internet has been widely recognized and utilized in healthcare services, known as eHealth. eHealth has the potential to reach a broader population, make information processing easier by using graphics, and enable interactivity and personalization. It also allows asynchronous communication and has the potential to mimic face-to-face interactions. The impact of eHealth is further enhanced by mHealth, which refers to the use of mobile devices and technologies for health management. Smartphones enable intervention delivery, data collection, and evaluation without time and space constraints, thus increasing treatment intensity and reducing the time and resources needed for application implementation. Leveraging the benefits of both eHealth and mHealth, smartphones with Internet connectivity and built-in functions, such as cameras, make it especially easy and convenient for users to record and transmit rich information at their convenience.

As a result of the ease with which it embeds in people’s daily lives, the use of mHealth interventions to influence consumers’ lifestyles has grown immensely, particularly with the boom in health and fitness smartphone apps. Popular apps include LoseIt! and MyFitnessPal for weight management, and Calorie Counter and Fooducate for healthy eating. However, the effect of mobile-enabled behavioral interventions on health behaviors is still uncertain, as consumer health or behavioral outcomes have only been evaluated for automated SMS, which have been found to usually have little or no effects, or been evaluated for the app as a whole but not isolated components. Although few apps with advanced features have been evaluated for behavioral outcomes, the evidence is only supported by observational studies (e.g. Helander et al. (2014)) or randomized experiments with small sample sizes (e.g. Wayne and Ritvo (2014)) or short periods (e.g. Byrne et al. (2011)). This gap in practice and research thus calls for additional evidence of the effect of smartphone apps on health behaviors.

Eating habits are a fundamental behavior associated with the risk of many chronic diseases. To promote healthy eating, the United States Department of Agriculture (USDA) introduced the food pyramid in 1992, which was further updated to MyPyramid in 2005. Nevertheless, although eating habits among the U.S. population have improved over time, the dietary patterns of the majority are still far from the recommended guidelines. For example, a recent report indicates that only 23% of adults consume enough fruits and vegetables per day.

Social cognitive theory suggests that people’s health behaviors can be influenced by environmental stimuli, or interventions, and the effectiveness of interventions can be further affected by the intervention components, intensity, and delivery mode. However, the effectiveness of interventions usually cannot be attributed to isolated components, as studies often evaluate the effect of a program as a whole with mixed elements. In addition, current interventions are usually delivered via traditional approaches and their treatment intensity has usually been low. To leverage the advanced functionalities of smartphone apps, this study proposes “upgraded” interventions to be
delivered by a smartphone app and evaluates their effects on user engagement and eating behaviors, on the basis of three commonly used intervention components.

The first intervention component is **self-monitoring, or dietary tracking**, which is the building block for behavioral change. Traditionally, it has required recording the amount of each consumed food item using unfamiliar measurements such as cups, ounces, or servings, which have been found to be burdensome and difficult to sustain. In addition, consumed portion size is commonly misperceived, which may lead to the consumption of more or less food than desirable.

The second common intervention component is the **support of healthcare professionals**, which aims to improve people’s knowledge to perform the desired behavior. Before eHealth, such support was usually provided during face-to-face encounters. However, the intervention intensity was low, as the encounters usually occurred only once over the course of weeks or months. When issues arise between sessions, this infrequent support usually fails to provide timely feedback. In addition, without objective references about consumers’ food intake, dietitians’ feedback based on users’ biased food diaries cannot be optimal. Although eHealth and mHealth enable frequent communication between professionals and individuals through forums or SMS, the information exchanged still may not contain objective references to consumers’ food intake. Moreover, without receiving meal-based feedback that can help individuals adjust their perceptions, people are still challenged to translate recommendations into practice.

The third commonly used intervention is **peer support**, which connects people with the same conditions or goals so that they can relate to each other’s beliefs and feelings. Before eHealth, peer support was provided via infrequent group sessions or phone calls, which was also low in intervention dosage. The use of eHealth and mHealth connects each individual online with peers 24/7, mostly via forums or sometimes via following or tracking others’ activities. However, the effect of online social support on health behavior or outcomes is still uncertain, and the literature consists mostly of observational studies, but not randomized controlled trials. Support from remote professionals and peers are not only made more accessible by the Internet, but also strongly desired by people; yet, how peer support interacts with professional support is an important but understudied issue. Specifically, while peer support may engender no effect or unexpected effects on some occasions, it is important to know whether it combines with professional support to become highly effective, to reach a saturation level, or to interfere with one another. However, studies rarely compare these two sources of support systematically together and thus the interaction effect remains unknown.

To address these limitations, this study proposes three mobile-enabled interventions that build on the three traditionally used interventions mentioned above. First, we propose the use of smartphones’ built-in cameras and the concept of MyPlate, a visualized food guide launched by the USDA in 2011, as the basis of visualized and simplified self-monitoring. It introduces a visual plate as a general guideline at mealtime and helps consumers think about their entire meal instead of counting calories, cups, ounces, or servings. Specifically, we ask users to take a picture of their meals using our smartphone app, compare their meals with MyPlate, and rate the portion size of each food category as just right, undersized, oversized, or none. This visual diary is intended to overcome the burden of traditional self-monitoring, as well as provide a reference for peer and professional support.

Secondly, with instant access to the online database that stores users’ image-based food records, the dietitian is able to provide meal-based feedback and calibrate users’ perceptions by acknowledging the ratings as their perceptions and using the food images as objective references. In addition, the continuous food records also enable the dietitian to review users’ meals for the entire week and provide feedback on their meal patterns. Both the feedback on specific meals and weekly patterns are intended to help users to adjust their eating behavior on the basis of their actual experiences.

Lastly, peer support is provided via a private version of social media, which is available only to our study participants. The social media application is designed in such a way that users can create and join groups of interest, as well as create, like/dislike, and comment on posts that may include text, images, and ratings of portion sizes with just a few clicks. Facilitated by smartphone apps, our study is also able to evaluate the interaction effect between professional and peer support at low cost to all the stakeholders, including the researchers, dietitians, and participants.

In summary, the purpose of this study is to compare the effect on user engagement of a visual diary enabled by a smartphone app to a web-based non-visual diary that requires users to record portion sizes in cups or ounces. For the
mobile-based visual diary, we systematically explore the effects of adding more timely and personalized dietitian support and peer support, both alone and in combination. We examine the effects of these external support mechanisms on engagement in self-monitoring and food choices. The effectiveness of our interventions is evaluated via a 4-month randomized field experiment. With rigorous studies about mobile apps being sparse, this study is expected to provide scientific evidence of the effects of our two innovative mobile interventions: visual diary and professional support. In addition, facilitated by mobile apps, this study is also expected to provide new evidence on the hitherto unknown interaction effects between peer support and professional support.

**Methods**

**Experiment design**

Our intervention effects were examined using a 4-month randomized field experiment. Participants were randomly assigned to one of five intervention arms, four of which included access to different versions of a mobile app, and a fifth control arm which used a web-based non-visual diary and no interpersonal support. The four mobile-app treatments all included the visual self-monitoring interface, with extra features derived from a 2 (peer support: present or absent) x 2 (professional support, present or absent) factorial design. The experiment design is summarized in Table 1 and the descriptions of each intervention will be detailed in the Interventions section. Participant demographics, food-related characteristics, and other usage behaviors were collected via a baseline survey and four, monthly, post-intervention surveys. Behavioral data on food consumption and app and feature usage were collected by our intervention tools during the entire course of the experiment, but were summarized as monthly measures. The entire experiment was conducted online without any physical encounters. The study protocol was approved by the University’s Institutional Review Board and was registered with Clinicaltrials.gov.

**Participants**

Individuals were eligible to participate in the study if they were Android smartphone users, at least 18 years of age, living in the United States, and not following specialized diets such as a diabetic diet prescribed by the participants’ doctors, fad, crash, or other diets that require drastic restrictions. 425 participants were recruited between March, 2014 and June, 2014. Following the completion of a brief screening and an online consent form on Qualtrics, participants were randomly assigned to one of the five intervention arms and were immediately notified of the assignment. Participants were then asked to complete a baseline survey and were compensated $8 with a chance to win $200 for the time spent in completing the baseline survey and all four monthly surveys. Access to the intervention tool (an Android app or a website) was then provided via email, including a username and password.

**Interventions**

Participants in all five arms received an education package that highlighted the importance of healthy eating, introduced the idea of MyPlate, and provided a tailored daily food plan suggested by MyPlate, downloaded from ChooseMyPlate.gov (http://www.choosemyplate.gov/supertracker-tools/daily-food-plans.html). They also received a video tutorial for the assigned intervention tool, a prompt for goal setting, and two reminders via email per week. All participants in the four mobile-app arms received the smartphone app with features corresponding to their randomly assigned condition. The control arm participants received the uniform resource locator (URL) to the web-based application.

**Mobile-based visual diary (M):** The basic function of the mobile app was to allow participants to record their food consumption by taking up to four pictures of their food per meal, providing text descriptions, and rating the portion sizes. Ratings were assigned by the participants according to their perception about whether the consumed food group is just right, undersized, or oversized according to MyPlate’s guideline. As can be seen in Figure 1a, after
taking a picture of the meal, the user describes the meal in the text box, rates the portion size of fruits, vegetables, protein foods, grains, and dairies by clicking the colored boxes, and chooses the consumed portion size. The plate image changes according to the selected portion sizes. They also check whether the meal has saturated fat, high sodium, and added sugar in the bottom of the screen, although this information was not used in this study. After the meal entries are submitted, the application compares the participants’ accumulated food consumption for the day with their daily goals, and provides suggestions for the rest of the day to help participants achieve their daily goal. Participants can also find statistical reports on their historical goal attainment.

Peer support (P): A platform was provided as part of the smartphone application, allowing those participants randomized to intervention arms with peer support to join in social groups in the platform. Separate platforms were maintained for each of the two arms, with and without dietitian support, to prevent cross-group contamination. Once they joined a social group, participants were also able to read, like, dislike and reply to existing posts, or to post new texts/images to share in one or more social groups. The posts could include text, food images, and/or meal ratings at participants’ discretion (Figure 1b–d). For example, Figure 1d shows a post which includes a meal picture, self-evaluations of portion sizes (the pie chart) and food components (the check boxes). A weekly digest summarizing posts in each social group was sent to all members of that group via email.

Image-based dietitian support (D): A registered dietitian was hired to provide meal-based feedback and consultation services via the mobile app to participants in intervention arms with dietitian support. Using a web-based dashboard, the dietitian was able to view meal-specific information, including time-stamped food images, descriptions, and participants’ ratings. The dietitian could also access subject-specific information, including gender, age group, daily activity level, diet pattern (e.g. vegan diet), and meal pattern (e.g. 3 meals a day). Given the meal-specific and subject-specific information, the dietitian was able to provide tailored and meal-based feedback to the participants on specific meals and on weekly meal patterns. The feedback on specific meals was provided on one randomly selected meal each week for each subject. The feedback included the dietitian’s evaluation of the portion size of the entire meal as well as Fruit and Vegetables (FV) consumption, calibration of the participants’ self-reported ratings, and suggestions to meet the recommended daily food plans (Figure 1e). The feedback on weekly patterns was provided at the beginning of each week by reviewing all food entries recorded by the subject during the previous week. Feedback included the dietitian’s evaluation of compliance with the key messages advocated by MyPlate, such as “eat colorful whole foods” and “vary your veggies” (Figure 1f). In addition to the meal-based feedback, participants also received the dietitian’s responses to their questions regarding healthy eating via the app’s message function.

Web-based non-visual diary (W): A non-visual diary that requires participants to provide an estimation of the food amount consumed in cups and ounces was published online to be used by participants assigned to the control group. The form is static and follows the format of MyPlate’s paper-based daily worksheet, which allows only text input. Participants were asked to report all meals consumed on a daily basis by classifying each food item into its corresponding food group and adding up the amount of each food group in cups or ounces each day. No reports or suggestions were provided.
Subject Characteristics: Demographic variables included gender, age group, daily activity level, race, and self-reported height and weight.

Outcomes: Healthy eating behaviors for each subject were captured by his/her engagement in self-monitoring and food choices at meal time. The intervention tools captured information on both behaviors, either through the mobile or web app. Adherence to self-monitoring was measured by the number of days that have at least one record in 4 weeks (DR). The healthiness of randomly selected meals was measured by two ratings judged by the dietician. The first was the dietician’s evaluation of the portion size of the entire meal (PS), ranging from 1 to 4. Based on MyPlate’s recommended energy consumption for each subject, a meal receives a score of 4 if the meal size is about right for the subject to meet his/her daily recommendation, and receives a score of 1 if the meal is far too small or large for that individual. This evaluation was based on a “meal-calorie” schedule that was developed by our dietician. The schedule allocated an individual’s daily calorie need to each of the meals that were usually consumed by the individual in a day, and these daily meal patterns for each individual were elicited at the baseline survey. The second rating was the dietician’s evaluation of the proportion of fruit and vegetables relative to the entire meal (FV), ranging from 1 to 4. Based on MyPlate’s guidelines, a meal is assigned a score of 4 if at least half of it is filled by fruit and vegetables, and a score of 3, 2, or 1 if it is near, far from, or very far from half of the plate. When evaluating the FV and PS scores for meals, the dietician was provided meal images, meal descriptions, and the suggested calorie goal for the subject, but was blind to the participants and their assigned intervention arms. A confidence level was also assigned to each evaluated meal indicating how confident the dietician was about her ratings, ranging from 1 (not at all confident) to 4 (very confident). Meals receiving a confidence level of less than 4 were excluded from analysis. For each subject, one meal was randomly selected for evaluation each week, but multiple ratings in 4 weeks were averaged to represent the eating behavior of the month. Therefore, the trajectories of each individual’s healthy eating behaviors in our 4-month study were portrayed by DR, FV, and PS, each having at most four data points.

Analyses
Comparisons between intervention arms at baseline were conducted using chi-square tests for categorical variables, and one-way ANOVA for continuous and normally distributed variables.

Four separate mixed models were used to evaluate the effects of our interventions on outcomes by controlling for subject random effects and fixed effects, including gender, age, daily activity level, race, Body Mass Index (BMI), and time in months of the observation since participation. The first model examines the impact of the mobile-based visual diary on DR. The remaining three models examine the impact of dietician and peer support on all three outcome variables (DR, PS, and FV). To examine the interaction effect between peer and dietician support, an interaction term between these two interventions was added to the last three mixed models. We used a normal distribution to model the distribution of the average FV and PS scores and log-normal distribution to model the engagement outcome, DR.
Statistical significance is defined at $p<.05$. Statistical analyses were performed using SAS 9.4 (SAS Institute Inc, Cary, NC), with the FREQ procedure for the chi-square test, GLM for ANOVA, and the MIXED and GLIMMIX procedures for the mixed models.

**Results**

From March to June in 2014, a total of 425 participants signed up for the study and were randomly assigned to our intervention arms. With a similar drop-out rate across arms, about 70–80 participants per arm stayed in the study for four months, which gives us a total of 375 participants. Among these 375 participants, only 239 (64%) recorded at least one meal during the entire course of the experiment and were thus defined as “users,” and only the data generated by these users were used for analyses. Table 2 shows the distributions of user characteristics for each intervention arm at baseline. The majority of the users were female, under age 25, white, sedentary, and at the boundary of normal weight and overweight. No statistical differences among intervention arms were found for any of the characteristics.

Note: M, P, D, W stand for mobile-based visual diary, peer support, image-based dietitian support, and web-based non-visual diary, respectively.

Overall, we did not find a significant effect of mobile-based visual diary on number of days of recording (DR), although the estimated median of DR for the mobile group was 18% higher than that for the web group, controlling for subject fixed effects (exp(β)=1.18, p=.80). However, there was strong evidence for the impact of the image-based dietitian support on DR. The estimated median DR for users with dietitian support was 3.74 times higher than that for users without dietitian support, controlling for subject fixed effects (exp(β)=3.74, p<.01).

As for users’ eating behavior, our image-based dietitian support did not have an overall effect on users’ FV consumption (β=.14, p=.19). Yet, the significant coefficient of the interaction term D*BMI reveals the heterogeneous dietitian effect for users with different levels of BMI (β=.04, p<.01). Specifically, without dietitian support, BMI was significantly and negatively associated with FV scores (β=-.03, p<.01), but this negative association was eliminated by dietitian support (Figure 2).

Peer support also did not have an overall effect on number of days of recording, but the significantly negative coefficient of the interaction term P*#Months shows that presence of peer support facilitated user disengagement (exp(β)=-.66, p<.01). This pattern can easily be seen by plotting the raw data for users without dietitian support, as shown in Figure 3, and a similar pattern can also be found for users receiving dietitian support. By including an interaction term between peer support and dietitian support in the models, we found that there may be “bonus effects” of having both types of support, although not statistically significant (exp(β)=2.05, p=.40 for DR; β=.01, p=.98 for FV; β=-.03, p=.86 for PS).
Discussion

Mobile-based visual diary

For the entire sample, our mobile-based visual diary did not improve users’ engagement in dietary tracking, compared to the web-based non-visual diary. The lack of a positive effect of the mobile-based diary on self-monitoring in our study is consistent with the results in some prior studies\(^{34, 35}\). Two possible reasons may account for the unexpected result. The first might be the lack of user-friendly and aesthetically pleasing interfaces, which are deemed important in models of user engagement\(^6\). The second possible reason for the result is that while some users might prefer the use of visual heuristics for convenience, others might prefer counting cups and ounces for precision. From our user survey, we did find such a split among our participants. As a result, the initial high intention brought by mobility might be impaired by the imprecise approach associated with self-monitoring. In fact, we also found from our surveys that there were two distinct groups of users with opposite preferences. Whereas one group preferred the use of heuristics, the other preferred precision. Therefore, a predictive model to suggest the best approach for self-monitoring given a person’s demographic characteristics may be an interesting line of research in the future.

Image-based Dietitian support

Dietitian support had an overwhelmingly positive impact on user engagement with strong evidence. This finding is in line with the findings in other empirical studies. For example, professional support is suggested to be effective in increasing user engagement\(^7, 36\) and diary submission\(^9\). While user or patient engagement is deemed critical in patient-centered care\(^6\), it is encouraging to know that it can be greatly improved by connecting consumers with healthcare professionals and by making professionals’ feedback really personalized and contextualized.

In addition to user engagement, our image-based dietitian support was also helpful for people with higher BMI to improve their fruit and vegetable consumption. While people with higher BMI tend to eat fewer fruits and vegetables than people within a normal weight range\(^6\), our finding suggests that image-based dietitian support is especially helpful for people who really need to improve their eating behaviors. On the other hand, while people with lower BMI might have been consuming enough fruit and vegetables, there might not be room for improvement even though dietitian support is indeed effective.

Peer support

While users’ engagement in meal recording significantly declined overtime, we found strong evidence that peer support facilitated this disengagement process. This unexpected effect of peer support might be explained by the “defensive avoidance hypothesis”\(^{37}\). The hypothesis posits that to cope with potential threats, people tend to reduce
their fear by simply not thinking about their high threat level"). In the context of our study, users might feel threatened if they believe that they are eating healthfully, but realize from social media that others are actually eating much healthier meals than them. In this case, according to the defensive avoidance hypothesis, they might avoid using the diary at all. This hypothesis might be exemplified by one incident that occurred during the study. One subject emailed the first author 2 weeks after his/her participation asking to drop out of the study just because of feelings of shame from watching other people eating so healthfully. Our analysis suggests that peer support may not work for everyone. Therefore, it may also be interesting to predict who may benefit more from receiving external support given a person’s demographic and other related characteristics.

Interaction between dietitian support and peer support

Our results show that although there may be “bonus effects” when both dietitian and peer support were provided, these effects were not statistically significant. These results suggest that at least the support from different sources do not contradict with each other, both for engagement and eating behaviors. However, under conditions of limited resources, it would be beneficial if the appropriate external support could be provided to each group of people.

Limitations and future work

This study has a few limitations. First, the evaluation of the healthiness of the meals was limited by the quality of the meal images and our assumption about the adequate portion size for the meal. Images with low quality usually resulted from a dim environment surrounding the meal setting and ambiguity about the mixture of the food items, such as in a soup or curry. Although we had excluded these images from analysis to avoid measurement errors, we were unable to avoid estimation bias as these low-quality images did not occur at random at the meal level. However, since the measures we used for analysis were smoothed over weekly time periods, we believe that the measures still fairly represent users’ average eating behaviors. In addition, we believe that these low-quality images can occur in all four mobile arms with equal probability, so the differences in the scores between intervention arms accurately represent the effect of the interventions. To evaluate users’ portion control for each meal, we used the users’ self-reported meal patterns in the baseline survey as the parameter for the “meal-calorie” schedule. However, the actual meal patterns may vary across days and thus introduce measurement errors for the portion size scores. Nonetheless, we believe that these measurement errors should also occur randomly across different intervention arms; thus, our estimates of intervention effects should still be valid. Second, due to the different user characteristics of different smartphone platforms, we are only able to generalize our results to Android users, but not iPhone users; people with higher ages are under-represented, because users with age between 18–25 account for 51% of our study sample. Lastly, because our study was conducted completely online, there were no in-person contacts with our participants. Therefore, some demographics such as BMI were self-reported and may not represent their true values.

Future studies will include analysis of the best interventions for given subpopulations. In addition, it will be interesting to verify our premise that the defensive avoidance hypothesis can explain the lack of beneficial peer effects. The networks, activity logs, and text contents in the social groups will also be analyzed to better understand how social media is used and how this usage behavior affects people’s health behaviors.

Conclusion

Drawing on Social Cognitive Theory, this study proposed and evaluated three mobile-based interventions, both in isolation and combination, in the context of healthy eating. We highlighted the value of the use of smartphones for advanced behavioral intervention delivery and efficient data collection. In particular, the use of smartphones makes photographic dietary tracking convenient, which then provides the opportunity for the dietitian to deliver contextualized feedback that greatly improves user engagement and eating behaviors. It also brings consumers closer to healthcare professionals by intensifying their communication. Furthermore, the use of smartphones for data collection also makes it easy to analyze the interactions between dietitian support and peer support.

To the best of our knowledge, this is one of the first studies in mHealth literature that evaluates the effects of mobile-enabled, abbreviated means of dietary tracking, image-based dietitian support on behavioral outcomes, using a rigorously defined and executed randomized field study over multiple time periods with a large sample size. Overall, we contribute to the mHealth literature by offering scientific evidence of the effect of three mobile-enabled intervention components. This study provides strategic insights about the design of mHealth behavioral interventions and is, we hope, generalizable to other health behaviors.
Acknowledgements

We gratefully acknowledge the use of the research funds provided by three Carnegie Mellon University faculty members, Carnegie Mellon University Graduate Small project Help (GuSH) Research Grant, and Berkman Award. Many thanks to P. Sandberg, K. Bhattacharya, B. Amoedo, and F. Battle (PHRQL Inc.) for providing access to their smartphone platform and technical support for the application, and P. Martin, Registered Dietitian at Carnegie Mellon University for providing feedback on the design of the study. We are also grateful to 17 graduate students who participated in the beta testing and pilot study.

The study protocol was approved by the Carnegie Mellon University (CMU) Institutional Review Board (HS13-080/HS14-249) and was registered with ClinicalTrials.gov (NCT02206893).

Abstract

Despite growing use of patient-facing technologies such as patient portals to address information needs for outpatients, we understand little about how patients manage information and use information technologies in an inpatient context. Based on hospital observations and responses to an online questionnaire from previously hospitalized patients and caregivers, we describe information workspace that patients have available to them in the hospital and the information items that patients and caregivers rate as important and difficult to access or manage while hospitalized. We found that patients and caregivers desired information—such as the plan of care and the schedule of activities—that is difficult to access as needed in a hospital setting. Within this study, we describe the various tools and approaches that patients and caregivers use to help monitor their care as well as illuminate gaps in information needs not typically captured by traditional patient portals.

Introduction

Hospitals are complex, dynamic, and information rich environments, yet patients and family members experience many information challenges when they are in this environment. Most hospitals have large, diverse care teams that must coordinate rapidly changing health data among providers. In addition, the information about the patient changes fairly quickly and the source of information is fragmented across hospitalists, nurses, surgeons, and different specialist services. When providing that information to patients, clinicians convey much of that information verbally and often quite rapidly. Yet, research shows that patients forget almost immediately 40-80% of what was said during a medical consultation1. Further compounding the issue, patients in the hospital are often severely ill, anxious, and stressed, which further decreases their ability to receive and process that information.

Although we know that providing outpatients with electronic information about their care can significantly improve their satisfaction with their care experience2, we know little of patient and family information needs in an inpatient context. Moreover, new initiatives to expand the role of patient portals and the pervasive presence of smart phones, tablets, and other electronic devices suggest a future where patients and families will be able to leverage real-time access to their care information while in the hospital. To explore this information space, we conducted in-hospital observations of patient-provider communication and used an online questionnaire to collect details about the experiences of patients and families. We provide a summary of the difficulty that patients and their caregivers face in obtaining and managing information while they are in the hospital and highlight information needs that are not typically a part of ambulatory patient portals. Our analysis illuminates opportunities to transform the hospital environment into an information workspace that supports greater patient and family engagement.

Background

The hospital environment creates unique challenges for patients and caregivers who are trying to access, manage and understand information about their care. We review related work that either examined the needs of patients and families in the hospital or analyzed the provision of patient-centered electronic access to medical record data.

Prior research has shown that patients perform extensive work to manage their health in the clinic3 as well as throughout their everyday lives4-6. In particular, the research suggests that patients and families are often engaged in background work, where “the workers themselves are quite visible, yet the work they perform is invisible or relegated to a background of expectation”7. In an inpatient context, patients and caregivers engage in activities to understand, organize, and manage information related to their care that is poorly understand and less visible to their care teams. Although new technologies exist to help outpatients with their work, within the hospital, patient access to information about their care is traditionally limited to verbal dialogue and occasionally to standardized, printed materials. The predominant non-verbal tool used to communicate with patients is the whiteboard, which is often used to provide information such as nurse and provider names, family contact information, and occasionally discharge expectations. Nonetheless, Marilyn Tan and colleagues found that whiteboards improved patient awareness of their care team and
the goals for their care. However, differences in use between different care providers and the difficulty in keeping the information up-to-date has constrained the effectiveness of whiteboards. Moreover, whiteboards are tools primarily managed by nurses and their design reflects a provider-managed view of determining what patients should know.

Skeels and Tan posited that technology could help patients learn about their health and care while filling the significant amount of idle time that they experience during their stay. Through inpatient interviews, the authors found that patients desired greater awareness of what was currently going on in relation to their care and more powerful and nuanced ways of communicating with their care team, families, and wider social network. In a pilot study by Weiland, et al., the authors demonstrated increased patient satisfaction and involvement in their care when cystic fibrosis patients were given a personalized schedule of their care. Simply having enhanced information about the process of care delivery in the hospital improves the patient experience. A systematic review from Prey, et al. further highlights the value of technology to support patient engagement in an inpatient setting, but also acknowledges that this space is still in its infancy. Prey and colleagues also conducted a field study where hospitalized patients were given printed copies of their raw medical record data—lab results, physician progress and consult notes, radiology reports, medication administration records—and found that even if patients did not understand all of the technical terms, they felt more informed and were able to “fact check” the information. Patient-facing technologies in the inpatient environment can improve patient awareness and management of information about their care activities.

In an ambulatory and outpatient context, health systems increasingly give patients access to their medical information through patient portals. Although evidence of their impact is still lacking, patient portals facilitate information exchange between patients and their providers and represent a larger movement to support patients in being more active participants in their care. The Open Notes project illustrates an enhanced approach to the traditional patient portal. Instead of providing a summary view of patient data and notes, Open Notes allows patients to have immediate access to the raw clinical notes created by providers as well as unfiltered access to imaging and laboratory data. In a pilot study of 19,000 patients across three institutions, most patients took time to log in and read their notes, and 99% indicated that they wanted to continue having access to their notes online. Increasingly, these types of tools show promise for supporting patients to identify medical record errors and thereby mitigate possible safety risk, but their evaluation has centered primarily in environments outside the hospital.

Other researchers have sought to enhance access to information for hospitalized patients by migrating the patient portal concept to the inpatient environment. Although limited to the emergency room environment, Wilcox and colleagues proposed a patient-facing, electronic, in-room display that would facilitate within-visit information sharing, encourage post-visit sharing and archiving, and serve as a useful memory aid as well as reference of the care delivered. They further explored the value of providing information from the medical record to give patients insight into the background activities performed by health care staff that is normally invisible to the patient. The same research group used the findings from this study to pilot a mobile-based process of care summary. Researchers have also explored a tablet computer interface to either provide access to patient portal information or deliver educational content. They found that patient awareness of their medication administration helped the patients assess their overall progress and health status. Overall, this early work suggests that creating tools to provide automated summary information for patients is feasible and highly desired by patients and families.

As patient portals become pervasive, patients are likely to have information about their health care available electronically, even in the hospital. These related studies make a case for the role that technology can play in sharing care activities (1) to promote useful awareness among patients, (2) to support decision-making, and (3) to improve patient-provider communication. However, we do not know whether a traditional patient portal designed for long-term, ambulatory use will meet the needs of inpatients. To understand the unique information needs in an inpatient setting, we explore the information work currently being done by patients and families while they are in the hospital.

Methods

We used two methods to explore the information needs of hospitalized patients: (1) observations of patient-provider interaction points conducted at two hospital facilities; and (2) an online questionnaire completed by patients previously hospitalized and by family members or other caregivers that took care of a hospitalized patient. This work was approved by the authors’ institutional review board.

Observation Study

We conducted 118 hours of observations at a children’s hospital (Site 1) and an adult tertiary care hospital facility (Site 2). The observations occurred at different interaction points with patients: physician and multi-disciplinary rounding, discharge, care conferences, physical and occupational therapy sessions, as well as ad hoc exchanges among
patients and the nursing staff. The observation findings were primarily based on open field notes and sketches of the patients’ environments. Our data reflects the perspective of care providers during their shift work, including hospitalist attending physicians, residents, specialist physicians, physical therapists, and direct nursing staff. In addition, we conducted in-room observations to observe communication and information flow from the patient’s perspective. Overall, we observed communication interactions with more than 50 individual patients. The observation notes were analyzed for factors that promoted patient information access, barriers that inhibited patient interaction during a hospital stay, and types of information managed by healthcare providers, patients, and caregivers. Our research team met regularly to review observation findings to identify preliminary themes and evaluate the extent of coverage of patient-provider communication during inpatient care.

Online Questionnaire
We also created an online questionnaire that asked participants about a prior hospital experience. Participants were recruited using convenience and snowball sampling through postings on social media sites, mailing lists, and website announcements. The questionnaire included topics across three areas: (1) importance and difficulty of receiving different types of information in the hospital, (2) approaches to managing information in the hospital, and (3) attitudes about care involvement and patient-provider communication. We received completed responses from 157 individuals from across the US and Canada who identified as being either a patient or a caregiver (e.g. family member) of a patient during a past hospitalization. We analyzed structured data from the questionnaire using descriptive summaries to identify general trends and patterns. Using an open coding technique and card sorting process24, we evaluated free text responses for related concepts and themes.

Sample population
Of 157 questionnaire responses, 61% self-identified as former patients and the remaining 39% identified as a caregiver who supported a patient during his or her hospitalization. Within the caregiver group, approximately 33% indicated they were a spouse of the hospitalized patient, 21% were parents, 21% were adult children caring for a parent in the hospital, and the remaining 25% were relatives or friends. The majority of the participants were female (75%) and ranged in age from 18 to 79. Fifty-eight percent indicated they were between the ages of 40 and 59. Respondents predominantly identified as white or Caucasian (87%). In addition, the survey participants tended to be highly educated, with 58% indicating that they have achieved some level of post-graduate education.

Forty percent (n=63) of the respondents had experienced a hospitalization within 12 months from the time they submitted the questionnaire, 23% were in the hospital between 1 and 3 years ago, and another 19% within 3 to 5 years. The reasons for the hospital admission were diverse. Many described an acute injury, while others mentioned pregnancy and various surgical procedures. Moreover, 33% of the participants described a hospital stay that lasted more than 7 days, another 29% were in the hospital between 2 and 4 days, 18% for 5 to 7 days, and the remaining 19% were hospitalized for 1 day or less. The majority of caregivers (84%) visited the patient in the hospital daily.

Results
Using mixed methods of an online questionnaire and in-hospital observations, we determined that patients and caregivers performed extensive background work to manage their information needs. To frame the context in which these stakeholders work, we begin with an overview of the patients room environment, characterized as an information workspace3. We follow these observations with an exploration of the patient’s experience receiving information based on provider workflow. By understanding the current state of information dissemination, we proceed to discuss the information gaps that patients and caregivers identified in the online questionnaire. The survey findings motivate our final observations regarding patient and caregiver work in using different tools to track information about their health.

The information workspace of a patient room
The patient’s hospital room serves as the primary focal point for information transfer among patients, caregivers, and clinical care providers. Typically, the design of the hospital room focuses on aesthetics, space for visitors, accessibility needs, support for monitoring equipment to address issues like risk of falling, noise25, and general patient satisfaction26. During our observations of patient, family, and care provider interactions in this environment, we found that different surfaces and spaces within the environment served as a means to organize, manage, and communicate care information. The design of the patient room in terms of how well the space supports information transfer is especially important considering the amount of idle time patients and caregivers experience while in the hospital.
Within the hospital rooms, we observed that patients have access to a variety of displays (Figure 1). TVs have the ability to display educational content, although that content is often standardized, rather than personalized to a patient’s situation; thus, the devices are primarily used for entertainment. Whiteboards provide a pseudo-dynamic space for patients to receive personalized information. They often have a structured layout with defined content areas for provider names, diet orders, frequency of vitals, and family contact information. Occasionally, pre-printed posters were used to display structured pathways that outlined the recovery from common surgeries like knee joint replacement. Importantly, the pathway diagrams were actionable, goal-oriented displays to assist patients in understanding the steps required before they could leave the hospital. We also observed temporary pieces of information taped above a bed or near the whiteboard that displayed instructions for nurses about patient-specific issues, such as not drawing blood from a particular arm. The displays that we observed were visible to patients and provided awareness about their care team, discharge criteria, and general care activities; however, the clinical care team primarily managed them.

Although hospital rooms have a variety of displays and surfaces to convey information to patients, we also observed challenges in being able to use these surfaces from the patient perspective. Patients had access to limited flat surface space and in-room computers frequently used by nurses were often positioned away from the bedside. We observed that the surface most accessible to the patient—a mobile tray table—was often covered with food, liquid containers, and trash that accumulate over the course of their stay. As a result, printed educational materials, notebooks, and the devices were often pushed into stacks in the corners of the room. Others described challenges with information scattered throughout a room: “Most of it I scrawled it on the back of some pamphlets that came out of a box of dressings because I didn't have any paper. They did have a whiteboard in my room so I could keep track of some of it there, but some of it was embarrassing and I didn't want it available to be read by anyone who walked in the room” (10466299). The whiteboard was rarely used by patients despite having a place for patient and family input. One caregiver described trying to use a whiteboard, “only later did we find out that it was only for staff and not for our questions for the doctor” (10276700). In our observations, many whiteboards were out of date and the information displayed was limited—typically listing only the names of care providers.

From the patient and caregiver perspective, visibility and access to information within the patient room was a challenging experience overall. To some extent, the shift to electronic systems compounds this problem because the “EMR eliminates ready review of what has been administered and when, etc. We learned to try and build good relationships with staff and were so happy when we had nursing staff that were kind, informative” (12878449). Rather than review a paper medical chart at the bedside, the patient and their family had to develop a good relationship with their nurses to stay up-to-date on care activities. Ultimately, patient room design appeared to support provider information dissemination primarily and less so the patient’s ability to utilize objects and surfaces in the room as a workspace for accessing and managing information for his or her particular needs.

**Staying informed through verbal dialogue: provider-centered access to information**

Not only are information displays in patient rooms set up primarily for provider use, but the way patients engage with information about their care is often through verbal dialogue driven by staff workflows. During rounding and other patient-provider interactions, we observed different challenges that can hinder patient and families ability to learn up-to-date information about their care. With the exception of using the call button, patients and caregivers often have to wait around for a provider to stop by in order to obtain updates about their care. Even within information exchanges like rounding and bedside handoffs, we observed providers referring to patients in the third person rather than directly engaging them in the conversation. The children’s hospital study site had instituted large, multidisciplinary rounds.
where more than a dozen providers crowded at the patient’s door and bedside. This large group creates an intimidating environment for young patients and caregivers to effectively communicate with their principal care team and to be involved in their care. Relatedly, participants in the survey were split in their agreement about being involved in decision-making (Figure 2). Fifty-nine percent agreed or strongly agreed, while 35% disagreed or strongly disagreed that they were as involved as they wanted to be. Over a third (37%) of those surveyed disagreed with the statement, “I was able to stay informed about all of the activities that occurred relating to the care provided”. Patients and caregivers appear to be very interested in being involved and staying informed but still experience communication barriers that inhibit their participation.

We also observed providers employ strategies to mitigate some of the communication challenges and help to engage patients. While observing a patient being admitted at the children’s hospital site, the admitting staff member finished talking to the parent, turned to the child patient, and told him she would need to hear from him if he felt better or worse as they treat him. She told him he was a “full partner” in this. Moreover, physicians would utilize their mobile computers or print out materials to share radiology images at the bedside. During one observation, a patient did not understand the reason why he was having difficulty swallowing food. The physician brought a computer with a large screen over to the bedside and showed the patient along with the patient’s family the latest CT scan. Not only the patient, but the patient’s entire family crowded around the display and engaged in collaborative question and answer dialogue as the physician explained his interpretation of the data. Patients and families experienced successful information exchange when their providers utilized a partnership model to collaboratively explore medical record data. Based on the experiences of survey respondents and our observations, we found that effective tool use and collaborative dialogue helped to address some of the communication challenges created by provider workflows.

**Gaps in information needs: prioritization of workflow and care activity data**

Traditionally, patients access information in the hospital through verbal interactions with care providers and occasionally through standardized, printed content. We elicited a number of information needs prioritized by patients and observed patient-driven approaches to informal information exchange with peers in the hospital.

Survey respondents identified the top three most important pieces of information that they wanted to receive during their hospital stay as: (1) medications administered, (2) the expected next visit from a nurse or doctor, and (3) lab and imaging results (Figure 3). Being able to access information on past medical history and at-home medications was less important than the other items listed in the questionnaire. Overall, respondents tended to rate information about care process activities as most important. For example, information about the “expected next visit from a nurse or doctor,” was highly rated by participants and serves as a key communication point for patients to get updates. However, this information is also difficult for hospitals to provide because of unanticipated changes in physician schedules. When asked about challenges in accessing information, more than 50% of survey participants marked the expected next visit from their provider, information about their care team, and information about patients that have experienced similar health situations as somewhat difficult or very difficult to access. As one caregiver respondent described, “We spent a lot of time sitting around waiting for the doctors. Then we would go to the bathroom or to get food, and come back and they would have been there without speaking with any of us. We would have to wait another day to ask our questions or share information or observations” (10264109).
Another notable item from the questionnaire was that 66% of patients and caregivers ranked information about the experiences of similar patients as either important or somewhat important. Despite being ranked less important than other items in the questionnaire, our observations of instances where patients engaged with their peers in informal, social interactions demonstrated the potential value of this type of information. For example, we observed one patient engaging in a physical therapy (PT) session as part of her recovery from a double-knee replacement surgery. These PT sessions often took place in a dedicated gym-like space where multiple patients and physical therapists are present. Our observed patient expressed a lot of uncertainty and doubt about her ability to climb a set of stairs but her attitude shifted after watching another patient complete the activity immediately before her and found out they both had the same type of surgery on the same day. Seeing another patient with a similar condition successfully perform the exercise, the patient appeared more confident at attempting the stair climb and succeeded in completing the activity. We also observed patients exchanging information with neighboring patients while walking around their hospital floor. Although these interactions were limited and not explicitly supported by clinicians, we observed patients providing social support and occasionally sharing information about their care experiences.

The patients and caregivers in our online questionnaire prioritized activity data—actions that have happened recently like medication administration, future plans related to scheduled tests and provider visits—when asked what information was most important. Patients also obtained valuable support through social interactions. These types of information needs indicate a desire for data about the background work of care providers and other patients.

**Patient and caregiver information work**

Based on observations and questionnaire results, patients and caregivers demonstrated active work to manage information about the care provided to them. When asked about items that they might track while in the hospital (Figure 4), survey respondents indicated that preparing questions for the care team was most important to them (90%). As one caregiver explained in the questionnaire, despite having “a robust care team...making sure we had a way to capture and communication our questions was essential” (10276700). However, their perspective on the challenge of keeping track of questions was more mixed; 47% indicated that it was either somewhat or very difficult to track. Keeping track of changes in symptoms, another item rated as important, was the most challenging item across the two groups to manage (50%). Other items, such as bowel movements or visits from family and friends, were marked as
In the survey, participants listed diverse reasons for choosing to track information during their stay. The most cited reason was to help prepare and manage questions for the next visit from their health care provider. One participant prepared captured written notes, "So we wouldn't forget our questions for the doctors, and so different members of the family could share information with each other or with the doctor or nurse when they arrived. We were never clear on when [the doctors and nurses] were coming by" (10264109). Others cited monitoring care quality as a reason for tracking. For one respondent, "The main reason I kept track was because of an error during surgery. So I knew I needed to keep a log because I wouldn't remember all the events" (11740791). Another caregiver explained how, "We wrote down "in's and outs" (nutritional intake and output) ourselves and then gave to the nurse at end of shift because this significantly increased accuracy for us to track the info ourselves" (10260629). Based on a prior event or because they believed their input was the most accurate source of data, patients and caregivers would actively record and share information with their care team.

The tools and methods used by patients and caregivers to track information about their health care varied widely. Of the respondents that stated they tracked information, almost half (49%) of these respondents used written notebooks or electronic data capture—often with a mobile phone—to document their care activities (Table 1). Some participants (18%) would keep track of things in the hospital through verbal interactions with their care team. These check-ins served as a way to reinforce what information needed to be remembered. For 5% of the respondents, they described relying on their caregivers to keep track of things for them. However, a substantial number of participants relied on their memory to keep track of things (19%). During our observations, even though many patients had a smartphone or similar device available to them, few used these devices to manage information related to their care. They served primarily as entertainment or external communication devices. We noticed that many of these devices were placed on a surface out of reach from the bedside or piled under papers and other items accumulated during the stay. The children's hospital would actually provide patients with a tablet device during their stay, but even this was often pushed to corners of the room. Patients also had to cope with physical limitations because, "with IVs in your arm and/or hand, it was difficult to write or type" (10269740). Patients and caregivers experienced difficulty using different tracking tools because of the unique constraints related to their health maintenance and the physical space of the patient rooms. The usability of the various tools also affected their ability to capture information for tracking purposes and manage information for communicating with their care team.

**Figure 4.** Within the questionnaire, percentage of Caregivers (orange square) and Patients (blue circle) that evaluated tracking different types of information while in the hospital as "somewhat important" or "important", shown on the left (a) and "somewhat difficult" or "very difficult on the right (b)."
Discussion
Through our observations and questionnaire, we found that patients often experience an information-poor environment outside of conversations with their care team. Our data illuminates patient barriers in using their hospital room as an information workspace, the difficulties that they experience in obtaining information outside of provider workflows, and their desire for information not normally displayed in the EMR or through patient portals.

Patient rooms reflect a provider-centered information workspace, despite being equipped to convey information to the patient through electronic interfaces and physical wall displays like whiteboards. For whiteboards in particular, we noticed incomplete and inconsistent usage throughout our observations that further reinforced the difficulties that patients experience in obtaining up-to-date information. Despite these challenges, the whiteboards and other displays occasionally served as useful places for physicians to diagram procedures or use visuals to help explain the patient’s condition and progress. The frequent presence of patient tools like smartphones and tablets suggest an opportunity to help patients organize all of the information collected over the course of a stay. Yet, these surfaces are frequently obscured by other objects or relegated to corners of the room away from the patient.

Within this physical environment, we found that the flow of communication is typically driven by provider workflows like rounding. Patients and caregivers experience communication challenges in this context because of the difficulty in being able to prepare for a visit that can occur at any moment. These interactions are also difficult because the information exchange is almost completely verbal and often time-constrained by the providers’ rounding schedules. In some instances, we observed providers enhance their approach to patient engagement by using collaborative behavior and electronic displays to discuss medical record data alongside the patients and caregivers. Increasing the use of visual tools at the patient’s bedside has the potential to enhance patient and caregiver participation in their care.

Finally, patients and caregivers expressed a variety of information and tracking needs related to their difficulty with managing their health information in the hospital. This extra patient and caregiver work was often motivated by concerns about care quality and wanting to stay informed when dealing with the care complexity of an inpatient environment. Accordingly, patients and caregivers indicated that information about their care team as being one of the most important and challenging pieces of information to manage. Our findings about tracking needs suggest that existing patient room displays and provider-driven information dissemination do not adequately support the patients’ and caregivers’ ability to use tools in their rooms and maintain awareness about their care activities. Moreover, the informal social interactions that we observed demonstrate that patients can obtain value through experiences of others. Reimagining the information workspace of a hospitalized patient should consider these needs and support opportunities for patient-driven care provider and peer interaction.

Addressing Information Needs
Providing enhanced access to information during a hospitalization can reduce the cognitive load for patients and improve common ground between the patient and their care team. The order that information is presented, modality, perceived importance, and health context can all have important impacts on the patient’s likelihood of remembering information. Something like a printed or electronic summary of the plan of care—upcoming activities, discharge goals,
provider visit times, and other items highlighted by our questionnaire participants—creates an opportunity for patients to process activities related to their care on their own time. They can then reassess situations with their care providers to ensure their expectations match with the documented plan of care.

Hospitals are increasingly migrating their outpatient portal into the hospital environment as one approach to addressing the problem of patient access to information about their care. This is a positive first step, but our observations and questionnaire data show that a traditional portal doesn’t address most important information needs identified by participants, such as being able to know the plan of care and when to expect the next provider visit. The interest in information about care activities suggests that an inpatient-specific portal should reflect the dynamic nature of hospital care. There is an opportunity to capture the metadata contained within order sets and to explore approaches to communicating expectations for uncertain events like when the physician will be visiting the patient next. Leveraging the process of care data embedded in the electronic medical record provides an opportunity to reconsider the patient portal as a mechanism for maintaining awareness of changes and updates in a dynamic hospital environment.

Addressing Information Work
The patients and their caregivers that participated in our questionnaire developed various strategies for coping with the information communicated verbally in the hospital. In particular, even though our respondents stated that they felt comfortable with asking their care providers questions and rated keeping track of questions as the most important activity that they could do, they also stated that keeping track of changes was one of the most challenging activities during their hospitalization experiences. This relates to our observation data showing that patients face barriers to using tracking tools. In part, this is due to constraints created by the physical environment. We often observed tracking tools such as smartphone devices, notebooks, and even pieces of paper were relegated to areas of the room distant from the patient’s bedside. Even tablets, which are increasingly used to provide access to patient portals and health records, were often out of reach of the patient. The only tool consistently at the patient’s side was the call button which can alert a nurse if the patient has a question but lacks the ability to track information. Moreover, patients and caregivers in the survey expressed how they are able to track certain types of information about themselves more accurately than the care team that may not always be present in their room. Current conceptualizations of the patient portal typically do not address tracking needs. In fact, patients and caregivers are using tools when they are available and cite the lack of resources as a major barrier to being able to manage the large amount of information and activity occurring during a hospitalization.

Limitations
Our qualitative, ethnographic approach to studying the patient experience has several limitations, including that the questionnaire sample skews toward a well-educated demographic. However, even within this group, both patients and caregivers experienced challenges with obtaining access to key information about their care. Ultimately, the questionnaire is not intended to be a representative population sample, but instead provide a means to explore a broad range of patient and caregiver experiences across the US. We integrated the questionnaire findings with observation data from two independent hospital environments help to strengthen the validity of our findings.

Conclusion
The findings of our online questionnaire paired with inpatient observations show that inpatients face many information and communication challenges during their hospital stay. Analyzing the patient’s room as an information workspace in the hospital illustrated challenges and opportunities for tools and displays that can enhance patient interaction with their care information. Moreover, when we consider the patient portal functionality that is typically used in an outpatient setting as a strategy to mitigate some of these challenges, we found that inpatients need additional support within the hospital context. In particular, patients and caregivers highly desired yet found it quite challenging to obtain the patient’s plan of care for each day. In addition, most patients wanted to track key aspects of their experience. Neither of these important functionalities are available in patient portals but often exist as metadata within the patient’s medical record. Our work highlights these important needs and suggests new functionality that emerging inpatient information systems need to support. This type of new functionality has the potential to transform inpatient care by empowering these patients and caregivers with the information they need to have a satisfying care experience.

Abstract

Electronic medical records (EMRs) are capturing increasing amounts of data per patient. For clinicians to efficiently and accurately understand a patient’s clinical state, better ways are needed to determine when and how to display EMR data. We built a prototype system that records how physicians view EMR data, which we used to train models that predict which EMR data will be relevant in a given patient. We call this approach a Learning EMR (LEMR). A physician used the prototype to review 59 intensive care unit (ICU) patient cases. We used the data-access patterns from these cases to train logistic regression models that, when evaluated, had AUROC values as high as 0.92 and that averaged 0.73, supporting that the approach is promising. A preliminary usability study identified advantages of the system and a few concerns about implementation. Overall, 3 of 4 ICU physicians were enthusiastic about features of the prototype.

Introduction

According to the American Medical Association, reducing cognitive burden is one of the top eight priorities for improving electronic medical record (EMR) usability1. One instance of high cognitive burden is information overload where an “individual’s efficiency in using information is hampered by the amount of relevant, and potentially useful, information available to them”2. The display of patient data in current EMRs is not specific to the clinical context and burdens the physician who must search through the data to compile a clinically relevant narrative of the patient.

As EMRs capture increasing amounts of data per patient, compiling a clinical narrative becomes cognitively more demanding. This information overload is particularly challenging in settings such as the intensive care unit (ICU) where large amounts of data per patient are collected. A study in a Canadian hospital estimated that the average ICU patient generates a median of 1,348 data points per day3. This equates to a new data point being added to a patient’s record almost every minute. An EMR that focuses the physician’s attention on relevant patient data could help reduce the time needed to assess the patient’s condition and improve the quality of the resulting judgments1, enabling improved decision making, reduced medical errors, and greater efficiency.

Research efforts in the display of patient data have progressed in various directions including graphical summaries4, methods to summarize and display temporal data5, and the context specific integration of data using either systems or disease6-9 based approaches. Integrated data displays aggregate information from different sources and display it in one location (e.g., a cardiovascular system view, or a diabetes management view). These displays can improve performance and efficiency of physicians. For example, Pickering et al. developed an interface called AWARE that dynamically presented highly valued data to the physician at the ICU bedside in an integrated fashion10. When evaluated, AWARE reduced time to task completion and medical error in the assessment of ICU patients with a hypothesized acute bleed10,11.

AWARE and other existing integrated systems use rules to identify which of the thousands of available data points are relevant for specific patient contexts12. Rules are usually manually constructed from disease models, ontologies, and expert opinion. Such rule-based systems have several advantages. They are likely to be clinically informative, since they are based on clinical knowledge, and they can be readily programmed and applied to patient data that are available in electronic form. However, construction of rules is tedious and time-consuming. Moreover, rules have
limited coverage of the large space of clinical conditions, and a rule-based display may not adequately portray the
context of a patient whose condition presents in an unusual way or a patient who has multiple maladies.

An alternative to a rule-based approach is to identify data that are relevant in assessing a patient’s current clinical
condition using a data-driven approach. Such an approach identifies patterns of useful patient data from data-access
activities of physicians on past patient cases, and these patterns are applied to a patient case to highlight data
relevant for that patient. Such an approach has several advantages. It does not require expert input to develop
patterns, the patterns are derived using a large set of past patient cases, and the patterns can cover a wide range of
clinical conditions. Moreover, such a system can continually update the patterns by learning from each interaction a
physician has with it and can adapt to the specific environment in which it was being used. In other words, it would
be a Learning EMR (LEMR).

Appropriate user-interface design will be vital to the success of a LEMR. Displays that adapt to suit the context of
use have the potential to optimize the use of scarce resources, including user attention and screen-display real
estate. To be successful, these designs must provide dynamic displays that inform without disorienting. Recent
efforts have explored novel designs for displays of laboratory data, configuration of multiple components in an
EMR display, and for knowledge-based adaptations of order entry menus. A successful LEMR would build
upon these results, using a combination of appropriate interface design techniques and arrangements with
context-sensitive adaptations based on patterns of system use.

We built a prototype LEMR that uses a data-driven approach to predict and highlight the data that are most relevant
to a patient case. A physician reviewed patient cases and identified the relevant data for each case. The identified
data became the dataset for training and evaluating classification models that predict if a data item is important to
understanding the current patient’s state. The results are used to determine if the data-driven approach is promising.
Four more physicians used the prototype LEMR in a usability study. We describe the physician reactions to both the
LEMR concept and the prototype. The results of the usability study provide an initial assessment of the desirability
of such a system and an evaluation of the prototype design.

Methods

1. LEMR prototype

For this study the LEMR prototype required (1) screens to display patient data, (2) a dynamic region of the screen
that could be filled with the clinically relevant data items, (3) the ability to record which data items a physician
found clinically relevant, and (4) a framework to connect all of the components.

