For example, diabetes research may target Type 2 diabetes mellitus (T2DM) patients by defining P0 as “patients with HbA1c above 7.5%”, while the real-world T2DM patients (P1) may be those patients whose HbA1c is above 7.0%, and the clinical trial study population (P3) may be a subset of real-world diabetes patients whose HbA1c is above 8.0%. Therefore, P1 subsumes P0, which further subsumes P3.

In [10], to reveal the population representativeness problem at a research community level, we aggregated multiple related clinical trials and used the distribution of trials over HbA1c values to represent the collective target population, i.e., the percentage of trials considering patients with a certain HbA1c value. In this work, we created P2 by sampling real-world patients based upon the percentage of trials considering them, thereby bringing the real-world patient population (P1) closer to the target population (P0). As such, P2 should be better represented in the collective target population (P0) than P1. Using P0 as the target, increasing generalizability will be observed in P1.

Methods

A conceptual framework for validating GIST

Ideally, the GIST metric can be validated by taking two or more trial sets with known different generalizability with respect to an eligibility feature and assessing if the difference in their GIST scores correlates with the expected generalizability differences. As illustrated in Figure 1(a), given TP1 and TP2 such that the population representativeness of TP1 is known to be better than TP2 with respect to a certain eligibility feature, GIST can be validated by verifying if GIST(TP1, PP) > GIST(TP2, PP). However, it is not feasible to obtain TP1 and TP2 because we have no evidence yet what kinds of trials have better generalizability with respect to a certain eligibility feature. Meanwhile, each trial set is affiliated with three different patient populations, i.e., the real-world patient population, the target population constructed from eligibility criteria descriptions, and the study population that includes all enrolled patients in the trial. Our method for validating the GIST metric is to simulate different patient populations that would result in a known generalizability difference with respect to the same trial set and assess if the difference of their GIST scores correlates with the expected difference. Therefore, we simulated a patient population that has better generalizability than the real-world patient population for the same trial set through weighted sampling of the real-world patient population. The relationships of these populations in our simulation-based validation method are illustrated in Figure 1(b) and their definitions are provided as follows:

\[
GIST(TP, PP) = \frac{\sum_{i=1}^{N} I[l_{\text{low}}, l_{\text{high}}]}{T} \times \frac{\sum_{i=1}^{P} I[l_{\text{low}} < y < l_{\text{high}}]}{P}
\]

where N is the number of distinct value intervals of the quantitative eligibility feature under consideration, T is the number of trials in the trial set included for aggregate analysis, P is the number of patients in the patient population PP, \(w_i\) is the inclusion value interval of the quantitative feature for the \(j^{th}\) study, such that indicator I can be defined as \(j^{th}\) study interval subsumes the \(k^{th}\) interval’s low and high boundary, and \(y_k\) is the observed value of the quantitative feature for the \(k^{th}\) patient such that an indicator I can be defined when \(k^{th}\) patient has a value of the quantitative feature falling within the \(j^{th}\) interval. Note that the GIST metric can also be applied to categorical variables, whereby the value intervals are integers.
P2, and P3, in order. Therefore, if the GIST scores for them follow GIST(P0,P1) < GIST(P0,P2) < GIST(P0,P3), we can conclude that GIST is a valid metric in quantifying the population representativeness of a trial set.

We first validated the GIST metric using this simulation-based method. Then we compared the GIST scores of trial sets that differ in their disease domains, sponsor types, study phases, and study designs. We hypothesized that:

**Hypothesis #1:** Weighted “real-world” patient population can serve as a good reference standard for validating GIST’s suitability for indicating the population representativeness of a set of related clinical trials, one eligibility-feature each time.