Highlighted Information Display (HID)

The LEMR prototype needed a clear and intuitive way to indicate which items were clinically relevant for a patient
case. For this purpose, we allocated a region of the screen to be dynamically populated with the clinically relevant
items. We called this region the Highlighted Information Display (HID) because the items found in it are the items
that should stand out to the physician user.

Recording data-access patterns

We relied on physicians manually selecting the items they found most clinically useful for the most recent day of
each patient case they reviewed. To indicate an item as useful, the prototype had a means for the user to move it into
and out of the HID. Every time that a user modified the contents of the HID, the prototype recorded the changes in a
database.

Components of the prototype LEMR

The prototype LEMR consists of four main components: a user interface, a web framework, a patient database, and
a module with statistical models. These components are shown in Figure 1. The user interface is implemented using
HTML, CSS, and JavaScript, and is powered by Django, an open source Python Web framework. Patient data are
stored in a MySQL patient database, which is queried to provide data shown in the user interface. This database also
stores data viewing activities that are captured during EMR use. These data are used to train statistical models that
predict data items (e.g., laboratory results) that are typically viewed in given a clinical context. These models are
then applied to a current patient case in the database to predict the data items that are likely to be viewed and thus
should populate the HID for that case.
Before enough training data are collected, the prototype relies on users viewing real patient cases and manually populating the HID with the data items in those cases that they think are most relevant. After some manual training data are collected, models start to automatically highlight the items that they predict to be of interest. When the HID is automatically populated from the models’ predictions, the user retains the ability to manually modify its contents. Any manual modifications then feed back into the statistical models to further improve them.

2. Predictive modeling

We developed and evaluated logistic regression models to predict laboratory test results that are relevant to understanding a patient’s current condition. We used de-identified data on 58 ICU patient cases that were randomly selected from a large ICU dataset that is described below. In this early study, we focused on predicting only laboratory test results using demographics and all laboratory test results as features.

ICU patient data

The patient data come from the High DEnsity Intensive Care (HIDENIC) dataset, containing fully de-identified and HIPAA-compliant EMR data on 12,000 patients who were hospitalized in ICUs at the University of Pittsburgh Medical Center (UPMC) from July 2000 through December 2001\textsuperscript{23}. HIDENIC contains structured data including demographics, physiological measurements collected at the bedside (including vital signs), laboratory values, medication and fluid administration records, and unstructured data in the form of a variety of clinical text reports (history and physical, progress, and operative procedure notes; radiology, EKG, and EEG reports).

The HIDENIC dataset contains patient information from ICU admission until ICU discharge. Because we were interested in physician behaviors during the review of an average day of an ICU patient, we defined the data for a patient case to be from admission to a random day during the patient’s ICU hospitalization. Using this dataset, we were able to show a patient case to a physician and have them act as if the case was a current patient of theirs.

Extracting the features

The features used for predicting the clinical relevance of each laboratory test were extracted from each patient case and included both temporal and non-temporal items. Temporal features included the most recent value of each laboratory test and a Boolean value for whether that test result had appeared within the last 24 hours of available patient data. There were 190 distinct laboratory tests in the dataset, so the temporal test features totaled 380 (= 190 * the two features extracted from each test). There were five non-temporal demographic features (age, sex, weight, height, and body mass index) and one additional temporal feature of days since ICU admission. Therefore, in total there was a set of 386 predictive features for every patient case.

Collecting the training cases

Each of the 190 laboratory tests defines a binary target (dependent) variable that indicates whether that test is clinically relevant in a given patient case, and therefore should be placed in the HID. To collect this target data, 59 patient cases were randomly selected from the HIDENIC dataset. The cases were loaded into the LEMR prototype and a single physician reviewer (author SV) used the prototype to identify the tests that are relevant for each patient case within a given clinical context. In particular, the reviewer imagined that he was the attending who was taking care of the patient. He read the clinical reports and examined the test results to determine the clinical course since admission to the ICU. Then, for the last day for which patient data were displayed, he identified which tests were relevant in providing evidence about (1) changes in the clinical condition of the patient, or (2) the emergence of a new clinical problem. Any test that the reviewer moved into the HID for a patient case was considered clinically relevant for that case and was combined with that patient’s feature set to create a positive training example for that test. Any test that the reviewer did not move into the HID for a patient case was considered not clinically relevant for that case and was combined with that patient’s feature set to create a negative training example for that test.
Modeling and evaluation

Each laboratory test had a training dataset constructed from the 59 patient cases that were reviewed. We used each test’s training dataset to train a penalized logistic regression model that predicts if that test is relevant to the current patient case. The models were build using the scikit-learn Python package24 and evaluated using leave-one-out cross-fold validation. We measured performance using the Area Under the Receiver Operating Characteristic curve (AUROC).

3. Usability study

A usability study was conducted to gauge physician assessment of the LEMR concept. Four fellows in UPMC’s Department of Critical Care Medicine participated in the study. This study was approved by the University of Pittsburgh Institutional Review Board (ID PRO14020588). Each physician used the prototype to review three to five selected patient cases. For each case, the physicians were shown a patient’s data from ICU admission to a random day during that patients ICU hospitalization. The physicians were asked to familiarize themselves with the case as if they were the attending physicians. No data were highlighted in the HID for the initial look at each patient case. Next, the physicians were shown an additional day of data that was meant to simulate rounding on the subsequent day. For the additional day, items had been manually highlighted, based on relevant items identified by a physician on the research team (SV). The physicians were asked to use the features of the prototype to highlight/unhighlight items until the highlighted items represented the data that they thought another physician who was looking at the same case would want to see when assessing the most recent 24 hours, given that they had been following the patient case during the current ICU admission.

During the review of each patient case, screen tracking software recorded all of the on screen actions and an audio recording captured each physician's think-aloud comments. After a physician reviewed the allotted patient cases, additional time was allocated for a semi-structured interview of him or her. We asked about their perceptions regarding the LEMR concept in general and the prototype specifically. The interviews were coded independently by two researchers (AK and HH) before meeting to create a consensus. The coding was used to identify general themes in the responses. Each physician also filled out the System Usability Scale25 based on their interactions with the prototype.

Results

1. Prototype

A screen shot of the user interface of the LEMR prototype is shown in Figure 2. Panel A, the patient demographics toolbar, allows the user to move between patients and gives a brief summary of the current patient’s demographic information and admitting diagnosis. Panel B contains quick access tabs for navigating among the various types of patient data, including laboratory test results, medication orders, and clinical text reports (e.g., history & physical (H&P) reports, progress notes, and operative procedure notes). Currently the “Labs/Vitals/Meds” tab is selected. This prototype uses times-series plots to display these non-text based clinical items (laboratory test results, vital signs, medication orders, and intake and output data). Panel C, the time range selector, is used to define time ranges of data to display. Below the time-range selector is the procedures axis, which is labeled with the defined times. Black diamonds on this axis represent procedures (surgeries, biopsies, etc.) that the current patient has had. Hovering over a diamond gives more details on that procedure. Panel D, the HID, shows high detail plots of selected clinical items. These plots have a labeled y-axis and blue bands to indicate the normal range. Panel E displays all available results, including those found in the HID, using plots with condensed y-axes. These plots give a notion of trends over time and are arranged by group type (chemistry, lipids, cardiac, etc.). The buttons across the top of this panel list all of the different group types and can be used to jump to a specific type. For both Panel D and Panel E, different colors are used to indicate when a value is within or outside of normal range (blue = below; green = within; red = above; black = no defined normal range).

For any given patient, the items highlighted in the HID are meant to be the ones that are most clinically relevant for that patient at the current time. The HID can be populated with items by both automatic and manual means. For automatic population, the LEMR uses stored statistical models to predict the probability that each item is relevant given the current patient state. The items that have a predicted probability above a set threshold are displayed. To make manual changes to the contents of the HID, a user clicks on the arrow buttons next to each clinical item’s name. There are buttons to move items into the HID and buttons to remove items from there.
2. Predictive models

We derived penalized logistic regression models for the 21 distinct laboratory tests that were identified as clinically relevant (accessed) for at least two patient cases in the dataset. The AUROC values for those models and the number of positive (# +) training cases in their datasets are shown in Table 1. The average AUROC is 0.73. The top seven tests shown in the table have an average AUROC greater than 0.80.

3. Usability study

The physicians were generally enthusiastic about the LEMR approach. They identified advantages, such as adaptation to different specialists and the potential for time savings. Concerns included the feasibility of the implementation and the possible implications of integration into workflow. For instance, some participants worried that over-reliance on highlighted items might cause physicians to miss important details in the remainder of the record.

Three of the physicians liked the timeline approach to displaying the data but would like to see the exact value of each result without needing to hover over a data point with the mouse. Two of the physicians discussed other information resources such as the summary sheet that they currently print out for each patient before rounding. One physician discussed a desire for the EMR to include a checklist of all the things that must be checked for each patient every day.

The System Usability Scale composite score for the four users was 78.75. The scale ranges from 0 to 100 and any score above 68 is generally considered to be above average usability26.
We developed and evaluated a prototype LEMR system that uses a data-driven approach to adapt its display to highlight the data items that are most relevant in a patient case. Our preliminary results show varying performance for the predictive models that identify when laboratory tests are relevant, but one-third of them had an AUROC of 0.80 or greater, supporting that this approach is promising. Moreover, in a usability study ICU physicians were generally supportive of the LEMR approach, and identified advantages and concerns with the prototype.

With the accumulation of data in the EMRs, physicians are at increased risk of making errors due to information overload\(^{27, 28}\). The LEMR system we are developing may help to reduce this risk by identifying and highlighting the small subset of the available information\(^ {29}\) that is relevant when making medical decisions for a patient. Similar data display techniques, such as Microsoft Word’s split menu font selection list, have resulted in faster selections and higher user performance ratings\(^ {19}\). Split menus combine the convenience of frequency ordered menus with the consistency of alphabetically ordered menus. The LEMR prototype has a similar structure where the HID provides convenience and the rest of the prototype provides consistency.

The LEMR also has similarities to other tools\(^ {18, 30}\) that have explored mining interaction patterns from previous users to inform the presentation of information/choices/etc. These other tools have benefited from crowd wisdom\(^ {31}\), where

Discussion

We developed and evaluated a prototype LEMR system that uses a data-driven approach to adapt its display to highlight the data items that are most relevant in a patient case. Our preliminary results show varying performance for the predictive models that identify when laboratory tests are relevant, but one-third of them had an AUROC of 0.80 or greater, supporting that this approach is promising. Moreover, in a usability study ICU physicians were generally supportive of the LEMR approach, and identified advantages and concerns with the prototype.

With the accumulation of data in the EMRs, physicians are at increased risk of making errors due to information overload\(^ {27, 28}\). The LEMR system we are developing may help to reduce this risk by identifying and highlighting the small subset of the available information\(^ {29}\) that is relevant when making medical decisions for a patient. Similar data display techniques, such as Microsoft Word’s split menu font selection list, have resulted in faster selections and higher user performance ratings\(^ {19}\). Split menus combine the convenience of frequency ordered menus with the consistency of alphabetically ordered menus. The LEMR prototype has a similar structure where the HID provides convenience and the rest of the prototype provides consistency.

The LEMR also has similarities to other tools\(^ {18, 30}\) that have explored mining interaction patterns from previous users to inform the presentation of information/choices/etc. These other tools have benefited from crowd wisdom\(^ {31}\), where
the collective knowledge of many people can be better than the knowledge of any individual in the population. In
terms of a LEMR, a physician who is inexperienced with a certain patient type could benefit from seeing items
highlighted based on the information that a more experienced physician would access. This would bring the
inexperienced physician’s attention to an important item that they may have otherwise overlooked. Highly
experienced physicians could perform the initial training of the system to further capitalize on this effect.

The AUROC performance of the models developed during this study ranged from ~0.50 to 0.92. The higher scores
are a promising sign for the approach because we used a small number of training cases and a limited set of possible
features. A dataset of only 59 cases leaves only 58 training cases for each fold of the validation. If a LEMR were
implemented in a hospital setting, it would learn every time a physician interacts with it. That would mean
additional training cases extracted for each patient every day. Using this approach, the size of the training set would
quickly grow to a huge number of samples. The feature set used in this study was purposely restricted to very basic
predictors. Many more temporal features, such as the slope between the last two values of a laboratory test, could
prove to be very useful when predicting if a test is relevant to a patient context. Numerous other data types, such as
vital signs and medication orders, were not considered but could be included as well. With an increase in the training
set size and an expanded feature set, the predictive accuracy of each model would likely improve.

Our usability study provided preliminary support for the feasibility of the LEMR idea. Participants’ concerns
regarding feasibility and integration into existing workflows are valid practical points that we hope to explore after
modeling and interface design issues are more mature. The possibility of over-reliance on highlighted items is a key
concern—EMR displays that encourage overly narrow readings of patient information may cause important data to
be missed. Design lessons from prior work in personalized interfaces and related areas will inform the
development of prototypes exploring alternative displays, with continued usability studies providing vital physician
feedback.

The continual extraction of training data is the biggest advantage a LEMR has over rule-based context sensitive
EMR systems. Rule-based systems do not generalize well and their display of data may not be optimal for any
patient who does not fit into a planned context. For example, a patient can have both diabetes mellitus and chronic
kidney disease. A display that was designed specifically for a patient with diabetes may not adequately represent the
complexities of the case. The LEMR, which learns from every interaction a user has with it, could represent some of
the important complexity of any case and could learn to meet information needs as they change overtime.

The data-driven approach we are taking also allows for the same LEMR system to be implemented in almost any
healthcare setting. For example, if the LEMR were implemented in a particular unit at a hospital, the combined
interactions from all of the physicians in that unit would aid the system in adapting to how patients are handled in
that environment. The system would not be limited to one set of models either; it could use hierarchical learning to
have a different set of models for each class of users, such as physicians of different specialties. The same theory
would apply when implementing the LEMR in a hospital wide setting. The models could customize to the different
groups of users in the different units.

Limitations

Our study has several limitations. The training of the predictive models was limited by the small training dataset. It
contained enough data to evaluate the prediction of 21 laboratory tests. This limitation will be addressed in a future
study where more patient cases are reviewed and other types of clinical data are included in the items whose access
is tracked. Moreover, we plan to develop predictive models for data items beyond laboratory test results.

The usability study was limited to four participants. In the future we plan to conduct usability studies with a larger
number of participants, potentially including side-by-side empirical comparisons aimed at understanding the impact
of alternative design strategies on physician interactions with the EMR, in terms of both accuracy and efficiency.

We obtained data-access information from a physician user who manually highlighted data items that were relevant
to a patient case. This manual acquisition of data-access information is a limitation of the current study. In a mature
LEMR that is deployed, such data-access information would be inferred automatically from computer mouse
activity, eye movement tracking, and from clinical notes (e.g., progress notes) in which pertinent data items are
recorded.
Conclusion

EMRs should synthesize and present patient data in such a way that it enhances the physician’s ability to understand the overall state of the patient and detect significant changes in the clinical course while decreasing the physician’s cognitive workload. We proposed a data-driven approach to displaying EMR data in a context specific manner. We built a prototype, trained and evaluated predictive models, and conducted a usability study as first steps in the development of a LEMR. This study supports the feasibility of the approach and provides insight on development concerns and opportunities. We plan to use the lessons learned from this study to extend the models using larger and more comprehensive datasets, to further refine the interface, and to conduct additional evaluation studies of the LEMR.

Acknowledgements

We thank Mr. John Levander for his help in developing the LEMR prototype. We thank Dr. Milos Hauskrecht for providing the ICU data that was extracted and processed in another project. A Multidimensional Data Warehouse for Community Health Centers

Kislaya Kunjan, MS, MBA1, Tammy Toscos, PhD1,2, Ayten Turkcan, PhD3, Brad N. Doebbeling, MD, MSc1

1Department of BioHealth Informatics, Indiana University, Indianapolis, IN; 2Parkview Research Center, Fort Wayne, IN; 3Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA

Abstract
Community health centers (CHCs) play a pivotal role in healthcare delivery to vulnerable populations, but have not yet benefited from a data warehouse that can support improvements in clinical and financial outcomes across the practice. We have developed a multidimensional clinic data warehouse (CDW) by working with 7 CHCs across the state of Indiana and integrating their operational, financial and electronic patient records to support ongoing delivery of care. We describe in detail the rationale for the project, the data architecture employed, the content of the data warehouse, along with a description of the challenges experienced and strategies used in the development of this repository that may help other researchers, managers and leaders in health informatics. The resulting multidimensional data warehouse is highly practical and is designed to provide a foundation for wide-ranging healthcare data analytics over time and across the community health research enterprise.

Introduction
Primary care practices and Community Health Centers (CHCs) are key components of the health care system in the United States (US), providing chronic and preventive care services to low income and medically underserved areas1. Incorporating health information technology (IT) systems for healthcare delivery has been recognized as a means to support improvements in patient outcomes, while yielding cost savings for patients, providers and payers2. CHCs are atypical in terms of their patient population, which in turn affects their overall clinical operations, including their health IT requirements. With over 96% of the CHCs using EHRs and handling over 90 million patient-visits a year3, they are an excellent source of clinical and administrative data and an ideal setting for research and development. However, when data resides in multiple disparate silos, the payers and providers cannot aggregate, analyze and assess the data in a cost-effective manner4. A data warehouse that can aggregate multiple disparate data sources, including patient records, clinical quality scores, and payer data for CHCs can be used to efficiently improve clinical and financial outcomes across the practice and the region at large5, 6, as well as to foster informatics and operations research.

In addition to the state-wide operational health information exchanges (HIEs) in the US,7 there exist several large data repositories/warehouses of significance, some of which include: Healthcare Cost and Utilization Project (HCUP)8; National Patient-Centered Clinical Research Network (PCORnet)9; Center for Medicare and Medicaid Claims Data10; US Food and Drug Administration’s Sentinel Initiative11; CancerLinQ12; and eMERGE (Electronic Medical Records and Genomics)13. Enterprise data warehouses to manage heterogeneous biomedical data have been developed for medical centers, such as Veteran Health Administration’s Corporate Data Warehouse14, Intermountain Healthcare’s CIS15, Massachusetts General’s COSTAR16 and Mayo Clinic’s Enterprise Data Trust17.

A CHC data warehouse that combines the best features of the HIEs and consolidated repositories like HCUP, along with health data analytics, can be particularly desirable for CHCs. In this paper we share our journey to create a multidimensional clinic data warehouse for seven clinics in the state of Indiana with whom we are collaborating to improve access to care for underserved patients. The primary research question guiding this work is how to design a CDW to support improvements in care delivery at community health centers.

Background
Indiana is home to the Indiana Health Information Exchange (IHIE)18, which is the largest HIE in the US. However, Regional Health Information Organizations (RHIOs) that manage such local HIEs have limited utility for CHCs because the participating facilities that share data into HIEs are typically hospitals and integrated health centers, in contrast to community clinics that are free standing and resource constrained. There are additional challenges with
HIEs such as: high start-up (upwards of $12 million) and operating costs; challenges in their business model, need for a dedicated infrastructure to managing streaming data from the healthcare facilities, while addressing issues of privacy and security, creating and maintaining a master patient index or record locator service and finding technologically capable exchange partners; and dealing with issues of distrust and data control issues among competitors. Furthermore these HIEs are primarily focused on patient-identifying clinical data derived from EHR and ancillary systems with a focus on allowing data to follow patients across delivery settings. They are not designed to be data stores or a data warehouse which capture operational and financial data and/or provide data analytics to members in the exchange network. In our research, we discovered that the CHCs in Indiana were not part of the IHIE member network, not much unlike the 280 other statewide operational HIEs in the nation who lack CHC involvement. Most CHCs we interviewed expressed keen interest in being able to effectively draw insights from their data, even as they encountered challenges in doing so. We chose to develop a unique community clinic data warehouse that would capture not only the medical record data but also include operational and financial data of the clinics in a very cost-efficient manner. To this multidimensional data warehouse, we intend to add an analytics platform, with a goal to support better patient care which can be defined in terms of improved access to care, shared decision making, and greater patient satisfaction. In addition, the intent is to enhance the operational and financial health of the community health care systems in the state of Indiana. We also believe there is great opportunity to foster community informatics research and development using this data to improve care delivery, patient engagement and efficiency.

The proposed work is an offshoot of an ongoing 3-year research project funded by the Patient Centered Outcomes Research Institute (PCORI). The larger project aims to improve access to care for CHCs by: identifying common barriers and successful patient-centered strategies; applying Delphi expert panel methods along with workflow and simulation modeling to identify feasible and valid patient-centered, strategies; and finally determining if implementing patient-centered systems can improve access to care, relative to existing approaches. The entire study, including the data collection from the clinics, has been IRB approved by the Indiana University Office of Research Administration.

Methods
We partnered with 7 CHCs geographically spread across the state of Indiana. The clinics were selected such that they represented urban, semi-urban and rural settings and provided care to diverse patient population in terms of race, ethnicity, insurance status, and income levels.

Design of the Community Clinic Data Warehouse
A common and widely accepted definition of a data warehouse is that it is a subject-oriented, integrated, non-volatile, and time-variant collection of data to support decision making. Data warehousing methodologies share a common set of tasks, including business requirements analysis, data design, architectural design, implementation and deployment. We present a data warehouse architecture that is simple, low cost, and one that can readily benefit resource constrained CHCs.

Our multidimensional Clinic Data Warehouse (CDW) captures clinical and operational data from community health centers in a uniform format to facilitate comparisons and analyses over time. There are four categories of data acquired from the clinics: 1) Clinic Operational Data; 2) Clinic Financial Data; 3) Clinic Quality Measures Data; and 4) Patient Level Data. These four data categories are captured and integrated into a common CDW. Downstream data analytics is applied to the data to create customized analytic reports of use to the clinic. Separately, patient analytics provide insights into optimizing care for the CHC’s patient population.

The information flow diagram for the CDW and associated analytics is illustrated in Figure 1.
The conceptualization of the CDW was based on the requirements gathered from all the stakeholders involved by conducting structured interviews with key informants that included clinic management, staff, providers, leadership, patients, as well as IT and QA/QI staff. While the initial choice of the data elements was driven by a narrow purpose to model and simulate clinic’s scheduling system, it soon expanded in scope to serve as a multidimensional repository sourcing information from various domains. The objective is to understand the implications of the clinic operational characteristics on the clinic performance and even patient outcomes over time. For example, the database will allow the study of the impact of scheduling method (such as open access) on appointment compliance (no-shows, cancellations, reschedules), staff utilization, and various patient outcome measures. The system architecture was defined in terms of: data sources, normalized common data model, interoperability requirements, data standards, data acquisition technologies, modes of acquisition, storage in a database server, privacy and security standards set up, data validity checks, data back-up performance and potential to build tools for data management and visualization. Roles and responsibilities were set for each of the above tasks, along with defining the business model.

**Obtaining Clinic and Patient Level EHR Data**

The clinic data category includes: Operational Data (such as, clinic type, certification status, locations, size, patient mix, payer mix, service mix, staff utilization, scheduling system, enrollment system, quality measures and other dimensions of care); and Financial Data (revenue, expense, margins, cash flow, payroll). The clinic operational/financial data was obtained from the audited financial statements of the clinics, IRS Form 990 (annual returns for certain federally tax-exempt organizations) and Uniform Data Systems (UDS) filings. This was supplemented with a structured questionnaire completed through an interview with the clinical manager, followed with workflow observations and opportunistic interviews as appropriate, in the clinic.

The patient level data serves as a backbone of the data warehouse. The data elements selected are those that are digitally captured as part of routine clinical practice and reported to federal agencies. Collecting this data required the design of a common data model, given that we were collecting information from different healthcare facilities using different Patient Management and EHR systems. The common data model helped promote efficient and streamlined collection of the data generated in each of the healthcare centers by organizing data into a standard structure. We developed a common data model that incorporated elements and practices of those used by other large organizations, including: HL7’s C-CDA, PCORnet and FDA’s Sentinel Initiative.
While we explored multiple ways to acquire patient data from the EHR, the one we selected was dependent on the EHR reporting capabilities, IT resources in the clinic, and the data architecture of the CDW. We realized that it was most efficient to obtain the data dictionary/metadata (tables, column names, definition/meaning, data type, predefined values sets/descriptive text) of the EHR where possible and identify the various data elements of our interest. The data elements were selected from well over 3000 tables present in the data dictionaries of the respective CHCs. We then generated SQL queries for each of the individual EHRs and gave them to the clinic staff to execute them on their database server. Once the data was extracted and the de-identification was verified in accordance with HIPAA safe-harbor provisions, the clinic shared the data with us through secure email. The raw data was prepped programatically before populating into our Microsoft SQL Database Server based on the common data model of the CDW and made ready for ad-hoc querying/reporting. Figure 2 shows this process flow of data collection from the clinic EHRs.

The core data element categories included: patient demographics, appointment data, date/time stamps of key events for patient and data flow, insurance information, provider information, medical problem list, encounter diagnoses, immunizations, medications, laboratory data, care plan, procedures, and healthcare referral information.

Results
We now present the results in terms of the common data model developed and a selection of graphs to illustrate the content of the CDW.

Common Data Model
A common data model for the CDW has been built which is guiding the collection of specific data elements. The majority of the data collection exercise, comprising up to five years of EHR and UDS data from all participating clinics, has been completed. For all subsequent data requests (which will be done on a quarterly basis to begin with), the clinic will only need to re-run the queries to append to the current database housed at our end. We mapped the data to the same consistent format (e.g., with the same variable name, precision, and other metadata). By undertaking this step, we created a platform that enables much more rapid analytic capabilities. The data model is expected to grow and evolve over time by including additional data elements that are analytically important.

Note that the data was already de-identified before populating into our database. A pseudo patient ID was used to map the data residing in different tables. In the first round of data collection, many of the raw data tables had to be prepared before loading into our database. Populating free text information was particularly challenging given the existence of delimiters like commas, tabs and new lines. But this was resolved programatically and by specifying the input file format. Future data loading will be much more streamlined. The main tasks in developing the common data model were the selection of appropriate entities/tables and attributes as well as data normalizations based on the three different commercial EHR systems we encountered.
The clinic data warehouse currently stores over 3 million patient-visit records from 2010-14 from the different CHCs and includes detailed information on appointments, prescriptions, lab tests, screening/preventive measures, immunization, and quality measures under Meaningful Use (MU) Stage 2 and UDS. This is a significant volume of rich longitudinal data that will readily lend itself to large-scale data analytics and operational and efficiency studies.

Select Measures on the Data Collected
We present here a partial selection of the key data measures graphically to illustrate the data content.

Figure 4 describes the racial distribution and insurance status of the patient population comprising each of the 7 Indiana CHCs. The distribution clearly shows that the clinics are not homogenous in their patient population and associated needs.

Figure 4: Summary statistics on race and insurance Status

Referring to the plots, it may be noted that the ‘White’ race includes Hispanic/Latinos, since the latter is not defined as a race, but as an ethnicity. In these CHCs, the percentage for Hispanic/Latino ethnicity ranges from a low 1.2% to high 38%. For insurance, a vast majority of them are either uninsured or have Medicaid, with income levels below
200% of the Federal Poverty Line. Yet, there is a sizeable percentage of patients with private insurance in couple of the clinics.

Among our seven partnering CHCs, four use traditional scheduling, while three use modified open access (a combination of same day open slots and traditional/advanced booking). High patient appointment no-show rates and the associated variability in workload due to prevalent practice of overbooking remains a significant challenge in all CHCs. For example, after analysis of the appointment data in the CDW for one of the CHCs, we found that their no-show rate for 2014 was 21% and the appointment cancellation rate was 13%. Providing clinics with easy access to this data and a means to benchmark their performance against other similar organizations can be powerful and create opportunities for design and testing of new technology solutions and positive change.

For another large CHC, we analyzed the visit statistics, in terms of clinic services utilized, and the top 6 disease diagnoses and the associated annual visit frequencies (see Figure 5). It is important to understand the most common medical conditions and service patterns for these predominant conditions in order to focus efforts on study of these problems, and identify potential technology tools that might help improve these challenges. Focus on highly prevalent problems is likely to have the greatest impact on the overall clinic efficiency and other operational and financial measures.

![Figure 5: Statistics on services utilized and medical conditions with associated visits at a large CHC in Indiana](image)

**Discussion**

We have established a novel information exchange/clinic data warehouse that will enable data-driven research, technology development and testing, and informed decision making over the years. We have presented only a small selection of the data in the repository for illustration and plan a number of studies to better investigate its use and applications. We believe this approach can provide an efficient and effective means for CHCs to leverage data to improve patient access and the quality of care delivered to underserved patients.

**Academic Research and Benefits to CHCs**

There are innumerable research opportunities that can come from analytic study of the CDW. These may be broadly classified as being, descriptive, predictive, and prescriptive analytics. A few examples under, ‘descriptive analytics’ are: development of enriched careflow/process models based on EHR time-stamps; ranking clinics based on adherence to evidence based best practices; and peer comparisons at the state and national level. Under ‘predictive analytics’ the plan is to build machine-learning models of patient no-show behavior and treatment compliance; to perform agent-based modeling and simulation of clinic operations to improve efficiency; and to perform longitudinal network analysis and risk stratification of diseases. Note that although the patient data in the CDW is deidentified, a pseudo patient ID will still allow us to conduct patient-centered longitudinal studies across

---

1 Enabling services in the pie chart include: case management, outreach, patient/community education, transportation, eligibility assistance, and interpretation services.
2 Mental Disorders in the graph is cumulative of 4 mental disorder types: Depression, Anxiety and PTSD, Attention Deficit Disorder, and Other Mental Disorders.
care settings. Assessing the impact of the affordable care act (ACA) on access to care will be of particular and timely relevance.

Under ‘prescriptive analytics’ we intend to incorporate findings from predictive analytics into standalone software applications or embed within patient management systems to provide personalized decision support based on patient profile and clinic characteristics. The data can be further enriched by including external variables, such as data from community/geo-spatial information systems. We also are particularly excited about the opportunity for research and development of new technologies for patient engagement and management in the community, as well as integration of disparate care providers and care sites (inpatient, outpatient, community, “minute” clinics, prisons, other) as part of a care management team. The community clinics stand to benefit from such analytics since they lack the infrastructure that is usually available to academic medical centers.

Ongoing Work
We are refining the design of a data-driven clinic dashboard that will be linked to the CDW. Figure 6 shows the mock-up of this dashboard under development, which initially will focus on measures of access to care and efficiency. It has a selection of key metrics across different categories (operational, quality, and financial) and has been derived from key informant interviews. It will allow clinic management to visually assess the impact of their operational changes (such as scheduling, staffing level, and policy changes) on clinical and non-clinical outcomes on a periodic basis.

Figure 6: Mock-up of a community clinic dashboard with associated metrics of relevance

We are also working on a secure web portal to serve as an interface for clinic data submission and running queries by researchers. The CDW portal will allow users to explore, interact with, and export data through charts, maps, reports, analyzer and locator tools, data downloads and data services, and widgets. Finally, we are developing strategies for interacting with technology developers and entrepreneurs, in order to test the feasibility of new tools and prototypes.

Challenges and Strategies
There were various challenges encountered in acquiring the data from the clinics. For most clinics, this was the first time they received such a request to extract EHR data. Thus far, the clinics primarily ran reports to fulfill government requirements, in tandem with manual charting. Even though the clinics lacked adequate time or
resources for learning and drawing insights from their data, they all readily recognized its importance to support their evidence-based quality improvement efforts, and be in compliance with the upcoming MU Stage 3 requirements and intent to seek PCMH certifications.

In terms of strategies, we sought to engage meaningfully with all the clinics and presented our value proposition to the clinic leadership. We interviewed the clinic staff and patients to understand their challenges and learn from their innovations, coupled with onsite workflow observations of key processes. We were able to obtain the EHR data dictionary from 2 different EHR systems (covering 5 out of the 7 clinics). These EHRs were based on client-server architecture. The data dictionary allowed us to identify all the data elements of interest to us and create the SQL queries to be executed on their database servers. This made it less onerous on the clinics as they were able to run the provided queries and share the extracted data with us in a secure mode. The remaining 2 CHCs were using a cloud-based EHR with no direct access to the database server. We had to work rather closely with them to pull the data from their web-based reporting tool.

Study Limitations
There were a few limitations to our study. First being, that since the data dictionaries were from three different commercial EHR vendors, the common data model may not reflect the universe of EHRs in the ambulatory care space. Furthermore, the data warehouse architecture has been partially influenced by the unique characteristics of CHCs in the state of Indiana and therefore may not reflect the particulars of other CHCs in the US. The model may be even less representative of other primary care practices who are not dedicated to meeting needs of the underserved. Finally, the design of the architecture and resource constraints imposes certain practical limitations on the frequency of data collected from the clinics, which in turn would define the type of analytics and decision support that can be performed.

Conclusions
We have described a multidimensional clinic data warehouse for CHCs spread across Indiana and one that integrates operational, financial, quality and patient data. We chose a centralized data architecture that is relatively easy to implement and sustain, yet is rich in scope and content, and relevant to the participating clinics. The goal is to enable free standing CHCs to participate in this data warehouse, in the same way that large hospitals participate in HIEs and benefit from large scale healthcare data analytics to improve overall clinic operational performance and achieve better scores on the ever evolving clinical quality measures. Developing strategies for interacting with technology developers and entrepreneurs, in order to test the feasibility of new tools and prototypes should speed innovation and dissemination of effective IT. Ultimately, we believe that providing the CDW will help CHCs better meet the needs of their patients.

Creating Shareable Clinical Decision Support Rules for a Pharmacogenomics Clinical Guideline Using Structured Knowledge Representation

Margaret K. Linan, MPH\textsuperscript{1}, Davide Sottara, PhD\textsuperscript{1,2}, Robert R. Freimuth, PhD\textsuperscript{2,3}

\textsuperscript{1}Department of Biomedical Informatics, Arizona State University, Scottsdale, AZ, \textsuperscript{2}Office of Information and Knowledge Management and \textsuperscript{3}Department of Health Sciences Research, Mayo Clinic, Rochester, MN

Abstract
Pharmacogenomics (PGx) guidelines contain drug-gene relationships, therapeutic and clinical recommendations from which clinical decision support (CDS) rules can be extracted, rendered and then delivered through clinical decision support systems (CDSS) to provide clinicians with just-in-time information at the point of care. Several tools exist that can be used to generate CDS rules that are based on computer interpretable guidelines (CIG), but none have been previously applied to the PGx domain. We utilized the Unified Modeling Language (UML), the Health Level 7 virtual medical record (HL7 vMR) model, and standard terminologies to represent the semantics and decision logic derived from a PGx guideline, which were then mapped to the Health eDecisions (HeD) schema. The modeling and extraction processes developed here demonstrate how structured knowledge representations can be used to support the creation of shareable CDS rules from PGx guidelines.

Introduction
In this work, we propose a consistent and reproducible methodology to generate platform-independent, shareable representations of PGx guidelines using existing and emerging standards. We modeled a published PGx guideline using UML activity diagrams, the HL7 vMR data model, and standard terminologies. The aim is to use these standards to build a structured, human-readable document and, ultimately, a shareable, machine-readable artifact. The motivation for developing a standards-based knowledge representation process that yields sharable policies is twofold. First, no commonly accepted, standard methodology currently exists for the extraction of CDS rules from PGx guidelines. Second, the creation of shareable CDS rules from PGx guidelines will provide clinicians and implementers with standards-based decision logic that can be used as a starting point for the design of evidence-based care delivery interventions.

Adverse drug reactions (ADR) cause more deaths than AIDS and diabetes, making it the fourth major cause of death for over a decade\textsuperscript{1}. Approximately 100,000 deaths and more than 2 million acute ADRs occur annually\textsuperscript{1}. Some of these ADRs are caused by variations in genes associated with drug metabolism or mechanism of action. Many of these gene-drug interactions are clinically actionable. Groups such as the Clinical Pharmacogenetics Implementation Consortium (CPIC) develop clinical guidelines that provide clinicians with information about known gene-drug interactions. These guidelines also provide clinicians with recommendations that help guide drug therapy\textsuperscript{2,3,4}.

Like most clinical guidelines, pharmacogenomics (PGx) guidelines are written for clinicians and are not available in computable formats. While CPIC is beginning to include some structured text within their published guidelines, formal representations of the knowledge are not available, which hinders the extraction and implementation of CDS rules\textsuperscript{1}. In addition, there are several other factors that complicate the implementation of PGx CDS. One of the main issues is the burgeoning amount of biomedical knowledge; there are currently 166 known gene drug interactions on the FDA website and 21 PGx guidelines have been published, and these numbers are growing rapidly\textsuperscript{5,6,7,8}. Another factor is the very costly and time consuming process that is required to extract PGx knowledge from narrative guidelines, implement them as CDS rules in electronic medical record (EMR) systems, and then maintain those rules as biomedical knowledge evolves. Also, there are differences in how a clinical practice guideline can be implemented as a CDS rule, due to differences in the interpretation of the guideline and local workflows. It may be possible to reduce the cost of rule development and improve the consistency of CDS implementations by sharing CIGs, but currently there are no best practices or knowledge bases available to support the authoring of CIGs\textsuperscript{9}. Therefore, a scalable approach is needed to extract, render and implement CDS rules from PGx guidelines. To accomplish this, common semantics and a platform-independent (vendor-agnostic) syntax is required.
Standardized data models and terminologies reduce variability in the representation and interpretation of clinical data by providing common semantic meanings for concepts and terms. For example, the HL7 virtual medical record (vMR) data model was developed to represent clinical data from an EMR in a platform-neutral manner, which can be used for CDS. Similarly, standard terminologies, such as SNOMED CT, RxNorm and LOINC, provide common definitions for clinical terms, drugs, and lab tests, respectively. While the use of common data models and standard terminologies increases comprehension and reduces semantic ambiguity in shared data, they are not intended to represent the workflow and decision logic inherent in CDS rules. To represent these aspects, different standards are needed.

Several modeling frameworks, such as the Guideline Elements Model (GEM) and the Guideline Interchange Format (GLIF), have been developed to represent the content of clinical guidelines. However, no existing framework has achieved broad adoption and the variety of approaches, formats and limitations of existing modeling tools prevents artifacts generated using these frameworks from being shareable in practice. Despite decades of work in this area, there remains a dearth of applications that can support the authoring of platform-independent, shareable CIGs for use in CDS systems. To address this challenge, in 2012 the Office of the National Coordinator (ONC) for Health Information Technology supported the creation of a harmonized format, known as the Health eDecisions (HeD) interchange format. The HeD standard defines a common metamodel for metadata, actions, events, and conditions as well as an expression language. HeD also recommends an XML-based serialization format and provides a schema for the validation of compliant documents. Together, the HeD model and its schema were designed to represent the workflow and decision logic of interventions such as CDS rules, order sets and documentation templates.

To complement the HeD schema, in the context of the SHARPc-2B project, a multi-institution team developed a more formal representation of the HeD metamodel, expressed in the form of an OWL ontology, and a standards- and model-driven application for the authoring CDS clinical knowledge artifacts. The HeD editor has several features that can potentially make it an ideal part of the process for modeling and testing the clinical decision logic for PGx guidelines. Specifically, it is compatible with several existing and pre-existing standards, has an intuitive user interface that can be used by knowledge engineers and non-technical staff, and uses semantic web technologies.

In this work, we modeled a published PGx guideline using UML activity diagrams, the HL7 vMR data model, and standard terminologies. We then utilized the HeD editor to render the modeled guideline in HeD syntax. This work builds on our previous efforts to create platform-independent, standards-based, shareable representations of PGx guidelines and is another step towards the development of a generalizable approach that can be broadly applied to other PGx guidelines.

**Methods**

Published CPIC guidelines were reviewed and evaluated in terms of both the complexity of logic and the availability of reference implementations of corresponding CDS rules. For this project, we sought a PGx guideline that contained straightforward decision logic that was based on unambiguous PGx data (genotype and phenotype). We also prioritized guidelines that had been implemented as local, non-shareable CDS rules, which would provide additional clinical context over that which was included in the published guideline.

A stepwise process was developed to transform a human-readable PGx guideline into a computable HeD artifact (Figure 1). The process began by carefully analyzing the selected PGx guideline and rigorously defining all of the concepts, both explicit and implicit, that were relevant to the implementation of a PGx CDS rule. This included concepts that pertain to the clinical context of the guideline, the relevant EMR data, and terminology. The process was informed by knowledge of actual CDS implementations of the selected guideline.

Figure 1. The workflow for modeling a PGx clinical guideline and expressing the information in HeD syntax.
Once relevant concepts were identified within the PGx guideline, candidate reference standards were reviewed and evaluated to determine which might best represent those concepts. Specifically, we evaluated the HL7 vMR, HL7 RIM, and LS DAM, to represent the clinical data for this PGx guideline\textsuperscript{21,22}. We also evaluated the RxNorm, NDF-RT, SNOMED CT, and LOINC standard terminologies. The standards that were selected were used in the next step, when the PGx guideline itself was formally modeled and rendered in HeD syntax.

The parts of the PGx guideline that were targeted for modeling were the decision tree (which contained the recommended clinical workflow), the therapeutic recommendations, and the table for the genotype-informed decision logic, as the content in these sections represented the information that would comprise CDS rules. The information from these sections was augmented with knowledge of the corresponding CDS rules at Mayo Clinic, which provided additional clinical context about real-world PGx interventions. Collectively, these data were used to create a high-level model, which was expressed using UML class and activity diagrams to describe the logic contained within the PGx guideline. To reduce its complexity, the high-level model was split into logical modules that each contained a small number of decision points.

Each of the modules were analyzed in detail to identify the data elements, terminology concepts, and functions (e.g., data retrieval from the EMR, result processing) that would be necessary for implementation as a CDS rule. This information was then used to determine which entities (e.g., classes, attributes, and terms) from the selected reference standards would be needed to represent the entities within each module. Elements that represented the entities from the reference standards were added to the UML model and associated to their respective classes from the PGx guideline. Lastly, activity diagrams were generated to refine the computational steps within each workflow. Together, the UML models captured the entities, workflow, and behavior contained within the PGx guideline, but an additional method was needed to represent the logic of the CDS rules.

The logic components of the PGx guideline were expressed in pseudocode, which described the flow of data between each step and represented the functions that would be needed to implement each CDS rule. The pseudocode was based on an early version of CQL, and was used to define variables and create if-then conditional logic blocks that evaluated clinical data represented by vMR classes and attributes.

Finally, the model and pseudocode were used to render the guideline in HeD syntax, referencing the data and terminology standards (Figure 2). The HeD editor was used to ensure the resulting artifacts complied with the HeD schema.

![HeD Pseudocode (Text)](Figure 2. The HeD editor was used to generate structured rules from an unstructured PGx guideline, which was modeled in UML. Data and terminology standards provided common semantic meaning, and the logic of the workflow was expressed using the HeD schema.)
Results

The CPIC guideline for HLA-B genotype and abacavir dosing was chosen because of its straightforward decision logic. In particular, the HLA-B genotype is expressed as a boolean result (HLA-B*57:01 allele present/absent) that determines whether or not abacavir is contraindicated. The core recommendations from the guideline are summarized in Table 1. This guideline has been implemented as a CDS rule at Mayo Clinic.

Table 1. Core recommendations from the HLA-B/abacavir guideline.

The HL7 vMR model, which was developed in part to support CDS use cases, was selected to represent clinical data elements. The vMR includes classes that represent the concepts of patient, drug order, ADR, test order and result, and communication events (e.g., CDS alerts). The RxNorm, SNOMED CT, and LOINC standard terminologies were chosen to provide coded concepts for drugs (e.g., abacavir), ADRs (e.g., adverse reaction to abacavir), and lab tests (e.g., abacavir genotype), respectively. While some of the coded concepts required for this project existed within the selected terminologies, several concepts were missing. Specifically, SNOMED CT did not contain a pre-coordinated term for an abacavir-related ADR but it would be possible to express this concept through post-coordination using "Antiviral drug adverse reaction" (292826004), "Causative agent" (246075003), and "Abacavir" (387005008). In addition, LOINC did not contain codes for the HLA-B*57:01 genotype test or results. Placeholder concept codes were used for the genotype test and results when rendering the rule in HeD syntax.

The HLA-B/abacavir guideline was modeled as five inter-related logical modules that represent the clinical workflow, therapeutic recommendations, and decision logic that would be necessary for implementation of the guideline as a CDS rule (Rules A-E, see Figure 3). These modules contain models that describe the entities, attributes, concepts, workflow relationships, and processing functions to search the patient’s record for a documented ADR (Rule A) and genetic test report (Rule B). CDS interventions are modeled in Rules C, D, and E.

Figure 3. Overview of the five inter-related rule modules that were generated for the HLA-B/abacavir guideline

When the CDS system detects an order for abacavir Rule A is triggered, which queries the EMR to see whether the patient has a documented adverse reaction to abacavir. If an adverse reaction is found then a CDS alert fires, instructing the clinician to cancel the drug order. If no adverse reaction exists then Rule B is triggered, which queries the patient’s record for HLA-B*57:01 genetic test results. If no results are found then Rule C is triggered, which recommends the clinician order the genetic test (if it has not already been ordered) or delay the drug order.
until the test results are available (if the test has been ordered and results are pending). If test results are found, Rule D is triggered, which examines the report for coded genotype results and either fires an alert to the clinician (HLA-B*57:01 allele present, abacavir is contraindicated) or allows the order to proceed (HLA-B*57:01 allele not present). If Rule D is triggered but coded genotype results are not available then Rule E is triggered, which examines the report for coded phenotype results (e.g., high/low risk of abacavir hypersensitivity). If coded phenotype results are available, the system acts accordingly (see Rule D); otherwise, the test results have not been codified and the CDS system will advise the clinician to manually review the genetic test results report.

The entities in each rule were mapped to the corresponding entities from selected data and terminology standards. This step resulted in the identification of the vMR classes and attributes that would be needed for each rule. For example, the classes identified for Rule A included EvaluatedPerson, SubstanceAdministrationOrder, AdverseEvent, and CommunicationProposal (Figure 4).

Some of the attributes have a datatype of CD (concept descriptor), which reference coded concepts from terminologies that can be defined by the implementer. The standard terminologies selected for this project were used, when possible, as sources for terms that were considered to be critical for the rendering of the rule in HeD syntax. For example, “abacavir” can be represented by RxNorm RxCUI 190521, which can be used in Rule A for both SubstanceAdministrationOrder.substanceGenericCode and AdverseEvent.adverseEventAgent (Figure 4).

**Figure 4.** Clinical workflow for Rule A, with concepts identified and mapped to HL7 vMR classes. Not all attributes are shown.
Each of the five workflows were refined into UML activity diagrams, which more carefully defined the actions required at each step of the workflow (Figure 5). The activity diagrams represented the final stage of UML modeling and, with the workflows described above, informed the generation of pseudocode.

Figure 5. An activity diagram for Rule A, showing the activities that need to be performed by the CDS system. These process steps were later expressed in HeD syntax.

The penultimate step in this process involved creating pseudocode to outline the underlying processes involved in the retrieval and analysis of clinically relevant information from the EMR (see Figure 6 for an example). The pseudocode facilitated the transformation of the information specified in UML into a more pragmatically defined structured language while still retaining some aspects of human readability.

```plaintext
valueset "Abacavir" = Valueset( x.y.z )
let AdverseReactionsToAbacavir =
    [ Occurrence of AdverseEvent : adverseEventAgent in "Abacavir" ]
let hasAdverseReaction = exists AdverseReactionsToAbacavir
let Message = 'Consider cancelling the order for patient ' + name.family + '...'
```

Figure 6. An example of pseudocode corresponding to a portion of Rule A. References to the vMR are shown in red, while defined variables and expressions are shown in blue.

An initial HeD rendering of Rule A was created using the HeD editor and the knowledge artifacts previously generated (e.g., UML models, pseudocode). This rendering included references to classes and attributes from the vMR, concept codes (or placeholders) from standard terminologies, and the workflow logic expressed using the HeD schema (Figure 7).
Figure 7. An example of the HeD syntax corresponding to a portion of Rule A. References to the vMR are shown in red; defined variables, expressions, and values are shown in blue; elements from the HeD model are shown in green.

Discussion

In this project we sought to develop a standards-based methodology to generate platform-independent, shareable representations of PGx rules. We modeled the published HLA-B/abacavir PGx guideline using UML class and activity diagrams, the HL7 vMR data model, and standard terminologies. These models were used to create pseudocode representations of the rules, which were ultimately rendered in HeD syntax. Thus, we began with an unstructured, human-readable clinical guideline and produced a shareable, machine-readable artifact.

This is the first time that PGx clinical guidelines have been formally modeled in UML with the specific aim of rendering the extracted rules in a platform-independent language, such as HeD. The use of UML to model the rules contained in the guideline facilitated the identification of data elements and coded concepts, and the subsequent mapping of those entities to standards. The UML modeling process also helped to provide a clear representation of key decision points in the rule and clinical workflow, and made explicit the computational tasks that need to be performed during the execution of the rules, such as data retrieval and processing. We anticipate this modeling approach will scalable and generalizable to other PGx guidelines. A review of other CPIC guidelines revealed variations in genetic test interpretations (e.g., phenotype) and the complexity of therapeutic recommendations, so it will be important to demonstrate this method can be used for a variety of PGx guidelines.
The HL7 vMR model, which was developed in part to support CDS use cases, was selected to represent clinical data elements. The vMR model was chosen, in part, because it provided the best coverage overall of the clinical concepts that were expressed in the PGx guideline and rules. We did not require the full expressive power and complexity of the HL7 RIM, of which vMR is a derivative, and other competing standards like FHIR were not sufficiently mature at the time this work was performed. We also did not consider logical or more detailed clinical models, such as the ones delivered as Clinical Element Models (CEMs) or OpenEHR archetypes as we decided that while we would likely find models for the more traditional concepts used in the rule, those sources did not provide PGx-specific models. For example, genetic test results were represented in the vMR as Observations, which is used for generic lab tests, but a refined domain model may be required to more fully capture the nuanced semantics of genomics data, including the concepts of allele, haplotype, copy number, and predicted phenotype. The HL7 Clinical Genomics Working Group is currently working in this area and we will evaluate the outcome of those projects when the work is complete.

The standard terminologies that were chosen for this project had variable coverage of the concepts contained in the PGx guideline. Both RxNorm and SNOMED CT contained a concept for "abacavir"; we chose to use the term from RxNorm as it is more likely to be supported by pharmacy systems. SNOMED CT did not contain a single term to represent a documented ADR for abacavir, but as noted above it would be possible to express this through post-coordination. Since the vMR model provides an attribute to specify the cause of an adverse event, though, this attribute was used with the code for "abacavir" rather than the more complex approach of using post-coordinated terms, since the class and the attribute already convey part of the semantics.

We were not able to locate an entry in LOINC that represented the HLA-B*57:01 genetic test or the results from that test; this was not a surprise, as standardized terminology is a known gap in the PGx domain. CPIC is leading a terminology harmonization effort that will provide more consistency among its guidelines and it is likely that the terms and value sets resulting from that project will be proposed for inclusion in LOINC. As those terms were not available at the time of this study, we used placeholder codes for these concepts in the HeD rendering of the rules.

The data and terminology standards provide common semantics that enable the sharing of rules derived from PGx guidelines. The actual implementation of CDS rules would require a site-specific mapping from the standard-based representation to local data models and terminologies, which reflects differences in where in the EMR data is stored and how it is coded. Similarly, while HeD is designed to represent the workflow and decision logic of interventions in a platform-independent manner, currently there is no consolidated way to execute HeD syntax or automatically transform it to an EMR-specific language beyond initial pilot implementations. These limitations represent significant opportunities for further research and tooling development.

Conclusion

In this work we demonstrated a method for modeling the HLA-B/abacavir PGx guideline in UML, which can represent the clinical workflow and decision logic as standards-based structured knowledge, and we illustrated how these models can be used to aid rendering the rules in the HeD schema. We anticipate this process will be generalizable to other PGx guidelines, although several important gaps in reference standards and tooling need to be addressed. This approach will enable the creation of sharable, platform-independent knowledge artifacts that may facilitate the implementation of and consistency among PGx CDS rules.

Analyses of Merging Clinical and Viral Genetic Data for Influenza Surveillance

Daniel Magee¹, Rachel Beard¹, Matthew Scotch PhD, MPH¹
¹Arizona State University, Tempe, AZ, USA

Abstract
The annual influenza vaccine is one of the most common public health interventions and is universally recommended for all individuals older than six months. Vaccine composition depends on viruses circulating over the past flu season and are estimated to be the most prevalent and representative strains in the current season. Here, we use clinical data outfitted with viral genetics to characterize confirmed influenza cases from the past two flu seasons and genetically compare them to the strains that they were vaccinated against that year. We show that case similarities to vaccine strains differ by geographic region and that the vaccines appear to have different levels of effectiveness by region. This study demonstrates the value of merging viral genetics with clinical data. Further research is needed to formally evaluate whether this improves biosurveillance efforts and enhances efficacy of influenza vaccines.

Introduction
One of the cornerstones of public health improvements over the past several decades is widespread vaccination against potentially threatening diseases such as tetanus, measles, mumps, rubella, and hepatitis. Of particular note, influenza has caused a number of pandemics as a result of novel strains circulating in the general population, such as the 1918 H1N1 Spanish influenza which caused an estimated 20-50 million deaths worldwide¹. More recently, global influenza infection rates are estimated to include 5-10% of all adults and 20-30% of children annually during a non-epidemic year² amounting to 250,000-500,000 deaths according to a 2014 a World Health Organization (WHO) report³. In an effort to curb these rates, programs to vaccinate a large portion of the population are carried out each year in countries such as the United States, resulting in annual vaccination rates falling between 39.4-42.2% of the population from 2009-2014⁴. However, efficacy of these vaccinations can vary significantly year to year by region, demographics, and time of vaccination⁵,⁷.