**Hypothesis #2:** GIST correlates with the population representativeness of a set of related trials.

To profile the patient populations used for GIST evaluation, we used the population health data from the National Health and Nutrition Examination Survey (NHANES), a continuous cross-sectional health survey conducted by the National Center for Health Statistics of Centers for Disease Control and Prevention (CDC) [12]. NHANES evaluates a stratified multistage probability sample of the non-institutionalized population of the United States. The survey samples are first interviewed at home, followed by a physical and a laboratory test in a mobile examination center. Its rigorous quality control standards ensure national population representativeness and high-quality data collection.

**Figure 2** shows the data collection and analysis pipeline employed in this study. We first extracted patient data from the NHANES database downloaded from the CDC website. We then retrieved the clinical trial summary text from ClinicalTrials.gov. We extracted and aggregated baseline characteristics of enrolled patients in T2DM trials with results. All the data were extracted with R and Python scripts, and subsequently stored in a MySQL database. After processing the data, we first evaluated the GIST metric. Then, we used GIST to compare population representativeness of trial sets of various characteristics. We will explicate each step as follows:

**Step 1: Extracting patient data from NHANES databases**

To ensure the statistical power of the analysis, we identified seven medical conditions in NHANES, each having more than 1,000 samples after combining data in multiple survey cycles. They were Type 2 diabetes mellitus (T2DM), asthma, arthritis, depression, sleep disorders, heart attack, and stroke. In the following, we will describe how we extracted and processed the NHANES data for these seven selected medical conditions.

**T2DM:** We combined the results of the Diabetes questionnaire of five continuous survey cycles between 2003 and 2012 and identified 3,304 diabetics who had their diabetes confirmed by a health professional and one HbA1c (Glycohemoglobin) measurement. As NHANES does not distinguish between two subtypes of diabetes, we employed a method used by Dodd et al. [13] to further identify 3,082 T2DM patients after excluding 222 samples with Type 1 diabetes who were (1) first diagnosed with diabetes before age 30; and (2) taking insulin. The rationale is that as one grows older, his/her lifestyle (e.g., dietary habits) will play a more important role in developing T2DM. Three quantitative eligibility features that are frequently used in T2DM trials, i.e., age (99.0%), HbA1c (53.6%), and Body Mass Index (BMI) (46.6%), were used for GIST evaluation. We combined the laboratory test results on HbA1c and examination data on body measures for five continuous survey cycles between 2003 and 2012. Out of the 3,082 T2DM samples, 2,695 had no missing values for age, HbA1c, and BMI. We used Chi-square test on two categorical variables, i.e., “gender” and “ethnicity”, to test the representativeness of these 2,695 patients with no missing values for all the 3,082 patients. No statistically significant difference was found ($P$-value > 0.05). Therefore, we concluded that these 2,695 patients is a representative sample of all the T2DM patients in NHANES and included them in our further analysis.

**Depression:** NHANES started to conduct interviews on depression in the survey cycle of 2005-2006. We combined the results of the Depression Screener questionnaire of four continuous survey cycles between 2005 and 2012. The
Depression Screener questionnaire uses a 9-item screening instrument that asks questions about the frequency of symptoms of depression over the past 2 weeks. For example, participants were asked how frequently they “have little interest in doing things” or “feel tired or have little energy.” Every question was rated from “0” to “3”, where “0” means “not at all” and “3” means “nearly every day.” Employing a method used by Xiao et al. [14], we identified 1,884 depressive participants who have a combined score of 10 or higher for the nine questions.

**Sleep disorders:** NHANES started to conduct interviews on sleep disorders in the 2005-2006 survey cycle. We combined the results of the Sleep Disorders questionnaire of four continuous survey cycles between 2005 and 2012 and identified 1,816 participants who were told by a doctor or a health professional to have sleep disorders.

**Asthma, arthritis, heart attack, and stroke:** After combing the results of Medical Conditions questionnaire of five continuous survey cycles between 2003 and 2012, we identified 7,009, 7,449, 1,235, 1,119 participants who were told by a doctor or health professional to have asthma, arthritis, heart attack, and stroke, respectively. It is worth noting that NHANES does not provide other laboratory tests to further validate these conditions.