Influenza vaccines to counter detrimental effects on public health were introduced in the 1940s, initially including at least one influenza A and B strain⁸. Each vaccine uses a dead or weakened strain of virus to promote the body’s immune response and help protect against an actual infection with little to no risk to the patient⁹. The Centers for Disease Control and Prevention (CDC) provides a recommended vaccination schedule for both children⁹ and adults¹⁰. Included in these schedules is the annual influenza vaccine which comes in two forms: inactivated influenza vaccine (IAV) and live, attenuated influenza vaccine (LAIV)¹¹ and are administered depending on the age and status of the patient. These vaccines are generally trivalent and can protect against three of the most common types of influenza: A/H1N1, A/H3N2, and B. It is recommended that all individuals at least six months old receive a vaccination annually¹² in time for the beginning of the flu season, which falls between weeks 40-20 in the Northern Hemisphere. In preparation for this demand, 150-160 million vaccines are annually produced for use in the United States.

The vaccines are created based off of recommendations by the WHO and are a result of a continuous process analyzing data and viruses that circulated during the previous flu season. There are 130 national influenza centers (NIC) in 101 countries¹³, including four in the United States. These centers are tasked with analyzing clinically-confirmed influenza cases by a variety of genetic and antigenic tests and determining the strains that are the most representative or novel. These strains are then forwarded to one of five WHO Collaborating Centers for consultation and further testing¹³. The additional testing involves inoculation into ferrets for antisera analysis, human serology studies, analysis of antiviral resistance properties, and phylogenetic clade analysis. After taking these results into consideration, primary selection of the H1N1, H3N2, and B viruses are made and initial vaccines are created for further analysis; the H1N1 and H3N2 strains are created by classical reassortment while the wild type B virus is used because there is no growth advantage for its reassortment. These vaccines are used to gather ferret antisera once more to ensure that growth properties and antigenic content are sufficient and that the antigens created are identical to those of the wild type viruses. In the event that the antigenic state or growth properties are insufficient, the WHO may decide to try to utilize all wild type viruses

1995
or may select entirely new strains. Once sufficient vaccines have been created and demonstrated, the WHO will make its recommendations for the upcoming flu season and these recommendations apply to the entire Northern or Southern Hemisphere; however each country generally has a local agency approve the recommendations or choose different, but antigenically similar, strains. In the United States, final approval is provided by the Food and Drug Administration (FDA). Mass production of vaccines begins after final virus selection is made, usually February through May, in order to have the massive amount of required stockpiles ready for the beginning of the vaccination period in October.

The most important takeaway from the selection and production process is that the strains selected for inclusion in the vaccine reflect highly educated guesses of the strains that will be the most representative in the upcoming flu season. Vaccine effectiveness depends on the actual strains circulating when the flu season arrives, the number of individuals that receive the vaccination, and several other factors. Early estimates of the 2014-2015 flu season in the United States indicate overall vaccine effectiveness at just 23% due to genetically drifted H3N2 strains in circulation. The same vaccine is generally distributed throughout the entire United States, with the exception of some quadrivalent vaccines that protect against an additional influenza B virus, and do not take into account locally circulating viruses in real time during the flu season. This enables phenomena like the current flu season where antigenically divergent strains predominate and reduce efficacy of the vaccine. Global geographic dispersal has been implicated as the main mechanism by which the influenza A virus survives and evolves into antigenically divergent strains between seasons. This demonstrates that geography can be a causal factor toward the prevalent strains during a flu season and led us to explore the use of clinical data from confirmed influenza cases to analyze genetic similarities between the cases and the viruses that were vaccinated against. These types of data may be used to help clinicians decide on treatment options vaccines that may be available to administer to patients in their area, and help governing bodies of public health better determine strains to target for vaccination at a more granular level. For instance, this type of analysis would be useful for physicians at the local level to prescribe drugs potentially more effective at treating patients based on the strain of influenza they are infected with. Additionally, given the availability of a complete data sets encompassing both genetic and clinical characteristics of a flu isolate and its associated host, this would allow tracking of effectiveness of vaccines for particular regions in conjunction with trends in strain resistance factors.

The CDC oversees a federal influenza surveillance program that includes participation from state health agencies. The current initiative includes subtyping, antigenic characterization, and antiviral resistance testing. There is also information on influenza-associated hospitalizations and outpatient influenza-like illness. Beyond Federal reporting, some individual healthcare facilities have begun to share both clinical and viral genetic data with the researcher community. For example, the influenza research database (IRD) contains a relatively new feature for facilities to share clinical data from influenza-related hospitalization as well as the sequences of the virus itself. Currently sixteen distinct facilities are participating including Beth Israel Deaconess Medical Center, Children’s Hospital Boston, the University of Rochester Medical Center, and the National Research Center in Egypt.

In this study, we analyze overall and geographic distribution of genetic similarities between the cases and vaccines and demonstrate the potential of combining clinical and viral genetic data to explore trends of influenza epidemics.

Methods

We collected clinical data for influenza cases from the IRD. We used the Human Isolates with Clinical Metadata function and searched for all data from Week 40-20 for each of the 2012-2013 and 2013-2014 flu seasons in the United States. Of the returned results, all categories of data were selected and downloaded. These included: GenBank database accession ID, age of the patient, gender, vaccination status and date, presence of fever and other clinical symptoms, as well as genetic data about the virus such as markers for antiviral resistance (adamantine or oseltamivir). We discarded any record that was not influenza A subtype H1N1, H3N2, or type B. Of the remaining cases, we discarded any record that did not contain a specific strain or sequence accession number. We used the accession IDs in our result set to search GenBank and download the hemagglutinin (HA) sequence for each case. We discarded all records containing a partial sequence and this resulted in the final dataset. In Figure 1, we show a flowchart of the data collection and preprocessing.
Figure 1. Flowcharts resulting in the cases we used for analysis in this study. A) 2012-2013 flu season with data representing 81.2% of all cases. B) 2013-2014 flu season with data representing 79.9% of all cases.

In order to compare the sequences with those contained within the vaccine, we collected a strain recommended by the WHO for inclusion in the respective flu seasons in the Northern Hemisphere from the IRD. The WHO recommends “like-virus” strains (e.g. A/Brisbane/59/2007(H1N1)-like virus) rather than a wild type strain, rather than specific strains, and the strains vaccinated against may differ between vaccine manufacturers. This makes it impossible to conclude exactly which strains each individual is vaccinated against in a set of deidentified data. For this reason, we collected a random HA sequence from GenBank matching the suggested strains within the IRD. In Table 1, we describe these strains.

Table 1. WHO Recommendations for Composition of Influenza Vaccines in the Northern Hemisphere by flu season and their corresponding GenBank Accession ID. These Accession IDs correspond to the specific HA sequence we used for analysis in this study.

We aligned sequences for each virus subtype from each season with the sequences representing the subtype contained in that year’s vaccine using Geneious Pro v.6.1.6 (Biomatters Ltd., Auckland, New Zealand) and MAFFT v7.017. We utilized the default parameters (Algorithm = auto, Scoring Matrix = 200PAM / k = 2, Gap Open Penalty = 1.53, Offset Value = 0.123). Post-alignment, we measured genetic distance in the number of single nucleotide polymorphisms.
(SNPs) from each sequence to the vaccine and translated the aligned sequences with Geneious to determine the number of nonsynonymous SNPs. We appended these distances to our clinical data file. In order to quantify the impact of geography among the cases, we appended a column in the clinical data file with the United States Department of Health and Human Services (HHS) Region corresponding to the state from which the case was isolated. There are ten HHS Regions\(^{25}\) in total representing each of the 50 United States and several territories including American Samoa, Guam, and others.

**Results**

The results we obtained focus on genetic variation among confirmed flu cases and the vaccinated strains as well as a metric of vaccine effectiveness among cases in both the regional and overall scopes. In Figure 2, we show the number of SNPs compared to the strain in which it was vaccinated against.

![Number of SNPs in Confirmed Cases Compared to Strain in Vaccine](image)

**Figure 2.** The number of post-alignment SNPs in our cleaned set of cases compared to the strain in which it was vaccinated against (Table 1). The blue and orange bars represent the average synonymous and nonsynonymous SNPs per virus per year, respectively, with error bars as standard deviations for n cases, listed above.

After eliminating cases with unknown vaccination status, we determined that 49.2% and 50.2% of our cases were vaccinated for the 2012-2013 and 2013-2014 flu seasons, respectively. The lack of control individuals here makes calculation of vaccine effectiveness and efficacy\(^{26}\) impossible. We summarize these data in Table 3.

Table 3. Summary statistics of vaccination status of each patient by HHS Region. UN refers to individuals with a status of “unknown” or “N/A”. $C|VS+,Y$ is the proportion of cases where the individual was vaccinated to the number of cases with a known vaccination status, expressed as a percent (previously defined in Table 2).

Figure 3. 2012-2013 flu season by HHS Region, indicated in boldface. Background color is represented by column $C|VS+,Y$ in Table 3 and genetic variation is represented in number of SNPs compared to strain vaccinated against.
Influenza B and H3N2 consisted of the bulk of cases for the 2012-2013 flu season. Region 1 had the most cases for H3N2 with n = 126 and showed an average variation of 20.4 ± 4.2 SNPs (51% nonsynonymous), while variation was largest in Region 5 with 28.7 ± 7.4 SNPs (45% nonsynonymous). For influenza B, the most cases and most variation, excluding Region 7 that had just two cases, was seen in Region 4, with an average of 96.3 ± 73.6 SNPs (23% nonsynonymous) for n = 28 cases and smallest in Region 6 with n = 27 cases and an average variation of 50.7 ± 39.3 SNPs (25% nonsynonymous). Genetic variation from the H1N1 strain vaccinated against was largest in Region 2 with n = 5 cases and an average of 29.6 ± 0.9 SNPs (41% nonsynonymous) and was smallest in Region 3 with an average of 25.7 ± 1.2 SNPs (47% nonsynonymous) in n = 3 cases. During this flu season the overall amount of nonsynonymous mutations for H1N1, H3N2, and influenza B were 46%, 49%, and 24%, respectively.

**Figure 4.** 2013-2014 flu season by HHS Region, indicated in boldface. Background color is represented by column C|VS+,Y in Table 3 and genetic variation is represented in number of SNPs compared to strain vaccinated against.

H1N1 was the predominant strain in our 2013-2014 flu season dataset. The most cases were in Region 6, with n = 66 cases and an average of 29.8 ± 2.2 SNPs (44% nonsynonymous) from the strain vaccinated against. Variation peaked for H1N1 in Region 3 with n = 4 cases and an average of 30.8 ± 2.8 SNPs and was smallest in Region 4 with an average of 28.8 ± 2.1 SNPs in n = 42 cases. Only Regions 3, 4, and 6 had any H3N2 cases, with n = 1, n = 2, and n = 3, respectively and only Regions 4, 6, and 9 had any influenza B cases with n = 2, n = 2, and n = 5, respectively. The average variation in Region 9 for influenza B was, on average, 153.2 ± 58.8 SNPs, 21% of which were nonsynonymous. During this flu season the overall amount of nonsynonymous mutations for H1N1, H3N2, and influenza B were 45%, 53%, and 21%, respectively.

In addition to the HA gene, some clinical records also contained GenBank accession IDs for each gene in the genome of the influenza specimen that infected the patient. For the 2012-2013 flu season, 134 of the 470 records contained an accession ID for the neuraminidase (NA) gene, another surface protein on influenza viruses in addition to HA. Three
of these records were from H1N1 cases, 129 were from H3N2 cases, and two were from influenza B cases. We also compared the NA strains with the corresponding NA reference sequences: NC_026434.1, KJ942682, and CY115185 for H1N1, H3N2, and B, respectively. Overall, H1N1 showed an average of 14.0 ± 1.0 SNPs (40% nonsynonymous), H3N2 showed 11.0 ± 3.9 SNPs (26% nonsynonymous), and influenza B showed 28.5 ± 2.1 SNPs (39% nonsynonymous) from their respective reference sequences. We did not further analyze the NA gene by HHS Region due to the limited samples.

Discussion

Our analysis has implications for a number of topics that overlap from both the public and clinical health perspective. For example, understanding trends in vaccination efficacy based on strain, emerging drug resistance, and patient drug response given their infection type are a few of many possible applications. However, making such inferences remain difficult given the lack of integration between clinical and viral genetic data. As seen in Figure 2, the genetic variation between cases and the strains vaccinated against was highest in the 2012-2013 influenza B cases and the 2013-2014 influenza A/H3N2 cases; however only seven cases exist for the latter, making the former, with 132 cases, a far more interesting sample. In Figure 3, we can see that influenza B variation is high per HHS Region (Region 1 had no influenza B cases for that season), which is consistent with the overall trend in high variation. Genetic variation among 2012-2013 A/H3N2 and 2013-2014 A/H1N1 cases was quite small, surprising given the large number of cases per year for those strains (n = 313 and n = 225, respectively). Unfortunately, 52.3% of all cases in the former (Table 2) had an unknown vaccination status, making it difficult to match a trend to these data. Reporting of vaccination status was greatly improved between the 2012-2013 and 2013-2014 flu seasons, with the percentage of unknown cases falling from 40.4% to just 6% between the seasons.

This improved reporting of vaccination status made it possible to reliably compare the statuses with genetic variation for the 2013-2014 season. As seen in Figure 4, the H1N1 virus has variation in the northern regions than in the southern ones, while no type B cases are observed in the northern regions, although data was sparse for this and the H3N2 viruses (Figure 1). Unfortunately, it is difficult to compare trends between the two seasons we analyzed because the reported number of cases per virus per year decreased drastically for H3N2 and B but increased drastically for H1N1, as seen in Figure 1. Regardless, the visualization of these trends indicate that perhaps a bold step such as regionalization of vaccines to better capture and protect against representative virus strains in circulation may prove beneficial to millions of individuals. We will consider this for future work, perhaps culminated by a meta-analysis of vaccination efforts, as completed by Osterholm et al. 16. This could be combined with a viral genetic analysis like we have shown here.

There are several notable amino acid changes in the HA gene that have shown to enhance transmissibility of H1N1 viruses, including the simultaneous 222G and 163E mutations27 as well as an independent 219K mutation28. None of these mutations were found in the samples from either flu season analyzed. A genetic motif (RERRRKKR) that has been linked to HA cleavage and a potential target for drugs against H5N1 influenza29 was an available column in the clinical metadata file but was generally left blank. No sequence was found to contain this motif, perhaps an indication that it is conserved within H5 viral clades. The analysis of the NA gene was also critical because the main pharmaceutical treatment of influenza, oseltamivir, is a neuraminidase inhibitor and several mutations in this gene have been shown to cause oseltamivir resistance, including 119V, 292K, and 274Y30. None of these mutations were observed in any of the 129 NA sequences. According to the CDC, oseltamivir resistance was seen in 0.7% (n = 687), 0.2% (n = 2,440), and 0.0% (n = 1,044) of tested H1N1, H3N2, and influenza B samples tested during the 2012-2013 flu season31. It is possible that our lack of similar findings is simply a result of the drastically smaller sample size.

The authors recognize several limitations of this study. These include the lack of control data that could have been used to measure true efficacy and effectiveness of the vaccines rather than our C|VS+,Y representation. This could have led to more confident assessments of potential regionalization of vaccine production. It is unknown whether control cases were intentionally excluded from these data sources or there were simply no control cases to report (i.e. no negative tests for influenza at the reporting clinics). Furthermore, the clinical data we obtained and used via IRD was hardly complete and many columns were entirely devoid of data. Examples of columns that were generally blank
included transmission properties such as “Increased Virulence” and “Enhanced Transmission to Human”, and pre-
visit and post-visit medications prescribed to the patients. While we were able to gather useful information from the
columns where data was entered, it shows that we were only able to represent a small portion of the potential of these
data. Having information about virus properties, particularly that of resistance, could have enabled us to
geographically visualize these trends as well, similar to Figures 3 and 4, but with perhaps more significance due to the
ever present concerns over enhanced mutation and transmissibility. Other limitations include the aforementioned lack
of specific information regarding vaccine contents, forcing the use of a random HA sample for each of the strains
vaccinated against. Data regarding where the patients were vaccinated and the specific vaccine that they received
would have been invaluable for geographic accuracy and reliability of this study. Patient symptoms were listed for
nearly every case, but we did not explore possible ways to capture severity of the cases based on these symptoms.

An innovative combination of viral genetic data with clinical records would certainly fall under the umbrella of the
Precision Medicine Initiative32, especially in relation to resistance of oseltamivir and other antiviral drugs. If these
clinical records were outfitted with human genomic data as well as the viral sequences, it could highlight biomarkers,
genes, and SNPs associated with susceptibility to antiviral resistance. This would not strictly be limited to influenza
surveillance and could easily apply to concerning clinical bacterial infections like methicillin-resistant Staphylococcus
aureus (MRSA) or emerging zoonotic pathogens like Middle East respiratory syndrome coronavirus (MERS-CoV).
While this paper constituted a review of one application of linking clinical records with genetics of an infectious agent,
the potential for an innovative informatics pipeline to identify medication-resistant motifs and associate them with
clinical symptoms, human genomic markers, and geography is a challenge yet to be adequately addressed. In order
for this to occur, however, it appears that more clinics would need to be willing to begin outfitting their records with
links to pathogen DNA.

In this study, we demonstrate the value of integrating clinical data with viral genetics. While most clinical
microbiology laboratories do not have the financial or personnel resources to generate full genomic viral sequences
for each clinical case, our work highlights the usefulness of how even a sample of cases can provide valuable insight
into geographic disparities to seasonal epidemics and vaccination effectiveness. While our geographic representations
are not unlike FluView by the CDC33, we have shown that individual clinics or research labs could create such maps
in real time as sequences become available. Clinics should be interested in these types of reports because data
demonstrating a differentiated diffusion of strains with particular mutations that are indicated for antiviral resistance
could inform physicians of optimal treatments. Furthermore, these data could show expected trends in viral properties
among patients entering the health centers with acute respiratory illnesses, increasing efficacy of care and reducing
healthcare costs to both the individuals and clinics. While ultimately the integration of human genomic data into health
records remains the ideal gold standard, accomplishing an additional step like the incorporation of virulence could
prove to be a valuable resource for reducing morbidity and mortality and improving overall public health and
biosurveillance of infectious diseases.

Exploration of Temporal ICD Coding Bias Related to Acute Diabetic Conditions

Mollie McKillop, M.P.H., Fernanda Polubriaginof, M.D., Chunhua Weng, Ph.D.
Department of Biomedical Informatics, Columbia University, New York, NY, USA

Abstract
Electronic Health Records (EHRs) hold great promise for secondary data reuse but have been reported to contain severe biases. The temporal characteristics of coding biases remain unclear. This study used a survival analysis approach to reveal temporal bias trends for coding acute diabetic conditions among 268 diabetes patients. For glucose-controlled ketoacidosis patients we found it took an average of 7.5 months for the incorrect code to be removed, while for glucose-controlled hypoglycemic patients it took an average of 9 months. We also examined blood glucose lab values and performed a case review to confirm the validity of our findings. We discuss the implications of our findings and propose future work.

1.0 Introduction
Administrative data, namely ICD (International Classification of Diseases) codes, have been widely used to identify disease specific cohorts of patients\textsuperscript{1,2}. Such codes are often used in clinical and health services research because they are easy to obtain, have low associated costs, and can be aggregated to form large study samples. The accuracy of study results derived from administrative data depends on how well a particular coding scheme can correctly describe a disease cohort of interest. It is especially important to document coding biases as EHRs become more widely adopted and relied upon for large-scale data reuse. Increasingly, EHRs are used to document macroscopic human conditions, or phenotypes, automatically feeding data for secondary re-use purposes such as clinical research, quality improvement, and public health initiatives\textsuperscript{3}. Such uses require high-quality data, which are often lacking in the EHR. Coding bias is important to document and characterize for diabetes, which is an increasingly prevalent disease and is a major source of morbidity and mortality. It is a leading cause of blindness, end-stage renal disease and cardiovascular disease and is associated with high healthcare costs\textsuperscript{4}. Coding bias related to complications of diabetes, specifically ketoacidosis and hypoglycemia, are particularly important to understand because they are acute, life-threatening conditions that require hospitalization. Accurate results from studies using the EHR to phenotype these patients must be aware of any coding bias related to these conditions.

The validity of ICD-codes for identifying patient groups has been challenged many times before and for a variety of conditions\textsuperscript{5,6}. These studies have shown that ICD codes are biased because concept definitions for codes are incomplete or are unsatisfactory in granularity. Moreover, variability in coding behavior also leads to incorrect code assignment. Researchers have previously questioned the validity and generalizability of ICD codes as applied to diabetes\textsuperscript{7,8}. However, these studies have not examined coding bias among complications of diabetes and uncontrolled glucose levels. To date, we could only find two studies that examined coding bias associated with ketoacidosis. They are small in scale and focus on data captured before 2009\textsuperscript{9,10}. We seek to build upon this work by validating these results and examining bias among a larger, more diverse, more recently treated population of patients. We also seek to report coding bias related to hypoglycemia, which to our knowledge has not previously been documented. Recognizing that human phenotypes are time-dependent, we aim to describe the temporal bias associated with ketoacidosis and hypoglycemia ICD-9 codes. Previous research has neglected the dynamic nature of such phenotypes when examining coding bias. Temporal bias is important to understand for accurate phenotyping and the full-realization of purported EHR benefits.

This study uses acute complications of diabetes and uncontrolled glucose as examples to investigate the temporality of ICD coding bias. Specifically, we ask the question, “do patients, who are initially coded for ketoacidosis or hypoglycemia, remain coded as such, despite controlling their glucose levels?” In other words, we hypothesize that patients who initially receive an ICD-9 code assignment for either ketoacidosis or hypoglycemia continue to be assigned these codes, despite little clinical evidence that such code assignment is reasonable. We examine the extent of this bias over time by using survival analysis to determine the time it takes, on average, for patients to have the incorrect code removed from their personal EHR. We also examine this bias for different disease subgroups (Type 1 versus Type 2) and among glucose-controlled and uncontrolled patients. Finally, we hope to describe our method in enough detail to allow other researchers to replicate our findings and test the strength of our conclusions by examining temporal coding bias among other acute conditions. This study was performed in compliance with the.
World Medical Association Declaration of Helsinki on Ethical Principles for Medical Research Involving Human Subjects and was approved by the Columbia University Medical Center Institutional Review Board.

2.0 Methods
2.1 Data description and processing

For our study we utilized the Columbia University Medical Center Clinical Data Warehouse (CDW), which contains 24 years of data on 4.5 million patients\(^1\). Data were extracted in a multi-step process as depicted in Figure 1 to generate our cohort for analysis. First, relevant ICD-9 codes were identified using the Center for Medicare and Medicaid (CMS) ICD-9 Code Lookup\(^1\). The relevant codes are listed in Table 1. All instances of these codes from 2004 to October 2014 along with corresponding fake patient-identification numbers and real timestamps for each code were extracted. This resulted in 4844 unique patients, 2242 with ketoacidosis and 2602 with hypoglycemia. Along with the ICD-9 codes, all HgA1c lab values for these patients along with fake patient IDs and real timestamps were generated from the CDW. Lab values occurring after the initial coding of ketoacidosis or hypoglycemia were selected. Patients were then separated by ketoacidosis and hypoglycemia. After selecting only the lab values occurring after the initial coding for ketoacidosis, 1309 patients were retained; after selecting only the lab values occurring after the initial coding for hypoglycemia, 1129 patients remained. In the ketoacidosis subgroup, 112 patients were selected for analysis based on having controlled glucose levels, which was defined as having a median HgA1c lab value less than 7, a threshold recommended by the American Diabetes Association\(^1\). In the hypoglycemia group, 156 patients were selected for analysis based on having a similarly defined controlled glucose level.

2.2 Data analysis
Survival analysis was performed separately on the remaining 112 ketoacidosis and 156 hypoglycemia observations to determine the probability of remaining coded for ketoacidosis or hypoglycemia, despite having controlled glucose levels. Survival analysis was chosen as the statistical method for analysis because it allows for the time to an event to be computed. In this case, the event was decoding of a glucose-controlled patient. For the ketoacidosis group, the granularity of the ICD-9 codes allowed us to further explore any coding bias among disease subgroups.

First, individuals who were identified as Type 1 or Type 2 ketoacidosis patients by ICD-9 codes had their time to decoding compared and assessed for statistical significance using a cox proportional hazards test. Second, individuals who were identified as uncontrolled or controlled ketoacidosis patients by ICD-9 codes had their time to decoding compared and assessed for statistical significance again using a cox proportional hazard test. Because HgA1c lab tests measure a patient’s average glucose level over several weeks, we looked at the blood glucose lab tests 14 days before any ICD-9 code timestamp after the first ICD-9 code assignment. This time frame was chosen based on administrative timetables, since reimbursement claims are generally submitted within two weeks of any services or procedures provided. Also, the ICD-9 timestamp represents the discharge date. Considering the acute nature of the diseases under study, we felt this was an adequate time frame to select blood glucose lab results from.

The blood glucose test was selected because it provides a way to characterize patients as either in a state of hypoglycemia or ketoacidosis. According to UpToDate, a blood glucose serum level over 350 can be used to diagnose ketoacidosis\(^1\) while a blood glucose serum level under 40 can be used to diagnose hypoglycemia\(^1\).
blood glucose lab values were extracted from the CDW using the Medical Entities Dictionary, which is a large repository of medical concepts that are drawn from a variety of sources either developed or used at NYP. For each patient, the mean and median percentage of times these blood glucose lab values indicated disease for either the ketoacidosis or the hypoglycemia group was calculated. The analysis was performed using Rstudio version 0.98.1091. The datasets and R code are available for public use by contacting the primary author (MM).

Finally, a case review of deceased patient notes for both the ketoacidosis group and the hypoglycemia group was performed by a physician (FP) to further examine the validity of our results and perform an error analysis. Since patients were selected from groups dependent upon ICD-9 code assignment, the clinical reviewer provided a comprehensive chart review of the deceased patient notes from both the ketoacidosis and hypoglycemia group. The main purpose of this review was to contribute to an error analysis and provide a definitive “gold standard” of whether the patient had ketoacidosis or hypoglycemia. The Annals of Emergency Medicine guidelines for chart review were followed as much as possible. The participating reviewer (FP) is a clinician and knew the purpose of the study but not the study’s full outcome. The variables to be collected from the chart, as well as how these variables are defined, were determined prior to and documented for the coder. Variables were selected using UptoDate Guidelines to construct coding rules. Once a positive diagnosis based on the coded variables was determined by the reviewer, no further case review for that patient was performed. Overall, the reviewer examined 5 ketoacidosis patients and 13 hypoglycemic patients.

3.0 Results
3.1 Descriptive statistics
In total there were 112 patients in the ketoacidosis group and 156 patients in the hypoglycemia group. All patients that occurred in the ketoacidosis group also occurred in the hypoglycemia group. In the ketoacidosis group, there were a median of 5 HgA1c lab values per patient with a minimum of 1 and a maximum of 40. In the hypoglycemia group, there were a median of 10 HgA1c lab values per patient with a minimum of 2 and a maximum of 203. The trend in HgA1c lab values over time by patient for the ketoacidosis group (left) and hypoglycemia group (right) is shown in Figure 2.

![Figure 2](image-url)

**Figure 2.** HgA1c linear trend for ketoacidosis patients (left) and hypoglycemia patients (right). Each line represents a unique patient and colors are used to help distinguish different lines. Horizontal axis is sequential order of HgA1c lab tests; Vertical axis is HgA1c lab value.

A generalized estimating equation, assuming data were missing completely at random, was fit for the ketoacidosis and hypoglycemia groups separately to test for significant linear trend associations between HgA1c and time. The hypoglycemia group was found to have a significant association (p-value = 0.0045) while the ketoacidosis did not have such an association (p-value = 0.11). Both tests had a negative coefficient. In the ketoacidosis group, there were a median of 15.5 ICD-9 code assignments per patient with a minimum of 1 and a maximum of 211. In the hypoglycemia group, there were a median of 10 ICD-9 code assignments per patient with a minimum of 2 and a maximum of 203. Among the ketoacidosis group split by diabetes type as determined by ICD-9 codes, there were 39 Type 1 patients and 73 Type 2 patients. Among the ketoacidosis group split by uncontrolled versus controlled diabetes type as determined by ICD-9 codes and not median HgA1c lab values, there were 53 ‘not stated as uncontrolled’ patients and 59 ‘uncontrolled’ patients.

3.2 Survival analysis for the ketoacidosis group
The Kaplan-Meier survival curve for the 112 observations is shown in Figure 3. Time was recorded in 3-month intervals to reflect national guidelines for diabetes screening. According to the survival curve, it takes approximately 7.5 months for 50% of patients, who were initially coded for ketoacidosis and have their glucose in control, to stop being assigned any of the four ICD-9 codes listed in Table 1.

![Survival Curve for all Patients](image)

**Figure 3.** Kaplan-Meier survival curve for all ketoacidosis patients. Time is in 3-month intervals. Dashed lines represent confidence intervals for the survival curve.

A cox-proportional hazard test was performed to determine if significant differences existed between any of the four ICD-9 codes. This test was found to be significant at a level of .01 (p-value=0.00538), indicating at least one of the ICD-9 code survival curves is different from the others. This difference was examined further by separating the population into different groups based on diabetes type and 'uncontrolled' versus 'not stated as uncontrolled' ICD-9 code assignment. The survival curves for Type 1 and Type 2 diabetes are displayed in Figure 4. These curves were not significantly different from each other at a level of .05 (p-value=0.316) using the cox-proportional hazards test.

![Survival Curve of 'Type1' vs. 'Type2'](image)

**Figure 4.** Kaplan-Meier survival curve for ketoacidosis patients by diabetes type. Time is in 3-month intervals. The blue curve represents Type 1 diabetics and green curve represents Type 2 diabetics.

A third cox-proportional hazard test determined a significant difference (p-value=.00821) at a level of .01 between the Kaplan-Meier survival curves of patients coded for ‘uncontrolled’ (ICD-9 codes 250.12 and 250.13) versus
patients coded for ‘not stated as uncontrolled’ (ICD-9 codes 250.10 and 250.11). The survival curves are displayed in Figure 5 and indicate patients coded for ‘not stated as uncontrolled ketoacidosis’ (blue line) are decoded from any ketoacidosis ICD-9 code 25.1% faster than patients coded for ‘uncontrolled ketoacidosis’ (green line).

Figure 5. Kaplan-Meier survival curve for ketoacidosis patients by ICD-9 code assignment for ‘Not Stated as Uncontrolled’ (ICD-9 codes 250.10 and 250.11) vs. ‘Uncontrolled’ (ICD-9 codes 250.12 and 250.13). Time is in 3-month intervals. The blue curve is for ‘Not Stated as Uncontrolled’ diabetics and the green curve is for ‘Uncontrolled’ diabetics.

3.3 Glucose lab value assessment for the ketoacidosis group

Patients were selected from those that had one or more ICD-9 code assignments for ketoacidosis after the initial coding for the disease. The glucose lab tests occurring 14 days before any ICD-9 code timestamp, except the first timestamp, were selected and assessed for positive indication of ketoacidosis based on a blood glucose cutoff level of 350 mg/dL as determined by UpToDate\(^4\). Only 90 out of the 112 patients had blood glucose labs occurring 14 days before the ICD code timestamp values under consideration. Positive disease indications were assigned a value of one and tabulated by patient. The mean number of positive disease indications was 210 with a median of 195, while the median percentage of positive disease indications was 6.33% of all blood glucose lab tests per patient. The mean percentage of positive disease indications over the number of blood glucose labs was calculated per patient and the distribution is shown in Figure 6.

Figure 6. Distribution of mean positive ketoacidosis indication by sequential ICD code assignments.
3.4 Survival analysis for the hypoglycemia group
The Kaplan-Meier survival curve for the 156 hypoglycemia patients is shown in Figure 7. Time was recorded in 3-month intervals to reflect national guidelines for diabetes screening. According to the survival curve, it takes 9 months for 50% of patients, who were initially coded for hypoglycemia and have their glucose in control, to stop being assigned any of the ICD-9 codes for ketoacidosis. Unfortunately, no further survival analysis of hypoglycemia subgroups could be performed due to the limited granularity of ICD-9 codes in this category.

![Kaplan-Meier survival curve](image)

**Figure 7.** Kaplan-Meier survival curve for all hypoglycemia patients. Time is in 3-month intervals. Dashed lines represent confidence intervals for the survival curve.

3.5 Glucose lab value analysis for the hypoglycemic group
Patients were selected from those that had one or more ICD-9 code assignments for hypoglycemia after the initial coding for the disease. The glucose lab tests occurring 14 days before any ICD-9 code timestamp, except this first timestamp, were selected and assessed for positive indication of hypoglycemia based on a blood glucose cutoff level of 40 mg/dL as determined by UpToDate. Only 33 out of the 156 patients had blood glucose labs occurring 14 days before the ICD code timestamp values under consideration. Positive indications were assigned a value of one and tabulated by patient. The mean number of positive disease indications was 120 with a median of 109, while the mean percentage was .8977% and the median percentage was 0%. The percentage of positive disease indications over the number of blood glucose labs was calculated per patient and the distribution is shown in Figure 8.
4.0 Discussion

4.1 Major Implications

The results of this study seem to suggest a coding bias related to ICD-9 ketoacidosis and hypoglycemia codes. It appears that those who are initially coded for ketoacidosis or hypoglycemia continue to be coded as such despite having their glucose levels in control, as indicated by median HgA1c lab values. This finding is also supported by the low median percentage of blood glucose lab tests indicating disease for the ketoacidosis group (6.33%) and the hypoglycemia group (0%). More importantly, this study examines the temporal nature of such coding bias. Because ketoacidosis and hypoglycemia are conditions that last several hours to days, our results show the extent of this bias seems severe when the temporality of coding behavior is considered. This bias persists when diabetes type and control, as determined by ICD-9 codes, are examined. For example, patients that are ICD-9 coded for ‘uncontrolled diabetes, ketoacidosis’ and have controlled glucose levels (as determined by HgA1c lab tests) have their inaccurate code removed 79.9% slower than the same patients coded for ‘not stated as uncontrolled diabetes, ketoacidosis’. This makes clinical sense considering those that have uncontrolled diabetes have a higher probability for ketoacidosis, a complication related to poor glucose control. With regard to hypoglycemia, temporal coding bias seems to remain and the effect is even stronger than in the ketoacidosis group. This may be due to differing disease severity in that hypoglycemia is a less severe disease than ketoacidosis, so more people are likely to be coded for its presence. However, it remains unclear why patients, who have lab values indicating their glucose is already controlled, continued to receive hypoglycemia codes. We hypothesize that because hypoglycemia is a less severe and a less formally defined disease than ketoacidosis, it is easier to interpret this diagnosis from patient notes and lab values. This allows for coders to more frequently assign hypoglycemia ICD-9 codes. Our findings are similar to previous studies that found ICD-9 coding bias among ketoacidosis patients. Moreover our results imply a potential overestimation of disease prevalence if ICD-9 codes are used solely to identify a ketoacidosis or hypoglycemia cohort.

4.2 Error analysis

In the ketoacidosis group all 5 patients were positively identified by manual case review as having ketoacidosis. In the hypoglycemia group, 5 patients did not have notes at any point two weeks before the first ICD code assignment, leaving 8 code assignments for our error analysis. It remains unknown as to why these notes are missing. Of these 8 assignments, 7 were confirmed as correct (patients had hypoglycemia) with the remaining incorrect code due to a patient having normal glucose levels. Major sources of error therefore include patients with normal glucose being coded for hypoglycemia as well as no clinical basis for code assignment, since no notes existed for several patients.

In addition to the error analysis, we also identified deceased patients who had repeated ICD-9 code assignments for their particular disease group. The purpose of this assessment was to see if repeated ICD-9 code assignments were
valid. Only one patient fit this description in the ketoacidosis group. In a case review performed in the same manner as the error analysis, the patient was identified as having normal glucose. In the hypoglycemia group, all 13 patients had repeated ICD-9 code assignments, with a total of 16 repeated assignments (one patient had 4 repeated assignments after the first assignment, while the rest of the patients had one). This analysis revealed that 8 of these ICD code assignments were missing all notes two weeks before the code assignment. Of the 8 remaining code assignments, 6 of these were found to be correct through case review of patients’ notes. The other two assignments for hypoglycemia were assigned to patients with normal glucose.

The survival analysis and mean blood glucose results along with the case review suggest a semantic gap between the physicians who author such notes and the coders who ultimately assign ICD-9 codes. The physician’s concept of the patient must be encoded in the patient notes and then from this computable representation the coder must form a concept of an ICD-9 code. In this process it appears that clinical information is lost or misunderstood. Either the concept is not encoded (i.e. no notes are present two weeks before a code assignment) or the concept is semantically altered once present in the EHR. The coding bias we describe could be partially explained by the over-use of copy-pasted text, which appeared multiple times in each of the case-reviewed patient notes. Finally, economic incentives for incorrectly coding patients should also be considered and further studied as a potential source of coding bias.

4.3 Limitations

This study has several limitations. First, the sample size of 112 ketoacidosis patients and 156 hypoglycemia patients is relatively small, and larger studies could reveal interesting differences in ketoacidosis coding between Type 1 and Type 2 patients. Moreover a larger dataset could allow for more complex measures of glucose control. Because the median number of HgA1c lab tests performed was only 5 for the ketoacidosis group, more sophisticated approaches, such as time series analysis, that can measure trends in glycemic control were unfeasible. Moreover, our goal was not to model HgA1c trends but to characterize a group of patients with reasonably well-controlled glucose levels. Therefore, median HgA1c lab values were used as a measure for glucose management. However, we feel this is a reasonable assessment of glucose control in relation to the acute complications we are exploring. Finally, it should be noted that all HgA1c measurements were collected observationally, and that there may be high variability in measurement quality.

In addition, it is possible our findings are due to repeated hospitalizations for patients who do in fact have either hypoglycemia or ketoacidosis, yet this seems unlikely given the low median percentage of glucose blood tests indicating either disease and the follow up we performed in our error analysis. Finally, the two groups of patients are not independent from each other, in that all ketoacidosis patients are also represented in the hypoglycemia group. This limits the generalizability of our findings to other patient groups.

Importantly, there may be outliers influencing the results of our analysis, as is implied by the relatively large difference between the number of maximum ICD-9 code assignments and median number of ICD-9 code assignments for both the ketoacidosis group and the hypoglycemia group. We did do a visual evaluation to identify these points, plotting the patient id against the number of ICD code assignments for both disease groups. There appeared to be two outliers among the ketoacidosis group and another two outliers in the hypoglycemia group. We did not remove these outliers since our aim was exploratory in nature and there appeared to be few outliers. In addition, we do not wish to propose a mathematical model for temporal coding bias but rather to prove the feasibility of a method for exploring this phenomenon. More robust and larger datasets could aid in determining why such outliers might exist.

Only 18 deceased patients’ records (5 in the ketoacidosis group and 13 in the hypoglycemia group) were reviewed. These patients may not represent each disease group accurately. Because only deceased patients’ notes were used for the error analysis, bias may be introduced by selecting patients who are perhaps more likely to die, and therefore more sick, than other patients. However, we feel this bias is limited, since its presence would shift our results toward concluding that there is less coding bias (as it is more likely that coders would assign ICD-9 ketoacidosis and hypoglycemia diagnosis codes). On the other hand, these patients may be so sick that coders fail to identify ketoacidosis and hypoglycemia as the patient’s primary reason for hospital visit in favor of codes representing more serious diagnoses. Yet, ketoacidosis and hypoglycemia are very serious life-threatening conditions that would probably outrank most other diseases in terms of prominence and importance during a hospital visit.

Finally, the numeric results of this study are probably not generalizable to other settings, because decoding of ketoacidosis could be due to either the coder stopping ketoacidosis code assignment or, perhaps more likely, the patient not returning to the New York-Presbyterian Hospital for care. In either case, the extent of this bias would alter our results in the direction of less temporal coding bias.
4.4 Future work

Future work should try to examine the reasons for the documentation discrepancies between physicians and coders as well as any financial motivations coders might have for assigning incorrect codes. Physicians could try to be more consistent in their terminology and use less copy-pasted text, so that coders have a clearer representation of the ketoacidosis and hypoglycemia concept. Coders and physicians could be better educated on the importance of communicating and picking accurate ICD-9 codes. In addition, more research should be done to develop accurate and automated methods of ICD-9 code assignment, which could overcome the coding discrepancies between physician and coder. This study also reveals challenges in secondary reuse of clinical data for research purposes. More relevant organization of clinical data would allow for easier data analysis and increase research efficiency. For example, this could occur through front-end applications that allow users to view, sort and analyze clinical data.

Conclusion

The results of this study indicate that temporal coding bias is a problem among patients with acute complications related to poor glucose control. This bias is significantly different between those coded as ‘not stated as uncontrolled’ vs. ‘uncontrolled’ with ICD-9 ketoacidosis codes and occurs among two different acute complications, i.e., ketoacidosis and hypoglycemia. A case review of patients’ notes further confirmed this bias. We also contribute a novel method for coding bias research related to acute diseases. Understating such bias is increasingly important as the EHR becomes more widely used for phenotyping and cohort selection. Future work should have a socio-technical approach, evaluating how these biases arise. Specifically, the coding discrepancies between physicians and coders should be further explored and documented.

Abstract

Objective: In a previous study, we investigated a sentence classification model that uses semantic features to extract clinically useful sentences from UpToDate, a synthesized clinical evidence resource. In the present study, we assess the generalizability of the sentence classifier to Medline abstracts.

Methods: We applied the classification model to an independent gold standard of high quality clinical studies from Medline. Then, the classifier trained on UpToDate sentences was optimized by re-retraining the classifier with Medline abstracts and adding a sentence location feature.

Results: The previous classifier yielded an F-measure of 58% on Medline versus 67% on UpToDate. Re-training the classifier on Medline improved F-measure to 68%; and to 76% (p<0.01) after adding the sentence location feature.

Conclusions: The classifier’s model and input features generalized to Medline abstracts, but the classifier needed to be retrained on Medline to achieve equivalent performance. Sentence location provided additional contribution to the overall classification performance.

Introduction

Most clinical questions raised by clinicians in the course of patient care can be answered by online primary literature resources, such as Medline. However, there are critical barriers to the use of the primarily literature at the point of care. Specifically, clinicians need to search, screen, appraise, and integrate literature findings into their decision making for a particular patient. This process is labor intensive and not compatible with busy clinical workflows. Several approaches have been pursued to improve efficient consumption of the primary literature, including improvements in the search process, question and answering systems, and automatic summarization of Medline abstracts and full-text articles. Despite substantial progress in these approaches, recent studies still show that clinicians prefer distilled recommendations in the form of guidelines and evidence summaries.

Significant effort has been dedicated to automatic biomedical text summarization. Yet, most previous studies aimed at generating summaries that resemble article abstracts written by study authors. However, article abstracts are written to summarize all elements of a study, such as purpose, methods, results, and conclusions. On the other hand, for patient care decision making, clinicians prefer sentences that provide patient-specific, actionable recommendations for a particular intervention as opposed to general background and study methods. For example, the sentence “Apixaban 2.5 mg twice daily, starting on the morning after total knee replacement, offers a convenient and more effective orally administered alternative to 40 mg per day enoxaparin, without increased bleeding” provides an actionable treatment finding for patients who undergo total knee replacement. Specific methods are needed for extracting clinically useful sentences from clinical studies.

In a previous study we developed a feature-rich classification model for extracting clinically useful sentences from synthesized evidence resources, such as UpToDate. The study was based on 4,824 sentences from 18 UpToDate documents on the treatment of six chronic conditions: coronary artery disease, hypertension, depression, heart failure, diabetes mellitus, and prostate cancer. In the present study, we attempt to apply the sentence classifier to the primary literature. Specifically, the study has two main goals: (1) to assess the generalizability of the feature-rich
classifier on extracting clinically actionable statements from PubMed abstracts; and (2) to assess if optimization of
the classifier for PubMed abstracts results in improved classification accuracy.

Background and Significance

In a previous study we designed and assessed a method for extracting clinically useful sentences from synthesized
online clinical resources. The method’s underlying assumption is that clinically useful sentences are actionable
statements that provide a specific recommendation for an intervention (e.g., medication treatment) that should be
employed with a specific patient population. To capture these characteristics, the method uses three sets of semantic
features from the PubMed abstracts. The method consists of a Kernel-based Bayes Network classification model
with Gaussian kernel density estimators that classifies each sentence as clinically useful or not. As shown in
previous research, the Kernel-based Bayesian Network is robust to highly imbalanced datasets such as the one used
in this paper. This classifier is a Bayesian Network that estimates the true density of the continuous variables
using kernels, which are weighting functions used to estimate random variables’ density function. The classifier is
based on three domain-specific feature types extracted from UpToDate sentences: 1) treatment-related UMLS
concepts and their semantic groups; 2) semantic predications; and 3) patient population. A summary of these
features is provided below.

The first set of features consists of treatment-related UMLS concepts, and their corresponding semantic groups,
extracted from sentences using MedTagger, which is an extension of the cTAKES natural language processing
(NLP) pipeline. The UMLS semantic group of each concept was obtained, leading to four features according to the
following semantic groups: Chemicals & Drugs (CHEM), procedures (PROC), physiology (PHYS), and disorders
(DISO).

Semantic predications are relations that consist of a subject, a predicate, and an object. The sentence classifier uses
treatment-related predications extracted by SemRep, a semantic NLP parser that uses underspecified syntactic
analysis and structured domain knowledge from the UMLS. Six types of predications were extracted as features: TREATS/NEG_TREATS,
ADMINISTERED_TO /NEG_ADMINISTERED_TO, AFFECTS/NEG_AFFECTS, PROCESS_OF /
NEG_PROCESS_OF, PREVENTS / NEG_PREVENTS, and COMPARED_WITH / HIGHER_THAN /
LOWER_THAN / SAME_A. For instance, from the sentence below:

> Adding corticosteroid injection to conventional treatment in hemiplegic shoulder pain improved shoulder range of
motion and decreased pain scores before treatment to the first and fourth weeks of treatment.

SemRep produces the following output:

  Shoulder Pain PROCESS_OF Hemiplegics
  Injection procedure TREATS Shoulder Pain
  Adrenal Cortex Hormones TREATS Shoulder Pain

which yields the following features:

  Total number of predications: 3
  PROCESS_OF instances: 1
  TREATS instances: 2

Finally, patient population determines whether a sentence includes a description of the types of patients who are
eligible to receive a certain treatment based on a pattern-based method. This produced one binary feature, which
indicates whether a sentence describes the target population or not. The method uses the Stanford lexical parser
and Tregex. The Tregex patterns are similar to regular expressions, but more advanced in extracting patterns such
as a noun phrase with two consecutive prepositional phrases, a verb phrase with two consecutive prepositional
phrases, and a noun phrase preceding a subordinating conjunction. For example, in the following sentence the
population extraction algorithm identifies that the sentence includes a target population (“patients with advanced
NSCLC),

> The addition of vandetanib to docetaxel provides a significant improvement in PFS in patients with advanced
NSCLC after progression following first-line therapy.”
In the present study, we test the generalizability of the described feature-rich sentence classifier to the primary literature and whether optimization of the sentence classifier results in performance gains.

**Methods**

The study methods consisted of the following steps: 1) development of a gold standard of clinically useful sentences from PubMed abstracts; 2) extraction of the three feature categories (i.e., concept, predication and population features) for sentence classification; 3) optimization of the sentence classifier to identify clinically useful sentences from PubMed abstracts; and 4) assessment of classifier performance.

All features for our sentence feature-rich sentence classifier in different experiments are summarized in Table 1. Specifically, these are the inputs for the Kernel-based Bayes Network classification model with Gaussian kernel.

**Gold Standard.** The gold standard consisted of 2,146 sentences from 140 PubMed abstracts that were randomly selected from 34,913 PubMed citations of high quality clinical studies published between January 2010 and October 2014. We focused on high quality clinical studies because they are likely to be more useful for patient care decision making. Citation quality was determined using the classifier developed by Kilicoglu et al.\(^4\) Sentences from the selected citations were retrieved from the SemanticMedline database, which contains sentences, and their semantic predications, extracted from all abstracts in Medline\(^25\).

For structured PubMed abstracts, we found that the gold standard contained clinically useful sentences only in the conclusion and results sections. Thus, we excluded all the sentences that were not in these sections. This filtering was done using the NlmCategory tag of the Medline citations in XML format, which provides standard section categories (e.g., METHODS, RESULTS, CONCLUSIONS) for abstracts that are written in a structured format. For unstructured abstracts, we included all sentences. As a result, the dataset was narrowed to 954 sentences from 124 structured abstracts and all 118 sentences from 16 unstructured abstracts (i.e., total of 1,072 sentences).

Next, the sentences in the gold standard were rated by one of the study authors (GDF) according to a validated clinical usefulness scale (Table 2), which was slightly adapted from one of our previous studies\(^26\). Sentences are rated from 1 to 4, with 4 being the most useful. The core principle of this scale is that clinically useful sentences follow the PICO format, i.e. sentences that define the study patient population, the intervention under investigation, the comparison (e.g., placebo), and the study outcome. The PICO format has been recommended to clinicians for formulating well-structured clinical questions and has been applied in several biomedical information retrieval studies\(^8,27,29\).

</tr>
</tbody>
</table>

The final dataset is available online for the research community. The distribution of sentences according to their ratings is shown in Table 3.

**Optimization strategies.** To optimize the feature rich classifier based on PubMed abstracts, two strategies were employed. First, the feature-rich classifier was re-trained on PubMed abstracts (instead of UpToDate documents) using the same features identified in our previous study. Second, sentence location was included as an additional feature to the sentence classifier. The location feature was extracted from structured abstracts using the NlmCategory tag of Medline citations in XML format. The possible values for the location feature were Conclusions or Results for structured abstracts, and Unknown, for unstructured abstracts.

**Assessment of classification performance.** We conducted three experiments to test the following hypotheses:

Hypothesis 1: The feature-rich classifier trained on UpToDate sentences has comparable performance on the primary literature. To test this hypothesis, we compared the performance of the sentence classifier when applied to the original UpToDate dataset versus Medline sentences. The goal was to assess the generalizability of the sentence classifier to the primary literature.

Hypothesis 2: Re-training the feature-rich classifier on the primary literature improves performance compared to the original classifier. To test this hypothesis, we assessed the performance of the feature-rich classifier trained on Medline sentences compared to the original classifier, which was trained on UpToDate sentences. Also, the enriched feature-rich classifier was compared to a baseline classifier where all sentences in the Conclusion section of structured abstracts and the last 10% of the sentences in unstructured abstracts were labeled as clinically useful (i.e., positive class).

Hypothesis 3: Adding sentence location to the feature-rich classifier improves its performance on the primary literature. To test this hypothesis, we compared the performance of the re-trained feature-rich classifier enriched with a sentence location feature versus the re-trained classifier without sentence location.

Experiment procedures. Ordinal ratings were converted into binary values: sentences rated as “4” were considered as the positive class (i.e., clinically useful sentences) and the remaining sentences were considered as the negative class. As a result, 89% of the sentences in the gold standard were labeled as positive. This distribution is similar to the sentences in the UpToDate dataset, with 87% positive sentences.

For the first hypothesis the feature-rich classifier was trained on 4,824 UpToDate sentences from our previous study, and then tested on 1,072 Medline sentences. For the second and third hypotheses we employed a 20-fold cross-validation strategy with each fold containing 7 abstracts.

Finally, classification performance was measured according to the average precision, recall, and F-measure across the 20 folds. F-measure was defined a priori as the primary outcome for hypotheses testing. For statistical significance test of all experiments, first we applied the Friedman’s test to verify differences among multiple classifiers. If significant at an alpha of 0.05, pairwise comparisons were made with the Wilcoxon Signed-Rank test. This statistical approach is aligned with the method recommended by Demsar.

Results

Similar to UpToDate sentences, descriptive statistics of the sentences and features in the Medline gold standard show that all feature types were correlated with useful sentences.

Hypothesis #1: The feature-rich classifier trained on UpToDate sentences has comparable performance on the primary literature. The F-measure for the feature-rich sentence classifier on the Medline dataset was 58% versus 67% on UpToDate (p<0.01) (Figure 1).

Hypothesis #2: Re-training the feature-rich classifier on the primary literature improves performance compared to the original classifier. The re-trained feature-rich classifier performed significantly better than the original classifier on Medline sentences and the baseline (F-measure = 68% versus 58% and 45% respectively; p<0.001 for both comparisons) (Figure 2). Moreover, the performance of the re-trained feature-rich classifier on Medline abstracts was comparable to the performance of the feature-rich classifier on UpToDate sentences (F-measure = 68% versus 67%; p=0.53).
Hypothesis #3: Adding sentence location to the feature-rich classifier improves its performance on the primary literature. As seen in Figure 3, adding the location feature further improved the classifier performance (F-measure = 76% versus 68%, p<0.01).

Discussion

This study investigated an automated method for extracting clinically useful sentences from primary literature resources such as Medline. To achieve this goal, we employed and adapted a feature-rich sentence classification model developed in a previous study. Such a method can be used in clinical decision support tools that use automatic summarization to help clinicians integrate findings from the primary literature into their decision making routine. We are currently integrating the optimized sentence classifier into one of these tools, known as the Clinical Knowledge Summary (CKS)\textsuperscript{31, 32}. The CKS automatically summarizes patient-specific evidence from multiple resources and can be integrated with electronic health record (EHR) systems through the Health Level Seven (HL7) Context-Aware Knowledge Retrieval (Infobutton) Standard\textsuperscript{33, 34}.