To account for oversampling, non-response, and post-stratification, NHANES assigned each participant a two-year sample weight (WTMEC2YR), which is the number of people in the U.S. national population that each participant can represent. According to the analytical guideline of NHANES [15], we calculated eight-year sample weight WTMEC8YR (1/4 * WTMEC2YR) for depression and sleep disorders patients, because their data in four survey cycles were combined. For the other five conditions, we calculated ten-year sample weight WTMEC10YR (1/5 * WTMEC2YR), because data in five survey cycles were combined for them. After applying the normalized sample weights in the analysis, the patients in NHANES can represent the U.S. non-institutionalized population in the midpoint of the combined survey period.

**Step 2: Retrieving trials data from ClinicalTrials.gov**

To facilitate large-scale systematic analysis of population representativeness of related clinical trials, we have built a computable repository of clinical trials called COMPACT, which stores fine-grained eligibility features and descriptive characteristics of all the trials in ClinicalTrials.gov [16]. COMPACT indexed trials by medical conditions, allowing efficient aggregate analysis of trials on the same condition. Based on COMPACT, we have built a Web-based visual analytic tool of eligibility features in clinical trials called VITTA [17]. VITTA allows its users to select trials of a particular medical condition, refine the selection of trials by various characteristics, and profile the collective target population with a single eligibility feature.

For each medical condition, from COMPACT we retrieved interventional studies that had their start date falling in the survey years of NHANES. Corresponding patient data were obtained. For example, because patient data with sleep disorders were obtained from NHANES between 2005 and 2012, we also retrieved interventional studies on sleep disorders with the start date between January 2005 and December 2012 from the COMPACT database.

**Step 3: Retrieving a convenience sample of enrolled patients in T2DM trials**

As the study population of enrolled patients should well represent the target population of a trial, the collective study population should yield better population representativeness than the “real-world” patient population. To test whether GIST score can reflect this expected difference, we retrieved the results data of T2DM trials between 2003 and 2012 that reported summary data of their enrolled patients in ClinicalTrials.gov. The summary data must report the number of participants, mean and standard deviation (SD) value of at least one of age, HbA1c, and BMI to be included. We aggregated the mean and SD of age, HbA1c, and BMI separately using the following formula (adapted from [18]), where $\bar{T}$ is the number of studies,

$$\text{Weighted}_\text{mean} = \frac{\sum_{i=1}^{T}(\text{mean}_i \times \text{number}_i)}{\sum_{i=1}^{T} \text{number}_i} \quad (2)$$

$$\text{Weighted}_\text{SD} = \sqrt{\frac{\sum_{i=1}^{T}(\text{SD}_i^2 \times (\text{number}_i - 1))}{\sum_{i=1}^{T} \text{number}_i - 1}} \quad (3)$$

Table 1 shows the number of T2DM trials that reported summary data of age, HbA1c, and BMI for their enrolled patients, the total enrollments of these trials, and aggregated mean and SD values of age, HbA1c, and BMI, respectively. Given that only a small number of trials reported summary data of their enrolled patients in ClinicalTrials.gov, these aggregated data represent a convenience sample of enrolled patients in all the T2DM trials.
Table 1. The mean and SD of age, HbA1c, and BMI of the convenience sample of enrolled patients in T2DM trials.

**Step 4: Evaluating GIST using simulation**

From COMPACT, we retrieved 2,731 interventional studies on T2DM with a start date falling between 01/2003 and 12/2012. The number of T2DM trials specifying permissible values for age, HbA1c, and BMI was 2,702 (99.0%), 1,463 (53.6%), and 1,274 (46.6%), respectively. We formed one trial set for each of the three features and included them for generating the distribution of trials (P0) over age, HbA1c, and BMI, respectively. These distributions were used for evaluating the GIST metric. For each feature, we generated three patient samples as follows:

**“Real-world” patient population (P1):** A random sample of 10,000 patients from the T2DM patients in NHANES using normalized NHANES sample weight with replacement. NHANES sample weight is the number of patients in the U.S. national population that one survey participant can represent. Therefore, this sample can represent the “real-world” T2DM patients.