We conducted three experiments to test different hypotheses. The first experiment showed that the classifier, trained on UpToDate sentences, loses accuracy when applied to Medline sentences. Specifically, the classifier’s precision significantly decreased on Medline compared to UpToDate, although its performance in terms of recall was equivalent. A possible reason is that Medline sentences have different syntactic and semantic structure from UpToDate sentences. UpToDate provides recommendations based on synthesis of the evidence provided by multiple studies (e.g., “In patients resistant to initial therapy with hydroxychloroquine (HCQ) or sulfasalazine (SSZ), we suggest adding methotrexate (MTX) or treating with a combination of HCQ, SSZ, and MTX, rather than switching to a TNF inhibitor or to a TNF inhibitor plus MTX.”). Original studies provide a conclusion of the study findings, but in most cases there is no clear recommendation for clinical practice (e.g., “In this treatment-refractory population, tofacitinib with methotrexate had rapid and clinically meaningful improvements in signs and symptoms of rheumatoid arthritis and physical function over 6 months with manageable safety.”)

In the second experiment, re-training the classifier on Medline sentences with the exact same features resulted in improved performance, equivalent to performance on UpToDate sentences. This finding
Figure 2: Average precision, recall and F-measure of the baseline method compared with the feature-rich sentence classifier in different training and testing settings.

Figure 3: Average precision, recall and F-measure of the feature-rich sentence classifier, with and without location feature, and trained and tested on Medline sentences.
confirms that the classifier’s model and features used for UpToDate are generalizable to Medline. Also, the retrained classifier outperformed a baseline classifier, which was just based on sentence location. This shows that advanced classification methods based on NLP techniques and machine learning algorithms are worth the gained performance and classification power. The last experiment confirmed the hypothesis that sentence location in Medline abstracts further improves classification performance. This finding was expected, since study authors often summarize the main study findings and their clinical implications in the conclusion section of Medline abstracts.

Analysis of false-positives and false-negatives showed two main error categories. The first category includes recommendations that were too general, such as in “Drug therapy is recommended to stabilize and relieve symptoms in patients with preserved ventricular function.” Future studies can try to address this issue by identifying general treatment concepts using UMLS concept hierarchies. The second category was clinically useful sentences for which SemRep and MedTagger were unable to extract predications and concepts, such as in “Augment™ may represent a safe and efficacious treatment alternative to ABG during foot and ankle arthrodesis.” Fine tuning of NLP methods are needed to address this kind of problem.

Limitations. The main limitation of this study is the use of Medline abstracts as opposed to full-text articles. Medline abstracts do not report all the conclusions of a study, therefore sentence classification is limited to clinically useful sentences available in the abstract. Moreover, the gold standard consisted of high quality clinical studies published in high impact journals, which have a higher rate of structured abstracts than other studies in Medline. Since the sentence classifier benefits from standardized abstract structure, the performance of the optimized classifier applied to a dataset with a higher rate of unstructured abstracts is likely to be lower.

Future studies. We are integrating the feature-rich sentence classifier with an interactive clinical decision support tool that provides patient-specific summaries of clinical evidence from UpToDate and Medline.3 Future studies also include applying and adapting the sentence classification method to full-text articles.

Conclusion

We investigated the generalizability of a feature-rich sentence classification model, which was trained on UpToDate sentences, to Medline abstracts. The feature-rich classifier’s model and input features were generalizable to sentences from Medline abstracts, but the classifier had to be retrained on those sentences to achieve equivalent performance. Optimization of the classifier by adding a sentence location feature improved classification performance. The resulting sentence classifier can be used as a component of text summarization systems to help clinicians’ patient care decision-making.

Desiderata for Major Eligibility Criteria in Breast Cancer Clinical Trials

Matthew L. Paulson, MPH, Chunhua Weng, PhD
Department of Biomedical Informatics, Columbia University, New York, NY

Abstract
Use of major eligibility criteria is a popular but unstudied folk practice for improving patient screening efficiency for clinical studies. This mixed-methods research study derived the desiderata for major eligibility criteria in breast cancer clinical trials. We randomly selected thirty interventional breast cancer clinical trials conducted at The New York-Presbyterian Hospital on the Columbia University Medical Center campus to create training (N=20) and testing (N=10) datasets. We utilized the Think-aloud protocol to gauge how clinical researchers identify and use major eligibility criteria to prescreen patients for clinical trials during an audio-recorded interview. A focus group session was held to understand the current prescreening process and investigate how it could be optimized to maximize recruitment rates. Using the grounded theory method, we annotated transcriptions to discover user rationale and desiderata behind major eligibility criteria in breast cancer clinical trials, which were later evaluated in a follow-up survey.

Introduction
Recruitment to clinical trials remains the biggest barrier to clinical and translational research. Most clinical trial studies have dozens of complex inclusion and exclusion eligibility criteria. Therefore, when using these eligibility criteria for subject screening, a common and cost-effective practice adopted by clinical researchers is to start with a small set of “major eligibility criteria”. If a patient does not satisfy any major criterion, there will be no need to waste the time to go over the complete eligibility criteria list. Moreover, many clinical research coordinators know that a lot of minor eligibility criteria are either irrelevant or rare among the target population so that the information gained from those minor criteria returns minimal value for screening eligible patients. Therefore, they focus on using major eligibility criteria to maximize information gain during prescreening processes.

Understanding the definition and characteristics of major eligibility criteria has three foreseeable benefits: (1) facilitating automated selection of major eligibility criteria for efficient electronic clinical trial prescreening using electronic patient data; (2) enabling cost-effective analysis of existing eligibility criteria; and (3) enabling understanding of the prioritization behaviors of clinical researchers to inform the design of advanced clinical trial screening methods. However, to the best of our knowledge, little is known about the selection of major eligibility criteria for clinical trial prescreening. With a focus on the important disease area of cancer, in this study our research questions are “is there a common definition for major cancer clinical trial eligibility criteria?” and “if yes, what are the characteristics of these major eligibility criteria?” In this study, we define a desiderata for major eligibility criteria of clinical trials as well as provide examples of standardized major eligibility criteria using a mixed-methods approach using qualitative and quantitative measures with clinical researchers at Columbia University Medical Center. The study was performed in compliance with the World Medical Association Declaration of Helsinki on Ethical Principles for Medical Research Involving Human Subjects, and was approved by the Columbia University Medical Center Institutional Review Board.

Background
1. Barriers to recruitment and the need for prescreening
Slow clinical trial recruitment is a significant obstacle to medical discovery. Recruitment obstacles can lead to trial completion delays from one to six months for most clinical trials. Automating a significant portion of the patient screening process could reduce recruitment delays by identifying potentially eligible patients. The prescreening of patients for clinical trials requires use of study specific predefined inclusion and exclusion eligibility criteria. The lack of standardization for eligibility criteria creates obstacles to comparing trials to one another. As a result, patient screening is a complex multi-step and multi-user process that requires significant and expensive human time and effort. Moreover, the complexity of eligibility criteria can cause potentially eligible patients to be overlooked. Information systems have the potential to decrease delays in clinical trial recruitment and minimize human resources that manually review records for prescreening. Weng et al. showed that a real-time screening alert for a single clinical trial before a patient clinical encounter improved the rate of recruitment over a twelve-month period by identifying patients that are “potentially eligible” for full screening. The challenge is to prescreen a patient for an entire portfolio of clinical trials.
2. Related work

Most prior efforts have focused on the standardization of eligibility criteria with expressive ontologies. For example, the Eligibility Rule Grammar Ontology (ERGO) provides a formal representation for eligibility criteria. ERGO is not sensitive to the complexity of criteria and does not represent the stability of eligibility data elements or support fuzzy representations such as “potentially eligible”. A related effort called the eligibility criteria extraction and representation (EliXR) extended ERGO by providing richer semantic information and decomposing complex eligibility criteria into more meaningful semantic segments. EliXR-Time further extended EliXR by supporting temporal representations. For example, a temporal constraint might require a medication washout period of three weeks. Such efforts have focused on rich semantics and the full expressiveness of the criteria, though none of them has been widely adopted yet or have generated real-world impact on clinical trial recruitment processes. In this study, we took a novel approach to this problem by addressing a real user need for classifying major eligibility criteria, which has been observed in folk practice of clinical trial prescreening and has remained largely unstudied.

3. Challenges of cancer clinical trial recruitment

Unique challenges exist for cancer clinical trials. The knowledge of cancer is increasing at an unprecedented rate along with its understood complexity. Patients that can be recruited for cancer clinical trials vary widely in terms of comorbidities, overall health, and cancer pathology. Previous studies have indicated that eligibility criteria concepts may be disease specific and differences in patterns of concepts for eligibility criteria were found between breast cancer and cancer in general. As a result, eligible patients must meet complex criteria, which are not standardized and vary by disease. In addition, not all cancer patients react similarly to the same therapeutic treatment. Heterogeneity in patient response to cancer therapies likely is caused by inter-individual differences in drug deposition and pharmacokinetics. As we enter the era of precision medicine, patients will not be assigned to drug trials without attempting to predict how they will respond to the therapeutic regimen. This complex problem will require efficient information systems that will need to be built within the clinic workflow. Major eligibility criteria offer one effective strategy for streamlining clinical trial recruitment in cancer centers and to potentially increase patient satisfaction by limiting wait-times and maximizing care quality by quickly presenting all available treatment options to patients during clinical encounters.

4. Our previous pilot study

We previously conducted a pilot study involving nine clinical researchers, including physicians, nurses, and clinical research coordinators. Participants were invited to take a survey about how they use eligibility criteria to screen patients for clinical trials. Our study revealed a concept known as “major eligibility criteria”, which could be useful to assist investigators by automatically prescreening patients with data kept in the electronic health record. However, the responses revealed no clear consensus for the definition of “major eligibility criteria”. Each expert panelist defined the concept slightly differently, yet we identified frequently cited major criteria, such as histology and disease stage of cancer, in the aggregate data. Trends also emerged regarding how the panelists used major eligibility criteria in practice. For example, panelists described how they use major eligibility criteria to prescreen patients. The results also uncovered disparities about which criteria should be considered major. Our pilot study helped us to identify the unanswered research question and informed this study, which is to perform in-depth interviews and a focus group to understand the design requirements for prescreening with major eligibility criteria. The pilot study also suggested that major eligibility criteria can potentially improve triage efficiency for clinical trial recruitment by identifying patients that are potentially eligible for clinical trials. However, to the best of our knowledge, no prior study has investigated major eligibility criteria for clinical research recruitment and discussed user requirements for this type of decision support. This study employs a mixed-methods approach that includes both qualitative and quantitative measures to understand how clinical researchers define, select, and use major eligibility criteria. Moreover, we harness their collective knowledge to inform future informatics designs for triaging patients for clinical research eligibility prescreening.

Methods

1. Study setting

We recruited physicians, nurses, and study coordinators from the Breast Cancer Program in the Herbert Irving Comprehensive Cancer Center (HICCC) at Columbia University Medical Center (CUMC). CUMC is an academic medical center in New York City that is affiliated with the New York-Presbyterian Hospital. Clinical researchers in the Breast Cancer Program at HICCC were sent an IRB-approved recruitment email with details about the study and invited to request more information. The protocol activities consisted of one initial interview that was audio recorded, one focus group session, and one survey after the focus group session that study participants completed independently. The invitees were informed that completing the survey was voluntary and they could opt out if they...
did not wish to participate. Eleven people requested information and were subsequently consented to the research study. We recruited eleven clinical research professionals, including five physicians, two nurse practitioners, one nurse, and three research coordinators. Two participants were male and nine were female. Their work experience with breast cancer clinical trials was an average of 6.8 years with a median of 6 years. All participants had experience in recruiting patients for breast cancer clinical trials. Figure 1 graphically depicts our study schema.

![Figure 1. The study schema.](image)

2. The eligibility criteria dataset

Thirty clinical trials were randomly selected from the portfolio of active interventional breast cancer clinical trials, which represented over 41% of the 72 available cancer trials at the point of study at CUMC. Our random sample included a mixture of protocol phases to create a representative sample. All of our selected trials purposely involve interventions done to the patient. Twenty trials were designated as the training dataset, while the remaining ten were the testing dataset. Since significant differences exist in the content and word counts between full text protocols and their summaries on ClinicalTrials.gov, which casts doubt on the reliability of clinical trial summaries, we decided to use eligibility criteria from full-text clinical trial protocol documents for this study.

3. The initial interviews

Ten research members participated in the initial interview to review eligibility criteria for six clinical trials and classified each criterion as either major or minor, so that each trial had three raters. Participants were given the title and all eligibility criteria for each clinical trial that they rated. The response rate was 100%. The survey was conducted using Qualtrics, an online survey platform (www.qualtrics.com). Participants were encouraged to “think aloud” while they completed the task so we could capture their thought process with audio recording, which was later transcribed. All identifying information was stripped from the audio recordings to ensure anonymity. The answers were downloaded from the Qualtrics website into Excel for analysis. The answers for the major eligibility criteria were analyzed individually for themes and then annotated by author MP, who is a subject matter expert in breast cancer clinical trial data collection with over nine years of experience. The initial interview completion rate was 100%. We assigned raters using a cascading structure to maximize variability in rater assignments, which ensured that each rater works with different participants on each clinical trial to maximize result validity.

4. The focus group

The focus group was held one week after completing the initial interviews. Eight participants, including five physicians, a nurse practitioner, a nurse, and a study coordinator, participated in the focus group. The focus group method was used to find areas of agreement and disagreement and participants were encouraged to have a discussion among themselves to complete the tasks. The participation rate of the focus group was 100%. The group started the session by drawing their perception of how the current pre-screening process works. The participants worked individually and were instructed to focus on how physicians, nurses, and study coordinators interact with one another during the prescreening process, if at all. Participants were also asked how, when, and where prescreening occurs.

Next, the group reviewed eligibility criteria that were considered major from the initial interviews using two steps. First, the results of selected trials were reviewed with all focus group participants at the same time. During the discussion, Author MP listed the qualities and attributes of major eligibility criteria on an easel pad to learn why participants considered some eligibility criteria to be major. Author MP updated the list as the conversation progressed during the focus group session. Second, the focus group reviewed their discussion and agreed upon a list of attributes for major eligibility criteria based upon their subject matter expertise and the discussion of the focus group. This data was recorded using an easel pad that was visible throughout the focus group session, where anyone could write a quality or attribute about major eligibility criteria during the conversation. Then, the focus group...
reviewed the attributes and came to a consensus on a final list of attributes. Finally, the focus group participants discussed and drew their version of an optimized prescreening scenario as a group using easel pads that were hung on the wall so all focus group members could participate.

5. The follow-up survey

The follow-up survey was designed to evaluate the standardized major eligibility criteria and desiderata that were derived from our content analysis of the initial interviews and focus group session. Our content analysis was completed in two steps. First, we extracted all eligibility criteria from the training data set of twenty breast cancer clinical trials that were considered major by all three raters and referred to them as consensus major eligibility criteria. Second, we reviewed the list of attributes created by the focus group for major eligibility criteria. To ensure saturation of major eligibility criteria attributes, both authors reviewed and annotated the transcripts of the initial interviews until saturation was reached. Both authors reviewed the interview transcripts separately and discussed their results before coming to a consensus on major eligibility criteria attributes. Differences were resolved by discussion among authors. The result was the desiderata for major eligibility criteria in breast cancer clinical trials.

Ten participants completed the follow-up survey two weeks after the focus group session. The follow-up survey was administered using the Qualtrics survey tool and consisted of three parts. First, study participants were asked to classify each standardized major eligibility criterion that was created from the initial interviews using a 5-point Likert scale with options “Definitely Major”, “Possibly Major-Depending on the Context”, “Undecided”, “Possibly Minor”, and “Definitely Minor”. The second part of the follow-up survey asked study participants to match examples of standardized eligibility criteria with each attribute of our derived major eligibility criteria desiderata. From the training dataset, twelve major eligibility criteria appeared in the training dataset more than once, so we included them in follow-up survey to have study participants match them with the derived desiderata. Study participants were directed to select as many or as few examples of major eligibility criteria for each attribute in our desiderata. The final part of the follow-up survey asked study participants to classify eligibility criteria as major or minor. Ten breast cancer clinical trials were randomly assigned to our ten participants so each participant would classify the eligibility criteria as major or minor for three testing clinical trials. We annotated the major eligibility criteria collected in the follow-up survey to see if any additional standardized major eligibility criteria were detected.

6. Data collection and analysis

Study data was collected with three methods: an online survey tool, Qualtrics, where the results were downloaded into Excel; audio recording and subsequent transcription; and the focus group session that created individual and group prescreening workflow artifacts and easel pad drawings. We utilized the “Think-aloud” Protocol to record the thought process of the study participants while they classified the training set eligibility criteria as either major or minor in the initial interview. Then, we analyzed and annotated the audio transcriptions for the initial interviews using grounded theory to ensure saturation of the desiderata for major eligibility criteria from the focus group easel pads. Finally, we asked study participants to evaluate the standardized major eligibility criteria as well as the desiderata in the follow-up survey.

Results

1. Qualitative study results

The average, median, maximum, and minimum time spent on the interview per participant was 22 minutes 42 seconds, 19 minutes 48 seconds, 40 minutes and 1 second, and 9 minutes and 42 seconds, respectively. Our interview transcript annotation revealed that all study participants differentiated major and minor eligibility criteria. There was 100% agreement amongst the participants that not all eligibility criteria should be given equal weight in the prescreening process. Participant 07 stated, “In my mind major eligibility criteria, I mean like who’s actually worth approaching upfront”. All study participants were able to find one or more major eligibility criteria for every clinical trial that they rated. Several major eligibility criteria were noteworthy and were reported below.

Disease staging was considered a major eligibility criterion for 100% of the study participants. Disease staging appears to be the most important factor to divide patients into subgroups for treatment decisions and recruitment for clinical trials. Participant 03 stated, “So, the disease staging, I would consider major. That’s your number one.” Participant 05 stated, “staging, this is probably one of the most major, most important”. This finding was confirmed by both transcription annotation and the follow-up survey, where 100% of participants identified disease stage as “Definitely Major”.

Transcript annotation also revealed a contextual sentiment about age. Several study participants stated that age could be considered a major or minor eligibility criterion depending on the context, such as how the numerical value of the age creates subgroups in the overall breast cancer population. For example, the age criterion can be major when its
threshold is meaningful, such as “greater than 50 years old”. In contrast, the age criterion “adults greater than 18 years old” is not major because the majority of the patient population satisfies this criterion. Participant 04 stated, “I’m assuming that there’s going to be (over 18)”. Participant 09 stated, “…most of the patients that we see are over 18, so that’s usually an assumption I make that I would call minor, definitely”. The reasoning for this is the degree to which the age value divides the overall breast cancer population into meaningful subgroups. Participant 03 stated, “Most people at least in this setting are going to be 18. When the cut off is larger, like 50, it’s when I would consider it more of a major (criterion)”. 

Physician, nurse, and study coordinator participants did not consider rare phenomena to be major eligibility criteria. Regarding previous cancers, participant 06 stated, “…it wouldn’t be considered a major criterion because for most patients, that’s not a major issue”. Participant 01 speaking about Hepatitis and HIV stated, “While that’s important, it’s not common”. Participant 03 stated, “Bilateral malignancy is relatively uncommon, I would consider that minor”. Participant 09 stated, “I would call that minor because I would say that the majority of the population is not HIV-positive”. Participant 02 stated, “The things that are less common become in my mind not major”. 

An area of contention in the transcript annotation was laboratory results. Specifically, a difference existed between a study coordinator and nurses. Participant 08, a study coordinator, stated, “I can assess the labs…so that’s a major to me”. Participant 09, a nurse practitioner, stated, “I would say in terms of pre-screening, labs are minor because the lab is usually the one we use when they actually come in for their screening visit”. Participant 07, a nurse practitioner, stated, “let’s say the patient is essentially eligible except for some lab variations, for the most part in my experience, this can be remedied”. However, the importance of laboratory results may increase for patients with advanced disease. Participant 07 stated “I feel as though the laboratory parameters…have more implications for patients who are treated in a metastatic setting because those women tend to be more sick”. 

A major eligibility criterion that generated significant conversation in the focus group session was around the concept of “prior treatment”. While prior treatment was not always considered to be accessible in the electronic health record, the focus group did consider it a major eligibility criterion that was available. However, it might take additional time to receive records from other clinicians that treated the patient. Focus group participants clarified that a patient’s prior treatment can be difficult to find, especially if they have been treated at multiple institutions. The focus group stated that the importance of prior treatment differs between early stage and advanced stage breast cancer patients and hence whether prior treatment is major is also a contextual decision. 

The disease staging of the patient may increase the likelihood of other eligibility criteria being considered major. For example, the focus group agreed that the importance of prior treatment proportionally increases in connection with the number of patient prior treatments. For a patient with multiple prior treatments, it is likely that prior treatment becomes a major eligibility criterion for that specific patient. Similarly, if a patient has not had any prior treatments, the concept of prior treatment is less important for that individual patient. This sentiment was also reflected in the transcription annotation. Participant 02 stated during the initial interview, “Given that this is a neoadjuvant study, most patients would not have had prior therapy. So probably not so important to know that they haven’t had prior treatment”. Therefore, prior treatment is more relevant to patients with advanced disease than for early stage disease. 

2. Desiderata for major eligibility criteria 

Desiderata for major eligibility criteria (Table 1) were derived based upon the transcript annotation from the interviews using grounded theory as well as from a group activity that was conducted during the focus group session. The desiderata were then evaluated in the follow-up survey. The desiderata attributes are ranked in descending order of frequency determined by counting the matched eligibility criteria for each term in the desiderata for all participants that completed the follow-up survey. The twelve most frequent major eligibility criteria from the training data set were used for the major eligibility criteria examples. In addition, the major eligibility criterion with the highest score from study participants is identified as a “Best Criterion Example”, where we have included more than one criterion in the event of a tie. 

3. The prescreening process 

During the initial interviews, participants identified different phases of patient screening. Participant 06 stated that major eligibility criteria are used for prescreening, while minor criteria will be used during manual reviews of data to give higher scrutiny to the patient. An example of a minor criterion is asking a patient if they would consider participating in a research trial. The transcript annotation revealed that different phases of patient screening occur at different time points. Participant 06 identified three different steps to screening. The first step is looking at “high level variables”. The second step is when you give a patient a more in-depth look for obvious problems that would prevent them from enrolling in the clinical trial such as organ failure. Thirdly, you have the official eligibility checklist, where you go line by line and see if they meet all eligibility criteria.
At the beginning of the focus group session, study participants were asked to draw the workflow of how patients are currently prescreened in their clinics. 100% of the focus group participants completed the task. Seven out of eight participants identified the first step of the prescreening process starting with the physician, where the physician directs nurses or study coordinators to do a manual screening of the patient. The one remaining participant stated that the prescreening could start with any clinical researcher, depending on the type of study. For example, study coordinators may recruit participants for behavioral or observational studies without physician input.

The final group activity of the focus group was to describe an optimized prescreening workflow. The prescreening process utilizes major eligibility criteria to automatically identify potentially eligible patients in the electronic health record. Study participants came to a consensus that decision support for clinical trials must be built into the everyday workflow of the clinicians. At CUMC, the clinicians view a patient schedule that is built for each physician’s clinic day. The focus group agreed that research staff should then be able to easily see potentially eligible patients in the physician’s daily schedule. This enables research staff to screen patients and communicate with one another to make an ultimate screening decision.
Figure 2 shows the optimized prescreening workflow as developed by consensus during the focus group session. In addition to describing the workflow, focus group participants also illustrated the type of information that would be useful in the user interface (Yes; No; Maybe). The relevant clinical trials for each patient are listed on the physician schedule. For example, Patient 1 is scheduled to see the physician at 8:00 AM and is potentially eligible for “Trial A” and “Trial B” as seen in Figure 2. The automated prescreening process, study coordinator, research nurse, and physician can each select “No–Not Eligible, “Yes–Possibly Eligible”, and “Maybe Eligible” after their respective reviews.

4. Quantitative study results

The quantitative results include the instance counts from the training and testing datasets as well as the Likert scale measurements from the follow-up survey. For the training dataset that composed twenty breast cancer trials, the average count of eligibility criteria per trial was 19.7 with a median of 18. There was more than double the amount of criteria that were classified as minor than were classified major. The average major criterion per clinical trial in the training set was 3.55. The average minor criterion per clinical trial in the training data set was 7.3. Similarly, the testing dataset had an average count of 22.5 total eligibility criteria with a median of 20. We again saw there was more than double the amount of criteria that were classified as minor than were classified major. The average major criterion per clinical trial in the training set was 3.2. The average minor criterion per clinical trial in the training data set was 6.9. We annotated the study participant agreed upon major eligibility criteria from the initial interviews as well as from the follow-up surveys. We did not detect any new standardized major eligibility criteria in the follow-up survey. The instance count of the training and testing datasets are seen in Table 2 sorted by total dataset instances. Study participants completed a 5-point Likert scale to classify each major eligibility criterion as “Definitely Major”; “Possibly Major–Depending on the Context”; “Undecided”; “Possibly Minor”; and “Definitely Minor”. We report the mode from participant responses from the follow-up survey Likert scale in Table 2.

Figure 3 below displays major eligibility criteria as ranked by study participants in the final survey in decreasing order of significance. The criteria are ranked by significance score, which was calculated by summing all participant scores for each criterion. The criteria received the following scores for each classification: “Definitely Major”=1; “Possibly Major–Depending on the Context”=2; “Undecided”=3; “Possibly Minor”=4; and “Definitely Minor”. The criteria are ranked by significance score, which was calculated by summing all participant scores for each criterion. The criteria received the following scores for each classification: “Definitely Major”=1; “Possibly Major–Depending on the Context”=2; “Undecided”=3; “Possibly Minor”=4; and “Definitely Minor”.

2031
Minor”=5. The criterion with the lowest score is considered the most significant. For example, “Disease staging” had the lowest significance score because all participants identified it as “Definitely Major”.

**Figure 3.** Major eligibility criteria measured with a Likert scale by participants in the follow-up surveys.

**Discussion**

Our training dataset was considered a representative sample of interventional breast cancer clinical trials at CUMC for three reasons. First, our results showed that “Hormone receptor status” was identified as the third most common major eligibility criterion with 12 total instances in our dataset and second most significant major eligibility criterion after disease staging. This observation confirmed sample representativeness since the prevalence of hormone receptor positive breast cancer in the entire breast cancer population is approximately two-thirds of all reported cases. Second, saturation was reached in our training dataset of major eligibility criteria instances since no new major eligibility criteria were detected in our testing dataset. Third, the sample represented over 41% of interventional breast cancer trials available at CUMC. The results of our mixed-methods study prove the existence of major eligibility criteria. In addition, both the training and testing datasets had similar summary statistics. The average count of total eligibility criteria for both training and testing datasets was 19.7 and 22.5, respectively. The average count of major eligibility criteria for training and testing data sets was 3.55 and 3.2, respectively. Minor eligibility criteria are more prevalent in our sample of clinical trials than major criteria. This finding is significant because automating a system that needs to search for fewer machine-readable standardized criteria is more efficient and feasible operationally. In addition, this finding questions prior efforts to provide a complex knowledge representation of highly expressive concepts that gives equal weight to all eligibility criteria. Our study suggests that time could be saved by focusing on major criteria that were identified by study participants. It is possible that raters identify minor criteria more easily than major criteria, but an inescapable conclusion is that complex knowledge representations that give equal weight to all criteria are perhaps less useful than previously thought. This is an area that requires further exploration.

We have derived a standardized list of major eligibility criteria for breast cancer clinical trials at CUMC. We have confidence in our list being complete because we did not detect any new standardized major eligibility criteria in our testing dataset during the follow-up survey. While we focused exclusively on breast cancer, our study provides a mixed-methods approach for discovering major eligibility concepts in other diseases. This approach will be helpful in future projects since clinical trials lack standardized eligibility criteria. As a consequence, recognizing similar criteria across two or more clinical trials remains a challenge even in the same disease realm.

Our approach differs from previous research attempts to create eligibility criteria knowledge representations by avoiding highly expressive standardization and temporal restraints in favor of focusing on only the most user-relevant concepts. The granularity of the major eligibility criteria desiderata is coarser than other knowledge representations and more comparable to available electronic health record data. The coarseness of our standardized criteria is a very strong advantage for the usefulness of major eligibility criteria because it takes into account practical considerations such as data availability in electronic health records and fitness to the clinic workflow. Our
focus group detailed how clinical research professionals use major eligibility criteria in their thought process while prescreening patients. Focus group data provide insight into building a clinical decision support system that is powered by major eligibility criteria to automatically suggest clinical trials that patients are potentially eligible for during clinical encounters.

We also sought to understand the rationale of major eligibility criteria. The study participants viewed HIV as less important for breast cancer clinical trial recruitment because it is rare among the target population. Other criteria, such as age, depend on context. Annotated transcripts from the initial interviews, the focus group session, and the follow-up survey provide evidence that prior treatment is significant, yet difficult to obtain. Thus, prior treatment is difficult to utilize in automatic prescreening. More advanced disease staging may increase the importance of some eligibility criteria such as laboratory results and prior treatment. As a consequence, clinical trials for early stage breast cancer could realize more of a benefit using major eligibility criteria for automated prescreening than studies for advanced disease stages.

The results of our mixed-methods study also identify the desiderata of major eligibility criteria for breast cancer clinical trials. While we utilized only breast cancer clinical trials, our desiderata could be scalable to other diseases. Furthermore, the desiderata could provide guidance about what features will create an optimal clinical trials recruitment tool for future clinical decision support systems. Since the desiderata terms are ranked by frequency, they provide weighted insight into how clinical researchers think while prescreening patients for clinical trials. For example, “Reliable” was the desiderata attribute that was most frequent to our major eligibility criteria followed by “Objective” and “Relevant to me”. The relatively highly ranked “Relevant to me” desiderata attribute suggests that a role-based analysis may provide additional insight into prescreening processes.

Limitations
Since the results are only from one academic medical center, we cannot speculate to the universality of the desiderata. We purposely included only breast cancer clinical trials in our dataset because previous research findings suggest that relevant eligibility criteria are disease specific. The applicability of our findings to other diseases is unknown. This study did not use any real patient data, instead relying on observing the opinions and thought processes of clinical research professionals using the “Think-aloud” protocol. As a consequence, we are unsure what effect a fragmented or incomplete patient electronic health record would have on influencing the major eligibility criteria desiderata. Finally, even though our study methods included qualitative and quantitative methods, our small sample size prohibits us from making definitive conclusions about breast cancer clinical trials in a larger context.

Future work
The scalability of the major eligibility criteria desiderata to other diseases and institutions is an unanswered research question that warrants additional exploration. Our desiderata may assist clinical researchers and informaticists to make informed decisions about prioritizing the standardization and collection of data in the electronic health record for clinical trial prescreening. 100% of study participants agreed disease stage was “Definitely Major” during the follow-up survey. This suggests that we should prioritize the capture of this information in a standardized, machine-readable way for efficient prescreening. Similarly, “Hormone receptor status” and “HER2 status” should be prioritized for standardized capture. Standardized major eligibility criteria could provide a basis for clinical decision support by triaging patients for clinical trial prescreening and other applications in personalized medicine.

Future work should evaluate how major eligibility criteria are captured in electronic health records and how prescreening results can be best presented to clinical researchers in the clinic workflow. Our study has shown how major eligibility criteria might be used in an optimized workflow to screen patients for clinical trials. Automated prescreening could reduce human effort and expense by reducing the manual review of patient charts. If financial or other barriers prevent major eligibility criteria from being collected in a standardized way or even preclude an automated prescreening process, the benefits of major eligibility criteria still exist. For example, major eligibility criteria can still inform the development of manual prescreening methods. Additional evaluation of the desiderata and standardized major eligibility criteria will be helpful for understanding how our research can be utilized when prescreening patients in real life scenarios.

Conclusion
Our results demonstrate that major eligibility criteria exist for breast cancer clinical trials. This study investigated how, when, and why clinical researchers use major eligibility criteria to triage patients for clinical trial prescreening. Our identified desiderata can potentially inform future design of clinical decision support for clinical trial prescreening. Future research is warranted to test the generalizability of our method beyond breast cancer trials and consider real patient data in order to gain insight into how the major eligibility criteria desiderata is influenced by fragmented or incomplete patient records and what steps might be taken to mitigate those effects.

Abstract

Family history is considered a core element of clinical care. In this study we assessed the quality of family history data captured in an established commercial electronic health record (EHR) at a large academic medical center. Because the EHR had no centralized location to store family history information, it was collected as part of clinical notes in structured or free-text format. We analyzed differences between 10,000 free-text and 9,121 structured family history observations. Each observation was classified according to disease presence/absence and family member affected (e.g., father, mother, etc.). The structured notes did not collect a complete family history as defined by standards endorsed by the U.S. Agency for Healthcare Research and Quality: the free-text notes contained more information than the structured notes, but still not enough to be considered “complete.” Several barriers remain for collecting complete, useful family history data in electronic health records.

Introduction

Family history has always been considered “a core element of clinical care.”1 It plays an important role in personalized medicine, being a free genetic tool that almost every patient has access to.2 Since the Human Genome Project, new genomic tools have been described,3 but family history is critical for identifying patients that may benefit from more intensive screening. Family history provides information that enables individualized disease diagnosis, treatment and prevention.

Several studies have shown that family history can help predict the risk of a patient developing certain diseases such as breast cancer, colorectal cancer, ovarian cancer, osteoporosis, cardiovascular disease, psychiatric disorders, and diabetes. Knowing that a patient is at increased risk of developing a disease based on family history enables disease prevention that can vary from intensive screening to prophylactic surgery, early diagnosis and/or early and tailored treatment. For example, current guidelines from the American Cancer Society define criteria for MRI eligibility in addition to mammography for breast cancer screening4,5. The guidelines recommend that patients that have lifetime risk of breast cancer greater than 20% by BRCAPRO6, Tyrer-Cuzick7 or Claus8 models should have screening MRI in addition to mammography. Each of these models was developed using different methods, different populations and different risk factors and each of them was developed to predict different outcomes, but all of them heavily rely on family history and presence of risk factors9. This is just one of many examples of the importance of family history information for clinical care.

Since several guidelines and models exist to estimate a patient’s risk for different conditions, clinical decision support systems have been developed to facilitate guided personalized medicine. One of the earliest research studies about the use of clinical decision support (CDS) systems in personalized medicine used was conducted by Emery and colleagues in 1999. The study identified that the CDS systems available were not appropriate for use in a primary care setting.10 To address this problem, they developed a system to record and interpret family history data in the primary care clinic. The system included family history relevant to breast, ovarian and colorectal cancer.11 Over time, other clinical decision support systems were developed to manage other types of cancers such as colorectal cancer and Lynch syndrome. All these systems used family history information to provide risk assessment.12

Currently, the U.S. Preventive Services Task Force (USPSTF) includes risk assessment based on family history for some conditions, demonstrating the importance of family history in clinical care. Conditions that include family history information as part of the USPSTF are screening for BRCA mutation and BRCA-related cancers13, osteoporosis14 and lipid disorders in adults15,16. A 2007 report commissioned by the Agency for Healthcare Research and Quality (AHRQ) recommended that collection of family history information should include diseases in first-degree relatives and second-degree relatives from both the maternal and paternal side, the relative’s age at the time of disease diagnosis, and each relative’s race and ethnicity.17
In electronic health records (EHRs), family history information may be collected in a structured or narrative (i.e., “free-text”) format. On one hand, structured documentation is ideal for data reuse since it may be coded and standardized. On the other hand, when clinicians are providing care, flexibility, efficiency, quality, expressivity are important. The purpose of this study was to understand how family history data were captured in an established commercial EHR system at a large academic medical center, and to assess the quality of the data collected.

Methods

With Institutional Review Board approval, we conducted a retrospective analysis of data from the Allscripts EHR (Allscripts Corp., Chicago IL) used at NewYork-Presbyterian Hospital/Columbia University Medical Center since 2004. Our study focused on the difference between family history data collected using structured fields vs. free-text. Each note template in the EHR contained one or more “observation” data elements. An observation could be a text box, a Boolean (e.g., a checkbox or radio button), or numeric value. Text boxes could be fully free-text, or they could be constrained to allow only items from a predefined list, such as the words “low,” “medium,” or “high.” Observations had an internal code and description specified using a configuration tool in the EHR. While our EHR vendor provided some predefined observations, the vast majority were locally defined and did not comport with any existing standard terminology.

The EHR system contained 1,560 active templates for documentation. Each of these templates contained one to several hundred discrete observations. There were 140,038 observations defined in the EHR; of those, 653 had an internal code containing the words “fam hx” OR “family hist.” We identified the note templates that contained these observations and queried the EHR database to identify the number of times each note template was used, as well as the number of unique patients who had at least one of these observations recorded. The number of times each note template was used varied from 1 to 79,505, and number of unique patients varied from 1 to 67,276 for each note template. The note templates that contained the most commonly used free-text and structured text observations were selected for analysis.

The most-used note template that contained structured family history observations was the Ambulatory OB/GYN Antepartum Record (Figure 1). This note template was used in our institution for obstetric patients in the institution’s ambulatory care network. Overall, this note template was used 79,505 times for 67,276 unique patients. The most-used free-text family history observation was the Neurology Admission Note (Figure 2). This note was used for every patient admitted to the neurology service. The Neurology Admission Note was used 49,656 times for 22,642 unique patients.

Figure 1. Ambulatory OB/GYN Antepartum Record: the most-used template note that contained structured family history observations.
For both the Ambulatory OB/GYN Antepartum Record and the Neurology Admission Note templates, 10,000 family history observation entries were randomly selected from notes between 2007 and 2014. Manual annotation by a clinical expert (FP) was performed in all 10,000 free-text observations, as well as in all structured observations that occurred more than once (9,121 observations). Categories were identified based on the content of information in the observations and the standards endorsed by AHRQ and were used to annotate both datasets. In total, 19,121 observations were manually annotated and assigned to a category. The categories used were: 1) presence of disease in specified relative(s), 2) presence of disease in unspecified relative(s), 3) absence of disease and 4) other (Table 1). The annotation results were compared between the datasets.

Results

Figure 3 shows the results of the manual annotation of family history observations. In the category “Presence of disease in specified relative(s),” 58.7% of the observations from the Neurology Admission Note (free-text) contained family history information including the disease as well as the relative affected. However, when analyzing data from the observations from the Ambulatory OB/GYN Antepartum Record (structured), only 5.2% contained information specifying the patient’s relative. In contrast, 7.3% of the observations from the Neurology Admission Note (free-text) contained information categorized as “Presence of disease in unspecified relative(s),” and 50.1% of the observations from the Ambulatory OB/GYN Antepartum Record (structured) captured this type of information (Figure 3).

Furthermore, 27.5% of the observations from the Neurology Admission Note (free-text) captured information about the absence of family history of a certain disease, while only 0.9% of the observations from the Ambulatory OB/GYN Antepartum Record (structured) captured information with this level of detail (Figure 3).

A large proportion (39.2%) of the observations from the Ambulatory OB/GYN Antepartum Record (structured) were classified as “Other.” The vast majority of these cases referred to family history described as “N/A.” Such description provides no information of the patient’s family history (Figure 3).

Discussion

When analyzing family history data collected using structured vs. free-text data elements, the clinical expert annotations revealed that there was a considerable difference between the content of the family history information collected. The structured template was shown to be a poor way to collect family history since the relative affected by the condition was not captured. Other important details such as age of onset and vital status were also not being captured. In the template shown in Figure 1, text could be optionally entered in the free-text box but this field was stored separately in the database from the structured component. In Figure 1, it was also unclear what was meant by “N/A.” Possible interpretations were that this could indicate that a patient would not or could not inform, had no knowledge or even that such questions were not asked. Another problem was that rows could easily be left empty and it is unclear what that means. It could mean that the clinician did not ask about the family history of a certain condition, or that the patient did not know. Furthermore, the free-text box was used to capture relatives, deny presence conditions, or even to record other types of information such as age, type of cancer, etc. Notes that used the...
free-text template were more comprehensive and often contained much useful information. However, not all of them contained pertinent and useful family history information.

Unlike some EHR implementations where family history information is kept in a centralized fashion, our institution did not have a centralized location to store this type of data. Family history data was collected and stored as part of the clinical notes. The fact that different healthcare providers collected this type of information in several different notes may have resulted in inconsistencies across notes. Our study discovered that our institution’s EHR 653 observations related to family history. Many different note-writing templates were available and many included family history sections, but there was no standardized method for collecting this type of data. One benefit of having so many different ways of collecting family history data was that we could assess the quality of data based on characteristics such as structured items vs. free-text fields.

We also observed that free-text boxes in both notes were often used to capture information that was unrelated to family history. For example, indicators were included such as: “intubated,” and “no family at bedside and pt nonverbal”. These are important pieces of information about the patient but should not be reported as part of the family history section.

Despite the well-known and well-described importance of family history, several barriers exist in its collection and analysis, as well as in its use for personalized management based on patients’ risk assessment. Barriers to collect family history can be classified in two major categories: clinician-related and patient-related.

Clinician-related barriers include lack of time to obtain, organize and analyze family history information; lack of resources and lack of reimbursement for such activity; underestimation of the value of family history data by the clinician; lack of expertise in obtaining and analyzing family history information; lack of standards for family history collection; and lack of clear guidelines to assess patient risk based on family history. The first, and perhaps the most critical barrier for family history collection is lack of time to obtain, organize and analyze family history information. Obtaining complete and accurate family history information, organizing it in a pedigree and analyzing family history data is extremely time-consuming. Furthermore, it is not sufficient to collect family history from patients only once. It is important to regularly update family history information, analyze it, and reconcile conflicting information. A 1989 study surveying four genetic clinics reported that the time patients spent in the first consultation varied from 3–5.5 hours, with over half of this time spent before or after the patient’s appointment. A 2011 study demonstrated that while the majority of clinicians (77.5%) reported collecting cancer family history on their patients, only 26.0% included minimum adequate cancer family history. Furthermore, 57.4% of clinicians updated family history information just once a year, and 22.2% of clinicians never updated family history information for their patients at all. When questioned about the barriers to collecting cancer family history, clinicians reported lack of time as the primary issue. The study focused on cancer family history, but it demonstrated how challenging family history is to collect and maintain, in general.

Lack of resources and reimbursement for family history collection is another important barrier. Clinicians are not reimbursed for the time spent on family history collection and risk assessment. In fact, in 2009, lack of incentives from the government was being described as one of the challenges prohibiting adequate collection of family history. In addition to misaligned incentives, lack of standards has also been reported as a challenge in this area. The lack of standards for data elements, terminology, structure, interoperability, and clinical decision support rules for family history data is a huge obstacle to implement it in the clinical workflow. This point is underscored by the existence of multiple EHR templates available to assist physicians in capturing family history data. Furthermore, limited knowledge and lack of expertise in obtaining and analyzing family history by clinicians is another barrier that has been described in several studies.

There are also barriers to collecting accurate family history data on the patient side. These include uncertainty about biological family composition; uncertainty about the health history of family members; inaccuracies in patient recall, language-related and cultural factors. Clinicians often cite uncertainty about biological family composition as a challenge when collecting family histories, especially in cases where the patient is part of a large biological family. Language-related and cultural factors can also be a factor that negatively affects collection.

There are now several initiatives to facilitate and encourage the use of family history data. These initiatives are focused on the use of these data for precision medicine, where the need for accurate and detailed family history data is great. Three such initiatives are: Stage 2 of the federal “Meaningful Use” EHR financial incentive program, the U.S. Surgeon General’s “My Family Health Portrait,” and the HL7 Clinical Genomics Family History/Pedigree Model.
Stage 2 of the Meaningful Use program included a requirement of clinician’s to use structured data entry for family history. Eligible hospitals had to have for 20% of their patients at least one structured family history data element, for at least one first-degree relative in the electronic health record. As discussed above, lack of incentives to collect family history is an important barrier. The Meaningful Use program will be a strong incentive for U.S. hospitals to collect family history information. Although the determined measure of at least one structured data entry for at least one first-degree relative is far from what is considered complete family history, it is a start.

Secondly, since family history data collection is extremely time-consuming, innovative tools have been created to facilitate this process. Some are leveraging patient input of family history data. The U.S. Surgeon General’s My Family Health Portrait, a federal initiative to collect family history, is a website that allows patients to collect family history information and share their information with family members and healthcare providers. A study conducted in 2011 described that the average time taken to input family history information was 15 minutes, in a range from 3 to 45 minutes. Instead of having a healthcare provider questioning patients about their family history, patients can enter their own data, saving clinician time—the major barrier for family history data collection. This practice also engage patients in their care and gives them time to review their family information and contact relatives and question them about information that they may not know. Engaging patients in this fashion encourages more accurate family history information. Of note, one advantage of using electronic questionnaires is that certain questions can be made mandatory, and branching logic can be employed. In contrast, in a clinical encounter, the doctor may forget to ask certain questions or may skip questions due to lack of time.

It is important to emphasize that to fully represent family history information, data representation must be multidimensional since it is necessary to not only capture the disease but also the relative affected, age of onset, and cancer type if applicable. Moreover, development of standards to support interoperability is essential for sharing data for clinical care and clinical research purposes. In the domain of family history, HL7 has a workgroup that specifically works on development of models for representing family history. The workgroup has developed the HL7 Clinical Genomics Family History (Pedigree) Model. It is a standard for capturing data within a system as well as to transmit family history data between systems. It includes patient’s family and familial relationships, diseases, genetic data and risk analysis. This HL7 standard is already used by the U.S. Surgeon General’s My Family Health Portrait application, and we believe it will be important for EHR vendors and other stakeholders to adopt this standard.

Limitations
The study analyzed only observations contained in two note templates (out of a total of 1,560 available) in our EHR. One note template was used in the ambulatory care setting and the other template was used for hospital admissions. Although the templates were selected based on the fact that they were the most frequently used templates at our institution, it is unclear if analysis of other EHR templates would yield different conclusions.

Conclusion
In summary, family history information is a valuable tool for personalized medicine. Computer-based tools can improve data collection, risk assessment and decision-making, facilitating effective use of family history in the clinic, engaging patients in their care, and therefore providing better personalized care. Our electronic health record vendors have not developed a user-friendly system to collect this type of data. Patient-facing tools for collecting family history data are not yet being used on a large scale. Numerous efforts have been made to collect family history data in the electronic format and to facilitate its use in the clinical setting, but several barriers remain unsolved. We have demonstrated that free-text observations were more comprehensive than structured observations; however neither was ideal for capturing patients’ complete family history.

Abstract

Brain science is a frontier research area with great promise for understanding, preventing, and treating multiple diseases affecting millions of patients. Its key task of reconstructing neuronal brain connectivity poses unique Big Data Analysis challenges distinct from those in clinical or “-omics” domains. Our goal is to understand the strengths and limitations of reconstruction algorithms, measure performance and its determinants, and ultimately enhance performance and applicability. We devised a set of experiments in a well-controlled setting using an established gold-standard based on calcium fluorescence time series recordings of thousands of neurons sampled from a previously validated neuronal model of complex time-varying causal neuronal connections. Following empirical testing of several state-of-the-art reconstruction algorithms, and using the best-performing algorithms, we constructed features of a classifier and predicted the presence or absence of connections using meta-learning. This approach combines information-theoretic, feature construction, and pattern recognition meta-learning methods to considerably improve the Area under ROC curve performance. Our data are very promising toward the feasibility of reliably reconstructing complex neuronal connectivity.

Introduction

Brain science is a frontier research area with great promise for understanding, preventing, and treating multiple diseases affecting millions of patients. With the launching of international initiatives like the BRAIN Project [1], and the Human Brain Initiative [2], comes the daunting task of dismantling the complicated, intertwined circuitry of the human brain. Accurately reconstructing brain structure and mapping it to function remains a formidable analytic challenge, vastly exceeding, at the present time, the difficulty of deciphering the structure and function of metabolic, transcriptomic or proteomic networks. Furthermore, mapping from genes to neurons to neuronal circuits to actual human behavior and intelligence poses a Big Data Science problem of unprecedented difficulty. The research community has been rapidly developing and testing methods addressing the above tasks. For example, recordings of about 80% of the hundreds of thousands of neurons of the larval zebrafish are publicly available awaiting efficient computational techniques to crack the circuit and recover the underlying connectivity network [3]. Reverse engineering of networks, like in the DREAM challenge [4], is common in bioinformatics and is now gaining momentum in neuroscience as well.

A significant pool of methods to draw powerful techniques from is causal discovery methods. These were developed to address the financial and ethical concerns associated with randomized controlled trials. A reflection of their significance is that they have been recognized with both the Turing Award (to Judea Pearl) and the Nobel Prize (to Clive Granger). For example, several variations of Granger causality (GC) have been used for causal structure discovery in neuroscience using different modalities like fMRI data [5] and electrophysiological (EEG) signals [6].

On the experimental validation front, calcium fluorescence imaging signals of neuronal cultures provide temporal, observational data for causal network reconstruction of neurons in vivo. It allows for the simultaneous recordings of thousands of neurons and can be combined with other state of the art technology like optogenetics [7]. This experimental model is less time consuming and less tedious than conventional experimental techniques like axonal tracing [8].

Problem and Approach

As shown in Figure 1, the data for reconstruction consists of calcium fluorescence imaging recordings of the activity of neurons in a given brain network. The aim is to predict the directed connections of the neuronal network from raw data. As experimental data lacks ground truth value to verify the inferred network, we use simulated data from a broadly accepted ground truth model with realistic behavior coming from the Connectomics challenge [9] that aimed to predict the directed connections (synapses) of a neural network, given calcium fluorescence imaging recordings of the activity of each neuron in this network. In a network of \( n \) neurons, there are \( n^2 \) potential directed connections.
Among the $n^2$ possible combinations, for each pair of neurons $(i,j)$, the problem is to determine whether there is a connection $i \rightarrow j$. 180,00 samples (1 hour at 50 frames per second) were generated.

![Image](real Calcium Fluoresce Imaging: Connections?)

Figure 1. Research design of the present study [10].

Causal-Structure Learning Techniques

Several reconstruction methods are used for causal structure learning. The reconstruction strategies can be classified as correlation-based, entropy-based, and GC-based.

Correlation-Based Measures

1. Pearson’s Correlation

Pearson’s correlation coefficient is a measure of the degree of linear association between variables. For variables $X$ and $Y$ with means $\bar{X}$ and $\bar{Y}$, Pearson’s correlation, for $X$ and $Y$ is calculated as in (1),

$$\text{Pearson’s correlation}(X, Y) = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2} \sqrt{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}},$$

where $n$ is the number of dimensions of $X$ and $Y$. 

2044
2. Cross-Correlation

Cross-correlation involves correlating variables over many different time lags. The shifting correlation in Cross-correlation can be achieved mathematically by introducing a time lag. The Cross-correlation, at time delay, $d$ between two time series $X$ and $Y$, with means $\bar{X}$ and $\bar{Y}$ can be calculated as in (2)

$$\text{Cross-correlation}(X,Y) = \frac{\sum(X_i - \bar{X})(Y_{i-d} - \bar{Y})}{\sqrt{\sum(X_i - \bar{X})^2 \sum(Y_{i-d} - \bar{Y})^2}}.$$  

(2)

The above can be computed for all time delays $d = 0, 1, 2, \ldots$ At time delay 0, this reduces to calculating correlation coefficient between time series $X$ and $Y$. Cross-correlation assigns a score to each possible link between two nodes based on the highest cross-correlogram peak for assigned time lags or delays.

Entropy-Based Measures

Entropy is defined as the amount of information change in a random variable or the average uncertainty of a random variable. The entropy $H$ of a discrete random variable $X$ is expressed as in (3)

$$H(p) = H(X) = -\sum_{x \in X} p(x) \log_2 p(x),$$  

(3)

where $p(x)$ is the probability that $X = x$.

The joint entropy of two variables $x$ and $y$ is defined in (4) as

$$H(X,Y) = -\sum_{x \in X} p(x,y) \sum_{y \in Y} p(x,y) \log_2 p(X,Y).$$  

(4)

1. Gini Index

Gini Index is a measure of statistical dispersion or inequality in a population. It measures the divergences between the values of the probability distributions of the target ($Y$) and attribute ($X$).

2. Mutual Information

Mutual Information (MI) expresses the amount of information that one variable contains about another variable. Mutual information is defined as the reduction in uncertainty of one random variable $X$ given the knowledge about another variable $Y$ and is calculated as in (5).

$$I(X; Y) = H(X) - H(X|Y) = H(Y) - H(Y|X) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)},$$  

(5)

where, $p(x,y)$ is the joint probability distribution function of variables $x$ and $y$, $p(x)$ is the marginal distribution functions of $x$, and $p(y)$ is the marginal distribution function of $y$.

This quantity measures the distance between the joint probability density or distributions between variables $x$ and $y$. The mutual information is the difference in the entropy of signal $X$ by itself and the entropy of $X$ when it is conditional on another signal $Y$ or, it is the measure of difference between the joint probability distributions of the variables and their independent distributions.