**Weighted “real-world” patient population (P2):** We generated a random sample of 10,000 patients from T2DM patients in NHANES considering both NHANES sample weight and the percentage of trials that consider such patients. Specifically, we separately normalized NHANES sample weight (i.e., WTMEC10YR) and percentage of trials (P0), and then used the average of these two normalized weights to sample the T2DM patients in NHANES. As such, the sample of weighted “real-world” patients generated by oversampling “real-world” patients who are considered by more trials and under-sampling “real-world” patients who are considered by fewer trials would be better represented in the target population of the trials (P0) than the “real-world” patient population (P1). Note that the values in both the normalized sample weights and normalized percentages of trials added up to 100%, while the sum of values in P0 did not.

**Study population of clinical trials (P3):** A random sample of 10,000 enrolled patients generated using Gaussian distribution with the mean and SD of the convenience sample of enrolled patients in T2DM trials (from Step 3).

In the ideal situation, the study population should represent the target population, assuming the enrolled patients match the eligibility criteria perfectly. Therefore, P3 should have the best generalizability of the target population among P1, P2 and P3. The same trial set should have better population representativeness for P2 than P1. For each feature (i.e., age, HbA1c, and BMI), we calculated the GIST scores for three patient samples. Taking sampling variability into account, we ran the experiment for 100 times. Note that P0 for each feature remained the same in all the experiments, whereas P1, P2, and P3 were generated once for each feature in an experiment. If the calculated GIST scores in all the experiments consistently follow $\text{GIST(P0,P1)} < \text{GIST(P0,P2)} < \text{GIST(P0,P3)}$, GIST correlates the expected difference of three patient samples and is therefore a valid metric for assessing the population representativeness of a given patient population in a given trial set.

**Step 5: Comparing population representativeness of trial sets of various characteristics**

To reveal the population representativeness problem at the research community level, we calculated the GIST score of age for each of the seven previously selected conditions: T2DM, depression, asthma, sleep disorders, arthritis, heart attack, and stroke. To compare population representativeness of different types of trials, we further performed stratification analysis on study phases, sponsor types, and study designs across multiple conditions. We used the GIST scores of age for trial sets that differ in these trial characteristics to compare their population representativeness.

**Results**

**Evaluation results of GIST using simulation**

For each of the three eligibility features (i.e., age, HbA1c, and BMI), we generated three patient samples (i.e., P1, P2, and P3, defined in Step 4 of the Methods Section) that have known differences in generalizability for collective target population (P0) of the same set of trials in one experiment and ran the same experiment for 100 times. Even though the difference between P1 and P2 may be minor if most trials accept broad range of values, the GIST metric should still capture the difference. To illustrate the differences among three patient samples, we visualized in Figure...
the distribution of P1, P2, and P3 against the target population of T2DM trials (P0) for age, HbA1c, and BMI in the pilot experiment. The widths of value intervals for age, HbA1c, and BMI are 1, 0.5, and 1, respectively. In each sub-figure, the green dot-and-dashed curve represents the target population of T2DM trials, i.e., the percentage of trials allowing a value interval. The blue solid curve represents the distribution of patients in the sample of “real-world” patients (P1) over consecutive non-overlapping value intervals of a feature. The red dotted solid curve represents the distribution of patients in the weighted sample of “real-world” patients (P2). The light blue solid curve with big dot represents the distribution of patients in the sample of enrolled patients in T2DM trials (P3).

There are two y-axes: the left one is for the three sample patient populations (i.e., P1, P2, and P3) and the right one is for the target population of clinical trials (P0).

Figure 3. Visualization of three patient populations (P1, P2, and P3) and the target population of T2DM trials (P0) with respect to (a) age, (b) HbA1c, and (c) BMI, respectively.
As can be seen in Figure 3(a), both distributions of P1 and P2 peak at age 80, which is considered by only about 40% of trials. The distributions of P1 and P2 are similar in the visualization, but a statistically significant difference between them was observed in two-sample Kolmogorov-Smirnov test (test statistic = 0.028 > 0.014 = critical value, \( P \)-value < 0.05). Figure 3(b) shows the visualization of three patient samples and collective target population regarding HbA1c. The distribution of P3 aligns with P0 better than that of P1 and P2. The peak of the distribution of P2 stands in between that of P1 and P3, confirming that the same set of trials does have better generalizability for P2 than P1. Figure 3(c) shows the visualization for BMI. We can see that all three distributions of P1, P2, and P3 peak at about 30 kg/m\(^2\), where the peak of P2 is higher than that of P1. As BMI value increases from 30 kg/m\(^2\), the curve of P2 gradually drops below that of P1. The reason is that the weight (i.e., target population) we used to generate P2 is set at about 30 kg/m\(^2\). WTMEC10YR or WTMEC8YR) of the survey participants with the corresponding condition listed in the year range. The GIST score of age for trials on the other five conditions ranged between 0.74 and 0.83, showing relatively good population representativeness.

To uncover the population representativeness issue at the research community level, we used GIST to compare the GIST scores of age for seven medical conditions ranked in ascending order (Column 5). The numbers of patients in the U.S. national population (Column 3) are the sum of the normalized sample weights (i.e., WTMEC10YR or WTMEC8YR) of the survey participants with the corresponding condition. The GIST score of age can assess how the target population of a set of trials using age as an eligibility criterion (Column 4) represents the “real-world” patient population (Column 3). We observed that among all the conditions, asthma trials had the worst population representativeness (0.54), while heart attack trials had the best population representativeness (0.89). The GIST of age for trials on the other five conditions ranged between 0.74 and 0.83, showing relatively good population representativeness.

Roumiantseva et al. have found that industry-sponsored studies differ systematically from government-sponsored studies in study type, interventions, and condition studied [19]. We are also interested in exploring the difference of population representativeness for trial sets of various characteristics.
Table 4 gives the GIST scores of age for trial sets in different study phases, study sponsors, and study designs on seven medical conditions, horizontally ordered in the same order as Table 3. For all the conditions, the GIST score of age increases from Phase I to Phase III. This is in accordance with the fact that Phase I trials aim to establish initial safety and efficacy profile of a treatment in a small group of patients, while Phase III trials seek to test the treatment with a large groups of people to confirm its safety and efficacy.

According to the GIST scores, industry-sponsored trials have better population representativeness than NIH-sponsored trials for asthma, sleep disorders, depression, T2DM, and arthritis. In general, randomized trials have a slightly better population representativeness than non-randomized trials except for asthma trials. With regards to primary purpose (study design), treatment and diagnostic trials have better population representativeness than prevention and basic science trials. These results confirmed our Hypothesis #2 that GIST correlates with the population representativeness of a set of related trials.

Table 4. The GIST scores of age for trials in different phases, sponsors, and study designs on seven medical conditions. The number of trials is enclosed by parentheses.

Discussion

This study validated the effectiveness of GIST at assessing the population representativeness of related clinical trials. The GIST scores consistently agreed with the expected differences of population representativeness for three population samples across 100 experiments for all three selected eligibility features. We further demonstrated the effectiveness of GIST in comparing population representativeness of trial sets that differ in their characteristics such as disease domains, sponsor types, study phases, and study designs. Among seven medical conditions, asthma trials had the lowest GIST score of age, reflecting the concern in the respiratory medicine research community [20]. Meanwhile, the GIST metric was further validated by the increasing GIST scores of age from Phase I to Phase III across all the seven conditions. Note that GIST can also assess the population representativeness of a single clinical study, as its primary use case of a pharmaceutical company will be to assess the generalizability of a study it is currently designing or even a study that it already has completed.