3. Generalized Transfer Entropy

In its original formulation [11], for two Markov processes $X$ and $Y$ of order $k$, where $x_n^{(k)}$ is a vector of length $k$ whose entries are samples of $X$ at time $n$, $n-1$, $\ldots$, the transfer entropy (TE) from $Y$ to $X$ is defined as in (6),

$$TE_{Y \rightarrow X} = \sum P(x_{n+1}, x_n^{(k)}, y_n^{(k)}) \log \frac{P(x_{n+1}|x_n^{(k)}, y_n^{(k)})}{P(x_{n+1}|x_n^{(k)})},$$  

(6)

From the original paper by Stetter, et al. [12], TE can be defined as the distance between the probability distributions or the Kulback–Leibler distance between the single-node transition matrix $P(x_{n+1}|x_n^{(k)})$ and the two-node transition matrix $P(x_{n+1}, x_n^{(k)}, y_n^{(k)})$. TE is zero if the two probability distributions are identical or the distance between them.
is zero. If it greater than zero, it indicates dependence of \( x \) on past values of \( y \). Synaptic time constants of the neuronal network (~1 ms) are much shorter than the acquisition times of the recording (~10 ms).

In [12], in the formulation of Generalized Transfer Entropy (GTE), causal interactions between same bin nodes or events that occur in the same time slice are accounted for. Also, the network switches between different dynamical states of bursting and non-bursting. The fluorescence histograms of networks 1 and 2 respectively in Figure 2 are right skewed and resemble Gaussians with heavy tails on the positive side. If one were to fit the Gaussian profile (with a Gaussian function) and the tail with another suitable function, the point where they intersect would be the conditioning level. To restrict the evaluation of the network to a consistent range reflective of the overall collective network dynamics, the signal is averaged for the whole network as in (7) [12].

\[
g_t = \frac{1}{N} \sum_{i=1}^{N} x_i(t)
\]  

(7)

All data points in which the average fluorescence \( g_t \) is below this predefined threshold called a conditioning level or \( g \) are included in the analysis. Therefore, the authors restrict themselves to only time points \( t \) that fulfill the condition \( \{ t : g_t < \bar{g} \} \). Hence, TE using the above two considerations is reformulated as in (8) [12].

\[
TE_{Y \rightarrow X}^* (\bar{g}) = \sum P(x_{n+1}^{(k)}, y_{n+1}^{(k)} | y_{n+1}^{(k)} < \bar{g}) \log \frac{P(x_{n+1}^{(k)}, y_{n+1}^{(k)}}{P(x_{n+1}^{(k)})}
\]  

(8)

Granger Causality-Based Method

\( Y \) Granger-causes \( X \) if for some \( s > 0 \), the mean squared error of a forecast of \( X_{t+s} \) based on \( (X_t, X_{t-1}, \ldots) \) is larger than based on \( (Y_t, Y_{t-1}, \ldots) \) and \( (X_t, X_{t-1}, \ldots) \).

\( Y \) fails to Granger-cause \( X \) if for all \( s > 0 \), the mean squared error of a forecast of \( X_{t+s} \) based on \( (X_t, X_{t-1}, \ldots) \) is the same as that is based on \( (Y_t, Y_{t-1}, \ldots) \) and \( (X_t, X_{t-1}, \ldots) \).

Experimental Design

The study consisted of the following steps:

1. Datasets and data preparation

The datasets generated for the experiments used a realistic neuronal connectivity network simulator [8, 12]. The goal of the inference algorithms is to predict whether there is a connection between neuron \( i \) and neuron \( j \) in a network of \( N \) neurons. The resulting connectivity scores matrix is a \( N \times N \) matrix where \( N \) is the number of neurons and each entry \((i,j)\) gives an estimate of the strength of the connection, \( i \rightarrow j \). The original ground truth network structure is provided in another similar \( N \times N \) matrix, where entry \((i,j)\) indicates connection between neurons \( i \) and \( j \). Training and test data for networks of around 100–500 neurons are generated using the neuronal connectivity simulator. Table 1 provides a description of the generated networks. The connection and inhibitory probability are based on similar studies from literature [12].

Using the NEST [13] simulator, realistic dynamics like light scattering artifacts, bursting activity, and spontaneous firing dynamics of real, excitatory integrate-and-fire neurons are incorporated in the networks. In order to analyze the performance of the algorithms and benchmark them, we generated synthetic calcium fluorescence time series from the simulated cultured neural network that exhibits realistic dynamics. Since the surrogate ground truth topology of cultures is also available, the quality of the reconstruction can be evaluated by comparing the inferred with the real network connectivity.

A random pair of neurons is selected and their connections are crossed while maintaining the indegree and outdegree of the nodes. The clustering coefficient (CC) of a network by Watts and Strogatz [14] is defined as follows. Let us suppose a vertex V in a graph has \( k \) neighbors. If every vertex is connected to every other vertex in the graph then a maximum of \( \binom{k}{2} = \frac{k(k-1)}{2} \) edges can exist between them. Let \( C^' \) be the fraction of these possible edges that actually exist between a pair of nodes. The CC is then the average of \( C^' \) over all V. The crossing process of the connections was repeated until a desired CC was obtained. The diagonal entries of the connectivity matrix representing a neuron’s connections to itself are removed.

The clustering coefficient (CC) of a network by Watts and Strogatz [14] is defined as follows. Let us suppose a vertex V in a graph has \( k \) neighbors. If every vertex is connected to every other vertex in the graph then a maximum of \( \binom{k}{2} = \frac{k(k-1)}{2} \) edges can exist between them. Let \( C^' \) be the fraction of these possible edges that actually exist between a pair of nodes. The CC is then the average of \( C^' \) over all V. The crossing process of the connections was repeated until a desired CC was obtained. The diagonal entries of the connectivity matrix representing a neuron’s connections to itself are removed.

**Algorithm 1.** Algorithm to generate connectivity matrix from ensemble learners.

1. Generate simulated time series data with realistic properties for each network.
2. Draw random chunks of sizes 500, 1000, 10,000, and 100,000 from original time series.
3. For each random chunk for each sample size:
   i. Apply discretization and conditioning.
   ii. Generate connectivity scores using base predictors—Correlation, Cross-Correlation with time lag 1, Mutual Information, Gini coefficient, and GTE.
   iii. Concatenate scores from base predictors to generate features for each pair of neurons. Training labels are obtained from ground truth data indicating presence or absence of synaptic connections.
   iv. Perform 10-fold cross-validation repeated over 10 iterations using classifiers RF, linear SVM, and NNs.
   v. Generate AUC.
4. Average AUC for each sample size for each network is calculated.

**Figure 2.** Calcium Fluorescence Histograms of Network 1 and Network 2, respectively.

2. Study design

The same preprocessing—discretization and conditioning— is applied for all analyses. In phase 1 of the study, we performed an initial benchmarking study of the algorithms performance with respect to sample size and parameters. Area under ROC curve (AUC) and Area under Precision Recall Curve (AUPR) were calculated. Ensemble learning or generating features using base predictors can improve classification [15-18]. Based on our benchmarking study, in phase 2 of the design we generated an ensemble of features. The features were constructed by concatenating scores from correlation, cross-correlation for time lag 1, mutual information, Gini coefficient, and GTE. The predictors used were Support Vector Machines (SVMs) [19], Artificial Neural networks (NNs) [20, 21], and Random Forests (RFs) [22]. Our algorithmic approach is outlined in Algorithm 1.
Linear SVMs classify into two classes, here the presence or absence of synaptic connections between a pair of neurons, by calculating the maximal-margin hyperplane separating them. We have used a LIBSVM [23] MATLAB implementation with a linear SVM and a cost parameter of 1.

RFs are an ensemble classification method which uses bagging and constructs multiple decision trees at training time. The label is the mode of the classes of individual decision trees. We have used an R implementation of the RF [24] with 100 decision trees and no pruning. We have also performed permutation testing, which revealed that results from RF were significantly better than random AUC values.

NNs are inspired by biological neural networks and can be used as pattern recognition tools. Given a specific prediction task, NNs use the input patterns to learn the class of functions by minimizing error. We have used the MATLAB Neural Network Toolbox [25] with 1 hidden layer, 10 hidden neurons, and 1000 training epochs.

We have developed a toolkit in Python consisting of algorithms for discretization, correlation-based, and information gain-based algorithms has been developed for calcium fluorescence imaging data and is available publicly [26]. Where possible this code is used. All experiments were performed on CentOS 6.3 with MATLAB v2013a and Python 2.7.3.

3. Performance and Error Estimation

We perform a 10-fold cross validation [27] and averaged results repeated over 10 iterations for two separate ensembles generated from random subsampling of the original calcium fluorescence data. The cross-validation procedure divides the subsamples drawn into 10 non-overlapping balanced subsets. The process is then repeated 10 times with 9 sets used for training and 1 for testing.

4. Performance Metrics

The network reconstruction performance was evaluated with the AUC [28]. The AUC is equivalent to the area under the curve obtained by plotting sensitivity, or true positive rate against 1 - specificity, or false positive rate at different thresholds.

Results

In phase I of our benchmarking study, for subsamples of 500, 1000, 10,000, and 100,000, the network reconstruction performance was evaluated for 1000, 500, 100, and 10 runs for conditioning levels of 0.10 and 0.15. Results were averaged over all the runs for a given network and sample size. From the Receiver Operator Characteristic (ROC) and precision recall (PR) curves we concluded that most of the reconstruction techniques converged quickly at less than 1000 time samples. Correlation-based and Information Gain-based techniques had the best reconstruction performances. We repeated the reconstruction procedure for smaller sample sizes from 100, 200, ..., 1000 for 1000 runs and AUC and AUPR with 95% confidence interval (CI) were calculated. Results were averaged over all the runs for a given network and sample size. From the ROC and PR curves we observed, that correlation-based and information gain-based algorithms had AUC ~0.8 to ~0.9 for even smaller sample sizes of 1000 and 10000. As the lags were increased, both Cross-correlation and GC performed worse. This is explained as slower time lags fail to capture the characteristic instantaneous causal interactions between neurons.

In phase II, the network reconstruction performance was evaluated for two sets of random samples of sizes 500, 1000, 10000, and 180000 drawn from the original calcium fluorescence series and repeated for conditioning levels of 0.10 and 0.15 for each base predictor and ensembles generated from them. The results from the SVM, NN, and RF classifiers repeated for 10 runs and 10-fold cross-validations on the base predictors and Ensemble 1, Network 1 are in Table 2. From Table 2, we observe both NNs and RFs boosted performance even for small sample sizes of 500 and 1000. For larger sample sizes of 180000, NNS and RFs boosted AUC performance from 0.91 to 0.94 over the best base predictors. The results from the SVM, NN, and RF classifiers repeated for 10 runs and 10-fold cross-validations on Ensemble 1, Network 2 are in Table 3. From Table 3, both NNs and RFs boosted performance even for small sample sizes of 500 and 1000. For larger sample sizes of 180000, NNS and RFs boosted AUC performance from 0.88 to 0.93 over the best base predictors. The results from the SVM, NN, and RF classifiers repeated for 10 runs and 10-fold cross-validations on Ensemble 2, Network 1 are in Table 4. From Table 4, while linear SVMs, RFs, and NNs all boost classifier performances considerably for smaller sample sizes of less than
1000, RFs and NNs improve AUC from 0.89 to 0.94 for larger sample sizes. The results from the SVM, NN, and RF classifiers repeated for 10 runs and 10-fold cross-validations on Ensemble 2, Network 2 are in Table 5. From Table 5, we observe, while linear SVMs, RFs, and NNs all boost classifier performance for even smaller sample sizes, RFs and NNs improve AUC from 0.87 to 0.93 for sample sizes of even 10,000. The ensemble learners also show convergence at approximately 1000 samples.

Discussion

We performed a benchmarking study of several algorithms with different parameters based on sampling distribution and variability. Based on the performance of the algorithms, we use the scores on the connections to construct features of a classifier and predict the presence or absence of connections under different experimental conditions. While other studies have extracted topological features by combining base predictors and trained RFs on them, our study advances the state of the art by adopting a unified data-driven approach to algorithm, parameter, and feature construction combination. We have also robustly tested for overfitting by performing permutation testing.

The net result is an important enhancement of reconstruction performance from ~0.89 of the best base predictors to ~0.93 of RF and NN ensembles for large sample sizes of 100,000. This is a fully generalizable methodology applicable to all brain connectivity datasets with even more realistic numbers of neurons. The methodology also admits incorporating additional methods as they become available for further performance enhancement. For example, edge orientation algorithms can be used to infer directionality of the connections. Causal feature selection [29] on the ensemble could also be used in future expansion of the method (but was not pursued here because such methods have not yet been customized for brain connectivity). Improved signal preprocessing such as network deconvolution, spike extraction, etc. may generate further improvements on performance.

Limitations of this study include the use of simulated datasets in the absence of ground truth from real time measurements of in vivo neuronal networks. On the other hand the use of realistic simulators enables generating the necessary sample sizes, allows for determine effects of noise and a multitude of other analytic factors, while it neatly isolates assay-related experimental effects from the effects of computational analysis. When data with robust ground truth becomes available from complex in vivo organism studies the methodology presented here can be readily used to derive new discovery methods. Moreover, finer parameter selection could boost classifier performances even more. Our findings can help advance the state-of-the-art methods to design massively scalable algorithms for modeling real neuronal systems and also aid causal structure reconstruction in other areas like finance, genomics, and psychiatry where such problems are common.

In conclusion the framework presented here studies the performance characteristics and combines information theoretic, feature construction and pattern recognition based meta-learning methods to considerably improve the Area under ROC curve (AUC) performance of prior techniques. The approach is generalizable and extensible. Our data are very promising toward the feasibility of reliably reconstructing complex neuronal connectivity.

Abstract
Despite federal incentives for adoption of electronic health records (EHRs), surveys have shown that EHR use is less common among specialty physicians than generalists. Concerns have been raised that current-generation EHR systems are inadequate to meet the unique information gathering needs of specialists. This study sought to identify whether information gathering needs and EHR usage patterns are different between specialists and generalists, and if so, to characterize their precise nature. We found that specialists and generalists have significantly different perceptions of which elements of the EHR are most important and how well these systems are suited to displaying clinical information. Resolution of these disparities could have implications for clinical productivity and efficiency, patient and physician satisfaction, and the ability of clinical practices to achieve Meaningful Use incentives.

Introduction
Electronic health records (EHRs) have become an increasingly critical component of modern health care delivery, and are used in all clinical disciplines.1 59% of hospitals and 48% of office-based providers currently use EHRs.2,3 However, despite the growing ubiquity of these systems, there is still substantial variability in adoption between different clinical disciplines.1,3 Specifically, adoption rates within surgical and medical specialties are approximately one half that of primary care physicians.1,4,5

In addition to these disparities in adoption rate, concerns exist that different medical fields may have varying levels of compatibility with current-generation EHRs. Numerous medical specialty societies have expressed the need for specialty-specific systems to meet the unique needs of their respective fields, including ophthalmology, orthopedic surgery, dermatology, oncology, obstetrics/gynecology, pediatrics, and pathology.6,7,8,9,10 These unique needs include differing workflow, information gathering, and clinical documentation requirements along with variations in baseline clinical volume, billing and compliance requirements, and specialty-specific terminology. Nonetheless, the widespread adoption of EHRs in the United States continues to increase, driven largely by federal incentives through the Centers for Medicare and Medicaid Services (CMS) Meaningful Use program.7,11 In 2015, penalties will begin to be levied against health care organizations that fail to meet several key EHR implementation requirements.14 Further incentivizing EHR adoption and making the avoidance of EHRs less practical for physicians, regardless of how suitable such systems are to their specialty-specific needs.

There are numerous potential implications if current-generation EHRs do not function adequately in medical disciplines of all varieties. These include decreased physician and patient satisfaction, impaired productivity and efficiency, and difficulty meeting Meaningful Use requirements.12,13 However, to date there is no experimental evidence as to whether or not such a disparity in functionality exists among different clinical disciplines, or what the nature of those differences in information-gathering needs might be. While various disciplines have expressed differing ideas of how the EHR should function and what it should provide, there is no evidence that these groups use current generation EHRs differently from each other in clinical practice.15,16 In order to better meet the health information technology needs of all clinical disciplines, determining whether such interdisciplinary differences exist and identifying their precise nature is imperative. To accomplish this, we developed a survey to characterize three parameters of physicians’ methods of clinical information gathering using EHRs when evaluating a new patient; these were 1) How the EHR is incorporated into typical clinical workflow, 2) Which elements of the chart are most important and useful to the clinician, and 3) The strengths and weaknesses of the electronic chart in displaying
relevant clinical information. These parameters were then compared between specialty and primary care physicians to identify any differences that may exist.

**Methods**

This study was approved by the Institutional Review Board at Oregon Health & Science University (Portland, OR). Acknowledgement of an information sheet by survey participants was used in lieu of informed consent.

**Survey Development**

The authors developed an 18-question survey for the purposes of data collection (Appendix). When answering these survey questions, respondents were asked to envision the scenario of evaluating a new patient rather than performing a follow up visit. This was because the former is a situation that physicians of all specialties have experience with, and because it provides the greatest insight into the strengths and weaknesses of the interaction between physician and EHR. Subjects were also instructed to envision using their own, most commonly-used EHR when responding to survey questions rather than a conception of a generic EHR system. Demographic characteristics were also collected, including primary clinical specialty, gender, clinical experience (years since graduation from medical school), level of computer experience, and primary practice setting (ambulatory vs. inpatient). The survey also included an optional free-text response elicting any additional thoughts or comments. Survey reliability was confirmed using test-retest and alternate form methods. Specifically, the survey was administered twice to 4th year medical students, each administration separated by one week. There was 91% agreement between pre- and post-test responses. Survey content and construct validity were established iteratively through expert interviews and feedback.

**Survey Administration**

An email containing a link to the questionnaire was distributed to all practicing physicians at three health care organizations in Oregon (Oregon Health & Science University/Portland VA Medical Center, PeaceHealth Medical System, and Legacy Emmanuel Medical Center) and one in Pennsylvania (Children’s Hospital of Philadelphia). These institutions were selected because of the wide variety of primary care and specialty disciplines represented at each site, and because they represented a mix of academic and community-based practices. The email was then resent to all recipients after one month. The survey was administered using REDCap electronic data capture tools hosted at Oregon Health & Science University.

**Statistical Analysis**

The primary purpose of this study was to compare several aspects of physicians’ information gathering methods using the EHR across different clinical disciplines. In order to perform this comparison, individual disciplines were combined into two groups: the Specialty group and the Primary Care group. Primary Care was considered to include General Internal Medicine, General Pediatrics, Family Medicine, and Geriatrics, in accordance with the definition of the term provided by Medicare. The Specialty group was defined as any clinical discipline other than these four Primary Care disciplines, and in this case included respondents from Obstetrics & Gynecology, Ophthalmology, Orthopedics, General Surgery, Surgical Sub-Specialties, Emergency Medicine, Internal Medicine Sub-Specialties, and Pediatric Sub-Specialties.

Three primary outcomes were compared between the Specialty vs. Primary Care groups: Outcome 1) How the EHR is incorporated into typical clinical workflow (Table 3); Outcome 2) Which elements of the chart are most important and useful to the clinician (Question 15; Figure 1); and Outcome 3) The strengths and weaknesses of the electronic chart in displaying relevant clinical information (Questions 17 and 18; Tables 4 and 5). Categorical response options were assessed using the Pearson Chi² test followed by multinomial logistic regression accounting for the covariates listed previously. Binary outcomes were assessed using the Pearson Chi² test followed by multivariable logistic regression. Ordinal outcomes were assessed using the Cochran-Armitage Test for Trend. One question (Question 15) provided multiple categorical responses for each respondent; in this case, proportions and 95% confidence intervals were compared between the Specialty vs. Primary Care groups for each potential response. Likert-type scale responses followed a nearly normal distribution and were treated as discrete continuous variables. An overall composite score was determined for each question by obtaining the group mean across all sub-sections, and these composite scores were compared between the two main predictor groups using multivariable linear regression. Thus overall scores of the ability of the EHR to display needed clinical information (Question 17) and of the severity of barriers to accessing needed information in the EHR (Question 18) were obtained from each respondent and compared between the Specialty vs. Primary Care groups. All analyses were performed using Stata SE12 (StataCorp, College Station, TX).
Results

Participant Demographics

Of the 3,649 physicians who received the survey link, 744 completed the questionnaire. This yielded a response rate of 20.4%. Of these 744 respondents, 90 were excluded either because they were not actively practicing medicine, did not use an EHR on a regular basis, or did not identify with a relevant clinical specialty, resulting in 654 responses being included in the final analysis. Three hundred fifty respondents (54%) identified with a clinical discipline in the “Specialty” group, and 304 (46%) with a discipline in the “Primary Care” group (Table 1). Subjectively, there were minimal differences between these groups with respect to clinical experience (number of years in practice), baseline computer experience, level of training, and primary practice environment (ambulatory vs. inpatient) (Table 2). However, there was a slightly higher proportion of males in the Specialty group (57%) compared to Primary Care (51%). A total of 13 EHR vendors were utilized by study participants; the most common of these were Epic (Verona, WI; 71%), Centricity (GE Healthcare, UK; 5%), CPRS/Vista (US Department of Veterans Affairs; 5%), Cerner (Kansas City, MO; 3%), and Allscripts (Chicago, IL; 3%).

Incorporation of the EHR Into Clinical Workflow (Outcome 1)

Approximately one half of physicians in both the Specialty and Primary Care groups used the EHR as the primary source of initial information when evaluating a new patient (Table 3). However, there were significant differences between the two groups with regard to the other sources of information utilized (Pearson Chi² test; p=0.02). Multinomial logistic regression confirmed this association even after adjusting for differences in level of training, amount of clinical experience, and practice setting. Specifically, Specialty physicians were significantly more likely to utilize another physician as their initial source of information on a new patient (OR=2.09, p<0.01). Primary Care physicians were significantly more likely to utilize the patient as their initial source of information than their Specialty counterparts (OR=1.47, p=0.05). There were no significant differences between the two groups regarding the likelihood of using the patient chart or a technician/ancillary staff as the primary source of initial information on a patient (Table 3).

Of the Specialty physicians surveyed, 296/332 (89%) reviewed the chart prior to entering the room with the patient, compared to 244/295 (83%) of Primary Care physicians (p=0.02). This relationship was not confounded by gender, amount of computer experience, or level of training. After adjusting for the amount of clinical experience and primary practice setting (ambulatory or inpatient), Primary Care physicians were still significantly more likely to delay chart review until during or after the patient encounter than Specialty physicians (OR=2.15, p<0.01). The duration of this initial chart review session was quite variable in both groups, with the majority of respondents

*Self-reported years since graduation from medical school
indicating a time frame of 2-10 minutes (64% in the Specialty group and 57% in Primary Care). There was no significant difference between the two groups with respect to duration of chart review (p=0.91).

Relative Importance of EHR Elements (Outcome 2)

Participants ranked several elements of the EHR to identify the top 5 “most important” when evaluating a new patient. Specialty physicians ranked these sections as (in descending order of importance): 1: Chief Complaint, 2: Past Medical History, 3: History of Present Illness, 4: Imaging, and 5: Lab Values. Among Primary Care physicians, these sections were: 1: Medications, 2: Past Medical History, 3: Chief Complaint, 4: History of Present Illness, and 5: Problem List (Figure 1). Two individual elements of the EHR were perceived as significantly more important by the Primary Care group compared to the Specialty group; the first was the Problem List, ranked among the top 5 most important sections of the EHR by 61% of Primary Care physicians (95% confidence interval [CI]: 55-66%) compared to only 27% of Specialty physicians (95% CI: 23-32%). Secondly, the Medications section was ranked in the top 5 by 76% of Primary Care physicians (95% CI: 71-81%) compared to 44% of Specialty physicians (95% CI: 39-50%). One element of the EHR was significantly more important to Specialty physicians; this was the Imaging section, ranked in the top 5 by 50% (95% CI: 45-55%) compared to only

**Figure 1: Relative Importance of Various EHR Elements among Primary Care and Specialty Physicians.**
Proportion of respondents ranking the indicated section among the top 5 “most important” EHR elements.
Hx=history; HPI=history of present illness.
27% of Primary Care physicians (95% CI: 22-32%). There were also small but statistically significant differences in the rankings of the Allergies, Social History, and Past Surgical History sections (Figure 1).

**EHR Utility and Ease-of-Use (Outcome 3)**

Two Likert-type scale questions assessed this parameter. The first (Question 17) asked respondents to rank how well information was displayed in various sections of the EHR on a scale from 1 to 5 (1 indicating the display was “Very good”, 3 indicating “neutral”, and 5 indicating “Very bad”). Average ratings of these sections ranged from mean ± standard deviation (SD) of 2.04 ± 1.08 for “Laboratory Results” to 2.64 ± 1.21 for “ICU Bedside Data” (Table 4). The composite score representing the overall ability of the EHR to display relevant clinical information had a mean ± SD of 2.40 ± 0.75 (range: 1-5). Multivariable linear regression showed no difference in this composite score between the Specialty and Primary Care groups (p=0.90). However, there was a significant association with practice setting. Specifically, ambulatory physicians rated the composite score significantly worse than inpatient physicians (2.48 vs. 2.29, respectively; p<0.01).

The second Likert-type scale question asked respondents to rank the severity of 6 potential barriers to accessing needed information in the EHR on a scale from 1 to 5 (1 indicating a “Not a barrier”, 3 indicating “Moderately strong barrier”, and 5 a “Severe barrier”). Average ratings of these barriers ranged from mean ± standard deviation (SD) of 2.84 ± 1.27 for “Information in the chart is inaccurate” to 3.32 ± 1.11 for “Others don’t record information consistently” (Table 5). The composite score of these six potential barriers had a mean ± SD of 3.11 ± 0.86 (range: 1-5). Multivariable linear regression showed a small but statistically significant difference in this composite score between the Specialty (3.20) and Primary Care (3.01) groups (p<0.01). This association was not confounded by gender, amount of computer experience, level of training, clinical experience, or practice setting.

**Discussion**

This study assessed potential differences in EHR requirements among different clinical disciplines. Key findings were: 1) Both specialty and primary care physicians relied on the EHR as the most common initial source of clinical information; 2) There were significant differences between primary care and specialty physicians regarding which sections of the EHR were considered most important; 3) Specialists identified stronger barriers than primary care physicians with regard to ability to access clinical information in the EHR.

The first key finding was that both specialists and primary care physicians identified the chart as the most important initial source of patient information. This emphasizes the critical role of EHRs in modern health care, and the potential impact of using systems that do not adequately meet all providers’ needs. Interestingly, while the importance of the EHR was uniform between both groups, its method of use and incorporation into clinical workflow were not. Specifically, primary care physicians were much more likely to delay initial chart review until during or after entering the patient room. This resulted in them being more likely to utilize the patient as their initial

SD=standard deviation
source of information, while specialists were more likely to obtain information from other/referring providers. These differences in workflow provide additional opportunities for optimization of EHRs to meet the varying needs of different disciplines.

The second key finding identified several elements of the chart that were considered important by one group but not the other. Specifically, primary care physicians showed significantly greater interest in the Problem List and Medications sections than their specialty counterparts. As one respondent stated, “I’m a surgeon…I write 2 or 3 prescriptions a month, but the patient’s pharmacy is thrust before me in almost every screen.” Conversely, specialty physicians considered the Imaging section much more important than primary care physicians. This sentiment was also echoed in the respondent comments; said one physician, “In image driven specialties, like neurosurgery, it is crucial to get actual outside imaging and not just reports. The difficulty in doing this often leads to unnecessary CT/MRI scans and better communication/transmission of these data would be valuable.”

The third key finding was that specialists face slightly stronger barriers than primary care physicians in accessing needed information from the EHR. This difference was small but statistically significant, and is consistent with the complaints raised by numerous specialty societies. One respondent summarized this by saying, “I think that most of the major systems that try to serve multiple specialties are full of an unbelievable amount of bloat. My system is specialty specific and is tailored to do exactly what I need it to do.” Said another, “The electronic medical record is very poorly organized for a pediatric ICU patient. We have to create workarounds to get the information displayed in a meaningful manner.”

These results clearly demonstrate several differences between primary care and specialty fields with respect to which elements of the EHR are considered most important when gathering clinical information, as well as their perceptions of how well these systems are able to provide such information. These differences have several important implications. The first is impaired satisfaction among physicians using systems ill-suited to their practice; one recent survey suggested that 31% of all surgical and medical specialists were “very dissatisfied” with their EHR systems, compared to only 8% of primary care providers. In addition to physician satisfaction, inefficiencies introduced by poorly-integrated EHRs could impair clinical productivity and in turn affect patient satisfaction as well. Another potential sequela of this situation is greater difficulty in achieving Meaningful Use criteria, with large potential impacts on reimbursement. This is important, as it has been shown that EHR selection is heavily influenced by financial and organizational factors independent of clinical demands. In response to this concern, several medical specialty societies have successfully advocated for the inclusion of rules, exemptions, and options in stage 2 of Meaningful Use to better suit the practices of specialists. However, prior to this study there have been no data to guide these modifications, making their adequacy uncertain. Importantly, CMS does permit Meaningful Use exclusions for providers that do not collect core measures outside their scope of practice; however, these exclusions must be applied for on an individual provider basis. This places the burden of appropriately collecting these measures on the end user rather than the system, and does not provide a large-scale solution to the problem.

The results of this study inform several potential interventions to address these concerns. First, EHRs must be targeted to meet the unique documentation needs of individual specialties. Several such “specialty-specific” systems already exist, but further assessment of the precise information-gathering requirements of each specialty is required to optimize these systems. Second, the method of implementation of EHRs across health care organizations must be carefully considered. The vast majority of EHR-using physicians in the United States practice in health systems employing a single EHR system incorporated across multiple clinical departments (the so-called “Enterprise” or “Single Vendor” EHR solution). This has benefits for interdepartmental communication and ease of logistical processes such as billing and scheduling, but as the results of this study suggest, it may be difficult for a single EHR to meet the needs of all specialties simultaneously. Alternatively, a “Best of Breed” approach involving a network of specialty-specific systems can be employed. However, establishing this network of multiple products from a variety of vendors is extremely challenging from logistical and interoperability perspectives, and can result in a fragmented and ineffectual hospital information system. More recently, a third strategy has emerged: the so-called “Best of Suite” approach. This strategy involves a point-by-point assessment of the relative merits of integration vs. differentiation at each node of the information system (i.e. individual clinical departments, billing, scheduling, etc.), resulting in a framework falling somewhere between the “Single Vendor” and “Best of Breed” models. This approach may provide a more balanced solution, improving hospital efficiency while simultaneously meeting the varying needs of different clinical disciplines as identified in this study.

This study has several limitations. First, the response rate is on the low-normal end for similar surveys of this nature. Thus our respondent pool may not be representative of the population as a whole, and may be a collection
of physicians with the most strongly-held beliefs on this topic. However, the wide ranges and standard deviations of responses to Likert-type scale questions indicate adequate variability of opinion among the respondents. Second, our grouping of clinical disciplines was fairly coarse due to overrepresentation of some disciplines compared to others. For example, there were many more pediatricians than surgeons in our respondent pool. However, subjectively there were minimal differences between individual specialties within groups, indicating an appropriate categorization scheme. Additionally, these differences resulted in inadequate power to identify differences between individual specialties, requiring the grouping of disciplines into “Specialty” and “Primary Care” categories. Consequently, our results provide a broad assessment of differences between clinical disciplines, but future studies are needed to identify differences between individual specialties. Third, not all EHR systems were represented in our study. However, our sampling scheme did capture several of the most heavily used products nationwide. Additionally, supplementary analysis revealed that the trends identified were present among both Epic and non-Epic users, indicating that the results are not unique to this system alone. Finally, Likert-type scale responses were analyzed parametrically, which assumes that the intervals between ordinal categories are of equal size. For example, we assume the difference between “Not a barrier” (1 out of 5) and “Moderate barrier” (3 out of 5) is the same as that between “Moderate barrier” and “Severe barrier” (5 out of 5). However, this assumption was supported by the fact that responses to these questions followed approximately normal distributions.

Conclusions
This study demonstrates several differences between specialty and primary care physicians in their methods of using EHRs for clinical information gathering and perceptions of the most important elements of these systems. This has important implications for clinical workflow and efficiency, patient satisfaction, physician satisfaction, and financial reimbursement. Future studies must continue to delineate the unique requirements of individual specialty fields to facilitate informed modification of EHR design, implementation, and governmental oversight.

Predicting Health Care Utilization After Behavioral Health Referral Using Natural Language Processing and Machine Learning

Nathaniel Roysden¹, Adam Wright, Ph. D¹ ¹²
¹Harvard Medical School, Boston, MA; ²Brigham and Women’s Hospital, Boston, MA

Abstract

Mental health problems are an independent predictor of increased healthcare utilization. We created random forest classifiers for predicting two outcomes following a patient’s first behavioral health encounter: decreased utilization by any amount (AUROC 0.74) and ultra-high absolute utilization (AUROC 0.88). These models may be used for clinical decision support by referring providers, to automatically detect patients who may benefit from referral, for cost management, or for risk/protection factor analysis.

Introduction

Optimization of cost while preserving or improving quality of care is a central focus of national health reform. One major predictor of high cost of treatment is mental health comorbidity—one study found that, on average, patients with a mental health diagnosis were 2.2 times more expensive than patients without a mental health diagnosis.¹ In addition to mental health diagnoses, there are other behavioral health issues that may not result in a diagnosis, but still predict increased rates of health care utilization.² This increase in utilization is theorized to be due to a decreased ability to care for self and high rates of unnecessary care.³ In addition to cost considerations, the additional health care utilization associated with behavioral health conditions may also pose the health risk of unintended negative treatment outcomes from unnecessary care.⁴

Given the potential for significant improvement of health status and reduction in health costs, patients who may benefit from behavioral health referral are an important cohort for identification. Similar to prediction of readmission, prediction of high care utilization post-referral may signal reconsideration of treatment planning, while prediction of decreased utilization may strengthen the decision to refer. A very high specificity model may even be used to automatically prompt referral for certain patients. Accordingly, the goal of this project is to be able to create a model which can accurately predict the health care cost outcomes of behavioral health referrals.

Machine Learning (sometimes also called “Data Mining”) and Natural Language Processing (“NLP”) methods have previously been used on Electronic Medical Record (“EMR”) and billing data for both predictive and text-classification purposes. While machine learning models excel at determining the content of medical notes,⁵,⁶ their application to prediction of clinical outcomes has varied. One study achieved good results predicting future morbidity of admitted cases of suspected sepsis using a neural network.⁷ Another study used a regression tree model to predict post-hospitalization suicides of Veterans Administration patients, again with good results.⁸ With regard to more specific clinical outcomes, yet another study employed machine learning models to predict cardiac arrests after an emergency department electrocardiogram.⁹ Other common models used in descriptive and predictive machine learning include support vector machines and random forests. He et al. used data mining methods to predict early hospital readmissions.¹⁰ The He et. al. paper is most comparable to this paper, due to its broad cohort and highly variable outcome. Their study differed in its focus on “feature selection and exclusive use of administrative data for ease of portability and understanding,” with use of a model that was suited to that particular approach.

We aim to use similar machine learning approaches to predict the outcomes of a patient’s first encounter with behavioral health providers (“BH patients”). The studied outcomes are cost-related in both a relative and an absolute sense. The first outcome is decreased health care utilization by any amount following a BH encounter. The second outcome is extremely high post-BH utilization, defined as utilization in the 95th or 99th percentile of non-BH patients. These predictions will be made using random forest classifiers trained on a robust clinical data set, including structured administrative data, free text from provider notes, and lab data.

Methods

Data sources
The Partners Research Patient Data Registry (“RPDR”)¹¹ is an integrated data warehouse with the ability to query an array of discrete databases storing Partners electronic health data from its various member institutions. For this study, the RPDR was queried for patients who were seen at least once in a Brigham and Women’s Hospital (“BWH”) primary
care practice. This query returned records for approximately 221,000 patients. Those records contained EMR free text notes, procedure codes (billing), encounters (scheduling), problem lists, diagnoses, lab results for A1c and Cholesterol, medication lists, and demographics. The Partners IRB approved this study.

A second set of data was downloaded from the online Medicare Physician Fee Schedule Value Files on an annual basis from 1999 to present and used to estimate standard payments for billed services.¹²

Tools
The Anaconda¹³ distribution of Python 3.4 was used with notable packages including the Python Natural Language Toolkit (“NLTK”), Matplotlib, Numpy, Scipy, and Scikit-Learn (“sklearn”), including the Scikit-Learn¹⁴ Random Forest Classifier (“RFC”)¹⁵ implementation. Other models from sklearn that were tested but not further described in this paper include AdaBoost Classifier and Random Forest Regressor.

Intervention
Clinic location was selected as the study intervention over psychiatric diagnoses because it represents the treatment benefit provided by any behavioral health services, even for patients who do not have a defined diagnosis.¹⁶ This intervention was recorded as the date of the earliest psychiatry, psychology, or behavioral health clinic encounter from the encounters dataset, based on the listed clinic location for each date of service.

Sample / Cohort Selection
Only patients with at least one behavioral health clinic visit after 2005 were included in the study cohort, reducing from 221,000 patients with at least one visit to a BWH primary care provider to 37,000 patients. Furthermore, only patients with at least one procedure code between 120 and 365 days before and after the first BH visit were included, resulting in a final cohort of 12,759 patients.

Health Care Utilization
The procedures (billing) dataset was converted from procedure codes to their most recent available Relative Value Unit (“RVU”) value via the Physician Fee Schedule files. These RVU values were paired with their corresponding dates for each patient. All entries prior to 2005 were removed from the data set, because there was a significant change in the billing data from 1995 to 2005—an exponential increase in apparent billing that likely represents changes in hospital electronic record keeping. This significantly biased early model attempts, by creating a set of patients who almost all showed increases in health care costs between 1995 and 2005. Billing data from 2005-2014 remained stable.

Health care utilization was calculated for procedure codes in the year prior and the year following the first behavioral health visit (“dateBH”) for each patient in the BH group, as shown in (Equation 1). Billing codes from more than one year prior or more than one year after the first BH visit were ignored. Patients with no billing codes more than 120 days before or without codes more than 120 days after their first BH visit were also removed. This 120 day requirement was intended to ensure that calculated values represented enduring trends in terms of usage before and after the intervention, not singular health interactions causing apparent health utilization to be inflated by a small denominator. Monthly utilization and three-month windowed utilization were each calculated in similar fashion.

\[
\text{Equation 1: } \text{Usage} = \frac{\sum_{i=0}^{n} RVU_i}{\text{dateBH} - \text{dateBH}_n} \quad \text{where date}_n \text{ is the date that maximizes the denominator}
\]
To ensure that utilization calculations were not affected by significantly different denominators, the summary statistics for the “delta days” term were calculated, as shown in (Table 1) below.

<table>
<thead>
<tr>
<th>Group</th>

</tbody>
</table>

Health utilization was calculated for patients without any visits to a behavioral health provider (hereafter “Comparison Group”) using the procedure codes within one year prior to the most recent recorded procedure code, also excluding patients without at least one procedure code occurring more than 120 days before the most recent procedure code. These values were used solely for reasonable cutoff values for classification of BH patients and therefore the slight difference in recorded days between BH and comparison patients does not affect the study outcome. (Table 2) below shows health care utilization in terms of RVU per day over a range of percentiles. These comparison group percentile cutoffs were then used to calculate static cutoffs for absolute utilization by the BH group. In other words, future categorization of BH patient utilization as “above the 99th percentile” means above the 99th percentile of the comparison group and does not reflect the proportion of BH patients falling into that group.

**Feature Extraction**

The frequency of health contacts was calculated as the number of unique dates of service divided by the number of days between the most remote and most recent visit in the year preceding the first behavioral health visit.

The diagnoses, labs, medications, and procedures data sets each include a date with every entry; entries following the first BH visit were discarded. The demographics data set returns values accurate to its date of access; entries were recorded for patients as of the date that particular subset of the data was returned i.e. Oct-Nov, 2014, with each possible value comprising a separate binary feature in the model. Two labs, A1c and Cholesterol, were included as features according to their most recent lab value prior to behavioral health visit. Text results like “cancelled” were entered as 0. Results satisfying the regular expression for “>14.0” were entered as 14.0. Medications were included as discrete features according to their “medication code”, a structured identifier of the medication without dosage information; multiple occurrences were counted. Diagnosis and procedure codes were recorded with each unique item entered as a separate feature; their values were entered as a count of the number of individual times they were encountered in each patient’s data set.

Finally, each patient’s notes—prior to their first behavioral health visit—were concatenated and then extracted into frequency distributions (counts) of tokens, bigrams, and trigrams after removal of the NLTK English “stopwords” set, with the exception of negating terms (“no, nor”).

**Cohort Evaluation**

(Figure 2) below shows a 40x40 bin heat map of health resource utilization in RVU/day before and after the first BH clinic encounter. The likelihood of a patient having decreased health resource utilization following their first BH encounter, by any amount, was 52.8%. The plot is log scaled by number of patients in each category as specified in the color bar on the side of the image, white areas represent no data.
Figure 2: Heat map of patient utilization before/after their first behavioral health encounter

(Table 3) below displays the same information but with a coarse and nonlinear binning. Notably, while patients in the <50th percentile and 50-80 percentile groups most often remained in their cohorts, 95th and 99th percentile patients typically fell to lower percentile groups—a minority remained persistently high utilizers. This analysis also revealed a fair comparison for the “above x percentile” models—the baseline assumption that patients will continue using the same amount of health care before and after their first BH encounter.

The overall effect of behavioral health visits on patient costs was quantified by converting the total amount of RVU’s counted in the before- and after- BH groups using $35.8 per RVU. At that reimbursement rate, the pre-BH group cost $78.6 Million per year, while the post-BH group cost $73.3 Million. Also of note, the 2% of pre-referral patients who were in the 99th percentile category accounted for 16% of annual pre-BH cohort costs; the 2% of patients in the post-referral group whose utilization was above the 99th percentile accounted for 17% of post-BH costs. The BH group falling into non-BH percentiles 0-80 together accounted for 24% of spending before and 28% of spending after the first BH encounter, while comprising 67% and 71% of the BH patient population, respectively.

Categorization
Three category vectors were created and used as outcomes for prediction in our models. The positive categories for each vector were: 1. Post-BH utilization greater than 99th percentile. 2. Post-BH utilization greater than 95th percentile. 3. Post-BH utilization below pre-BH utilization by any amount.

Feature Selection
The two calculated features, utilization and visit frequency, and all of the structured data were exempted from feature selection and normalization. Throughout the feature selection process, each selection method was trained on the training data and then applied to both the training and test data.

Before feature selection, token vectors, bigram vectors, and trigram vectors were separately normalized along the sample axis. Next, n-grams that occurred in fewer than 3 or more than \((n_{samples}-3)\) samples were removed from the feature set using a variance selection method. This reduced the feature space from over 17 million features to approximately 1 million. Finally, one sklearn f_classif selector, which chooses features based on their Anova F-value, was trained to select the best 100,000 features (“above percentile” model) or 20,000 features (“decreased utilization” model) from the total set of n-grams. Approximately 163,000 (83,000) features were included in each model.
Model Creation
Structured grid search was performed on a randomized test/train set to find the optimal settings and number of included n-grams for each model, detailed below. Two metrics were used to optimize grid search: Matthews Correlation Coefficient (“MCC”) (Equation 2) and F1 Score (“F1”) (Equation 3). The MCC is a metric that balances all four quadrants of the confusion matrix and is a conservative optimization approach. The F1 score reflects performance of the precision-recall curve and is less conservative than the MCC but more conservative than the Area Under the Receiver Operating Characteristic curve (AUROC).

Equation 2: \[ MCC = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}} \]

TP, TN, FP, and FN are, respectively, True Positive, True Negative, False Positive, and False Negative

Equation 3: \[ F_1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \]

The number of trees in each forest was partially limited by the need to balance the demands of runtime and development time, especially with classifiers trained using the max_features = None argument. The number of included features was similarly limited by runtime and available memory: only about 200,000 maximum features could fit in memory when stored as a dense array.

Above Percentile Classifiers: Each Random Forest Classifier was trained using 5000 trees with samples weighted according to the inverse of class frequency and otherwise default settings.18

Increased/Decreased Utilization Classifier: 100 trees were calculated with balanced sample weights and the max_features parameter set to None, meaning that each tree would consider all possible features to determine optimal split.

Cross Validation
Stratified three-fold cross validation was performed to train and test each classifier. Feature selection methods were trained on each separate training fold and applied only to each corresponding test fold. Similarly, each classifier was created on the train fold and applied to the test fold. No information or model parameters were shared between folds of the cross-validation process. Each fold of the cross-validation required approximately 20 minutes for the “Above Percentile” classifier and approximately 40 minutes for the “Increased/Decreased” classifier. Runtime for an individual sample (patient) on a trained, loaded classifier is in the sub-seconds range.

Results
Predicting Decreased Utilization
(Figure 3) below shows the Receiver Operating Characteristic (“ROC”) and Precision-Recall (“PR”) curves corresponding to the classifier’s ability to predict that a patient’s utilization will decrease after their first BH clinic visit.

![Figure 3: ROC and PR curves for predicting decreased utilization after BH encounter.](image-url)
(Table 4) below details classifier performance metrics for each fold of the cross validation. The “Optimization” label details which performance metric was optimized to set the threshold value used in the classifier: the remaining metrics are reported at that given classifier confidence threshold. Both the Matthews Correlation Coefficient (“MCC”) and, separately, the F1 score (“F1”; also called “F-measure”) were calculated for each fold of the cross validation. With a mean Area Under the Receiver Operating Curve (“AUROC”) of 0.74 and average precision—the precision-recall curve correlate to AUROC—of 0.74-0.75, the model performs much better than random chance.

</table>
The maximal values of the mean rows were used to compare the classifiers with the base case assumption that a patient would continue using the same amount of health care before and after referral. The maxima were used because, unlike said basic assumption, a classifier model can give a range of values based on the individual sample being predicted. While the 99th percentile prediction model significantly outperforms the prior utilization assumption, the 95th percentile model is only a mild improvement, with its major additional contribution being higher recall.

Discussion

Significance
This paper is novel in three ways: First, the studied intervention—a patient’s first behavioral health clinic encounter—is both novel in its scope and aligns the studied intervention with resilience theories of behavioral health; in other words, the importance of the intervention is that a patient sought and received behavioral health care, not the precise reason for that interaction. Second, the outcome of patient health care utilization as a primary endpoint, although not entirely novel by itself, has not been well studied using methods similar to this paper. Finally, in addition to structured administrative data, this model uses data derived from lab results and, less common in predictive healthcare research, free text from provider notes.

Using this robust data set and a random forest classifier, we achieved significant improvement over random chance and over prior probability for predicting patient health utilization after behavioral health referral. Furthermore, this
method achieved similar performance metrics to the latest models for predicting early hospital readmission.\textsuperscript{10} (Table 8) below compares the classifier metrics reported in He’s paper with the metrics in this paper. Ranges for He’s paper reflect their lowest and highest reported performance metrics on two different patient cohorts and applied to both same-site and outside institution data sets, as well as the class balance of their data sets in comparison to ours.

Because of the relatively unfiltered cohort and broadly defined behavioral health intervention, the decreased utilization classifier may be able to detect patients with behavioral health problems that increase their likelihood of seeking unnecessary care, but which can be hard to for clinicians to detect or appropriately refer.\textsuperscript{20} If that is true, it may lead to reduced negative unintended treatment effects, benefiting the physical health of those patients and reducing the cost of unnecessary care.\textsuperscript{21, 22} The high-utilization classifier may also be useful in determining which patients need additional supervision, or may be useful in future work evaluating the predictors of high medical costs.

**Applications**

We envision use of these classifiers in a clinical decision support role. Such a tool would be especially useful to primary care physicians in accountable care organizations and patient centered medical homes, who have a duty to optimize both health status and costs of their panel. Thanks to the high precision across the recall range of the decreased-utilization classifier, providers could see a useful patient-specific estimation of whether referral to a behavioral health provider will be likely to reduce that patient’s health care costs. This model may also be able to detect patients who should be referred to behavioral health on an automated basis i.e. running in “the background” of the EMR. For example, patients with “confidence” values in the 0.8 to 1.0 range would have a very high chance of having decreased healthcare utilization following referral. Identification of a patient in this range could prompt an automated notification to their primary provider or to the provider of their next clinic visit, suggesting that the provider might consider whether that patient would benefit from behavioral health services. However, this should not imply that an increase in costs would not be justified by the other benefits of mental health care; additional considerations would be required in a clinical implementation setting.

**Lessons**

This project taught the student author about the use of appropriate metrics. AUROC seems to remain the standard metric for reporting classification performance in the medical literature. However, classification problems can be highly unbalanced, such as in the case of the 95th and 99th percentile models in this paper. While an AUROC approaching 0.9 may sound impressive, it does not tell the whole story. In a skewed class situation, a strong AUROC may not correlate to strong PR performance and may, if used as the main descriptive measure, mask poor performance.\textsuperscript{23} Explicitly, it is possible, as demonstrated by this study’s performance in classifying very-high utilization patients, to achieve a high ROC curve while having a low PR curve. Similarly, as in the case of the increased and decreased utilization model, while a high PR curve and strong F1 score are useful descriptors, they still ignore the influence of true negative predictions. Thus, the Matthews Correlation Coefficient, a binary classification analog of Pearson’s r that includes all four quadrants of the confusion matrix, was selected as a primary performance metric.

Sometimes, a simple model can be as powerful as a complex model. The classifiers used in this study to predict very high utilization patients were only modestly able to outperform the extremely simplistic prediction that patients will use the same amount of health care before and after the intervention. Not only is this a humbling result, but it also raises an essential question: how much can health spending be predicted by a model? Moreover, were the modest gains in model performance due to poor feature and model selection, or do they reflect the inherent randomness of the measured outcome?

**Limitations**

One significant limitation of this paper is the fact that the models were tested without a final holdout group. While parameters from model training were not shared between training phases, the core model settings were based on grid search for optimal performance on random test/train slices of the data. Therefore, although test and train groups were randomized, it is possible that the model was over-fitted to the BWH cohort, with test sets acting as internal validation, not a true, fully unseen set of test data.
This study does not have a strong comparison model or baseline clinical prediction. While some studies use clinician chart review as a baseline for comparison, this would have been cost and time prohibitive for our current study. Future research regarding the model’s ability to predict changes in cost and to detect patients who would benefit from behavioral health referral would ideally include a clinician comparison. Implementation of the model as a clinical decision support tool would also require modeled prospective implementation and true prospective implementation before being fully adopted.

A potentially significant limitation of the study is hidden in the setting. Brigham and Women’s Hospital is a world-renowned tertiary care center. The Psychiatry department at BWH, thanks to its focus on psychosomatic medicine, is particularly focused on treatment of patients with a high amount of comorbid psychiatric, behavioral, and medical complexity. Referrals for more “typical” psychiatric problems or “more healthy” patients, due to finite in-house psychiatric services, are often made to providers outside the Partners system. For these reasons, there may be a selection bias to this cohort, which may limit the generalizability of this model outside the Brigham system. Furthermore, this setting of high medical and psychiatric complexity may limit the generalizability of conclusions regarding the cost-effectiveness of behavioral health services to BWH, where this study’s data implies that behavioral health care may be mildly, but not significantly, cost saving.

Although speaking strongly to generalizability, this study used a completely unselected patient cohort and an outcome variable—costs—that can include a range of variables, including pure randomness, human behavior, and disease progression. In addition, the intervention—any sort of behavioral health clinic visit—is exceptionally broad and does not specify whether the studied patients already had mental health diagnoses or mental health treatments. This may have limited the predictive ability of the models. Additionally, it cannot be known from this study whether the intervention is causative of the observed and predicted changes, simply that there is a correlation. In other words, this model may be able to predict changes in healthcare utilization at other points in time, not just after a behavioral health visit.

**Further Work**

In order to address the limitation caused by the lack of a holdout group, a data request is currently being processed by RPDR for a set of patients from the rest of the Partners Healthcare system. This set of patients will be tested as a holdout group for the models trained on BWH patients. We are also interested in evaluating how many patients from the non-BH cohort will be classified by the model as being potential “reduced utilization” patients.

Thanks to the ability of random forest classifiers to output feature importance values, these models could be used to help discover why some patients use significantly higher levels of care after referral and could also help discover what specific features play a role in predicting beneficial outcomes of behavioral health referrals.

Now that a pipeline has been established for analysis of RPDR-sourced data, this method can be easily modified to train on and predict other outcome variables. Future work will evaluate more specific outcomes, like reduction in glycated hemoglobin (“HbA1c”) in diabetic patients following behavioral health encounters. This author also hopes that future work will be in collaboration with other Partners institutions, which may include access to summative clinical data like symptom surveys and validated risk scores; both could serve as additional interesting features and outcome variables. We also hope to utilize Partners high performance computing to annotate provider notes for the studied patients using MetaMap, which may be able to strengthen the signal gained from free text notes beyond our current “bag of n-grams” approach. This process would be a one-time computational cost that could be stored and shared with other projects.

**Conclusion**

Our study details the development of a random forest classifier that is able to predict patients who will have decreased health resource utilization following their first behavioral health visit, using structured administrative data, lab results, and free text notes as features. We are also able to identify a subset of patients who use very high amounts of resources following behavioral health referral. These models are both an improvement over comparison prior probabilities and compare favorably to similar studies. We hope that this method will be able to improve the timeliness and accuracy of referrals to behavioral health services, improving patient physical and mental health and reducing the financial costs associated with behavioral health comorbidity.

Abstract

The task of mapping neurological disorders in the human brain must be informed by multiple measurements of an individual’s phenotype - neuroimaging, genomics, and behavior. We developed a novel meta-analytical approach to integrate disparate resources and generated transcriptional maps of neurological disorders in the human brain, yielding a purely computational procedure to pinpoint the brain location of transcribed genes likely to be involved in either onset or maintenance of the neurological condition.

Introduction

The literature contains a wealth of discoveries from structured functional magnetic resonance imaging (fMRI) experiments designed to better characterize the association between behavior and regions in the brain [1-8]. Advances in the field of imaging genomics have been slow due to small sample sizes, different processing strategies, and focus on one or a small set of phenotypes [9]. This has led to a landscape of isolated findings that cannot easily extend to other measures of phenotype. Pioneering work has used GWAS and higher density genomics approaches to map disease-risk variants to particular anatomical locations in the brain [10-16]. Other efforts are addressing the problem of small sample size by compiling tens of thousands of brains for study [17-25]. Here, we attempt to complement these studies with a computational approach aimed at harnessing the compendium of knowledge represented in brain imaging research published during the last two decades. Specifically, we test whether published neuroimaging research can be mined for signal relevant to understanding genetic regulation in the brain as it pertains to both behavior and to disease. We derived a set of maps between experimentally verified psychological behaviors and regional gene regulation in the normal human brain, and asked whether these regulatory maps of behavior meaningfully related to neurological impairment and psychiatric illness. This work was divided into two parts: 1) to characterize enrichment of transcriptional regulation in neurological disorders, and 2) to confirm that the genes responsible for significant enrichment are related to neurological function and impairment. This effort represents the first attempt to combine disparate data in order to map behaviors to gene regulation in specific regions of the brain and to use this mapping to identify localized brain impairment and its relationship to onset or maintenance of neurological conditions.

Methods

Our strategy focused first on integration of large-scale neuroscience results with publicly available gene expression datasets. We mined the published corpus of functional Magnetic Resonance Imaging (fMRI) to generate mappings between behavioral terms and localized regions in the brain (Section 2.1). We then triangulated these coordinates with brain-region specific patterns of gene expression to create an initial series of spatially-specific brain maps, each location having a collection of genes known to be regulated at those positions (Section 2.2). Because patterns of gene regulation in the brain contain noise, we used a statistical approach from game theory in an attempt to minimize the noise and assemble statistically significant sets of up- and down- regulated genes for each behavioral term (Section 2.3). These procedures yielded a comprehensive mapping of behaviors tested in fMRI experiments to both brain regions and genes expressed at those brain regions. To assess if these mappings could be used to inform brain regions, and concomitantly, genes impacted in neurological disorders, we tested for enrichment of the brain maps in the gene expression profiles of a collection of neurological disorders (Section 2.4). We then used
unsupervised machine learning to summarize the outcome from this enrichment experiment, and to identify regions of the brain likely to be under regulatory impairment for each disorder (Section 2.5). Finally, we confirmed through analysis of gene function that our hypothesized brain-to-disorder maps were enriched in neurological function, impairment, and previously determined to play roles in neurological disorders (Section 2.6). A summary of our workflow is included in Figure 1.

**Figure 1:** An overview of our pipeline. We summarized activation results from the neuroscience literature (Bibliome of FMRI Experiments), and generated behaviorally-relevant brain maps (Brain Maps). We used the Allen Brain Atlas to refine these maps to meaningful sets of uMp- and down-regulated gene probes (Brainterm Gene Sets), tested refined gene sets against neurological disorders (Neuro-Disease Gene Expression), and developed a novel visualization strategy to comprehensively summarize our results (Brain Lattice Visualization).

### 2.1 Associating behavioral terms to brain regions

The NeuroSynth database [26] is a robust collection of activation points from the neuroimaging literature that collects and organizes at a voxel level disparately reported data relevant to activation of brain activity and its association to behavioral terms such as “anxiety.” The NeuroSynth algorithm mines neuroimaging papers to find the coordinates of meaningful voxels provided in structured tables and generates a 2 x 2 contingency table of counts for each voxel to indicate if activation is present or absent when a specific behavior term is present or absent. A Chi-Square test of independence is then used to determine if there is a significant dependence between the term and activation, and p-values are false discovery rate (FDR)-adjusted to account for multiple hypothesis testing at a threshold of 0.05 [28]. At the time of our study, NeuroSynth contained 100,953 activation points from 3,489 neuroscience studies from the top 17 neuroscience journals. Using the procedure above, we generated brain maps of 525 psychologically relevant behavioral terms, “brainterm maps,” each voxel a binary value representing a spatial location linked to a specific behavioral term.

### 2.2 Regulatory patterns within brainterm maps

The Allen Brain Atlas (ABA) [29] contains experimentally catalogued gene expression in normal brain tissue. At the time of our study, the ABA contained expression profiles for 3,702 spatial locations in the brain from a set of six brain specimens across 58,871 gene probes. We associated each sample location with an MNI (Montreal Neurological Atlas) coordinate and cross-referenced this list with the MNI coordinates found in our brainterm maps. Because the ABA did not contain expression values for every MNI coordinate present in our brainterm maps, we adopted a sampling strategy that assigned the MNI coordinate at the center of each voxel location in our brainterm maps to the closest MNI coordinate in the ABA, allowing for a voxel center to be no more than 3mm away. We then
performed a statistical procedure to generate two lists for every braintree map, “braintem gene sets” detailed in the following section.

2.3 Refining braintree maps to regionalized gene expression in normal brain.

To ensure that our braintem gene sets associated with each of the braintem maps contained a highly robust and interrelated collection of transcripts, we deployed a strategy from game theory that has proven useful for identification of the most important genetic contributors to a condition or phenotype of interest [30]. The specific method, called Shapley Value Regression, is a coalitional game method that aims to assess the relative importance of a set of players to the outcome (in our case, a pattern of expression) of a game. The method has been described previously [31], and essentially serves to perform feature selection to derive a more precise collection of transcripts for each braintree map. A Shapley Value is calculated for each gene probe \( i \) to determine the worth of a particular set of genes, \( S \):

\[
\phi_i = \frac{1}{n!} \sum_{S} \left( P(S, i) \cup \{i\} \right) - v(P(S, i)),
\]

\[1\]

The first term calculates the Shapley value for the set of all gene probes that included gene probe, and the second term calculates the Shapley value for the set not including \( i \). \( n \) is the number of gene probes in \( N \). Intuitively, removing a gene probe that explains little or no variance will have little or no impact on the score. However, removing a gene probe that explains a large percentage of the model variance will result in a smaller Shapley Value. Since we were interested in the gene probes that were expressed relatively up and down across the entire set, we generated binary input matrices that calculated over and under expression, respectively, as the mean expression +/- 1 standard deviation to define our conditions of interest (under and over expression coded by 1, and neutral expression coded as 0). Finally, since it is computationally expensive to calculate the Shapley value according to equation 1, we used a heuristic method developed by Moretti et al [31] that is computationally tractable and has been shown to produce reliable results. We ran a resampling procedure over our observed Shapley values with the MTP function in the multtest package version 2.18 [32] to remove genes with high Shapley values that could be attributed to chance. This procedure generated 1000 bootstrap matrices, and calculated corresponding unadjusted p-values that were corrected (FDR < 0.05) to adjust for multiple comparisons. This procedure allowed us to statistically filter out genes of low or no influence, resulting in a mapping of significantly up-regulated and down-regulated genes for each of our braintem maps. We mapped the gene probes to 29,131 gene symbols to annotate the collections.

2.4 Testing the enrichment of braintem gene sets in neurological disease

We compiled a list of 466 neurological disorders and psychiatric conditions from the National Institute of Neurological Disorders and Stroke [33], and the Diagnostic and Statistical Manual (DSM) Version 5. We queried the Gene Expression Omnibus (GEO) with MedLine defined disease terms to find 173 datasets across 47 of these disorders, and downloaded these for use in our analysis [34]. We focused only on human experiments of microarray gene expression with samples from case and control, and data available to match probe identifiers to gene symbols. These experiments were loaded into R with the GEOquery package version 2.34 [35]. We manually examined each data set to assess for proper normalization using MA plot, a transformation of gene expression data onto the log intensity ratios (M) on the y-axis and the mean average scales (A) on the x-axis [36]. Proper normalization means that most gene log intensity ratios would be 0, resulting in a plot with a straight line at Y=0 [37]. In instances where the data were not properly normalized, as indicated by log intensity ratios above or below 0, we applied quantile normalization via the BioConductor package “preprocessCore” version 1.3 [38], and manually re-examined the data. Samples across each probe set were carefully filtered to include only cases and controls specific to the phenotype of interest.

We explored the sets of differentially regulated transcripts in our 47 neurological disorders using Gene Set Enrichment Analysis (GSEA). GSEA tests the hypothesis that a particular set of genes – in our case the braintem maps described above – is significantly associated with a particular phenotype. GSEA uses Kolmogorov-Smirnov statistics to score braintem maps, and then calculates significance by empirical permutation, correcting for multiple
2.5 Visually summarizing significant brainterm maps

To visually summarize sets of brainterm maps associated with brainterm gene sets enriched in a disorder, we used an unsupervised method from machine learning, Self-Organizing Maps (SOM) [40] implemented via the kohonen package in R version 2.0.18 [30] to transform our 525 brainterm maps to an intuitive 2D space, a “brain lattice.” This brain lattice is a 2D grid of nodes, each of which is labeled with one or more of the behavioral terms, and distance in the lattice corresponds to similarity of these maps. To perform the labeling, we developed a strategy to reduce a set of significant brainterm maps associated with a disorder to one summary image with the most representative voxels across the sets. We used sparse hierarchical clustering as the strategy for feature selection of this subset of voxels from the map, using the ”sparcl” package in R version 1.0.3 [41] with the squared Euclidean distance as the dissimilarity metric. We chose the tuning parameter by assessing a range of 50 values, and the optimal value was determined based on the maximal gap statistic. Sparse hierarchical clustering achieves variable selection by way of a lasso-type penalty to generate weights: a weight is calculated for each voxel such that a larger value is indicative of the region being more important for the clustering. The highest weights are indicative of the most informative features, and so to threshold our data, we converted weights to Z scores and selected those in the upper tail of the distribution (p < 0.025). The original set of brainterm maps were finally thresholded to only include these voxels, and a mean image was generated to be mapped to the brain lattice. We flattened each mean brain image associated with a disorder into a vector, and then calculated a similarity metric, the cosine distance, of each of the nodes in the SOM. A color gradient of ten levels (white to red) was generated using the RColorBrewer package in R version 1.1-2 [42] in the range of the absolute minimum value (0), to the absolute maximum value (1) across all of the disorder mean images. The final brain lattices for each disorder can then be evaluated for degree (strength of color) and extent (portion of map colored), allowing for a straightforward evaluation of the regional patterns as they pertain to groups of behavioral terms for our significant results.

2.6 Functional analysis of the significant brainterm regions and associated genes

The brain lattice provides a high level, qualitative summary of the significant brainterm maps for each result, thus it was necessary to conduct a more thorough investigation of the brain regions within these maps and to specifically examine how they compare across disorders. We used the brain structure labels (N=414) provided by the Allen Brain Atlas to assess overlap of regions with significant enrichment between disorders. We first created a matrix of disorders and regions, with each value a count of the number of times a region is present in each brainterm map with significant enrichment for the disorder. To account for the fact that some disorders have more significant brainterm maps and thus overall higher counts, we divided each disorder row by the total sum of counts for the row. We could then use the hclust function from the stats package in R version 3.0.2 [43] to perform hierarchical clustering, and generate a dendrogram to assess regional similarity between disorders. To investigate the underlying regions of the groups defined by our clustering, we took the intersection of regions shared between disorders in a group, and manually annotated each region with high level functions to do a qualitative assessment of shared function.

In order to characterize the biological functions of the gene sets associated with the diseases previously defined in this study, we mapped each gene to the KEGG (Kyoto Encyclopedia of Genes and Genomes) BRITE database [44,45]. BRITE is a collection of manually created hierarchical text files capturing the functional organization of various biological objects. It allows for the exploration of entire functional pathways, enabling us to characterize the link between disease-related genes and biological function at a variety of levels. The BRITE hierarchy is structured in 6 levels, from level A (describing biological functions at the most general levels; e.g. “Organismal Systems”), to level E (describing the precise cellular processes in which each gene is involved; e.g. “mitochondrial carrier adenine nucleotide translocator”), and finally at level F, the gene symbol. Since a gene can be involved in several pathways, we weighted each gene by dividing it by the number of different pathways in which it is involved.
Using the KEGG API, we identified the unique KEGG IDs for each gene symbol used in the GSEA. We retrieved the corresponding BRITE hierarchy and explored them using Krona, a software package that allows the exploration and visualization of BRITE data [46]. Examples of the analyses and results conducted using Krona are available in the online Supplementary materials. Additionally, we used a published tool “Genehawk” [47] to conduct PubMed queries to retrieve disorder-related, original research articles as another test of our ability to reproduce known findings about genes in disease. Genehawk is a rule-based text-mining algorithm with keyword matching that can extract target disorders, genes with significant results, and the type of study described by the article.

Results

3.1 Regulatory patterns within brainterm maps.

We generated 525 brainterm maps for a set of 525 psychologically relevant terms. Each of the maps was mapped to corresponding MNI coordinates in the Allen Brain Atlas using the procedure detailed above. Matched sets of sample points in the Allen Brain Atlas ranged in size from 27 to 952 for the 525 sets. Each of the 525 brainterm maps was associated with an up- and down-regulated set of genes, resulting in total of 1050 gene sets. Of these 1050, there were a total of 912 with a core of significant genes as determined by Shapley Value Analysis. The number of genes in these final brainterm gene sets ranged in size from 28 to 1006 genes (mean = 78.02, sd = 116.70). We systematically compared each of these sets to the pattern of gene expression in all 47 neurological disorders included in the study. Of the 47, 8 had at least 1 brainterm gene set passing the significance threshold of FDR < 0.1. These were Autism Spectrum Disorder (ASD), Alzheimer’s Disease (AD), Lupus (L), Multiple Sclerosis (MS), Parkinson’s Disease (PD), Post Traumatic Stress Disorder (PTSD), Rett Syndrome (RS), and Schizophrenia (S) (Table 1). The number of brainterm maps enriched across these 8 disorders varied from 1 to 304, with totals of 2, 304, 25, 199, 1, 1, 3, and 1 for ASD, AD, L, MS, PD, PTSD, RS, and S, respectively (Table 2).

3.2 Visually summarizing significant brainterm maps

“Brain-lattice” maps for each of our 8 disorders (Section 2.5) are available (http://www.vbmis.com/bmi/n2g). The AD and MS brain lattices showed high levels of transcriptional activity across a large percentage of brain regions (as indicated by the dark orange across a majority of the brain lattice). The brain lattice for Lupus also had a large extent of activation across the brain, but to a lesser degree, again suggesting that brainterm maps with significant genes cover a large portion of the brain. On the contrary, the brain lattices for the other disorders (ASD, PD, PTSD, SZO, and RETT), were matched to brainterm maps with more localized and far less widespread spatial activation, resulting in a smaller region of the map. For ASD, enriched regions of the brain map included those involved with emotional salience (“mood”, ”anger”, ”happy”, ”affect”, ”emotion”), as well as threat response (“threat”, ”anxiety”) and perception (“vision”). The PD brain lattice was enriched for areas related to language (“linguistic”, ”spoken”), auditory perception (“hearing”, ”sound,” ”prosody,” ”speech”), and “violation,” a term possibly indicative of “violation of social norms.” The SZO brain lattice was enriched for areas associated with synthesis of language (“comprehension,” ”sentences,” ”language,”), sound (“vocal”, ”syllable”, ”auditory”) as well as “violation.” Finally, the PTSD brain lattice was enriched for areas that correspond to decision making (“classification,” ”incorrect”), as well as emotion (“empathy”), memory (“2-back”, ”rule”), and reasoning (“non-verbal”, ”reasoning”), and RETT included a larger set of terms associated with various functions (“languages,” ”reading,” ”writing,” ”goal”, ”thinking”). Interactive brain lattices are available at http://www.vbmis.com/bmi/n2g.

3.3 Functional analysis of the significant brainterm regions and associated genes

Hierarchical clustering of our matrix of regional features described previously (Section 2.6) revealed two groups, including PD / SZO, and ASD / RETT, and the remaining four disorders (MS, AD, L, and PTSD) in isolated clusters (Figure 2). The top functions of brain regions shared by ASD and RETT included motor (globus pallidus, medial group of nuclei, red nucleus, intralaminar nuclei, lateral group of nuclei, precentral gyrus), sensory (postcentral gyrus, lateral group of nuclei, intralaminar nuclei, middle temporal gyrus, medial group of nuclei), and language (inferior frontal gyrus, supramarginal gyrus, planum polare, planum temporale, supramarginal gyrus, middle temporal gyrus). For PD and SZO, the top functions associated with the overlapping regions included language (supramarginal gyrus, planum polare, angular gyrus, middle and superior temporal gyrus), and movement (caudate...
nucleus). Overlap between PTSD, PD, and SZO included one brain region, insular cortex. Notably, the top functional annotations for regions in significant maps for ALZ and MS included cerebellum, motor, and memory, and for PD, language (supramarginal gyrus, temporal gyrus, angular gyrus), motor (caudate nucleus, putamen, substantia nigra), and relay (intralaminar nuclei, thalamus, medial nuclei, reticular nuclei, claustrum).

To confirm that the genes enriched across each of our disorders play roles in brain function and neurological impairment, we performed a functional analysis of these genes using BRITE [44,45] from the Kyoto Encyclopedia of Gene and Genomes (KEGG) database. Although each gene set contained genes that did not map to a specific function (varying from 5% of genes in AD to 51% for SZO), a large percentage of genes in each set have been determined to play roles in a small and unique constellation of pathways. The central and peripheral nervous system were enriched in 7 out of the 8 disorders (grouped and referred to as the nervous and sensory system in the BRITE category). The immune system appeared as enriched in 6 out of 8 disorders. 45 genes linked to AD were related neurological functions (Receptors, Signaling Pathways, Peripheral Nervous system and Synapses), further suggesting global brain dysregulation of gene expression. 4 of the 28 genes implicated in ASD were implicated in central nervous system functions, notably the GABRR1 gamma-aminobutyric acid (GABA) receptor subunit. The MS gene set contained 178 genes, and 7 are related to neurological functions specific to the Peripheral Nervous System. L, PTSD, and SZO affected only Receptors and Peripheral Nervous system. Finally, RETT impacted the Peripheral Nervous System via PRKCH, which is involved in inflammatory mediator regulation. Complete functional results have been made available at http://www.vbmis.com/bmi/n2g.

In addition, leveraging a PubMed literature mining tool to retrieve disorder-related original research articles [47] we determined that the gene sets associated with RETT (21 genes), ASD (26 genes) and PD (9 genes) have not been significantly linked to these diseases in the literature. 44, 7, 12, 1, and 1 of the genes associated with AD, L, MS, PTSD, and SZO, respectively, have been reported in the literature as positively associated with each disease (Table 2).

**Figure 2:** Assessment of regional similarity: We used hierarchical clustering to show groups of disorders with similar significant regions. Significant brain regions maps associated with each disorder were reduced to a set of unique anatomical labels provided by the Allen Brain Atlas, and normalized counts of these labels were clustered to show disorders with significant genes from a similar distribution of regions in the Allen Brain Atlas.

**Discussion**

In the present analysis, we used meta-analysis of functional imaging studies and a database of normal gene expression in the human brain to derive sets of up- and down-regulated genes across spatial locations, each of which was associated with a psychological term from the neuroscience literature. We then examined whether these mappings significantly associated with certain human neurological disorders, and identified significant associations
to 8 out of 47. Both the regions implicated and genes associated with the disorders have been recognized as important in neurological disease, supporting the potential of our computational approach to map neurological dysfunction to localized regions of the brain.

**Functional Assessment**

It is notable that ASD and RETT were clustered together based on regional similarity, as RETT was listed as a specific type of ASD in DSM-IV and ICD-10, and there is a large subgroup of individuals with RETT with severe symptomatology of autism [48]. Both disorders have impairment in motor, sensory, and language [49,50], and specifically, brain imaging studies have found impairment in the overlapping regions between these disorders for motor [51-54], sensory [54,55], and language [56-58]. The grouping of PD and SZO is also compelling, as both disorders are linked to malfunction of the dopaminergic system [59], and in this context, the high overlap of regions with the functional annotation “movement” supports their regional similarity. Additionally, both disorders have marked deficits in language systems [60,61], an observation that gives insight to the commonality of regions annotated with “language.” Our regional results also confirm the clinical manifestation of PD, including aberrancy in regions related to motor, relay, and language, notably the substantia nigra [62] and thalamic nuclei [63]. Similarly, for ALZ and MS, the spatial maps support the known fact that these disorders affect the brain globally [64,65].

**Limitations**

While we confirmed that brain maps of genes are implicated in neurological function, and have been previously associated with disorders (Section 3.4), we cannot claim that a gene set associated with a brainterm map indicates that the genes are directly involved with the manifestation of the behavior represented by the functional map. Our results however show promise for use of computational tools to generate a more precise understanding of brain regions, functions, and aberrant transcriptional patterns across many disorders.

**Conclusion**

We aimed to use computational approaches to map regions in the brain to neurological disease at the level of regulation of gene transcripts. We believe this is the first effort to use a purely computational approach to map the regulatory patterns of neurological disorders in the brain using meta-analysis and synthesis of published data from the field of neuroimaging genomics. Our resulting maps of transcriptional regulation in a subset of disorders is informed by spatial location and gene expression, a result that can be investigated in multiple dimensions by either zooming in to the level of genes, or out to the level of terms. The benefit of our method is that it is not limited to a particular type of brain map, type of expression profile, or method to select the gene subsets. Therefore we can use neuroimaging maps that represents regions with significantly different structure or function between phenotypes, or functional networks derived on an individual level. Additionally, the validation of the brainterm gene sets need not be limited to gene set enrichment analysis; other methods could be used to make an assessment of the signature of a set of genes in expression data. Our methods can be extended to more data types, possibly including data from different tissues, different conditions, and different cell types.

Automated Detection of Benzodiazepine Dosage in ICU Patients through a Computational Analysis of Electrocardiographic Data

Maxwell T. Spadafore¹, Zeeshan Syed, PhD¹, Ilan S. Rubinfeld, MD, MBA²
¹University of Michigan, Ann Arbor, MI; ²Henry Ford Hospital, Detroit, MI

Abstract

To enable automated maintenance of patient sedation in an intensive care unit (ICU) setting, more robust, quantitative metrics of sedation depth must be developed. In this study, we demonstrated the feasibility of a fully computational system that leverages low-quality electrocardiography (ECG) from a single lead to detect the presence of benzodiazepine sedatives in a subject’s system. Starting with features commonly examined manually by cardiologists searching for evidence of poisonings, we generalized the extraction of these features to a fully automated process. We tested the predictive power of these features using nine subjects from an intensive care clinical database. Features were found to be significantly indicative of a binary relationship between dose and ECG morphology, but we were unable to find evidence of a predictable continuous relationship. Fitting this binary relationship to a classifier, we achieved a sensitivity of 89% and a specificity of 95%.

Introduction

Maintaining proper sedation of intensive care unit (ICU) patients undergoing mechanical ventilation requires careful and continuous monitoring and adjustment of drug delivery rates. When done manually, this can be tedious, time-consuming, and more importantly, imprecise, with one study finding one preventable error for every five administered doses¹. Closed-loop computerized control systems, with their ability to integrate more information and make higher-frequency, more granular adjustments, are a promising solution to this problem, and they have already been implemented for operating room anesthesia delivery as well as postoperative hypertension management²–⁵. Their use in administration of sedatives in the ICU, however, remains largely unexplored. This may be due to the fact that, unlike anesthetic concentration or hypertension, which can be measured directly and quantitatively, sedation depth is a much more qualitative concept⁶. Traditional methods for monitoring depth of anesthesia, including the bispectral index (BIS), which is derived from electroencephalography (EEG), are inconsistent among ICU patients at the same level of sedation⁷. As a result, qualitative scales, such as the modified Ramsay sedation scale (MRSS), are often preferred⁸. Closed-loop control models have been proposed which use the MRSS as their measurable input, but they are specific to only one drug (midazolam) and make the assumption that the MRSS is always available⁹.

A more reliable quantification of sedation depth is needed. Electrocardiography (ECG) is a key biosignal with massive physiological relevance that is ubiquitous in the ICU and is often continuously monitored. As such, it is an ideal measurement source for a closed-loop control system if it demonstrates detectable changes in the presence of sedatives.

In this study we evaluated the feasibility of one aspect of this potential control system - the ability to computationally detect the presence of a given sedative (lorazepam and midazolam) using only a single lead of ECG. We present answers to three core research questions (RQs):

1. Is there a relationship between a subject’s ECG and the amount of drug in his/her system?
2. Does this relationship vary continuously with dosage, or is it binary?
3. Is the relationship (binary or continuous) strong enough to be reliably computationally predicted?

Benzodiazepines and ECG

Several studies have demonstrated the effect of lorazepam and midazolam on cardioconductive activity. Lorazepam and midazolam belong to a class of psychoactive drugs known as benzodiazepines, which function by increasing the effect of the neurotransmitter GABA. This in turn gives the drugs sedative, hypnotic, anxiolytic, anticonvulsant, and muscle relaxant properties, as well as a strong propensity for abuse¹⁰. In addition to their primary effect on neurotransmitter response, benzodiazepines also block potassium (K+) channels in cardiac tissue, which causes changes in cardiac repolarization. These changes then present themselves in the ECG as deviations in T-wave morphology, specifically as changes in T-wave length, notching, QT interval, QT variability, QT dispersion, and T-
wave area. These deviations (and others) have been shown by many to be effective in predicting K+ channel blockage, and Manini et al. demonstrated their use for successful prediction of adverse cardiovascular events in the extreme case of poisoning by benzodiazepines and other psychotropic drugs. Whereas Manini et al. used manual annotations of high-quality, hospital-grade 12-lead ECG to predict between controls and patients subjected to extremely high (toxic) doses of benzodiazepines and other drugs, our study used computational annotation of only one lead (lead II) sampled at only 125 Hz, with varying non-toxic doses of benzodiazepines.

Lorazepam and midazolam were chosen from among the pool of benzodiazepines because they are commonly prescribed for sedation in a hospital setting rather than as common anti-anxiety medication or muscle relaxants. As such, we hypothesized that lorazepam and midazolam dosage would promote significant ECG morphology changes above baseline while remaining a reasonable model for real-world benzodiazepine administration.

Methods

Data for this study were used with permission from the Multiparameter Intelligent Monitoring in Intensive Care (MIMIC) II clinical database, which consists of demographics, de-identified medical records, and waveforms for 32,536 patients over seven years across several individual intensive care units (ICUs) at Beth Israel Deaconess Medical Center in Boston, Massachusetts.

Subjects

Subjects were selected based on the following inclusion criteria. Subjects were given one or both of midazolam (Versed) or lorazepam (Ativan) during their ICU stay; had associated ECG waveforms, specifically lead II ECG; and experienced no cardiovascular complications of any kind during their ICU stay. The latter criterion controlled for possible cardiovascular confounders that could present at any point during a subject’s ICU stay, and was implemented by excluding any subject billed with one or more ICD9 codes between 390 and 459 (“diseases of the circulatory system”), inclusive.

Of 14 subjects who met these criteria, five were excluded due to poorly digitized (very low resolution) lead II ECG or ECG from other leads mislabeled as lead II. A total of nine subjects (eight men, one woman; mean age 42.4 years) were included in the study.

Doses

Each subject received a series of doses of midazolam or lorazepam during their ICU stay. Together, these doses formed a “dose pattern” over time that was specific to each subject (see Figure 1). Two-minute samples of lead II ECG centered on the peak effect period of each dose were acquired. Peak effect period differed for midazolam (0.5 hours after dosage) and lorazepam (3 hours after dosage). For the nine subjects, there were 539 doses (and thus 539 2-minute lead II ECG samples), with 279 as lorazepam and 260 midazolam. The dosages for the two drugs were standardized using a dose equivalency table to that of diazepam (Valium). The mean equivalent dosage was 0.253 mgkg/hr.
Figure 1. A dose pattern for a certain subject. Each subject was associated with a specific dose pattern, the plot of his/her lorazepam or midazolam dosage versus time.

For control samples, 5 minutes of lead II ECG were acquired from the moments leading up to the patient’s first dose. This served as our best approximation of the patient’s “undosed” baseline state. Because control samples were longer than dose samples, they were divided into groups of 30 beats, which were then treated as individual “control doses” for a given subject.

Beats and Feature Extraction

The PhysioToolkit programs *wqrs* and *ecgpuwave* were used to computationally label the start, peak, and end of the P-waves, QRS complexes, and T-waves within the dose and control lead II ECG samples. These annotations were further filtered so that only beats with completely annotated P-QRS-T (all of start, peak, and end for each wave) were kept. From these, the following morphological per-beat features were extracted. Length: P-wave, T-wave, QRS length, and total beat length; and Interval: QT, RT, ST, and RR.

Because dose samples were taken at many different times throughout a subject’s stay, we found it important to correct all of the above features using Bazett’s method, and we used only the corrected features in our analysis. For the remainder of this report, any reference to the above feature names implies their corrected variants.

We then extracted variability features (standard deviation) from all of the previously mentioned features.

All T-based features were extracted for their previously described connections to benzodiazepine dose. QRS length, P length, and total beat length were extracted to investigate the effect of benzodiazepines on overall beat morphology. Variability features were extracted to investigate the effect of dosage on inter-beat irregularity and autonomic nervous system regulation.
The feature extraction process (left) and data architecture (right) used in our method. Both control and dose samples undergo the same process. Beats are extracted using ecgpuwave and other PhysioNet tools, then filtered for PQRSST completeness. Length-based features and their variability-based counterparts are then extracted from the beats. Before classification, the control beats are used to normalize the dose beats, and the average for each feature across all beats is taken for each dose/control sample.

Doses as the Unit of Analysis

We chose dose/control samples, rather than beats, as the individual units of analysis, averaging the above features across all identified beats in a sample to produce one value for each feature for each sample. This decision was made for several reasons. First, doses most nearly model our target real-world situation; each dose sample represented a titration of medication. Second, although not as independent as individual subjects, doses separated by hours are far more independent than beats separated by seconds, which lends more credence to statistical analysis. Third, averaging features across all beats in a dose/control sample allowed us to reduce inter-beat variability in non-variability-based features while capturing it in the variability-based features.

Methods of Analysis

Specific methodologies were used to answer the aforementioned research questions.

To answer RQ1, we performed a two-sample, unpooled, one-sided t-test comparing the mean raw (non-normalized) values of each feature across all dose samples (at any dose level and across all subjects) against the mean raw values of each feature across all control samples. As previously described, we expected the features to increase when affected by the benzodiazepines. The number of dose samples was 536, and the number of control samples was 115. We tested at two significance levels, one without Bonferroni correction for multiplicity at \( \alpha_B = 0.05 \) and one with Bonferroni correction at \( \alpha_B = 0.05/16 = 0.0031 \). The results for these tests are given in Table 1.

In answering RQ2, we calculated the Spearman correlation coefficient \( R_s \) for each feature between each subject’s dose magnitudes and the feature, leaving us with nine correlation metrics (one corresponding to each subject) per feature. We chose the Spearman correlation coefficient over the Pearson metric because it captures both linear and nonlinear covariation between two variables and is more resistant to outliers\(^{20}\). Because the small sample size precluded the use of a parametric test of significance, we performed a 10,000-iteration permutation test on the correlation metrics for each of the features, randomizing the signs of each subject’s correlation and computing a t-statistic on each iteration. P-values were then the ratio of the number of times the randomized t-statistic exceeded the actual to the total number of iterations. The results for these tests are given in Table 2.

In our analysis of RQ3, we set up a binary classification task in an attempt to separate control samples from their dose counterparts. Features were first standardized in a by-subject fashion. Each subject’s features across each dose were standardized by the mean and standard deviation of the corresponding features from the subject’s entire control sample. Features for control samples were standardized against their own respective means and standard deviations. This method of standardization makes two key assumptions: that a subject’s baseline feature values are always known prior to their classification by the system, and that these baseline values are unbiased. We found the first assumption justifiable because pre-sedation ECG is often available and clinicians often choose to wake
their mechanically ventilated patients once per day\textsuperscript{21}. The second assumption is more tenuous in the context of our study’s data source, an issue discussed in the Limitations section.

After standardization, the data was fit to a support vector machine (SVM) with a radial basis function (RBF) kernel using scikit-learn, with parameters \( C \) and \( \gamma \) chosen by manually-narrowed grid search\textsuperscript{22}. RBF was chosen because visual inspection of features showed dose data points “curving” around controls (figure not shown). Leave-one-subject-out cross validation was used to prevent overfitting and to evaluate model performance on a by-subject basis.

Three different feature sets were used, corresponding to three different slices of the significant features taken from Table 1. In this case, significant features were taken to be those significant at \( \alpha_0 \), to allow for the maximum number of useful features to be included in the model. The first feature set included all significant features that were not variability based (5 total), while the second included all significant features that were variability based (7 total). The third consisted of all of the features from both the first and second - all significant features (12 total). For each feature set, we calculated average recall, specificity, balanced accuracy, and the area under the receiver operating curve across all subjects. Balanced accuracy is defined as one-half the sum of sensitivity and specificity and is used to correct for any imbalance between the number of dose and control samples\textsuperscript{23}. These results are presented in Table 3.

Results

RQ1: Is the computationally measured effect of non-toxic levels of benzodiazepines on ECG significant?

</tbody>
</table>

Evident in Table 1, the benzodiazepines exerted a significantly large effect on the features. As expected based on the previous work described in the “Benzodiazepines and ECG” section, T-based features showed large differences, with QT interval significant at \( \alpha_0 \) and T length and ST and RT intervals significant at \( \alpha_B \). This shows that ECG is indeed affected by benzodiazepines even at moderate doses, and that computational methods can be relied upon for the extraction of features traditionally extracted manually by cardiologists from a high-quality 12-lead ECG.

Of interest and warranting further investigation are the small \( p \)-values resulting from the variability-based features. An increase in variability arising for the doses could be caused by a variety of factors, with some legitimate, including physiological compensation for dosage and differences in dose patterns, and some confounding, such as wavering subject condition.

RQ2: Is this effect binary or continuous?

With the analysis from the previous section showing that there was indeed a computationally identifiable effect of benzodiazepines on ECG, we investigated if the magnitude of this effect varied with the magnitude of the dosage.

</tbody>
</table>

Only two features, ST Interval SD and RR Interval SD, showed a significant Spearman correlation with dosing, and their respective significant correlation coefficients were quite low. Simple visual inspection (see Figure 3) demonstrated that even these significant relationships were tenuous and would yield poor predictability. As such, it was decided that our data did not support the existence of a simple continuous relationship between benzodiazepine dosage and our features.

However, physiological reactions to drugs are extremely complex, and our model - a time-delayed linear relationship - was extremely simple, though two of our features showed significance even when this simplified model was employed. A more robust model of dose interactions through time, paired with our features, could elucidate a clearer, more predictable continuous relationship between ECG and benzodiazepine dosage.

![Figure 3.](image)

Figure 3. Although the Spearman correlation $R_S$ was significant at $a_0 = 0.05$ for feature RR Length SD, visual inspection showed a general lack of predictable correlation, illustrated here.
RQ3: Is this effect reliably predictable?

</tbody>
</table>

With a maximum sensitivity of 89%, a maximum specificity of 95%, and a maximum AUC score of 0.97, our method successfully differentiated between each subject’s control and dose samples. This demonstrates that a completely computational, unaided system is capable of recognizing the presence of sedative benzodiazepines using only a single lead of ECG.

For our best-performing feature set, although recall and specificity are at their highest overall, the recall is a full six points lower than the specificity. This provides some proof that some subjects may have been under the influence of benzodiazepines prior to their entry into the ICU. With untainted controls, more separation between dose and control features could be attained, leading to increases in both sensitivity and specificity.

Figure 4. Receiver Operating Characteristic curve for the Non-SD + SD feature set

Discussion and Conclusion

Summary

Due to the qualitative nature of sedation, automated sedative administration in an ICU setting via closed-loop control systems is largely unexplored. We envision a system that uses ECG to quantitatively monitor a patient’s physiological response to sedatives, and we have demonstrated the feasibility of the drug-detecting portion of this system, focusing specifically on benzodiazepines. We started with features commonly examined by cardiologists looking for evidence of cardiotoxicity in poisonings, and we generalized the annotation and extraction of these features from manual annotation of high-quality 12-lead ECG to automated annotation of low-quality ECG from a single lead. We tested the predictive power of these features using nine subjects from the MIMIC II clinical database.
who had received lorazepam or midazolam during their stay, controlling insofar as possible for any pre-existing cardiovascular conditions. Features were found to be significantly indicative of a binary relationship between dose and ECG morphology, but our simplified model for dose interactions was unable to find evidence of a predictable continuous relationship. Fitting this binary relationship to a classifier, we were able to detect the influence of benzodiazepines with a sensitivity of 89% and a specificity of 95%.

Limitations
This study has limitations. With this proof-of-concept study, we were aiming for hypothesis generation and demonstration of preliminary feasibility. As such, we traded sample size for optimal experimental conditions, namely the lack of cardiovascular complications during the subjects’ ICU stays and the need for Lead II ECG to be recorded for the subject in the MIMIC II database (only 2,809 of the 32,536 subjects had associated waveforms). These two restrictions alone reduced the subject pool from 2,971 patients to the nine our study included. As we progress past this proof-of-concept, we will remove these restrictions, increasing our sample size.

Previous medical history for each subject, including possible cardiovascular issues, was located in textual dictations of their attending physicians. As such, it was not possible for us to exclude subjects with a prior history of heart disease. However, these subjects were excluded if they were billed for any treatment related to their cardiovascular conditions at any time during their ICU stay. In a similar vein, information regarding the events of the subject’s hospital stay leading to transfer to the ICU was unavailable, and thus a control sample could have been tainted if the patient had received benzodiazepines during their stay prior to the ICU. There is some evidence suggesting that this may have been the case. This confounder would bias the results against any relationship between dosage and ECG morphology, however, so we do not see it as invalidating this study’s results. Additionally, we were unable to control for change in some extraneous factors, such as pain, intubation, and oxygenation, between control and dose periods.

For the sake of ensuring a reasonable sample size, patients were not excluded if they died while in the hospital. However, only one subject died while in the ICU, and this was verified not to affect the results. While our results are promising, our small sample size limits the external generalizability of our findings.

Future Directions
The high accuracy of our method warrants further exploration and reproduction in larger samples. To demonstrate the validity of our findings, a larger observational study, with less restrictions on eligible subjects, should be conducted. Additionally, a more powerful model for benzodiazepine dose interactions through time should be investigated to aid in the prediction of dose as a continuous, rather than binary, variable.

Abstract

Ontology search interfaces can benefit from the latest information retrieval advances. This paper introduces a Conjunctive Ontology Browser and Explorer (COBE) for searching and exploring SNOMED CT concepts and visualizing SNOMED CT fragments. COBE combines navigational exploration (NE) with direct lookup (DL) as two complementary modes for finding specific SNOMED CT concepts. The NE mode allows a user to interactively and incrementally narrow down (hence conjunctive) the search space by adding word stems, one at a time. Such word stems serve as attribute constraints, or “attributes” in Formal Concept Analysis, which allows the user to navigate to specific SNOMED CT concept clusters. The DL mode represents the common search mechanism by using a collection of key words, as well as concept identifiers. With respect to the DL mode, evaluation against manually created reference standard showed that COBE attains an example-based precision of 0.958, recall of 0.917, and $F_1$ measure of 0.875. With respect to the NE mode, COBE leverages 28,371 concepts in non-lattice fragments to construct the stem cloud. With merely 9.37% of the total SNOMED CT stem cloud, our navigational exploration mode covers 98.97% of the entire concept collection.

Introduction

Search and browsing interfaces are an integral part of ontological system dissemination. Although ontology search interfaces are distinct from general search interfaces because of the semantic and structural information already contained in the ontologies, they can still benefit from the latest developments in information retrieval. For example, conjunctive exploratory navigation interfaces CENI and SCENI [1, 2, 3] have been developed for exploring consumer health questions with health topics as dynamically search tags complementing keyword-based lookup. The conjunctive exploration mechanism allows users to quickly narrow down to the most relevant results in the most effective way.

In this paper, we introduce a conjunctive ontology browser and explorer (COBE) for searching SNOMED CT concepts and visualizing SNOMED CT fragments. The COBE search interface has three prominent features. First, it supports both direct lookup and navigational exploration to retrieve concepts. In the direct lookup mode, a user comes with specific terms or SNOMED CT identifier, enters into the search interface, and retrieves a list of relevant concepts. In the navigational exploration mode, a user may not have a targeted term, or cannot easily or effectively formulate descriptive lookup terms, and may rely on navigational features to browse and explore the concepts. COBE provides conjunctive search combining direct lookup with navigational exploration. Second, COBE meets the need of a concept retrieval interface to reach and visualize erroneous SNOMED CT fragments for quality assurance. Third, in the navigational exploration mode, COBE utilizes a cloud of core stems mined from non-lattice fragments. In previous study [4], mining SNOMED CT non-lattice fragments have been shown to be an effective approach for detecting abnormal structures that are inconsistent with the principle that the subsumption relation (is-a) in an ontological system should conform to the lattice property. This principle is further enforced in more recent work [5], where non-lattice fragments have shown up to 40 times the change rate against background changes in the evolution of SNOMED CT.

The effectiveness of COBE for retrieving SNOMED CT concepts is evaluated in two ways. For the direct lookup mode, it is compared with the well-known IHTSDO SNOMED CT Browser [6] and NLM SNOMED CT Browser [7]. Evaluation against manually created reference standard showed that COBE attains an example-based precision of 0.958, recall of 0.917, and $F_1$ measure of 0.875. For the navigational exploration, we conduct an evaluation experiment on the search stems. The result shows that only using stems generated from 28,371 concepts which occurring in the upper bounds (uppermost level) of fragments, which is 9.37% of total, as navigational exploration menus covers 98.97% of all SNOMED CT concepts.

2092
1 Background

1.1 SNOMED CT

SNOMED CT is the world’s largest and most comprehensive clinical healthcare terminology, developed and maintained by the International Health Terminology Standard Development Organization (IHTSDO). From a structural perspective, SNOMED CT can be seen as a series of large directed acyclic graphs, one for each of its 19 sub-hierarchies: Procedure, Physical force, Event, Staging and scales, Substance, Environment or geographical location, Situation with explicit context, Body structure, Observable entity, Pharmaceutical/biologic product, Physical object, Qualifier value, Special concept, Specimen, Social context, Clinical finding, Organism, Linkage concept, and Record artifact. Each concept comes with a unique SNOMED CT identifier, and concept descriptions associated with it. The version of SNOMED CT used in this study is dated September 1, 2014. It contains 302,902 active concepts, which are organized into 19 hierarchies linked by relationships such as is-a.

1.2 SNOMED CT Browsers

SNOMED CT Browsers are applications and tools used for viewing terminology content or hierarchy structure. Typically, a SNOMED CT browser can display descriptions and relationships of a concept by providing searching terms or identifier. The official IHTSDO SNOMED CT Browser[6] is an online, multilingual, multi-edition ontology browsing application. It enables browsing of International Edition of SNOMED CT, as well as various National Editions. User can enter terms or navigate in the taxonomy hierarchies to find target concept, with filters in semantic, refset, or language. The application can provide almost everything related to the concept, including descriptions, parents and children, attributes and diagram of structure. Another online browser, provided by U.S. National Library of Medicine (NLM), is NLM SNOMED CT Browser[7]. Different from the IHTSDO SNOMED CT Browser, searching and displaying SNOMED CT content, as included in UMLS Metathesaurus, is provided in NLM SNOMED CT Browser. It expands searches to include synonymous terms from over 100 Metathesaurus vocabulary sources. CSIRO provides a graph-based interactive interface for navigating SNOMED CT concepts, which is called Shrimp[8]. One can expand the hierarchy graph by clicking the concept, which provides an intuitive visualization of its relationships.

1.3 Conjunctive Navigational Exploration

There are two basic search modes in information retrieval. One is direct lookup (DL), and the other is navigational exploration (NE). Direct lookup is a basic search mode where a user knows precisely what to look for and comes up with input strings leading uniquely to the search target. On the other hand, in the navigational exploration mode, a user may not be able to easily and effectively formulate a descriptive search string, and must rely on navigational mechanisms such as menus to browse and explore the content in order to inform the user “what is there.”

Conjunctive Exploratory Navigation Interface (CENI[1]) is a recently introduced technique for effective access of online consumer health information using navigational exploration. CENI was achieved by assigning multiple topics for information items using semantic tagging[2, 3]. Crowd sourced comparative evaluation revealed that anonymous users from Amazon Mechanical Turk preferred 2 to 1 for CENI against other search mechanisms[1].

A defining feature of CENI is an interface which provides the user multiple paths to quickly narrow down to relevant contents. By selecting one topic at a time, in an incremental fashion, a user arrives at narrower and narrower content areas that are relevant to all the topics selected so far, conjunctively.

A novel feature of COBE is the NE mode, adapted from CENI. Instead of consumer health topics as menus in CENI, COBE uses word stems from an important sub-collection of SNOMED concepts – those appearing in non-lattice fragments as defined in[4]. Such word stems serve as attribute constraints, or “attributes” in Formal Concept Analysis, which allows the user to navigate to specific SNOMED CT concept clusters in multiple ways.

1.4 SNOMED CT Quality Assurance

It has been noted that the biomedical domain is developing tremendously. For example, SNOMED CT releases a new version almost every 6 months. The quality of an ontology is a key issue that determines its usability. Many auditing methods exist to ensure the quality of ontologies. They include but are not limited to lexical[9], structural[10],
semantic [11, 12] and statistical-based [13]. A lattice structure is often one of the criteria of the well-formedness of ontologies [4]. A lattice is a structure that every two concepts in the ontology have no more than one minimal common ancestor or maximal common descendant. MaPLE [5] has found a large number of such non-lattice structure in SNOMED CT. Figure 1 is a non-lattice fragment from SNOMED CT. The double-circled concepts “Tissue specimen from breast” and “Tissue specimen from heart” share two minimal ancestors: “Tissue specimen” and “Specimen from trunk,” highlighted in pink, which makes them a non-lattice fragment. To make it lattice-conforming, one could add the concept “Tissue specimen from trunk” (dashed in Figure 1) [4, 5, 10].

Figure 1: A non-lattice fragment in SNOMED CT [5].

2 Methods

Figure 2 depicts the overall architecture of the proposed COBE to search SNOMED CT concepts and facilitate the retrieval of non-lattice fragments in SNOMED CT. For the navigational exploration mode, SNOMED CT concepts are preprocessed (dotted rectangular box) to obtain a collection of core stems for tagging concepts. SNOMED CT concepts are filtered by non-lattice fragments, and performed word tokenization and frequency ranking. As a result, a collection of core stems are mined and used for tagging concepts. In the navigational exploration (NE) mode of the COBE search interface, a user’s input (NE-input in Figure 2) is the selection of stem tags, based on which COBE performs NE-based conjunctive search and returns to the user a list of relevant concepts as well as numbers of related non-lattice fragments. In the direct lookup (DL) mode of the COBE search interface, a user’s input (DL-input in Figure 2) is a specified term formulated by the user. COBE performs term splitting, and DL-based conjunctive search to find a list of relevant concepts as well as numbers of related non-lattice fragments and returns them to the user.

2.1 Navigational Conjunctive Exploration

In the navigational exploration mode, a user may want to explore “what is there,” or may not be able to easily or effectively formulate a descriptive lookup term to find non-lattice fragments. In either case, the user may rely on navigational menus or facets to browse and explore. To address such need, we construct a cloud of informative terms serving as the navigational menus for the user to effectively explore SNOMED CT concepts and non-lattice fragments. To achieve this, we perform the following preprocessing steps:

• First, we extract all active concepts from the SNOMED CT distribution files. For each active concept, its identifier and descriptions (including fully specified name, preferred name, and synonyms) are further extracted and stored in a MySQL database.

• Second, we filter active concepts by non-lattice fragments, and only keep those concepts appearing in the uppermost level of non-lattice fragments. If a concept appears in the uppermost level of a non-lattice fragment, then the non-lattice fragment is called related to the concept.

• Third, for each of the remaining concepts, we remove punctuation marks and all stop-words such as “of” and “out” from its descriptions, which is then tokenized into individual stems. The resulting collection of tokenized singular words forms our COBE stem collection. Note that this is different from “word stems” in linguistics which refer to the prefix strings serving as the root of a word. When we mention stems in this paper, it is meant to be in the sense of COBE stem.

• Fourth, for each stem, we compute the frequency it appears in the remaining concepts to determine the order of the stems in the search menus.
After the above steps, the stems ranked by the precomputed frequencies serve as the navigational menus. Each stem is guaranteed to hit at least one fragment, which prevents the circumstance that retrieved concepts from COBE have no related non-lattice fragment.

Given a selection of input stems by a user, COBE performs conjunctive search to retrieve matching concepts, that is, only concepts matching all the selected stems are returned, ranked by the number of related non-lattice fragments in the descending order. COBE allows concepts being investigated and narrowed down by several times of navigation sequentially. For example, clicking navigation stem “heart” followed by clicking “attack” will narrow down the results to “Myocardial infarction (disorder).” COBE enables the combination of navigational exploration and direct lookup. For instance, clicking “attack” followed by typing “heart” in the direct search box will narrow down the results to “Myocardial infarction (disorder).”

2.2 Direct Lookup

The other way to navigate to non-lattice fragments is specifying a targeted term in the direct search box instead of formulating a term by the available navigation stems. In this direct lookup mode, a user knows what to look for, comes with specific term or exact SNOMED Identifier, and tries to retrieve a list of concepts. After a user types a specific term into the direct search box, COBE splits the term into stems and performs conjunctive search to retrieve concepts matching all these stems, and returns them by the number of related non-lattice fragments in the descending order.

2.3 Evaluation

We evaluate COBE in two ways. For the navigational exploration mode, we evaluate if the search stems obtained from the preprocessing step covers a wider range of concepts. To calculate the percentage of the coverage, we use the total number of concepts as the denominator, and the number of concepts that can be reached by at least one search stem as
For the direct lookup mode, we evaluate the search performance of the COBE interface by comparing it to other two SNOMED CT browsers: IHTSDO SNOMED CT Browser [6] and NLM SNOMED CT Browser [7]. We randomly select 24 concepts as search tasks (one lookup term per task) from the CORE Problem List Subset of SNOMED CT [14] to compare the three browsers. Since most SNOMED CT concepts have short length of descriptions, the terms chosen for the search tasks are 1-word, 2-word, 3-word or 4-word to make sure a certain number of concepts get returned by the browsers. 6 concepts (search tasks) are randomly selected for each word length. For each search task, an evaluator uses three browsers to retrieve a list of relevant concepts, respectively. A reference standard is created for each search task: the common concepts found by all three browsers are considered correct results and included in the reference standard; for the other concepts found but not shared by all three browsers, the evaluator manually reviews them and includes the relevant concepts into the reference standard only if the evaluator considers the result concepts correct. We use the example-based precision, recall and $F_1$ measure [2, 3, 15, 16] to evaluate the performances of the three browsers.

Let $R$ be the reference standard consisting of $m = 24$ search tasks $\{(s_i, Y_i) \mid i = 1, \ldots, m\}$, where $Y_i$ is the set of all concepts included in the reference standard for the search task $s_i$. Let $Z_i$ be the set of concepts retrieved from a search interface for $s_i$. The example-based precision ($P$), recall ($R$) and $F_1$ measure ($F_1$) are calculated as follows:

$$P = \frac{1}{m} \sum_{i=1}^{m} \frac{|Y_i \cap Z_i|}{|Z_i|}, \quad R = \frac{1}{m} \sum_{i=1}^{m} \frac{|Y_i \cap Z_i|}{|Y_i|}, \quad F_1 = \frac{1}{m} \sum_{i=1}^{m} \frac{2|Y_i \cap Z_i|}{|Z_i| + |Y_i|}$$

(1)

### 3 Results

Among all the 302,902 active concepts, only 28,371 are in uppermost level of non-lattice fragments. We used 28,371 concepts to generate 12,623 search stems for navigational exploration. Table 1 displays the 10 most frequent stems appearing in the concepts related to non-lattice fragments.

#### 3.1 Conjunctive Ontology Browser to Explore SNOMED CT Fragments (COBE)

Figure 3 shows a sample screenshot after clicking “neck” and “head” from search stems for navigational exploration and typing “region” for direct search. The left column displays the list of navigation terms, while clicking the navigation menu bars of the left column, the chosen words are displayed inside the horizontal bar on the top of the right column, where the “Reset” button is used to start a new exploration by clearing the search words. The leftmost button of the right column shows the number of non-lattice fragments where the upper bounds contain this concept, where green button indicates existing non-lattice fragments and orange for no fragments found. The center area indicates the fully specified name and blue button for the SNOMED CT concept identifier. When hover the name COBE shows all the preferred terms and synonyms. Clicking either the green button or the concept name links to the page for visualizing relevant fragments. By default, all the concepts are displayed in the descending order of the number of fragments, if neither search term nor search keyword is specified.

#### 3.2 Visualizing Non-lattice Fragments

As shown in the right column in Figure 3, COBE enables user to find some specified concepts listed in the concept displaying area. Once the concepts are displayed, a user can click the leftmost green or orange button to link to the index page of related fragments and finally direct users to the fragments visualization page.
Figure 3: A screenshot of the conjunctive ontology browser explorer interface COBE.