In this work, we used NHANES to profile the “real-world” patient populations (P1) and weighted “real-world” patient populations (P2). Compared with EHR data, NHANES has several advantages. First, its sophisticated sampling mechanism ensures the population representativeness at the national level. In contrast, EHR data contain mostly diseased patients or patients receiving care and hence may be biased towards certain population subgroups. Second, structured survey data are readily analyzable, whereas EHR data often require preprocessing to address data
quality problems. Therefore, NHANES is more cost-effective than EHR data for lightweight population-based studies. However, due to the limited data in NHANES, it may not be suitable for longitudinal analysis or studies on medical conditions that are not included in the interview questions.

Limitations
This study has limitations. We only included seven medical conditions that have a fair amount of patients (over 1,000) in NHANES. Ideally, more conditions should be analyzed. The self-reported medical conditions in NHANES may have resulted in some misclassification of samples. The GIST metric has intrinsic limitations. First, GIST does not take into account the enrollment value of a study. Currently, ClinicalTrials.gov has only one field for enrollment, which can be planned or actual. Quite a number of trials have not updated the planned enrollment with actual enrollment even after completion. Second, it does not consider the geographic location of the trial, which is one major factor for patient recruitment. Nevertheless, by aggregating many patients and clinical trials, we have minimized the impact of these factors for generating meaningful results in the research community level. Third, the GIST metric cannot reveal the reason behind the population representativeness problem. Visualization such as Figure 3 can serve as a good complement to GIST for assessing the population representativeness of related trials.

The long-term goals of this line of research
As the main purpose of most RCTs is to test the efficacy and safety of a treatment for a certain medical condition in people, it is often required to minimize confounding factors that may potentially affect the results. Therefore, it is a common practice that RCTs usually recruit patients who do not have comorbidities and are not too old or too sick to treat. Instead of enforcing a trial to be generalizable to the broad patient population, the goals of this line of research are (1) to improve the transparency of clinical trial eligibility criteria design biases across multiple studies; (2) to facilitate evidence-based data-driven precision design of clinical trial eligibility criteria [21]; and (3) to address the rising need for patient-centered outcomes research in the clinical trial domain. This information can be provided to clinical trial designers to help them better justify the trade-offs between the internal validity and the external validity when designing a new trial. This information can also help clinical investigators and policy makers efficiently identify population representativeness issues in clinical studies of certain characteristics and take measures accordingly. When applying clinical trial eligibility criteria to observational data, one can compare and contrast the effects observed between eligible and ineligible patients, which may reveal more profound problems in trial design and clinical research in general.

Future work
In the future, we plan to use GIST to identify restrictive features among multiple frequently used eligibility features among clinical trials of a certain medical condition. We will first leverage controlled terminologies such as SNOMED CT to develop structural, semantic, and lexical methods for meaningful aggregation of similar qualitative features. Then we will compute GIST scores to identify stringent features (with relatively low GIST scores). In this paper, we compared the population representativeness of trials on seven medical conditions with respect to age using GIST. However, this method is not efficient when more eligibility features are included in the analysis. Moreover, eligibility features may have inherent correlations. For example, a previous study has reported that impaired fasting glucose generally increases with age for diabetic patients [22]. Meanwhile, eligibility criteria may be operationalized as an interaction of multiple features, e.g., “pregnant female over 40 years old.” In the future, we will investigate how to assess the collective population representativeness using multiple eligibility features simultaneously.

Conclusions
In this work, we used real-world population-level data to validate a novel metric for quantifying the population representativeness of clinical trials. The study results confirmed that the GIST metric is reliable for its purpose. These findings suggested the future potential of a systematic approach for providing prognostic tools to facilitate the clinical trial design process as well as post hoc evaluations to investigate the generalizability of studies already underway or completed. By integrating the real-world experience of patients with the study design attributes of existing clinical trials, researchers designing new clinical studies can improve both the efficiency and generalizability of their designs with this proactive data-driven approach.