Figure 4: Searching “neck head region” in both NE and DL modes to render related non-lattice fragments. The upper left part of Figure 4 demonstrates the navigational exploration mode of COBE, and upper right part for the direct lookup. Using each mode or combining using these two modes leads to the visualization part. The lower left part of Figure 4 is the fragment index page for the concept “Pain of head and neck (disorder).” The left column of the index page contains all fragments denoted by upper bounds concept identifiers, and right column displays the corresponding concept labels. After clicking the concept identifiers of a fragment, the browser directs to the page for...
the visualization of that fragment which is shown in the lower right part. The green nodes represent the upper bounds of the fragment, the yellow ones represent lower bounds and the gray ones represent intermediate nodes in between. The solid gray edges represent is-a relationship of two concepts. For example, “Chronic pain (finding)” and “Pain of head and neck region (finding)” are upper bounds of the fragment, while “Chronic neck pain (finding)” and “Chronic pain in face (finding)” are lower bounds of the fragment. The leftmost gray edge means “Chronic neck pain (finding)” is-a “Chronic pain (finding).”

3.3 Navigational Exploration Evaluation

Instead of using descriptions of all 302,902 concepts, we used a subset of 28,371 concepts related to fragments to generate the search stems for navigational exploration. Each of the 28,371 concepts must occur in the upper bounds of a fragment at least one time. 12,623 search stems were generated after punctuation marks removed, tokenized, and stop-words removed. To evaluate the search stems, we queried all search stems for each of the 302,902 concepts, and found that 299,789 concepts can be reached through at least one the search stems. This implies that using navigational exploration, at most 3,113 concepts might be missed. These 3,113 concepts must have no occurrence in the upper bounds of fragments. The coverage of the search stems to reach overall concepts is 98.97% (299,789/302,902). This indicates that our search stems formed by a small subset of concepts can cover most SNOMED CT concepts.

3.4 Direct Lookup Evaluation

To evaluate the search interface, we formulated 24 search tasks to compare the three SNOMED CT browsers’ performances: IHTSDO SNOMED CT Browser, NLM SNOMED CT Browser, and COBE interface. We randomly picked 24 concepts from the CORE Problem List Subset of SNOMED CT and used their descriptions as the searching key words for three browsers. To make sure certain number of results can be returned, we limited the search tasks to 1-word, 2-word, 3-word or 4-word concepts. Then the evaluator used three browsers to perform the search tasks. The reference standard was created for each search task: the common concepts found by all three browsers are considered correct results and included in the reference standard. For those concepts found but not shared by all three browsers, the evaluator manually reviewed them and decided whether to include them into the reference standard or not, according to the relevancy of the result and the search task. Only those concepts considered relevant by the evaluator were included into the reference standard.

Table 2 shows the search tasks, the number of concepts in reference standard, the number of concepts found by each browser and the number of concepts included in reference standard found by each search interface. Three interfaces yielded the same results for 17 of the 24 search tasks. The example-based precision ($P$), recall ($R$) and $F_1$ measure ($F_1$) were calculated based on the results and the reference standard using formula (1) in Section 2.3. Table 3 shows the overall example-based precision, recall, and $F_1$ for the results of 24 search tasks using NLM, IHTSDO and COBE. The result shows COBE carried out the best recall of 0.917; NLM achieved the best precision of 1.0; both COBE and NLM had the best $F_1$ measure of 0.875. This indicates that COBE is comparable to the state-of-the-art SNOMED CT browsers for looking up concepts.

4 Discussions

Our evaluation of the direct lookup mode of COBE is limited with respect to the reference standard. Since SNOMED CT contains 302,902 concepts, going through the entire concept list to find all relevant concepts of each search task to build the reference standard is infeasible for the evaluator. The other limitation is that we only had one evaluator. This also could possibly introduce bias to the reference standard creation. A third limitation is that only stem coverage was used to evaluate the navigational exploration mode of COBE. It would be helpful to conduct a comparative user evaluation for the navigational exploration mode. However, there are no similar mechanisms in other ontology browser for us to compare COBE with.

We also performed an experiment using the entire SNOMED CT to generate search stems and compare the performance with the search stems from concepts involved in non-lattice fragments. 83,139 search stems were generated from the entire 302,902 concepts. The number of stems generated by non-lattice fragments was 12,623, which is 15.18% of the entire stems. However, such 15.18% of the entire stems already covers 98.97% of SNOMED CT concepts.
Table 2: Comparison of searching results of 3 SNOMED CT Browser. $Y$ - the number of concepts in reference standard $Y$. $Z_C$ - the number of concepts found by COBE. $Z_C \cap Y$ - the number of concepts found by COBE that included in reference standard. $Z_I$ - the number of concepts found by IHTSDO browser. $Z_I \cap Y$ - the number of concepts found by IHTSDO browser that included in reference standard. $Z_N$ - the number of concepts found by NLM browser. $Z_N \cap Y$ - the number of concepts found by NLM browser that included in reference standard.

In related work, existing ontology visualization toolkits such as KC-Viz [17] and ProtégéVOWL [18] are not designed for searching and visualizing non-lattice fragments. Therefore, COBE uniquely fulfills this need.

5 Conclusion

In this paper, we presented a conjunctive ontology browser COBE to search and explore SNOMED CT concepts and non-lattice fragments for ontology quality assurance. The direct lookup and navigational exploration of COBE allow multiple entry points for users to explore information of interest. The combination of searching and visualization mechanisms in COBE provides a novel way for structural auditing of SNOMED CT. Navigational exploration and direct lookup offer complementary modes for finding specific SNOMED CT concepts. With respect to the direct lookup mode, evaluation against manually created reference standard showed that COBE attains an example-based precision of 0.958, recall of 0.917, and $F_1$ measure of 0.875. With respect to the navigational exploration mode, COBE leverages 28,371 concepts in non-lattice fragments to construct the stem cloud. With merely 9.37% of the total
SNOMED CT stem cloud, our navigational exploration mode covers 98.97% of the entire concept collection. COBE has been deployed as the resident search interface for linking, exploring, and rendering of SNOMED CT non-lattice fragments, which represent an active area of ontology curation work.

Abstract

Despite their widespread use, audit and feedback (A&F) interventions show variable effectiveness on improving professional performance. Based on known facilitators of successful A&F interventions, we developed a web-based A&F intervention with indicator-based performance feedback, benchmark information, action planning and outreach visits. The goal of the intervention was to engage with multidisciplinary teams to overcome barriers to guideline concordance and to improve overall team performance in the field of cardiac rehabilitation (CR). To assess its effectiveness we conducted a cluster-randomized trial in 18 CR clinics (14,847 patients) already working with computerized decision support (CDS). Our preliminary results showed no increase in concordance with guideline recommendations regarding prescription of CR therapies. Future analyses will investigate whether our intervention did improve team performance on other quality indicators.

Introduction

The widespread uptake of electronic patient records (EPRs) provides unprecedented opportunities to monitor clinical performance and improve care quality. As such, audit and feedback (A&F) interventions based on interrogating EPR databases are increasingly used to aid health care professionals in improving their performance. A&F provide care professionals with an objective summary of their clinical performance over a specified period of time [1]. Yet despite their expanded use, A&F interventions show variable effectiveness on improving quality of care. A recent Cochrane review of 140 randomized trials of A&F interventions reported a median 4.3% absolute improvement (interquartile range 0.5% to 16%) in quality of care, with a quarter of the studies showing a strong positive effect, but with another quarter showing a negative or null effect [1].

Previous studies have attributed much of the observed variability in effect of A&F interventions to feedback design characteristics and contextual factors. They suggested A&F to be most effective if baseline performance is low, when feedback is provided by a supervisor or colleague, more than once, both verbally and in writing, and when it includes explicit targets and an action plan [1-4]. Furthermore, the effect of indicator-based performance feedback is likely to be stronger when it is combined with educational meetings [1]. Other suggested effect modifiers are the perceived quality of the data underlying the feedback, motivation and interest of the recipient, organizational support for quality improvement (QI), and how performance targets or benchmarks are derived [5]. Besides these literature results we had a conjunctural expectancy based on the actuality that modern medicine, including the care for chronically ill patients, is not just a matter of individual professionals but largely the responsibility of multidisciplinary teams embedded in complex organizations. Therefore we expected that, specifically in chronic disease management, engaging the entire multidisciplinary teams and their managers in the QI process is an important success factor of A&F interventions [6]. We developed a multifaceted A&F intervention that both incorporates successful characteristics described in the literature [1-5] and that is specifically directed at multidisciplinary teams [7]. It comprises the use of a web-based system that provides periodic performance feedback with benchmark comparisons and support for concrete QI action planning. In combination with educational outreach visits the systems facilitates active team engagement in improving their performance [8].

We implemented our intervention in the field of cardiac rehabilitation (CR) in the Netherlands. Within this field an EPR system with computerized decision support (CDS) functionalities was previously developed to stimulate
concordance with guideline recommendations for the patient tailored CR program [9]. Although the CDS has proven to be effective [10], there remained considerable non-concordance due to a lack of resources and other organizational constraints [11]. Further improvement of guideline concordance required organizational and procedural changes that individual users considered to be beyond their own tasks, influence and responsibilities. Use of the CDS system alone was insufficient for inciting users to involve decision makers at team and organizational level to realize those changes [11]. This finding stressed the need for an intervention specifically directed at the decision-making processes at these levels to create the necessary conditions and resources for further improving guideline concordance. Hence, guideline concordance was one of the targeted behaviors of our A&F intervention.

We performed a multicenter cluster randomized trial to assess the effect of a multifaceted A&F intervention on clinical performance of multidisciplinary teams in the field of CR. In this paper we present preliminary results regarding the intervention’s effect on concordance of CR therapies with guideline recommendations.

**Methods**

**Setting: cardiac rehabilitation and computerized decision support**

CR is a therapy provided by multidisciplinary care teams to support cardiac patients recovering from a cardiac incident or intervention on both the physical and psychosocial domain [12, 13]. CR is recommended for all patients who have been hospitalized for an acute coronary syndrome (ACS) and for those who have undergone a cardiac intervention [12, 14]. A meta-analysis shows consistent evidence of the effectiveness of exercise-based and multimodal (e.g., psychosocial and stress management) CR interventions with regard to mortality and prevention of future cardiac events (relative-risk reduction 21–47%) [15]. CR teams usually include cardiologists, physical therapists, nurses, psychologists, dieticians, social workers, and rehabilitation physicians. However, in many Western countries, CR services are under-utilized and poorly standardized and do not follow the available scientific evidence [16]. A recent study in the Netherlands shows that only a minority of patients eligible for CR actually receive it [17]. The CR uptake rate was 28.5% among patients with an ACS and/or intervention.

Consistent with international standards, the Dutch Guidelines for CR [18] state that professionals should conduct an extensive needs assessment procedure (NAP) where 80 to 130 data items concerning the patient’s medical, physical, psychological, and social condition and lifestyle are gathered. Based on this procedure, a patient-tailored rehabilitation program should be prescribed which can contain up to four group-based therapies: two psychosocial therapies (disease-specific education; lifestyle modification) and two physical therapies (exercise training; relaxation and stress management training), and can be supplemented by individual counselling (e.g., by a psychologist, dietician or social worker) when needed. In the Netherlands, there are two commercial vendors of EPR systems with CDS for CR (referred to as EPR1 and EPR2) that can be used for data collection. Both systems are based on the Dutch guidelines for CR [18] and follow the same data model. They guide their users through the NAP and provide advice for the decision about each out of the four considered CR therapies for the prescribed CR program [19]. However, one of the EPRs is a stand-alone product in which, based on results of usability evaluation of a beta version of the system [20], the data entry navigational structure is organized flexible around an overview screen. Complete data collection is stimulated by showing users which steps of the NAP they already have finished and which steps they still need to complete. The other system is integrated into the hospital EPR from one vendor and offers a more straightforward data entry structure. This system does not provide feedback on finished NAP steps. After data collection in both systems, the patient specific CDS advice is discussed with the patient. Thereafter the prescribed CR program, including the decisions for each out of the four CR therapies (which can deviate from the CDS advice), are recorded in the EPR. While we focus on prescribed therapies in this study, we note that there are sometimes discrepancies between prescriptions and therapies that are actually received by patients. After participation in the program (which typically lasts for 6-12 weeks), patient are reassessed to determine results.

**Study design**

The effect of the intervention was evaluated in a multicenter cluster-randomized study in which each CR clinic received the A&F intervention, but its contents were randomly limited to one of two complementary domains that jointly constitute CR: the psychosocial domain (disease-specific education; lifestyle modification) or the physical domain (exercise training; relaxation and stress management training). In this way, both study arms served as each other’s control, and we minimized the risk of clinics dropping out of the study because they did not receive any intervention. Cluster-randomization was chosen to avoid contamination among professionals within the same clinic. We refer to the study protocol for further details of the experimental design [7].
Eligible CR clinics and patients

All CR clinics that used an EPR with CDS during the NAP and that were willing to share their data for research and to set up a local QI team were eligible to participate in the study. There were 91 CR clinics in the Netherlands, the majority affiliated with hospitals [21]. Twelve clinics were located in specialized rehabilitation clinics [21], which have regional functions and can treat both simple and more complex referred patients. All types of clinics were eligible to participate in the study, provided that they worked with either one of two commercial EPR systems for CR that could be used for data collection for our study. During the inclusion period of the trial from July 2012 until December 2013, this was the case for 22 clinics. The study dataset consisted of (i) patient identification data (31 items), (ii) CR needs assessment data (80–130 items), (iii) data on selected rehabilitation goals and therapies (79 items), and (iv) CR evaluation data (105 items). All consecutive CR patients that underwent the NAP in one of the participating clinics during the study period were eligible for enrollment in the study. Clinics that participated agreed to enter all data of these patients in their EPR.

Intervention

Our multifaceted A&F intervention was provided through a web-based system, called CARDSS Online [8]. When designing the intervention we followed the A&F literature which underlines the importance of combining periodic performance feedback with benchmark comparisons, action planning with concrete, self-formulated goals, and educational outreach visits to actively involve care professionals in a continuous QI process. To this end CARDSS Online supports four tasks: (i) monitoring of indicator-based performance by means of quarterly feedback reports including benchmark information, (ii) selecting indicators for QI that are locally perceived as important and upon which improvement is deemed feasible, (iii) developing a QI plan consisting of QI goals and concrete actions to accomplish these goals, and (iv) during follow-up iterations updating the QI plan based on new performance measurements and experiences with executing the QI actions in practice. Benchmark comparisons were summarized by a colored icon next to each indicator score which depicted whether the performance was acceptable (green checkmark), borderline (yellow checkmark), or poor (red exclamation mark). The benchmark comparisons were based on the clinic’s performance score and the average score across all clinics (details available in [7]).

Educational outreach visits were held following each feedback report. During these visits CARDSS Online was used to guide the clinics’ local QI teams through the process of systematically defining, implementing and monitoring QI actions. The QI teams consisted of at least one local CR coordinator (usually a specialized nurse), one professional from another discipline (e.g. a physical therapist), their manager and the responsible cardiologist. The visits were chaired by an investigator (MvEV) who supported the QI team with interpretation of the feedback and drafting (or during follow-up visits monitoring and updating) a concrete QI plan. Indicators were included in the plan based on the benchmark information and discussion on importance, feasibility, and expected time needed to improve. For each quality indicator, the QI team could specify the problem, presumed causes, improvement goal, and concrete actions on how to reach that goal. If clinics agreed upon extended participation after the minimum study period of one year (comprising of four A&F iterations), they received up to two more quarterly feedback reports in combination with telephone support rather than a face-to-face visit.

We previously developed a set of eighteen primary quality indicators to provide performance feedback in our system [22]. This was done in close collaboration with an expert panel (representatives from all disciplines involved in CR) and patient panel, using a modified RAND method [22]. Results from both panels were combined with results from a literature search and guideline review in an extensive rating and consensus procedure. The expert panel did not select concordance of prescribed therapies with the guidelines as one of the eighteen primary quality indicators. However, the tailoring of CR programs to individual needs of patients is an important quality theme in CR, and indirectly reflected by many indicators that were chosen. Furthermore, we did include concordance of prescribed therapies with the guidelines in the feedback reports, which enabled QI teams to include improvement actions aimed at guideline concordance in their QI plans. Besides results on indicators and concordance, the feedback also included patient characteristics (e.g. age and diagnosis), information referring to general processes (e.g. time between discharge and NAP) and structures (e.g. presence of patient satisfactory research) to reduce the risk of attrition.

Outcome measurement

Our intervention was targeted at health care professionals and was therefore expected to have a direct effect on process outcomes but only an indirect, long-term effect on patient outcomes. The outcome measure was therefore concordance to national CR guidelines regarding the CR program that was prescribed during the NAP. We defined concordance at the level of the patient; it implied prescribing therapy to patients who should be treated and not...
prescribing therapy to patients who should be untreated, according to the guidelines. This was determined for each of the four group-based therapies separately.

**Cluster randomization and allocation**

Randomization of CR clinics was stratified by size (more/less than 30 patients starting CR per month). Per stratum, we generated a randomization scheme with randomly assigned block sizes of either two or four CR clinics using dedicated software. This scheme was concealed to those enrolling and assigning CR clinics [7]. Due to the character of the intervention, it was not possible to blind participants or those involved in providing the intervention.

**Statistical analysis**

For each of the four CR therapies (education, lifestyle modification, exercise training, and relaxation training) we performed a separate mixed-effect logistic regression analysis [10, 23] to assess the effect of the intervention on concordance with guideline recommendations. To this end we included covariates study arm, time, and the interaction between study arm × time. We focused on the interaction term to assess the difference in change over the study period between the two arms—that is, the effect of the intervention—because we expected concordance to improve gradually. We used random effects to model the variation in baseline concordance between clinics (random intercept for each clinic) and the variation in change in concordance over time (random slope for time). To adjust for differences in case mix between the study arms, we included in our analysis three patient level variables (age, sex, and indication for CR) and two clinic level variables (weekly volume of new patients, and whether the clinic is a specialized rehabilitation center or part of a university or teaching hospital) as covariates.

Patients who were seen in the last month of a clinic’s study period were excluded from the analysis because their prescription data was often not yet complete. We also excluded patients for whom the indication for CR was missing. Furthermore, for each of the four analyses of guideline concordance on specific CR therapies we excluded patients for whom it could not be determined whether the prescription of that therapy was concordant with the guideline (either because the guideline’s recommendation or the actual prescription could not be determined).

![Figure 1. Flow diagram of CR clinics through the trial.](image-url)
Results

Participants

Of the 22 eligible CR clinics 18 clinics accepted our invitation to participate in the trial, of which twelve clinics were assigned to intervention arm A (receiving multifaceted A&F intervention on psychosocial therapies), and six to arm B (receiving intervention on physical therapies) (see Figure 1). CR clinics were enrolled in the study between July 2012 and December 2013. On average, the time between randomization and the first educational visit was 3.5 months (standard deviation [SD] 0.7). The average time between subsequent visits was 4.0 months (SD 1.4). Table 1 shows the baseline characteristics of clinics and patients. During the study period a total of 14,847 patients were seen for a NAP in the participating CR clinics. After exclusions in the overall database 11,932 patients were included for the analyses on concordance per CR therapy. The analyses were performed on data from 10,730 (education), 10,774 (lifestyle modification), 10,953 (exercise training), and 8,804 (relaxation training) patients.

Implementation of the intervention

Table 2 shows detailed information on how, and to what extent, the main components of the A&F intervention were implemented in the participating clinics. Due to limited availability of the QI team, one clinic in arm A completed only three A&F iterations during the study period instead of four. There were no differences in QI team size, number of indicators selected as QI goal and number of actions per goal in the QI plan, attendance to the visits, and mean study period between the two study groups. Attendance to the visits remained the same during the study period. The mean number of selected QI goals in each QI plan decreased from 8.0 (SD 2.4) during the initial A&F iteration to 5.0 (SD 3.2) in the final iteration. QI teams in both groups reportedly resolved 1.8 of these QI goals per A&F iteration, on average.

Effect of the intervention

Table 3 compares crude concordance rates between baseline (first three months) and follow-up (remaining time in the study period) for each of the four therapies. Despite random allocation of the participating clinics into two study arms, Chi-squared testing showed significant differences in baseline concordance for lifestyle modification (p<0.001), exercise (p=0.004), and relaxation training (p<0.001) between the two study groups. Table 3 also presents the results of the mixed-effect logistic regression analyses, which compare the trend in concordance over time between intervention and control groups while adjusting for patient age, sex, and indication for CR and adjusting for clinic type and weekly patient volume. No significant differences were found for any of the four therapies. For three of the four therapies (education, lifestyle modification, and exercise training) there were few missing data (around 10%) with respect to recommended and prescribed care, but for relaxation training we found missing data in 26.2% of cases. This was due to six clinics having substantially lower data quality for the relaxation therapy. A sensitivity analysis in which we excluded these clinics from our dataset did not yield different results.

Discussion

Summary of findings

Our multifaceted A&F intervention did not increase concordance of prescribed CR therapies with guideline recommendations. There appeared to be a high variation in baseline performance and data quality between participation CR clinics. Especially for the relaxation training we had a high percentage of missing data on guideline concordance. Although our intervention facilitated active engagement of local multidisciplinary QI teams in setting their own performance improvement goals, the teams often did not succeed in completing the actions that were needed to achieve those goals.

Strengths and weaknesses of this study

The main strength of our study is that we designed our multifaceted A&F intervention based on both existing knowledge from the literature on effective characteristics of A&F interventions [1-5] and an extensive analysis of potential barriers to further increase guideline concordance in the field of CR [11]. The use of CARDSS Online combined with outreach visits actively involved local QI teams, including managers and cardiologists, in the improvement process. By the development and regularly update of a QI plan with concrete, self-formulated goals, we focused on the decision-making processes at the organizational level to create the necessary conditions for improving guideline concordance. Also, as participating clinics were already working with an EPR with CDS functionality, they did not need to change their workflow to participate in the study and collect data. This pragmatic aspect of our study design may have optimized CR clinics’ willingness to participate and minimized the loss to follow-up. Although this resulted in a relatively large sample of CR clinics in which all different CR clinic types were represented, there were large differences in baseline performance between participants.

A limitation of our study is that only CR clinics that used an EPR with CDS that facilitates registration of our study dataset were eligible to participate. These clinics needed to be willing to share their data for research and to allocate resources to establish a QI team. This potentially resulted in a volunteer bias, as eligible CR clinics were less likely to be understaffed and more likely to have information technology to facilitate routine collection of CR data. The generalizability of our results may thus be limited to clinics that are motivated and equipped to systematically monitor and improve the quality of care they deliver. Second, the intervention allowed QI teams to formulate any improvement actions, even if those were not specifically targeted at improving concordance to a specific guideline recommendation. Although this may have optimized the engagement of the team in the improvement process and the commitment to goal attainment, it undermined the connection between the intervention and our primary outcome measure. This link was further diluted because the set of quality indicators chosen by the expert panel did not include guideline concordance for prescribed CR therapies as a separate indicator. However, we did include concordance statistics on each of the four therapies in our feedback reports. In addition, clinics might have started to improve both CR domains and not just the domain covered in their study arm because the intervention has raised their overall awareness for QI. Last, sometimes there are discrepancies between prescriptions and therapies that are actually received by patients caused by e.g. quality of the content of therapies or patient motivation. The effect of our intervention on received rather than prescribed CR therapies might be different.

c) Odds ratio of improvement in guideline concordance after receiving the A&F intervention for 1 year versus no intervention; adjusted for patients’ age, gender, indication for CR, and clinics’ type and size.
d) Patients for whom the CDS could not provide advice caused by missing data and/or it was not recorded whether the therapy was included in the patients’ CR program.
Strengths and weaknesses in relation to other studies

Our multifaceted A&F intervention included the development and revision (up to five times) of a QI plan based on indicator-based performance in quarterly feedback reports. Such iterative cycles and repeated use of data over time are generally considered key features to improve health care processes. However, a recent systematic review of studies employing the plan-do-study-act method showed that less than 20% of such studies use iterative cycles of change, and only 14% of them repeatedly use data over time [24].

Furthermore, the combination of A&F with both web-based guidance through the process of systematically developing a QI plan and outreach visits to encourage the local QI team to regularly monitor the feedback and update their plan, stimulated engagement of the QI team. Although this is a known characteristic of effective A&F interventions [1-5], other studies struggle with active engagement of health care professionals in goal setting and action planning to improve their performance [25-27]. Ivers et al [27] performed a qualitative study to understand the usefulness of A&F among family physicians and examined barriers to using it to improve quality of care. Their main findings address some general concerns during implementation of A&F interventions to improve professional performance. Participants reported that the feedback increased their awareness of gaps between ideal and actual performance. This resulted mainly in efforts to “try harder” patient by patient. Key barriers to acting upon feedback in a systematic manner included a perceived discordance between population-level quality targets and patient-centered care (“It [A&F] talks about whole populations as opposed to the one individual and I think my approach to this job is the one person at a time”), as well as competing priorities at both the patient and organizational levels (“How much time do you want your doctor devoting to that [A&F], because the more … the less time I am [devoting] to the patient”). A qualitative analysis which is currently underway should point out if similar barriers were present during the implementation of our multifaceted A&F intervention.

Meaning and implications of findings

Further analyses should point out whether participating clinics were able to improve their performance on individual quality indicators, and whether this was related to the selection of these quality indicators in QI plans and to achieving self-formulated improvement goals. If there was indeed improvement on individual indicators, the failure to achieve progress in concordance of prescribed CR therapies with guideline recommendations is probably due to a poor link between these indicators and guideline concordance of therapeutic prescriptions. If there is no improvement on individual indicators, then our A&F intervention has simply failed to stimulate clinicians to work on QI actions outside their daily routine. The large number of unattained QI goals (Table 2) points in this direction.

According to Ancker et al [28] the evaluation of health information systems, like our web-based A&F intervention, often show mixed results. This may be in part attributable to the evaluation frameworks used. They developed a model for evaluation, named the Triangle Model, in which they emphasize the sociotechnical view that organization, technology, and users influence and change each other during implementation processes. The lack of success of our web-based A&F intervention might not have only depended on the technology used but also on the organizations and professionals involved. Similarly, the Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS) framework [29] emphasizes that a thorough needs analysis should be performed to determine organizational readiness before initiating change. This might uncover underlying issues within the institution (e.g. equipment problems or staffing shortages) which first should be resolved to make the QI effort succeed [29]. Also the Systems Engineering Initiative for Patient Safety (SEIPS) model [30] presents a broad approach with a focus on system design and its impact on processes and outcomes. This model describes the structure of a health care organization as a work system with five components (person, tasks, tools and technologies, physical environment, organizational conditions) who interact with each other and affect both work (e.g. maintenance and supply chain management) and clinical care processes. Both processes in turn influence the patient, employee, and organizational outcomes of care [30]. Capturing more detailed predictor variables about the technology, users, and the surrounding context might have increased the ability to interpret our findings of process variables (e.g. organization – professional processes such as culture and workflow [28]) during the evaluation of our intervention.

Future work

Although A&F interventions are increasingly used to aid health care professionals in improving their performance, they might not qualify as the best basis for improving concordance of prescribed therapies with guideline recommendations. Our future work will include results on the intervention’s effect on concordance of the received CR therapies with guideline recommendations, as well as results on team performance (the intervention’s effect on all quality indicators); and results of a qualitative process evaluation. During this evaluation we use the concept
mapping methodology (including focus group sessions) to explore experiences from participating CR clinics with
the intervention to gain insight into barriers and facilitators of the implementation.

Conclusion

A web-based A&F intervention with outreach visits did not increase concordance of prescribed CR therapies with
guideline recommendations in a pragmatic evaluation using EPRs for data collection. There appeared to be a high
variation in baseline performance and in data quality among participating CR clinics. Although QI teams in the
clinics formulated QI goals and associated actions at the start of each quarterly A&F iteration, most goals were not
attained. We recommend to align data registration in participating clinics before starting an A&F intervention that
uses EPRs for data collection. Future analyses should show whether our intervention did improve the overall CR
team performance measured by change in quality indicators results, complemented with qualitative information on
factors which influenced the implementation of the A&F intervention.

Abstract
Constructing a biological model using an established ontology provides a unique opportunity to perform content auditing on the ontology. We built a Markov chain model to study tumor metastasis in the regional lymphatics of patients with head and neck squamous cell carcinoma (HNSCC). The model attempts to determine regions with high likelihood for metastasis, which guides surgeons and radiation oncologists in selecting the boundaries of treatment. To achieve consistent anatomical relationships, the nodes in our model are populated using lymphatic objects extracted from the Foundational Model of Anatomy (FMA) ontology.

During this process, we discovered several classes of inconsistencies in the lymphatic representations within the FMA. We were able to use this model building opportunity to audit the entities and connections in this region of interest (ROI). We found five subclasses of errors that are computationally detectable and resolvable, one subclass of errors that is computationally detectable but unresolvable, requiring the assistance of a content expert, and also errors of content, which cannot be detected through computational means. Mathematical descriptions of detectable errors along with expert review were used to discover inconsistencies and suggest concepts for addition and removal. Out of 106 organ and organ parts in the ROI, 8 unique entities were affected, leading to the suggestion of 30 concepts for addition and 4 for removal. Out of 27 lymphatic chain instances, 23 were found to have errors, with a total of 32 concepts suggested for addition and 15 concepts for removal. These content corrections are necessary for the accurate functioning of the FMA and provide benefits for future research and educational uses.

Introduction
The Foundational Model of Anatomy (FMA) ontology¹ seeks to represent knowledge within the domain of human anatomy in a symbolic way. It attempts to formalize all parts and relationships in the body, and intends to be a “resource for developing the anatomy content of applications that target specific user groups,” which includes biomedical research applications.¹ A human biological model may focus on the anatomy and physiology of a particular organ system or body part, and may therefore only concern itself with a subset of elements from the FMA. Isolating and using these specific concepts from the FMA allows for better linkage and recycling of models, as the terminology of the FMA can be used to bridge gaps between the authors of these models. More importantly, perhaps, and the focus of this paper, model building also helps to enhance the content of the FMA itself. Certain weaknesses in ontological structure as well as internal inconsistencies can be brought to light through the demands of practical application.

In this paper, we focus on a specific use case as an example: modeling tumor dissemination in the lymphatics of the head and neck. HNSCC is a major form of cancer that arises in the mucosa of the upper aerodigestive tract. This particular form of cancer is known for a high propensity towards metastasis, with the spread of tumor cells occurring nearly universally through the lymphatic system.²,³ For HNSCC, standard treatment involves surgical resection and/or irradiation of part of the neck to remove the mass and lymph nodes in which metastasis is suspected. Because both surgical removal and over-irradiation of surrounding tissue have negative consequences to the patient, it is in the clinician’s interest to minimize collateral damage. Ideally, only lymphatic regions with high probabilities of microscopic disease would be treated. Determining the locations within the head and neck with high likelihood for metastasis is critical in guiding surgeons and radiation oncologists in selecting the boundaries of treatment.⁴–⁶ In this region of the body, the metastatic trends generally follow known, but not precisely defined paths.⁷,⁸ Markov chain models have shown promise in quantifying the probabilities of metastasis to particular nodal regions⁹; we attempt to build such a model using the lymphatic topology represented in the FMA.
The anatomical underpinning of the model is retrieved from the FMA ontology. This allows us to establish consistency between our model and existing knowledge about lymphatic anatomy. Nodes in our Markov chain model are populated using terms and relationships derived from the relevant portions of the FMA. In most cases, the ontology provides a sufficient representation of the regional lymphatics. However, we were able to determine several areas of insufficiencies. These include failures to distinguish between instances and superclasses of lymphatic objects, missing concepts, and to a much lesser degree, incorrect concepts or connections. For many of these issues, we were able to fill in the gaps of knowledge using existing information in the FMA (i.e., by relocating mis-located information, or inferring information from existing relationships). In other cases, we contended with issues in the fundamental organization of the FMA, and a more significant discourse was necessary.

Our strategies for error detection and correction can be used to improve other parts of the FMA ontology. Some of our methods are outlined below; it is our hope that these techniques can be used to assess other parts of the FMA and bring about changes which will ultimately improve its logical underpinnings, consistency and usefulness.

Methods
We evaluate errors in the FMA ontology that can be categorized into the following classes: (1) computationally detectable and resolvable, (2) computationally detectable and unresolvable, or (3) undetectable. All errors can be addressed through the addition or removal of select concepts. Errors of class 1 and 2 can be described in logical terms and algorithmically discovered. Of these, fixes for class 1 errors can be constructed from pre-existing information in the FMA ontology. Fixes for class 2 errors cannot be automatically generated, and these errors must be addressed by content experts. Lastly, errors of class 3 can neither be detected nor fixed using computational methods. These are errors of content, where the ontology disagrees with established literature. These errors can currently only be detected through systematic validation by an anatomical expert. In the construction of our model, we were able to discover and determine fixes for all three classes of errors described above. Computational methods for automatic error detection were attempted in all cases. Once all possible detectable errors were found and fixed, an anatomical expert assessed and completed the auditing of the edited ontology.

We begin by describing the role of the FMA in the construction of our Markov chain model. Our ROI includes parts of the head and neck which constitute the mucosa of the upper aerodigestive tract, the lymphatic objects that drain these parts, and their lymphatic connections to venous circulation. We follow by describing the classes of errors that we found in this region, and how we infer concepts for addition and removal for each error class.

All anatomical parts, their names and properties were retrieved from the latest release of the FMA in the Web Ontology Language (OWL), version 3.2.1 (University of Washington Structural Informatics Group (UW-SIG)). SPARQL (SPARQL Protocol and RDF Query Language) queries were written and stored in the Query Integrator (UW-SIG) and accessed through an interface written in Clozure Common Lisp version 1.7 (Clozure Associates, Brookline, MA). All graphs of the lymphatic network were generated using Graphviz version 2.36 (AT&T Labs, Austin, TX).

Using the FMA to construct our model
The process of cancer metastasis can be represented using Markov chains, a type of memoryless stochastic model useful for describing the probability of events based on previous known states. For our Markov chain model of metastasis, each node captures both the anatomical location and the severity of disease. In cases of HNSCC, metastasis occurs along known lymphatic drainage paths. We can therefore model locations as lymphatic concepts from the FMA and severity using the cancer T-stage grading system.

Lymphatic flow can be modeled as a unidirectional process. The lymph fluid is assumed to flow only in the direction of the two great lymphatic vessels: the thoracic duct and the right lymphatic duct, before entering venous circulation. At any point in time, all nodes downstream of the primary tumor site have some probability of hosting metastatic disease. Our model therefore must consist of all lymphatic structures reachable by a particular primary tumor. Because there are known connections between identifiable lymphatic regions, we can construct a partial map of lymphatic drainage in the head and neck. We do this by extracting the relevant anatomical concepts and connections from the FMA.

The lymphatic network in the FMA is organized under the terms trees, trunks, branches, tributaries, chains and nodes. The right and left lymphatic trees are considered organs, and the subbranches and subtrees that form them are considered organ regional parts. Within these lymphatic trees, the trunk identifies the main stem of the tree. Further bifurcation of the stem yields branches and tributaries. These further consist of chains, whose members are nodes. Although this mode of organization may not be analogous to all accepted conceptualizations of the lymphatic system,
Figure 1. Values under the lymphatic_drainage property of the FMA object Soft_palate are queried and used to generate a full map of lymphatic flow downstream from the origin site. All unlabeled arrows between lymphatic objects represent the efferent_to relationship.

it does provide an appropriate number of subdivisions which can be used in modeling. The states in our Markov chain model refer to lymphatic chains, the smallest subdivision that is well-represented in the FMA. For the purposes of this article, specific entities and relationships from the FMA will be referred to in italics, with underscores in place of spaces.

Each tumor has an identifiable origin site, which corresponds to an entity in the FMA (e.g. Tongue, Soft_palate, Floor_of_mouth etc). Organ entities have a property lymphatic_drainage whose values are the lymphatic objects that drains the site. A SPARQL query can be written to extract this information, returning all lymphatic objects which directly drain an organ or organ part. For example, if a tumor is located in the tongue, we expect a query to retrieve the lymphatic objects \{Right_jugulodigastric_lymphatic_chain, Left_jugulodigastric_lymphatic_chain, Submental_lymphatic_chain, Basal_lingual_lymphatic_tree, Central_lingual_lymphatic_tree, Right_marginal_lingual_lymphatic_tree, Left_marginal_lingual_lymphatic_tree\}. The number of results can then be reduced by increasing the detail of the query, i.e., by querying on a regional part of the tongue, such as the Apex_of_tongue or Body_of_tongue. The FMA should be able to accommodate the most specific and anatomically relevant organ part, and return only those results appropriate for that entity. As you will see shortly, the annotation on the tongue is incomplete, and some modifications must be made to achieve these expected results.

Once we determine the direct lymphatic drainage of the tumor origin, we set out to define all possible paths of drainage. The FMA defines a relationship efferent_to for all lymphatic objects. This property points to lymphatic chains which are downstream of the chain of interest, i.e., closer to the great lymphatic vessels. Chains with multiple values under this property represent branching points in the lymphatic network. A full drainage map can be constructed by querying recursively over all efferent lymphatic chains until each one terminates in one of the two great lymphatic vessels. By combining the lymphatic objects at the tumor origin and the chains defined by the efferent_to relationship, we form a map defining all possible routes of metastasis for a particular tumor through the lymphatic network. The lymphatic objects in the final map can then be used to define nodes in the Markov chain model. Figure 1 shows the lymphatic drainage map constructed using entity Soft_palate as the seed tumor origin.

Inconsistencies identified in the FMA representation of the lymphatics
The FMA provided in large part a description of the lymphatic network which was accurate and detailed enough for our needs, such as the output presented in Figure 1. However, in many cases, the methods described above did not generate
drainage paths which correctly represented lymphatic anatomy. Inconsistencies arose in the connections between lymphatic chains, as well as in the definition of the lymphatic_drainage property. Five subclasses of class 1 (detectable and resolvable) errors were discovered: (1a) organs whose direct lymphatic drainage incompletely represents the drainage of their regional parts, (1b) organs with lymphatic drainage by lymphatic chain superclasses, (1c) lymphatic objects with efferent connections to inappropriate objects, i.e., superclass objects, (1d) connections between lymphatic chain superclasses, and (1e) erroneous connections between objects in the left and right side lymphatic trees. One subclass of class 2 (detectable and unresolvable) errors was discovered, (2a) lymphatic objects with no efferent connections. Class 3 (undetectable) errors were also found through anatomical expert review following the detection and correction of the previous error subclasses.

We use the following notation to indicate specific types of objects in the ROI. Allow $A$ to be the set of all lymphatic objects in the ROI. $A$ consists of $S$, the set of superclass lymphatic chains, $C$, the set of instances of superclass lymphatic chains, and $G$, the set of great lymphatic vessels, defined as $\{\text{Thoracic duct, Right lymphatic duct}\}$. $S$, $C$ and $G$ are mutually disjoint, and $S \cup C \cup G = A$. The FMA consists of structural entities, material objects in the body, i.e. left/right lung, and abstract entities, i.e. lung. The members of $S$ are abstract entities, whose members’ instances $C$ refer to structural entities in the body. Consequently, each member $s_i$ in $S$ has two instances representing bilaterally placed chains, $s_{iL}$ and $s_{iR}$, the right and left side chains respectively, both of which are members of $C$.

$C$ then consists of $L$, the set of lymphatic chains in the left side body, $R$, the set of lymphatic chains in the right side body, and $M$, the set of lymphatic chain instances that are located medially. $L$, $R$, and $M$ are also mutually disjoint and $L \cup R \cup M = C$. For any lymphatic object $c_i$ in $C$, allow $F(c_i)$ to represent the set of all lymphatic objects with a one-step efferent, to relationship to $c_i$.

Any organ or organ part $N$ consists of recursive regional parts $P = \{p_1, p_2, ..., p_n\}$. Each regional part $p_i$ in $P$ is drained by some set of lymphatic objects $Q_i = \{q_{i1}, q_{i2}, ..., q_{im}\}$. $N$ also has lymphatic drainage objects $D = \{d_1, d_2, ..., d_k\}$, acquired from querying on the lymphatic_drainage property of $N$.

Error constraints are expressed using set theoretic notation in Table 1 for clarity and portability. These are the foundations of queries ultimately used to extract inconsistencies from the FMA. All errors are described in greater detail below.

**Table 1. Descriptions of all error class constraints using set theoretic notation**

</table>

**Subclass 1a** An organ is necessarily drained by all the lymphatic objects which drain the organ’s regional parts. Conversely, however, the lymphatic objects that drain all of an organ’s regional parts may not represent all of the chains that drain the whole organ. For example, a query on the entity Tongue returns the lymphatic drainage object $\{\text{Jugulodigastric_lymphatic_chain}\}$, yet a query on all of the tongue’s regional parts returns $\{\text{Basal lingual_lymphatic_tree}, \text{Marginal lingual_lymphatic_tree}, \text{Central lingual_lymphatic_tree}\}$. The first is not a superset of the second, violating the constraint given above.

**Subclass 1b** No organ or organ part should be drained by superclass lymphatic objects. The entity Tongue is drained by the Jugulodigastric_lymphatic_chain, a superclass object, which violates this constraint.

**Subclass 1c** No lymphatic object should have efferent connections to inappropriate objects such as superclass lymphatic chains. For any lymphatic object $c_i$ in $C$, $F(c_i)$ must contain only appropriate objects such as members of $C$ or
Subclass 1d Superclass chains should not have efferent_to relationships to other objects. The FMA is inconsistent with this distinction and some superclasses are connected erroneously. As an example, the Superior_lateral_deep_cervical_lymphatic_chain has an efferent connection to the Inferior_lateral_deep_cervical_lymphatic_chain. Both of these objects are superclass lymphatics, and the connection is erroneous.

Subclass 1e As above, the right and left sides of this ROI are drained by distinct lymphatic trees. Right side lymphatic chains connect to other right side chains and similarly for the left side. The starting lymphatic object Left_subscapular_axillary_lymphatic_chain, for example, has efferent chains \{Right_central_axillary_lymphatic_chain, Right_apical_axillary_lymphatic_chain\}. The starting object is a member of \(L\), yet both of its efferent objects are members of \(R\), violating our constraint. This example is outside of our ROI, and although no subclass 1e errors were detected within the scope of this paper, we felt it important to include the class definition here for future use.

Subclass 2a All lymphatic objects must have efferent relationships to other lymphatic objects. Examples of lymphatic objects in the FMA with no efferent objects are the left and right submandibular lymphatic chains. Querying the efferent_to property of either returns the empty set. Although we were able to detect these errors, we could not infer corrections from existing concepts in the ontology.

Class 3 Type 3 errors involve incorrect information in the FMA ontology. Certain efferent connections between lymphatic objects may not agree with the prevailing literature.\(^{14-19}\) These content errors must be identified and corrected through expert review.

Using existing information in the FMA to correct inconsistencies

Many of these inconsistencies can be corrected systematically. Subclass 1a errors in which an organ is not correctly labeled with a superset of the lymphatic drainage objects of all of its regional parts can be addressed by adding the missing relationships to the FMA. For each organ in the ROI, we construct two queries: one to find the lymphatics that drain the organ directly, \(D\), and one to find the union of lymphatics which drain all of the organ’s recursive regional parts, \(\bigcup_{i \in I} Q_i\), \(I = \{1, 2, ..., n\}\), which we refer to as \(Q\). If the result of the first query is not a superset of the result of the second query, the lymphatic objects in \(Q \setminus D\) should be added as lymphatic_drainage objects of the organ. This process is then applied to all organ parts and parts of parts to achieve complete annotation.

For subclass 1b errors, we detect all organ or organ parts which are drained by superclass lymphatic objects. For each organ, we use the same query results for \(Q\) given above. Members of set \(Q \cap S\) should be removed as the lymphatic_drainage for the organ. Additionally, for each inappropriate drainage relationship, two new efferent concepts can be inferred. Lymphatic drainage relationships can be inferred between the organ and the left and right side instances of the inappropriately connected superclass object.

Likewise, subclass 1c errors can be detected by querying for efferent connections between lymphatic instances and superclass objects. For each lymphatic object \(c_i\), concepts in the set difference \(F(c_i) \setminus (G \cup C) \cap \{c_i\}\) are marked for removal as efferent_to values of \(c_i\).

We can also use the inappropriate connections in this case to infer correct but missing connections. The entity Central_lingual_lymphatic_tree for example, is a medial lymphatic chain (member of \(M\)). Querying on its efferent_to relationship returns \{Superior_lateral_deep_cervical_lymphatic_chain, Submandibular_lymphatic_chain\}, both of which are superclass lymphatics (members of \(S\)). Although this violates the constraint for subclass 1c errors, the intention of these connections may still be correct. If so, we extrapolate that Central_lingual_lymphatic_tree does in fact connect to both of these efferent chains, but to the right and left instances rather than the superclasses. We can then infer the addition of four efferent connections to:

\{Right_superior_lateral_deep_cervical_lymphatic_chain, Left_superior_lateral_deep_cervical_lymphatic_chain, Right_submandibular_lymphatic_chain, Left_submandibular_lymphatic_chain\}.

Subclass 1d errors can be identified and extraneous connections between lymphatic chain superclasses removed. In cases where the left and right side connections do not exist, the erroneous superclass connection can be used to infer them. After verifying the existence of appropriate connections between the right and left instances and their respective efferent objects, the connections between the superclass lymphatic objects are marked for removal.

Subclass 1e errors can be corrected by changing inappropriate efferent connections to point to the ipsilateral lymphatic chain instance. We identify all lymphatic objects that connect efferently to lymphatic objects on the contralateral side. These connections are marked for deletion. If the connection to the analogous ipsilateral lymph chain does not
already exist, a new efferent connection is added.

Subclass 2a errors cannot be addressed without input from a content expert. On occasion, the FMA harbors incorrect connections to superclasses (subclass 1c or 1d errors) that can be used to infer missing connections. In most cases though, it is impossible to conclude from existing information in the FMA how disjoint lymphatic objects should connect to the lymphatic network. This information must instead be found in the literature and propagated back into the FMA following review. Some examples of disconnected instances in the FMA are the right and left submandibular and the right and left paratrachael lymphatic chains. An existing connection in the FMA between the superclass Submandibular_lymphatic_chain and the Jugulo-omohyoid_lymphatic_chain indicates that this is the potential correct connection for the left and right instances. For the paratrachael chains, however, there is no available superclass connection from which to draw similar conclusions, and an anatomist must be consulted.

Diagrammatic representations of these error subclasses are given in Figure 2. Most errors could be detected and corrected computationally. Those errors that could not (class 3) were detected and corrected by a content expert.

Results

Within the upper aerodigestive tract, we extracted 106 distinct organ and organ regional parts from the FMA. There were 27 distinct lymphatic chain instances (right, left or medial) and 11 distinct superclasses of lymphatic objects in the ROI. Table 2 gives the number of inconsistencies detected for each error subclass, as well as the numbers of concepts suggested for addition and removal. These suggestions were generated first by programmatic rule evaluation and then confirmed with an expert anatomist. Counts in the table labeled with * are based solely on expert review, and represent circumstances in which the FMA differs from anatomical literature. Some suggestion counts may
disagree with the numbers implied in the Methods section, and this is either due to repetition in suggested concepts, or removal of suggestions based on expert review.

Prior to this round of content auditing, many lymphatics within the ROI were disconnected from the rest of the system (12 out of 27) or were connected erroneously to superclass entities (3 out of 27). Following automated inference and auditing, the number of disconnected entities drops to 4 out of 27, with no entities connected to superclass objects. Further concepts were added or removed by an anatomist, resolving class 3 errors, resulting in a final lymphatic map with no disconnected lymphatic instances. The structure and interconnectivity of the lymphatic ROI is shown in Appendix A. The network is shown in its original form (preceding any auditing) and at the completion of our review. Only right-side and medial lymphatic instances are shown for clarity. Final suggested concepts are in the process of being propagated back into the FMA.

**Discussion**

The FMA has been open to both changes to its underlying structure as well as content auditing. Over the past several years, it has undergone a dramatic change from a Frames-based system to an OWL representation.\(^{20,21}\) This change did not resolve many content issues, but increased the flexibility of the ontology, allowing for easier content auditing. Several attempts have been made in this regard, all of which have led to incremental improvement. In 2009, Gu et al. detected potential incorrect relationships by studying the implicit relationship between the *is-a* statement and structural relations such as *part-of*. An object A which is part of another object B, for example, may not also be an instance of B. Entities found to violate the implicit logic of these relationships were vetted by an expert anatomist and removed or corrected in the FMA.\(^{22}\) In the same year, Kalet et al. specifically suggested the auditing of the FMA’s representation of the lymphatic system.\(^{23}\) A study in 2012 expanded on some of these approaches by specifying and detecting “graph motifs,” small sets of relationships known to be problematic. SPARQL queries were used to fetch fragments of the FMA matching these motifs, and these problem concepts were then validated or changed in the FMA.\(^{24}\) Most recently, Luo et al. used the assumption of structural self-bisimilarity to detect potential anomalies in the FMA. They contend that certain types of relationships are expected to be symmetric on the two sides of the body, and differences in bilateral connectivity may be a strong indicator of error.\(^{25}\)

The techniques used in this paper share similarities to some of those mentioned above. One major difference though, is that the current auditing happened in the context of model creation. The deficiencies found needed to be addressed to allow us to continue to use the FMA as a tool. Addition and removal of suggested concepts were immediately vetted not only by an anatomical expert, but through the rigor of modeling use and testing. The corrected portion of the ontology is therefore less likely to contain significant further errors.

Overall, we believe that the structure, organization and intention of the FMA is a suitable foundation upon which to build our Markov chain model of cancer metastasis. However, the prior state of the FMA was unable to support our modeling needs. In our attempts to use the FMA to populate nodes in our model, we were able to systematically review relevant parts of the anatomical representation, specifically the lymphatic system in the mucosa of the upper aerodigestive tract. The classes of errors identified through this process generated a constraint set which may apply broadly to other parts of the lymphatic tree. It is our hope to extrapolate these auditing techniques to the rest of the lymphatics and other analogous systems such as arterial-venous circulation and the peripheral nerves.

**Limitations**

The methods described above have only been used to audit a small section of the FMA ontology. It is yet unknown whether they are applicable to the rest of the lymphatic system or other analogous systems as represented in the FMA.
For example, in the upper body, relationships between lymphatics generally show bilateral symmetry. In the abdomen and lower body, however, lymphatics drain only into the thoracic duct, and this property no longer holds. Also, the organs are asymmetric within the abdominal cavity, so there are no clear superclass and instance relationships. This more complex topology existing in the rest of the body will require not only a reevaluation of the error classes we have defined in this paper, but will likely introduce opportunities for new error definitions. Likewise, applying such methods to the arterial-venous circulatory system or the peripheral nervous system may yield an analogous but different set of constraints.

This paper focused primarily on classes of errors that can be defined and identified computationally. Some errors, although detectable, cannot be automatically corrected. These content errors benefit from automated content auditing by being discovered, but we have no way of proceeding without review by a content expert. We touched on this briefly when discussing subclass 2a errors. For these errors, we cannot infer the correct efferent connections to a disconnected lymphatic object; deductive reasoning will not suffice. We attempt to infer some possible solutions for subclass 2a errors using other pieces of information that already exist in the FMA, such as erroneous connections between superclasses. However, these inferences may not hold in all cases. Often, we cannot infer any new knowledge at all. This limitation is foreseen and expected. After all, we attempt only to detect connections which are potentially erroneous, and not to automatically generate novel content.

Likewise, errors of content, which are not logical in nature and cannot be expressed in mathematical formulae, are extremely difficult to find in an ontology the size of the FMA. Although we were able to discover and fix some of these content errors by hand, the process was laborious and would not scale well to larger subsets of the FMA. Our techniques may therefore face additional challenges when applied broadly to the FMA ontology.

Additionally, we were unable to audit certain other classes of content errors within the scope of this paper. For example, an organ may be fully annotated while none of its parts are. This is of concern when information is missing at our specified resolution, e.g., when we want to know the lymphatic drainage of an organ part, but there is no drainage information at that level in the FMA. We have yet to determine a cheap or systematic way to discover these types of ontological errors.

Conclusions

Many models of biological processes are fundamentally rooted in anatomy. In order to be “anatomically correct,” a model should satisfy the relational and spatial constraints imposed by human anatomy. For example, the human heart has a set of properties, such as having two atria, two ventricles and four valves, and would not be considered a proper heart if these statements were untrue, or if the relative locations of these objects were incorrect. Likewise, in building a functional model of a heart, the modeler would also want to include all of the above constituent parts and their relationships. Otherwise, there is a high probability that the model is inaccurate. Although this is an overly simple example, one could conceive of assessing the accuracy of a model by judging the correctness of its represented anatomy. A mismatch between a model and the known anatomical worldview would not necessarily invalidate the model, but would indicate potential points of improvement.

An ideal anatomical ontology would be able to fulfill these needs. The FMA, in its conception, attempts to represent human anatomy correctly and faithfully. The current state of the FMA has certain insufficiencies that increase barriers to its use, but many of these issues can be addressed through systematic content auditing. The best way to reach the correct anatomical description perhaps, is to selectively use, validate and correct subsets of the FMA ontology. Making edits in such a piecemeal way may not seem like the most efficient course of action, but what it lacks in breadth it makes up for in practicality.

Abstract
Within clinical discourse, social history (SH) includes important information about substance use (alcohol, drug, and nicotine use) as key risk factors for disease, disability, and mortality. In this study, we developed and evaluated a natural language processing (NLP) system for automated detection of substance use statements and extraction of substance use attributes (e.g., temporal and status) based on Stanford Typed Dependencies. The developed NLP system leveraged linguistic resources and domain knowledge from a multi-site social history study, Propbank and the MIPACQ corpus. The system attained F-scores of 89.8, 84.6 and 89.4 respectively for alcohol, drug, and nicotine use statement detection, as well as average F-scores of 82.1, 90.3, 80.8, 88.7, 96.6, and 74.5 respectively for extraction of attributes. Our results suggest that NLP systems can achieve good performance when augmented with linguistic resources and domain knowledge when applied to a wide breadth of substance use free text clinical notes.

Introduction
Social history (SH) factors including alcohol, drug, and nicotine use (collectively referred to as “substance use”) are increasingly recognized as risk factors for preventable disease, disability, and mortality. A number of studies have been published describing the linkage between social risk factors and their associated morbidity or mortality(1-4). For example, nicotine abuse continues to be the leading preventable cause of morbidity and mortality in the United States(5), and the severity of substance use disorders is strongly associated with the magnitude of comorbidity(3). In 2006, the Institute of Medicine (IOM) report on “Genes, Behavior, and the Social Environment: Moving Beyond the Nature/Nurture Debate” described the need for improving existing datasets, developing new data sources, and establishing strategies and models for incorporating behavioral and environmental factors and their interactions(6). In realizing this important link, the last decade has had increasing attention on substance use in its many forms with respect to health and disease(6-11).

The availability of electronic documents within electronic health record (EHR) systems provides an opportunity for clinical researchers to access a wide range of information about an individual’s social environment and use of this information for secondary purposes (e.g., disease surveillance or evidence-based medicine) as well as primary uses for patient care (e.g., decision support). However, large amounts of detailed substance use information in EHR systems are stored predominantly in free-text rather than structured format(12, 13), underscoring the need for automated information extraction or other natural language processing (NLP) techniques specific for identifying social history information such as substance use.

In this study, we sought to develop an NLP system for detecting three main sub-categories of substance use (alcohol, drug and nicotine use) statements within free-text clinical notes and extracting related information (e.g., temporal, amount and type) within these substance use statements.

Background

Substance use information in clinical documents and structured modules in the EHR

This research group has previously performed a multi-institutional study on social history information in EHR system clinical notes(14). In this initial study, social history information contained in clinical notes from different sources (MTSamples(15), University of Vermont Medical Center [UVMMC; formerly Fletcher Allen Health Care], and University of Minnesota affiliated Fairview Health Services [FHS]) was analyzed and the adequacy of HL7 CDA-based models(16) and openEHR(17) archetypes for representing social history information within relevant statements across the three sources was studied. Table 1 shows an example of the alcohol use statement type identified in the study along with categories of information within statements for this type and a common set of data
elements and values. Table 2 illustrates the representation of information within a social history statement for nicotine use.

Among modules for EHR substance use, two follow-up studies showed that free-text comments with alcohol and nicotine use were often added due to the limited ability of structured parts of the EHR to describe some elements (e.g., amount and frequency) for both alcohol and nicotine usage (12, 13).

Extracting substance use information from clinical texts with NLP

Natural language processing (NLP) technologies have been used for extracting a wide range of information (e.g., drugs, diseases, and findings) from clinical notes (4, 18-20). Currently, most established clinical natural language processing systems (e.g., MedLEE(19) and cTAKES(21)) as well as clinical annotated corpus (e.g., MiPACQ(22)) are primarily focused on extracting named entities such as Unified Medical Language System (UMLS) concepts (e.g., diseases, medications, or procedures). A number of efforts have focused on using automated NLP techniques to extract smoking status (e.g., “Past smoker,” “Current smoker,” and “Smoker”) and assess clinician adherence of tobacco treatment guideline from clinical notes such as discharge summaries (23-29). In Uzuner’s work, the authors described several systems for classifying the smoking status of the patients by using machine learning and rule based algorithms. These systems presented in the paper reported F-scores from 84 – 90. In this study, our preliminary classification results showed that a rule-based classifier could achieve F-scores from 85.9 – 95.9. For extracting of deeper information related to substance usage other than status such as amount, type, there has been limited work on collecting these detailed information on substance use more comprehensively.

We previously incorporated a family history model into our open-source clinical NLP system, BioMedICUS(30), for automated extraction of family history information that identifies observations (e.g., disease or procedure), relative or side of family with the attributes (e.g., vital status, age of diagnosis, certainty, and negation) and predication. In this study, we sought to extend BioMedICUS for automated detection of substance use statements and extraction of detailed information within each statement. We aimed to utilize the patterns and lexicon collected from the multi-site sources used in previous work (14) along with the deep dependency relationships between tokens within statements provided by the Stanford Dependency parser (31) to extract elements from social history statements. To augment our system performance, we also leveraged semantic labels in the Propbank corpus and the MiPACQ corpus.

Methods

Corpora and annotation

The corpora used in this study included 491 “Consult - History and Physical” notes from MTSamples.com (MTS), a public web repository with about 5,000 sample clinical notes (“Development Corpus”), and 200 “HP” notes from the University of Pittsburgh Medical Center (UPMC) de-identified clinical notes repository (32) (“Evaluation Hold-out Corpus”). The final corpora included clinical notes in a range of different specialties from both acute and ambulatory settings. The corpora annotation consisted of three rounds of annotation. First, the collected clinical notes were annotated for the social history contents as well as social history section headers with the General Architecture for Text Engineering (GATE)(33), a Java framework for developing NLP pipelines. To establish
agreement regarding annotations, a subset of 100 notes were studied collectively by TJW and EWC prior to annotating the remaining set of annotations. In the next step, annotated social history text of each note was extracted from the GATE XML output and categorized into different sets of statement types (e.g., “ALCOHOL_USE,” “OCCUPATION,” and “DRUG_USE”) with same annotation tool. Finally, sentences of three social history statement types, “ALCOHOL_USE,” “DRUG_USE,” and “TOBACCO_USE” were further annotated for elements (e.g., amount, frequency, and temporal) as well as the relationships between those elements with the brat rapid annotation tool (BRAT)(34), a web-based tool for structured annotation. Table 3 shows a brief description of the six elements that were extracted from our annotation guidelines for substance use.

**Table 3. Description and examples of elements for alcohol, drug and nicotine use.**

<table>
<thead>
<tr>
<th>Element</th>
<th>Brief Description</th>
<th>Alcohol Use</th>
<th>Drug Use</th>
<th>Nicotine Use and Exposure</th>

</thead>
</table>
| Amount        | How much a substance used | • Few glasses wine/day  
• beer or wine 1-2 per month | • <1 joint QOD for pain  
• Daily 1 pill 4X/day | • 1-2 cigarettes/day  
• heavy tobacco use |
| Status        | Current or past substance use. | • quit many years ago  
• current drinker | • clean since 2004  
• History of drug abuse | • Minimal smoker  
• Current tobacco |
| Type          | Type of substance use or exposure | • Few glasses wine/day  
• beer or wine 1-2 per month | • Used OxyContin prescribed to mother  
• Overdose of Molly | • Occasional Cigar  
• Smoked pipes and cigars |
| Frequency     | How often substance used | • one every 2 months  
• Occasional beer | • very rare  
• Marijuana 2x/week | • 1-2 cigarettes/day  
• a pack per week |
| Method        | How substance used or how exposed | • drinks wine | • Injected heroin for years  
• Occasional IVDU | • smokes a couple  
• secondhand smoke exposure |
| Temporal      | Temporal information e.g., date started, age started, date quit and duration of use | • started drinking in 1985  
• drink since age 20  
• quit recently  
• drink for 20 years | • First joint in 1987  
• methadone 2007 stopped  
• used 10 years | • started smoking in 1985  
• quit years ago  
• Smoked for 4-5 yrs |

Figure 1 shows the annotation of a set of alcohol use sentences using BRAT. For each social history statement type, 10% of the sentences of each statement type were annotated by two annotators for inter-rater agreement on the annotation of elements. Four informatics experts provided manual annotations, including a physician, one biomedical informatics PhD, and two biomedical informatics graduate students.

![Figure 1. Annotation of “ALCOHOL_USE” sentences in clinical notes. Green shaded box represent elements and arrows represent relationships between elements.](image-url)
**Substance use statement detection**

Figure 2 shows the overview of the substance use statement detection module development. The substance use statement detection rules were built with half of the 246 MTS “Consult - History and Physical” notes. Another two sets of MTS notes were used as a development set (N=123) and a holdout test set (N=122).

All UPMC “H&P” notes were used as a separate evaluation set. Text was extracted and split into sentences by a sentence splitter. All tokens within were normalized based on the SPECIALIST Lexicon (35) and substance use sentences were extracted.

A substance use detection lexicon was collected from all our previous work on social history and substance use as key features for substance use statement detection (13, 14, 36). Overall, three lexicons for alcohol, drug, and nicotine were created from MTSamples/FHS/UVMMC notes, UVMCC comments, and HL7 Social History Observation and openEHR alcohol related archetypes. Section headers and sub-headers of each statement were also used as a feature for substance use statement detection. Section header identification was aided by a limited set of header expressions, capitalization, spacing, and punctuation header patterns. A set of regular expression based rules for substance use statement classification was manually developed using the lexicons, section headers, and iterative error analysis on the training dataset to improve the system performance. In each iteration, rules were modified and new rules were included to capture cues from section headers or sentence text. For example, if a sentence contains any family member, then the sentence was not classified as a substance usage statement. In total 10 rules were created for substance classification. The developed substance use statement detection system was evaluated on two evaluation sets: MTS test set notes (N=122) and UPMC evaluation notes (N=200).

In this study we also implemented a support vector machine (SVM) model for alcohol usage statement detection. Latent dirichlet allocation (LDA) and information gain (IG) were used for feature selection. Selected features are then used by supervised SVM machine learning to classify each statement in the training dataset. LDA with Gibbs Sampling (iteration = 1500) was implemented in Stanford Topic Model Toolkit (TMT-0.4.0) (37). Topic numbers range from 50–800 were chosen. Keywords for each topic were obtained from the output files. We then used IG to rank those keywords for each topic and chose filtered top numbers of keywords as features to implement classification.

**Elements extraction**

As shown in Table 4, the number of occurrences for some elements (e.g., amount and frequency) was limited in the small MTS development corpus. Thus, the attribute extraction module was developed on all MTSamples annotated
statements for alcohol (N=243), drug (N=130), and nicotine (N=311) use for the six elements (e.g., amount, frequency, and temporal). The UPMC annotated statements were used as the single holdout test set for evaluation of element extraction. Annotated sentences were first parsed by Stanford Parser(38) for constituent and dependency parses. The constituent parse of a sentence provides syntactic cues for elements extraction. For example, a phrasal phrase with a time period token (e.g., year and month) could be a temporal element (e.g., “since this year”). Based on this fact, a set of rules was built to detect for temporal elements by using constituent parses. For instance, the constituent parses provided prepositional phrases which were helpful for temporal elements such that the pattern “(PP (IN (for|until|since|in|on|at))” and with a time marker could be used for temporal element detection. The dependency parse of a sentence can provide the dependency structure of the sentence. A dependency structure represents a directed graph between the tokens of a sentence, where edges denote pairwise grammatical relationships (e.g., determiner [the – patient] or adjectival modifier [significant - modified]).

Figure 3 shows an example dependency structure for “She denies any significant tobacco or alcohol...” The dependency structure of a sentence captures relationships between elements and the substance (e.g., alcohol or drug). These relationships can help to extract only related elements for a complicated sentence or sentences that with multiple substances. For instance, the dependency structure for “She is a smoker about a pack and a half for 38 years and notes rare alcohol use.” can help to detect the right substance, smoking presumably tobacco or alcohol in this case, and the amount phrase “about a pack and a half for 38 years” is related to smoking. In our training dataset, we observed that for sentences like “No history of tobacco, alcohol, or illicit drug use.,” which occurred frequently in clinical notes, the distance based algorithms is obviously will not be able to detect the correct relationship between entities. On the other hand, a dependency parse can easily detect such a relationship. In this study, we used Stanford Parser v3.5.1 to generate dependency structures for social history statements.

For temporal extraction, we observed that temporal elements varied largely in terms of syntactic patterns and lexicon (e.g., “most of her adult life,” “up until about ten years ago,” “for a while”). The syntactic patterns and lexicons collected from our previous studies were not adequate to extract temporal elements. In addition to the lexicon collected from previous study, we used the temporal semantic role (ARG-TMP) annotations from Propbank(39) and MiPACQ(40) – the latter of which is a clinical corpus annotated with PropBank-style predicate argument structures. The Propbank and MiPACQ are two large corpora annotated with semantic roles (e.g., goal, temporal, manner, purpose) of all the phrases in a sentence. This semantically annotated sentence shows an example of how the temporal role annotation on constituent parse which includes temporal expressions “TMP”: “(S (NP-SBJ (DT The) (NN patient) ) (VP (MD will) (VP (VB be) (ADJP-PRD (JJ ready) (NP-TMP (NNP Feb.) (CD 15) )))) (.) )”. Temporal lexicons and patterns collected from the temporal semantic role annotations in these two resources were included into the rules for temporal elements detection. For example, temporal phrases like “at the same time” and “yesterday” were included as extra lexicon. The resulting new syntactic patterns captured additional temporal patterns including many that are not in the training dataset or the original lexicon and had improved performance. For each element of the three types of substance use statements, a set of regular expression heuristic rules were developed based on the lexicon, syntactic structure, and dependency structure. The created module was tested on substance use statements annotated from 200 UPMC notes.

In order to extract all 6 elements, each alcohol, drug and nicotine statement was first searched for patterns (e.g., “up to 6 drinks”, “3-packs”) and lexical items (e.g. “significant”, “dips”), represented by regular expressions. Then, the constituent parse of the statement was searched for syntactic patterns of each element (e.g., “(PP IN until)”. The searched phrases were validated by dependency parse of each statement. The patterns, lexicon and syntactic patterns used for elements extraction were collected from multi-site sources in our previous work14, MiPACQ and Propbank, with a number range from 6 to more than 3,000. A set of rules was manually created to determine if a searched phrase is related to the particular substance of interest by using iterative error analysis on the training dataset. In each iteration, rules were modified and new rules were included to accurately detect the correct relationships. Below are two examples of such rules. Some element types often needed more rules (e.g., 15 rules for temporal) to validate
which substance was associated with a searched phrase. On average, 5 rules (median 3, range 1-15) were created for each element extraction task.

Example 1). IF all parents of tokens in the searched phrase consist of the drug token AND the searched phrase is not negated THEN the searched phrase is associated with the drug token.

Example 2). IF the statement contains only the drug token without alcohol or nicotine keywords THEN the searched phrase is associated with the drug token.

Results

Table 4 summarizes the statistics of overall annotations of the corpora. From 491 MTS notes, 234 sentences were marked as alcohol use related, 124 were drug use related, and 260 were nicotine use related. From UPMC notes, 138, 72 and 148 sentences were marked as related to alcohol, drug and nicotine use. The number of occurrence of each element with these sentences is also listed in Table 4.

The Cohen’s kappa inter-rater agreement between two annotators for elements of alcohol, drug, and nicotine use statements was 83.4, 80.9, and 90.6. Table 5 shows substance use statement detection performance on the MTS test set (N=122) and UPMC test set (N=200). As summarized, detection of alcohol, drug, and nicotine use statements was good with high F-scores.

Table 6 summarizes the performance of the system for extraction of substance use elements on UPMC substance use statements. The type, method and amount detection showed good performance based on F-scores for alcohol, drug and nicotine use sentences. Frequency and status detection for drug and nicotine use showed better performance for drug use statements and for nicotine use statements compared to alcohol use statements.

After inclusion of extra patterns and lexicon from general English semantic resources and clinical annotated semantic resources, temporal detection improved greatly, though this was still not as good as the performance of other elements, primarily due to the large variety of potential temporal expressions. Figure 4 shows the improvement of temporal element extraction with alcohol use and drug use statements achieved by adding in outside lexicons and patterns from MiPACQ and Propbank.

Figure 4. Temporal element detection performance improvement.
Discussion

In this study, we developed an NLP system for substance use statement detection and element extraction from clinical notes based on previous substance use models and the addition of developed lexicons(14). The system provides functionalities to detect three types of substance use statements: alcohol, drug, and nicotine use from free-text clinical notes, as well as extraction of important semantic elements as defined in substance use models previously developed(14) including amount, frequency, type, status, method and temporal. Overall, the developed system performed well, although certain elements like temporal expressions had challenges due to the variability in expression with these items.

Similar to previous work on family history extraction from clinical texts(41), we used the dependency structure for capturing relationships between phrases and tokens in the substance use statement. We found that the dependency relationship could help attaching possible element tokens or phrases to the right substance (e.g., alcohol or drug). However, due to dependency parsing errors on long, complicated sentences, relationships were sometimes wrongly collected from the dependency structure sometimes leading to errors on attaching tokens to correct types or methods. Further study is needed for reducing this type of errors. In our experiments, we did not observe sentences that caused the parser to break. Constituent parsing errors also caused sentence-segmenting errors, which in turn affected the element detecting process.

As shown in previous work(41), rule-based approaches can achieve comparable performance as machine learning approaches. In this study we choose to implement a rule-based NLP system by leveraging features from a number of sources and previous work, particularly to improve substance use lexicons. Substance use statement detection results of the rule-based systems showed good performance on both the MTS and UPMC test sets for all three types of substance use statements. Further, our pilot experiments on alcohol statement detection using models based on topic analysis and machine learning showed no performance improvement compared with the rule-based statement detection.

We recognize as a limitation that our system would ideally have a baseline gold standard with which to evaluate itself against. Currently, gold standard corpora and comparable systems do not exist. In the future, we plan to release publically available corpora with annotations so that future systems will have a baseline corpora with which to evaluate itself.

This study was also limited in that development of statement detection and elements extraction portions of the NLP system were built on one corpus (MTS notes) and tested on a relatively small hold-out corpus (UPMC notes). While this approach suggested that our findings could be generalized to clinical notes from other sites, validation with data from another institution would be helpful in confirming these results. A next step will therefore include setting further assessments of the system on institutional clinical notes and expansion of the system for substance use comments from the structured EHR social history module. Annotations used for extracting frequency, method and temporal for drug use statements were limited in this study. Although the same approach used for extracting these same elements for alcohol use and nicotine use had good results, validation with additional drug use statements would help with confirming our findings.

Conclusion

In this study, we achieved reasonable performance for both substance use statement detection and element extraction from two clinical notes corpora. The results of this study are promising for automated detection of free-text substance use statements and extraction of detailed substance use information from clinical notes. Next steps include further refinement of element extraction for better performance, additional evaluations to demonstrate generalizability of the system, and development of modules for extraction of additional social history statements.

Conversational Agents for Automated Inpatient and Outpatient Health Counseling

Timothy Bickmore, Ph.D.¹
¹College of Computer and Information Science, Northeastern University, Boston, MA

Abstract
Conversational agents are computer-animated characters that can simulate one-on-one, face-to-face counseling with a health provider. These agents have now been used to provide automated health education and health behavior change counseling in a wide range of medical domains. In the inpatient setting they have been used to counsel on options for surgical anesthesia, post hospital-discharge self-care, and to provide continual hospital bedside education, sleep promotion, and patient activation. Conversational agents have also been integrated with sensor systems so that they can provide context-sensitive counseling and explain events occurring in the hospital room to patients, as well as provide a mediated communication channel between patients and their providers. In the outpatient setting they have been used to collect family health histories, screen for and counsel on substance abuse, and to provide medication, exercise, diet, breastfeeding, and preconception care promotion. This medium has been shown to be particularly effective for patients with low health literacy, and has been linguistically and culturally tailored for several populations, including Latino and Chinese. Several of these systems will be demonstrated, and the development methodology and underlying technology described, including 3D animation systems, dialogue engines, and behavioral ontologies for driving automated health behavior change counseling. Evidence from trials comparing conversational agents to more conventional methods and technologies will be presented.

Specific purpose/problems
Patient behavior, such as non-adherence and poor lifestyle health behavior, is a leading cause of morbidity and mortality. These problems are especially severe in disadvantaged populations with high prevalence of inadequate health literacy. Providers do not have the time these patients require to ensure they have the understanding, confidence, and motivation to take care of themselves.

Innovation
Conversational agents combine procedural animation with dialogue systems and sensors to provide a simulated face-to-face conversation with an empathic, expert health provider.

Degree of deployment
Over 25 randomized clinical trials have been completed or are underway to evaluate virtual agents in the role of health counselors.

Navigating between Drug Classes and RxNorm Drugs with RxClass

Olivier Bodenreider, M.D., PhD, M.S., Lee Peters, M.S., Thang Nguyen, M.S.
National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA

Contact information: RXNAVINFO@LIST.NIH.GOV

Abstract: RxClass is a web-based, interactive browser and companion application programming interface (API) to explore the relationships between RxNorm drugs and drug classes from several sources including ATC, MeSH and NDF-RT. Like RxNav, RxClass is publicly available at: http://rxnav.nlm.nih.gov

System Description:

RxClass supports the following drug classification systems:

- The Anatomical Therapeutic Chemical drug classification (ATC) is a resource developed for pharmacoepidemiology purposes by the World Health Organization Collaborating Centre for Drug Statistics Methodology.
- The Medical Subject Headings (MeSH), developed by the National Library of Medicine (NLM), provides a rich description of pharmacological actions for the purpose of indexing and retrieval of biomedical articles.
- The National Drug File-Reference Terminology (NDF-RT), developed by the Department of Veterans Affairs, provides clinical information about drugs and contains the following class types: FDA Established Pharmacologic Classification (EPC), Disease classification, Chemical Structure and Classification (Chem), Mechanism of Action (MoA), Physiologic Effects (PE) and Pharmacokinetics (PK) class types.

ATC and MeSH provide both the vocabulary for drug classes and the drug-class membership relations. In contrast, several sources - DailyMed, FDASPL and NDF-RT - provide drug-class membership relations in reference to the NDF-RT vocabulary for classes. All drugs are normalized to RxNorm.

RxClass provides a graphical interface to explore the hierarchical class structures of each source and examine the corresponding RxNorm drug members for each class. Some features of RxClass:

- The user can navigate through the drug classes via the hierarchical menu (left pane), or use the search feature to identify a drug class or RxNorm drug (top search bar). RxClass contains an autocomplete function which will help identify class or drug names in search mode, as well as spelling suggestions for misspelled drug and class names during search.
- Selecting a class displays the list of its drug members in a table (main area), showing their identifiers and names in both RxNorm and the original classification system.
- RxClass supports the exploration of all classes for a given drug across multiple classifications (All/classes/Show button).
- RxClass provides a list of similar classes based on drug membership to the selected class. Users can select a class from the list and view a detailed table listing the drug members of each class with a Venn diagram highlighting the overlapping members.

Companion API. RxClass is supported by functions from an application programming interface (API), which can be used independently for integrating drug class information in programs. The API serves the latest information available from the drug information sources. The RxClass API can interoperate with the RxNorm API. The demonstration will include examples of using the API to mimic the functionality displayed in RxClass.

RxClass has been operational since July 2014. From October 2014 through June 2015 RxClass has received an average of 1254 queries per month. The drug information sources are updated monthly. The RxClass API has been operational since September 2014. RxClass supports the analysis of medication datasets with different drug classification systems, as well as the analysis of medication value sets in reference to drug classes.

Acknowledgments: This work was supported by the Intramural Research Program of the NIH, National Library of Medicine.
SEMCARE - Semantic Data Platform for Healthcare

Philipp Daumke¹, Claudia Riede¹, Thomas Fassbender¹, Ángel Honrado², Markus Kreuzthaler³, Pablo López-García³, Stefan Schulz³, Erik van Mulligen⁴, Herman van Haagen⁴, Jan Kors⁴, Hanney Gonna⁵, Xinkai Wang⁵, Elijah R Behr⁵

¹Averbis GmbH, Freiburg, Germany; ²SYNAPSE Research Management Partners S.L., Barcelona, Spain; ³Institute for Medical Informatics, Statistics and Documentation, Medical University of Graz, Austria; ⁴Erasmus University Medical Center, Rotterdam, The Netherlands; ⁵St. George’s University of London, United Kingdom

Description

The need for exploiting medical data for secondary use has grown tremendously over the last years and covered in various research initiatives such as EHR4CR¹, i2b² and eMERGE³. Aggregated patient-level data can support the identification of disease mechanisms and new discovery areas, improve drug safety surveillance and decrease patient recruitment cycle times for clinical trials. Exploiting patient-level data can optimize clinical studies in several ways, e.g., by enabling the definition of appropriate study design or ensuring that inclusion/exclusion criteria map to an existing patient population. As large parts of patient-level data in electronic health records (EHRs) are only available as free text, language technologies are an indispensable prerequisite for this process. SEMCARE is an EU-funded project that is building a semantic data platform able to define patient cohorts based on clinical information scattered in heterogeneous resources. Three hospitals from the Netherlands, UK and Austria serve as pilot sites, focusing on cardiology use cases. However, SEMCARE’s long-term objective is to build a flexible information extraction and semantic indexing platform that can be adapted to a broad range of languages and clinical contexts.

Figure 1 shows the different modules of the SEMCARE platform. Data integration deals with the management and transformation of heterogeneous data (e.g., ASCII, Word, PDF, XML or HL7) into homogeneous formats. State-of-the-art text mining technologies⁴ based on the framework Apache UIMA⁵ and multilingual semantic resources (e.g. UMLS subsets, ICD10, LOINC, ATC) are used to extract information from EHRs. The results are fed into a hybrid free-text and concept-based search engine. The anonymization service⁶ allows text de-identification to ensure patient privacy and to make clinical data accessible to a broader research audience.

In the demo session, we will present the semantic data platform developed in SEMCARE based on anonymized clinical data. We will show how this platform is able to identify patient cohorts based on patient-level criteria, much of which are found in weakly structured text. In addition, we will present the clinical evaluation of the platform that is currently tested by three major European hospitals in a cardiology use case.

Leveraging Health Information Exchange to Create Neighborhood Health Records for Public Health Agencies

Brian E. Dixon1,2, P. Joseph Gibson1,3, Karen Frederickson Comer4, Jian Zou5, Jennifer Williams2, Marc Rosenman2,6
1IU Fairbanks School of Public Health, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, IN; 3Marion County Public Health Department, Indianapolis, IN; 4Indiana University-Purdue University Indianapolis, Polis Center, Indianapolis, IN; 5Worcester Polytechnic Institute, Worcester, MA; 6IU School of Medicine, Indianapolis, IN

Abstract
Assessment is a core function of public health. Traditional methods leverage surveys, vital records, and paper-based disease reporting. Increased adoption of electronic health records and health information exchange present an opportunity to enhance health assessment activities by enabling access to up-to-date data on disease burden and outcomes, with sufficient geographic density to allow small area analyses. Furthermore, when combined with community-level data relevant to social determinants, HIE has the capacity to create a neighborhood health profile that measures and tracks health risks and disparities at a community level. In this demonstration, we will present how we’ve leveraged routinely collected and geospatially-enhanced EHR data available from a regional health information exchange to create neighborhood health profiles for a county health department. The discussion will highlight neighborhood level indicators developed for the project, data visualizations, and issues of representativeness or bias in the data.

Introduction
Public health authorities monitor population health to identify burden of disease, manage health assets, establish policy, and evaluate interventions. This assessment usually relies on information available through surveys, vital records, and paper-based disease reporting. These sources capture sparse data at the community level. Electronic health record (EHR) systems may provide more timely and dense data for geographic areas of interest. Yet there exist a number of challenges to routine use of EHR data, including linking them to social determinant data, and adjusting them so they reflect the general population rather than those most likely to use health care services.

Description of the System Demonstration
In this demonstration, we will describe how we developed and implemented neighborhood health profiles for use by a local health department. We will show the profiles created and discuss how we calculated health indicators using EHR data. Furthermore, we will describe the tools (e.g., Web-based Analysis and Visualization Environment: Weave) used to enable custom visualizations of the health indicator data joined with population level data.

Neighborhood health profiles consist of community-level indicators using EHR data integrated with a community information system (CIS). These indicators represent geographic units smaller than a county, the traditional unit extrapolated from large population-based surveys and datasets. The neighborhood health profiles were created using a large health information exchange with over 5 billion clinical observations from heterogeneous EHR systems. Patient level data were geocoded and aggregated then integrated with data from the CIS, which possesses data on transportation, crime, education, poverty, and other social determinants of health. Neighborhood level indicators include the prevalence of diseases of public health interest (e.g., diabetes mellitus type 2, depression, chlamydia infection) and several HEDIS-like clinical quality indicators (e.g., number of eligible patients screened for chlamydia, number of diabetics receiving annual HbA1c testing). Indicators were calculated at various levels of geographic granularity (e.g., ZIP code, census tract, census block group, neighborhood, city-county council district).

Once generated, neighborhood health profiles were shared with the local health department for review and feedback, and were compared to results from a random population sample survey. Geospatial visualization as well as statistical models were developed in partnership with the health department to aid interpretation and application to public health practice as well as policy. Such uses for EHR and HIE infrastructure are novel and address gaps identified by recent Institute of Medicine as well as Robert Wood Johnson Foundation expert panels which published recommendations for strengthening public health surveillance and research.
System Description and Areas of Innovation

The Observational Health Data Sciences and Informatics collaborative (OHDSI, pronounced ‘Odyssey’) was formed in 2013 with the goal of creating reliable scientific evidence through large-scale analytics of observational health data. A cornerstone of OHDSI is the use of a common data model (CDM) by all participants. Specifically, OHDSI leverages a CDM that was first developed in 2008 as part of the Observational Medical Outcomes Partnership and is now in its 5th iteration.

In this demonstration, we will be presenting open-source tools from the OHDSI software ecosystem. All source code for these tools is available on Github (www.github.com/ohdsi) and live demos can be found on the OHDSI website (www.ohdsi.org/demos). We will focus on several key innovations essential for collaborative data analytics. First, we will introduce software resources for transforming diverse datasets into the CDM, including an automated dataset mapper and native support for multiple database dialects (e.g., SQL Server, Oracle, Postgres, Netezza).

We will then take the audience through a clinical use-case, introducing a series of web-based tools that leverage the CDM for dataset characterization and quality assessment, patient cohort development, and data analytics and visualization (Figure 1). We will also present a novel tool for exploring multiple standardized vocabularies, a cornerstone for creating cohorts and performing large-scale observational studies. The OHDSI visualization library, based on D3 (www.d3.js), will be described in conjunction with these tools.

For the final section of the demonstration, we will return to OHDSI’s core objectives of evidence generation and dissemination. We will demonstrate the use of the OHDSI research platform, which leverages the R statistical package to disseminate and customize analyses for individual study sites. We will also highlight the OHDSI pharmacovigilance API, a REST web service for retrieving evidence on adverse drug events from a wide variety of sources, including product labeling, adverse event reporting, the scientific literature, clinical registries, and other sources.

Current Deployment: As of October 2014, 58 distinct databases had been converted or were in the process of being transformed into the OMOP CDM. As of March 2015, OHDSI tools are in use at more than 10 sites, including Columbia, Stanford, Regenstrief Institute, University of Pittsburgh, National Institutes of Health, Ajou University, Erasmus MC, Janssen Research and Development, and AstraZeneca.
Towards an Open EHR Platform: Porting a Complex Application using SMART on FHIR
Alistair Erskine, MD1; David P McCallie, MD2; Marcy Stoots DNP, RN-BC3
1Geisinger Health System, Danville PA; 2Cerner Corporate, Kansas City MO; 3xG Health Solutions, Columbia MD

Abstract
The Rheumatology App is a sophisticated, web-based application for managing a rheumatology ambulatory encounter, developed by Geisinger Health System. The Rheumatology App synthesizes information from several sources, including the EHR and presenting disease-specific data in a graphical summary view. It assists in the formatting of a progress note for the visit, incorporating relevant data from all sources. The Rheumatology App was initially developed to run on a major commercial EHR (Epic). Subsequently, it was adapted to take advantage of the SHARP grant funded SMART platform and emerging HL-7 FHIR resources, given that these draft standards are publicly available, non-proprietary and facilitate the exchange of clinical data in an EHR-agnostic manner. The data set used for these RESTful APIs were derived from the Meaningful Use Common Dataset, as promoted by the Argonaut Project and the Office of the National Coordinator (e.g. LOINC, RxNORM, SNOMED-CT). The process of converting the Rheumatology App from an embedded state within one commercially available EHR into a “SMART on FHIR” state into another EHR was shorter than expected, measured in weeks, not months or years. Converting the full functionality required at least eleven (11) FHIR resource types, some of which were both read and write access to the EHR. This is one of the more complex implementations using SMART on FHIR to appear in the literature to date. We will demonstrate the Rheumatology App executing as a “SMART app” in the context a commercial EHR. We will discuss the process, the learning from the conversion exercise and deploying the Rheumatology App as SMART on FHIR functionality embedded directly and unobtrusively within the framework and workflow of the various EHRs, from the perspective of both the health system application developers, and the EHR vendor.

Purpose of the System
The Rheumatology App presents clinical information in a format that supports the cognitive process of a clinician treating rheumatic disease. All Geisinger Rheumatologist use this Rheumatology App to manage their patients. The workflow includes touchscreen questionnaires for the patient, designed to collect information about symptoms of their new or chronic rheumatologic condition. The patient generated data is rendered into views that, when assembled with data imported from the EHR and data from clinician input, facilitate shared decision making and visualization of the next best actions to perform for the patient. Following the Learning Health System principles, as a by-product care administered, this data entry and integration supports the development of a rheumatic database for research and decision support. In addition, increases in clinician efficiency and productivity were measured using the Rheumatology App. The SMART on FHIR implementation of the Rheumatology App demonstrates the feasibility of delivering complex and specialized clinical functionality using a standards-based open platform approach.

Deployment Status
In its native implementation, the Rheumatology App has been used in production for several years, and seen widespread adoption among eligible clinicians. The SMART-on-FHIR version of the APP is currently running as a proof-of-concept. Below is a screenshot of the Rheumatology App executing in a commercial EHR.
RapTAT: A Tool for Assisted Annotation and Reviewer Training via Online Machine Learning

Glenn T. Gobbel, DVM, PhD, MS\textsuperscript{1,2}, Ruth M. Reeves, PhD\textsuperscript{1}, Brett R. South, MS, PhD\textsuperscript{3}, Wendy W. Chapman, PhD\textsuperscript{3}, Jay Jarman, PhD\textsuperscript{4}, Steven Lay, BS\textsuperscript{4}, Michael E. Matheny, MD, MS, MPH\textsuperscript{1,2}

\textsuperscript{1}Tennessee Valley Health System VA, Nashville, TN; \textsuperscript{2}Vanderbilt University, Nashville, TN; \textsuperscript{3}University of Utah, SLC, UT; \textsuperscript{4}East Tennessee State University, Johnson City, TN

Abstract
Manually annotating clinical free text to extract the valuable information it contains is time-consuming and expensive. The task commonly relies on medically-trained human reviewers to identify concepts related to treatment and care. Although natural language processing (NLP) systems can partially automate the data extraction process and thus reduce the cost, such systems still depend on manual annotations for system training and testing. We have developed the Rapid Text Annotation Tool (RapTAT), the goal of which is to reduce the burden of free text review by assisting with both annotator training and the annotation process itself. Training of the tool relies on real-time online learning to identify the phrases and concepts of interest to the annotator, and it employs this training to pre-annotate subsequent documents, thus reducing the time required to find and annotate phrases of interest. The tool also assists with annotator training by providing visual feedback that compares and contrasts annotations of inexperienced or non-expert reviewers to those provided by a reference standard.

Description
The Rapid Text Annotation tool (RapTAT) currently consists of two modules: 1) a reviewer versus reference (RVR) module and 2) a pre-annotation (PA) module, both of which are incorporated into an existing annotation tool, eHOST.\textsuperscript{1} During annotator training, the RVR module provides feedback to inexperienced reviewers by calculating performance scores relative to the reference standard (F-measures) for each concept of interest; it also provides visual cues highlighting differences between the annotations of the trainee and an expert-generated reference standard. The tool tracks changes in performance score for each concept of interest versus the number of documents annotated to help users assess the benefits of further reviewer training. Once an annotator is trained, the PA module uses real-time online machine learning based on both the reference standard and information provided by ongoing reviewer annotations to pre-annotate concepts of interest before document review. The tool does not rely on a manually-generated dictionary for pre-annotation; instead, it uses natural language processing (NLP) dynamically to model the annotations of the reviewer. The NLP uses a novel probabilistic model for identifying phrases for annotation and a token -order-specific naïve Bayes model for concept mapping. It continuously updates and uses this model to identify concepts for annotation within subsequent documents. As the annotation process and tool training continues, PA module pre-annotations more closely match those of the reviewer, which gradually shifts the annotation task from one of searching and highlighting phrases of interest to one focused on review and correction. This approach to pre-annotation has been used to annotate concepts predictive of acute kidney injury and pressure ulcer development and for determining document quality; it can reduce reviewer annotation time by up to 50%.\textsuperscript{2}

Deployment
The tool has been deployed to two sites in addition to the site of tool development. A study underway will assess the impact of tool use on the speed and accuracy of annotations of both medical experts and those without medical training. The results of that study should establish whether the tool can effectively reduce the time spent on annotation and reviewer training.

The Scalable Collaborative Infrastructure for a Learning Health System: Facilitating Agile Comparative Effectiveness Research

Jeffrey G. Klann, PhD,1,2,3, Marc Natter, MD1,4, Doug MacFadden, MS1, Sarah Weiler, PhD1, Kenneth Mandl, MD, MPH1,4, Shawn N. Murphy, MD, PhD1,2,3

1Harvard Medical School, Boston, MA; 2Partners Healthcare, Boston, MA; 3Massachusetts General Hospital, Boston, MA; 4Boston Children’s Hospital, Boston, MA

Abstract

The Scalable Collaborative Infrastructure for a Learning Health System (SCILHS, pronounced “skills”) is a growing network of health centers across the United States. SCILHS is a Clinical Data Research Network (CDRN) in the Patient-Centered Outcomes Research Institute’s PCORnet, a national effort to instantiate a ‘network of networks’ that supports large-scale comparative effectiveness research. SCILHS uses Informatics for Integrating Biology and the Bedside (i2b2) as its technical backbone and has adopted the PCORnet Common Data Model (CDM) as its foundation for interoperable data exchange. We developed an i2b2 ontology that represents the CDM, and we developed extensive documentation and spreadsheets to assist the mapping process. We made this ontology publically available, and portions of it are used by several other CDRNs. SCILHS uses the Shared Health Research Information Network (SHRINE) platform for distributed querying. SCILHS sites have developed mutual trust relationships, which enable the SCILHS SHRINE hub to perform live queries across all sites and return aggregate counts in real-time. This prep-to-research functionality enables SCILHS to rapidly identify patient cohorts with specific conditions who meet eligibility criteria for observational research or clinical trials. SCILHS is a successful demonstration of an approach for live, distributed queries across diverse environments with disparate data.

Overview

Nationwide networks of hospital systems’ clinical data are emerging to enable large-scale comparative effectiveness research (CER). To facilitate agile CER, we find two often-overlooked elements are very important:

- **A low-friction methodology that supports participation of many sites, with data in many different formats.** Informatics expertise and technological infrastructure vary widely across hospital systems. Therefore, to attract a diverse group of sites, it is necessary to provide a well-documented methodology to support a variety of data formats.

- **Live querying on limited query types, to enable rapid identification of patient cohorts with specific conditions.** The prep-to-research activity of cohort identification is most effective if results are available without delay. As an example, consider determining if a network has enough patients to support a particular clinical trial. This query is not human subjects research and therefore with proper agreements and supportive technology, the result could be made available without personnel at each site signing off.

SCILHS includes these elements by leveraging previous successes developed in the Shared Health Research Informatics Network (SHRINE) platform. SHRINE is a distributed query protocol for i2b2 that is used in several active networks nationwide to provide live cohort-identification queries. SCILHS is unique among SHRINE networks in that:

- **SCILHS has enhanced SHRINE** to support more complex queries and to allow the patients found in these prep-to-research queries to flow into disease-specific research data marts for further analysis.

- **SCILHS has developed a new methodology for supporting semantically interoperable querying without modifications to underlying data.** This new methodology is easier for sites to implement, directly supports data transformations, and improves query speed over previous SHRINE approaches.

- **SCILHS represents the most diverse SHRINE network that is actively used for clinical research,** in terms of the governance and infrastructure of its sites, which required regulatory innovations.

Description of System

As of this writing, SCILHS is live at 7 sites in four states, covering over 8 million patients. Seven more sites are expected to be live by Fall 2015. Live cohort-finding queries can be run on all of this data, and we have begun characterizing specific diseases and generating disease-specific datamarts. Here we will demonstrate queries running at the SCILHS hub, i2b2 implementation of the PCORnet CDM, and the methodology that has allowed us to be a network that supports live prep-to-research queries. Queries are built in the SCILHS Common Data Model using the graphical SHRINE query tool. Queries are automatically sent to individual sites through the SHRINE Adapter. Each site’s i2b2 runs the query and returns aggregate counts to the SCILHS hub, which obfuscates the counts and displays the results. Attacks on the network to gain access to identifiable data through the SHRINE are impossible by design, because the queries are transmitted in an XML format that limits query complexity.
Electronic Health Management Platform (eHMP): The Next Phase of VA’s EHR

Jonathan R. Nebeker MS MD*† W. Paul Nichol MD* Shane McNamee MD* Jessica Murphy MD* James Hellewell MD* Reese Omizo MD* Kristian Johnson RN* Kensaku Kawamoto MD* Margaret McDonald MD* Theresa Cullen MD* Elaine Hunolt* Scott Woods PhD* Jennifer Herout PhD* Charlene Weir PhD*. *Dept. of Veterans Affairs; †University of Utah;

Abstract

VA is in the second year of its EHR modernization program called VistA Evolution. The Enterprise Health Management Platform (eHMP) is next generation EHR system. eHMP incrementally delivers new capabilities necessary for new models of healthcare that we desire to implement, while it preserves the business processes that we desire to keep. Technically, eHMP builds upon VistA, our current MUMPS system, with a data aggregation layer, service layer using modern open-source components, and a modular user interface that allows addition of compliant applications from outside VA. New data elements will be natively stored using national standards. Many new services use standard implementations and interfaces such as OpenCDS and Business Process Management Notation. This demonstration will highlight the ability of this system to collect and operate on data from 130 different VistA EHRs, DoD, and community partners participating in Connect or Direct data exchanges. It will also highlight the new user experience that is heavily informed by social and cognitive psychology.

Description

Enterprise Health Management Platform (eHMP) is a general-purpose EHR system. It addresses both technical and functional problems with VistA and many other EHRs. By the time of the presentation, it will be deployed throughout most of the VA system.

This demonstration will briefly highlight eHMP’s technical solution to the interoperability problem. Data collection is accomplished through remote procedure calls from 130 different instances of VistA worldwide, national health exchanges, and a special pipeline to DoD data. Incoming data is parsed and standardized, currently using maps, and stored as JSON objects. These objects are called by services and the user interface. An older version of this technology is in use at DoD. Together these technologies allow service members and Veterans to have a seamless medical record from acute treatment in Germany to ongoing treatment between Walter Reed and area VA medical centers.

The demonstration will also highlight eHMP’s innovative user experience. eHMP integrates traditionally segregated data (laboratory results, medications, problems, notes, etc) into workspaces. Data integration promotes contextual awareness and easy navigation, as users focus in and out on data during their workflows. Benefiting from standardized data, the user experience summarizes most displays by concept such as a medication ingredient or diagnosis instead of displaying individual records. Summarization at the top level of the user interface allows scanning and analysis behaviors. Consistent drill-down capabilities support quick-look, inspection, and browsing behaviors. These behaviors have analogs in mind-set theory and related theories about human understanding and action. Another innovation is incorporation of patient-tailored goals. These are editable on a patient level and are more prominently displayed instead of traditional reference ranges. Finally, eHMP also allows users to manipulate their information environments to explore a temporary question or to customize their environment to support specific workflows. Current capability focuses on diagnosis-driven workflows.
PhEMA: Phenotype Modeling, Sharing and Execution Architecture

Jyotishman Pathak, PhD\(^1\); Joshua C. Denny, MD, MS\(^2\); William Thompson, PhD\(^3\); Luke V. Rasmussen, BS\(^4\)

\(^1\)Department of Health Sciences Research, Mayo Clinic, Rochester, MN
\(^2\)Department of Biomedical Informatics, Vanderbilt University, Nashville, TN
\(^3\)Center for Biomedical Research Informatics, NorthShore University, Evanston, IL
\(^4\)Department of Preventive Medicine, Northwestern University, Chicago, IL

Abstract. The phenotype modeling, sharing and execution architecture (PhEMA) platform provides a comprehensive solution for standards-based phenotype algorithm authoring, integration with the Phenotype Knowledge Base website (PheKB, \url{http://phekb.org}) for community-wide sharing, and execution on standardized and normalized EHR data using advanced workflow management via the open-source Konstanz Information Miner (KNIME, \url{http://knime.org}). In this system demonstration, we will highlight the key features of the platform and provide hands-on experience in authoring, sharing and executing phenotype algorithms using de-identified, standardized electronic health record (EHR) data. The platform is available at: \url{http://projectphema.org}.

Background and System Description. EHRs can be used for many different types of research including disease-based, response to treatment, clinical biomarkers, redefining “normal”, and analysis of changes over time of clinical variables and parameters. Deriving such phenotypes from EHR data can be challenging, including the ability and process for authoring and executing phenotyping algorithms\(^1\). The PhEMA platform attempts to address these challenges by providing a comprehensive solution for standards-based authoring, sharing and execution of phenotyping algorithms\(^2\). More specifically, we use the National Quality Forum (NQF) Quality Data Model (QDM2) and HL7 Health Quality Measures Format (HQMF) for standardized representation of phenotype algorithms, and use PheKB - developed within the eMERGE Consortia - to provide a collaborative authoring, accessing and sharing of QDM-based phenotyping algorithms. These algorithms conform to Meaningful Use standards, and hence are amenable to implementation and execution within multiple EHR settings. This is enabled by using advanced workflow and rules-based technology - KNIME - by automatically translating and executing QDM-based phenotype definitions for execution within i2b2 installations as well as institution-specific data warehouses.

System status. At the time of submitting this proposal, an alpha version of PheMA is available at \url{http://projectphema.org}. The source code is released under Apache 2 licensing, and available at \url{https://github.com/PheMA}.

ePAD: Leveraging image data in learning healthcare systems

Daniel L. Rubin, MD, MS,1,2 Dev Gude,1 Cavit Altindag,1 Hakan Bulu, PhD,1 and Debra Willrett, MS1
1Department of Radiology and 2Medicine (Biomedical Informatics Research), Stanford, CA, USA

Abstract
As biomedical informatics efforts are undertaken to build the learning health system, there is a need to include the information provided by medical imaging in these efforts, since imaging provides detailed information about the disease phenotype for diagnosis and its response to treatment. However, at present, radiology images are not leveraged in many healthcare applications (other than viewing the raw images) because the disease phenotype information they contain is unstructured and not directly machine-accessible. We developed the electronic Physician Annotation Device (ePAD), a freely-available Web-based platform for capturing and storing the phenotypic information contained in radiological images (quantitative and semantic image features) in an explicit, standardized, and machine-accessible format that is interoperable with medical standards such as DICOM and HL7. The ePAD platform is extensible, permitting the community to extend its capabilities with respect to extracting and computing image features, as well as enabling developers to build applications that leverage the information in images in combination with other clinical data. ePAD is being used at several institutions internationally as well as in national resources such as The Cancer Genome Atlas (TCGA) project of the NIH to enable a coordinated national collection of minable radiological image data.

System Description
We will demonstrate ePAD (http://epad.stanford.edu), a freely-available Web-based system to enable researchers who view radiological images to annotate them to make the semantic contents explicit and machine-accessible. It also computes quantitative image-based features of disease, creating a comprehensive representation of the semantic and quantitative contents of images (“image metadata”) as “image annotations.” ePAD runs in a Web browser as a rich Web application, with a virtual machine back end that stores the images and image metadata. ePAD is not FDA approved and is presently intended for use in research, though its principles of standardized capture of image metadata can be incorporated into commercial image viewing workstations and clinical practice in the future.

The ePAD tool displays images and collects information from the user about the “image phenotypes” of disease (semantic features) using structured reporting templates superimposed on the images. Users can draw regions of interest and invoke a variety of tools (extensible via a plugin mechanism) to compute quantitative image features. All of semantic and quantitative image data are collected seamlessly as part of the routine image viewing workflow, and all image metadata are saved in the standardized Annotation and Image Markup (AIM) format developed by the NCI. Users can view and make image annotations very quickly via a display which shows all the abnormalities that were annotated previously; this enables users to view images and annotations with a single click of the mouse. ePAD also enforces minimum information requirements in image annotations, e.g., lesion name, measurements, a lesion type, and the anatomic location of the lesion. Semantic terms in ePAD are matched to ontologies.

We will demonstrate using ePAD to view and annotate images from cancer patients, and show new developments that enable user to build applications on the ePAD platform as plugins that leverage the image data to (1) reveal image-based treatment response for oncologist decision support, to (2) retrieve images containing similar-appearing abnormalities for radiologist decision support, and (3) compute novel quantitative imaging biomarkers and integrate them into clinical trials to improve assessment of cancer treatments. We will also discuss interoperability with DICOM and HL7 standards. Technical details about building plugins and applications with ePAD will be presented as well as how to become involved in submitting feedback and future plans for ePAD development.

ePAD is assuming a key role in national collaborative projects to build databases of minable image metadata for discovery and to incorporate image data into learning healthcare systems. The TCGA project is using ePAD to coordinate multiple centers who are collaboratively annotating radiology images of brain cancers so they can discover semantic and quantitative features of imaging phenotypes that identify disease subtypes correlated with survival. Multiple centers internationally are developing plugins to the ePAD platform to extend its capabilities and to create applications that leverage annotated image data for a variety of clinical use cases, such as content based image retrieval, radiology/pathology correlation, and linking image features to molecular data for radiogenomics discovery. A recent NCI-funded effort is using ePAD in a national effort to collect image annotations of radiology images to establish a ground truth in challenge competitions to optimize image segmentation, compare quantitative image features, and identify new image features that predict cancer treatment response and other clinical outcomes.
The SDIDS System for Integrating Global Health Surveillance Data: An Example Application to Malaria Surveillance in Uganda

Abstract

Data that could be used for global disease surveillance are divided across diseases, countries, and organizations. The integration of this data requires substantial effort and malaria surveillance is an example of how data fragmentation can hinder evidence-based decision-making. In order to achieve allocative efficiency in malaria control programming, access to timely and accurate malaria surveillance data across a variety sources is necessary. The Scalable Data Integration for Disease Surveillance (SDIDS) is a software application designed to enable the integration and analysis of data across multiple scales to support global health decision-making. We present a prototype of SDIDS to demonstrate how it can be used to integrate malaria surveillance data collected by multiple organizations in Uganda. SDIDS is a web-based platform that automates the integration of heterogeneous data from multiple sources, and supports visualization, analysis, and sharing of these data. Specifically, it contains semantic integration of disparate data sources, automatic computations of health indicators, and an open interface for requesting standardized data and analysis.

Introduction

The growing volume of data generated by systems and devices around the world presents a tremendous opportunity for global health surveillance. These data, however, are fragmented, or “siloed” in many ways, across diseases, countries, governmental and non-governmental organizations, and clinical institutions. This fragmentation poses a barrier to analyses that could benefit from using multiple data sources as the data must be integrated manually for each analysis, requiring a considerable amount of effort. Malaria surveillance, including the monitoring and evaluation of malaria control activities, is an example of how data fragmentation can hinder analyses. Matching effective interventions to specific factors in each area requires epidemiological analysis of data integrated across multiple sources. This type of data is generally not available to malaria control and elimination activities due to the challenges in identifying, accessing, and integrating data hosted within the wide range of organizations contributing to malaria control efforts. SDIDS (Scalable Data Integration for Disease Surveillance) is a software application designed to enable the integration and analysis of data across multiple scales to support global health decision-making. In this demonstration, we present a prototype of SDIDS and show how it can be used to integrate malaria surveillance data collected by multiple organizations in Uganda.

System Description

SDIDS is a web-based, ontology-driven software platform that automates the integration of heterogeneous data from multiple sources, and supports visualization, analysis, and sharing of these data. SDIDS contains the following features:

• **Semantic integration of disparate data sources.** A uniform data representation framework encoded in an ontology is used within SDIDS to integrate existing data sources. The current prototype integrates data from over eleven administrative and clinical sources describing factors such as clinical care, interventions, and demography.

• **Access to a variety of health indicators.** The system automatically computes numerous health indicators from malaria-related data and provides multiple stratification options. The indicators are organized in a meaningful way along multiple axes using a domain ontology, which encodes knowledge about malaria.

• **An open interface for requesting standardized data and analysis.** External applications can connect directly to SDIDS to request data for further processing or to request the results of analyses applied to the integrated data. Three such applications have been developed to demonstrate the functionality of this interface in SDIDS.

A central characteristic of SDIDS is its ability to scale-up and integrate data from other geographical regions and for other priority diseases. This scalability means that a wide range of data sources can be mapped once to SDIDS and then accessed and analyzed repeatedly by a wide range of global health users and applications.