JuFiT: A Configurable Rule Engine for Filtering and Generating New Multilingual UMLS Terms

Johannes Hellrich, Stefan Schulz, MD, Sven Buechel, Udo Hahn, PhD

1 Jena University Language & Information Engineering (JULIE) Lab, Friedrich-Schiller-Universität Jena, Jena, Germany; 2 Medizinische Universität Graz, Graz, Austria

Abstract

We here describe JuFiT, an easily adjustable rule engine which allows to filter non-natural terms (i.e., ones usually not occurring in running citation texts) from the UMLS metathesaurus and even adds new terms to the UMLS (by rewriting non-natural terms). Unlike previous attempts (with METAMap or CASPER), JuFiT serves multilingual purposes in that it runs for English, Spanish, French, German and Dutch documents, as well – the most prominent European languages in terms of UMLS coverage. We evaluated JuFiT under a variety of experimental conditions and found evidence that it increases annotation quality for English, and most likely also for German and Spanish.

Introduction

The Unified Medical Language System (UMLS) metathesaurus (‘metathesaurus’ will be omitted for brevity) constitutes one of the most important biomedical term repositories, integrating 179 source vocabularies in 21 natural languages. Unfortunately, a large number of UMLS entries are ill-suited for usage besides manual indexing, since they occur in a ‘non-natural’ format, e.g., as terms exhibiting syntactic inversions (such as ‘failure, renal’ instead of ‘renal failure’) or contain semantic meta data, as is the case for terms that originate from SNOMED CT. Such UMLS terms, however, are unlikely to appear in real texts, like clinical narratives or medical literature, and are thus probably worthless or even harmful for advanced NLP applications like information extraction or text mining.

Such non-natural appearances of entries can be removed or even corrected with automatic tools, as prominently demonstrated by the METAMap system. Yet, currently there exists no general-purpose tool for dealing with such non-natural formats for UMLS entries. METAMap acts as a filter (e.g., by correcting syntactic inversions or generating variants without possessives) when used to process text. However, its filtering component is not available as a stand-alone tool and thus inapplicable for many applications. In addition, METAMap is known to be rather slow. The CASPER tool was developed as a stand-alone solution for filtering and correcting UMLS entries, yet, just as METAMap, focuses on English only. This is troublesome in times when multilingualism is considered an important issue within the health care community due to ever-increasing economic globalization, international tourism and immigration streams. Improved term quality could not only improve biomedical NLP for non-English languages but also yield benefits for machine translation systems and the internationalization of the terminological infrastructure of the life sciences as evidenced by the UMLS, which is still very much English-centric (cf. Table 1).

We alleviate this lack of a stand-alone tool suited for multilingual environments by providing the Jena UMLS Filter Tool (JuFiT), a rule-based open-source tool.\(^d\) JuFiT uses rules similar to those in MetaMap and CASPER, but extends these by adding support for multiple languages and their language-specific phenomena, e.g., German compounds. We provide rules for English, Spanish, French, German, and Dutch, yet the declarative implementation of these rules makes it possible to add support for further languages without changing JuFiT’s source code.

Using rule-based systems to transform biomedical terms is, by no means, a new idea. It originates from the work of McCray and colleagues for the English language carried out at the U.S. National Library of Medicine.\(^{10-12}\) Such transformations were previously shown to be useful for mapping terminologies\(^{13}\) and for increasing system performance in retrieval experiments.\(^{14}\) Filtering UMLS entries could also lead to consistent improvements in terminology-assisted machine translation, where results are quite mixed at the moment.\(^{7,15}\)

Our rules were evaluated both manually and automatically, first, by looking at the number of dictionary entries as influenced by each rule, second, by using these dictionaries to annotate multilingual texts and counting the number of matches and, third, by taking a sample of terms only annotated or no longer annotated thanks to our rules. The multilingual texts were taken from the cleaned EMEA corpus\(^6\) portion of the MANTRA challenge material\(^6\) and can be assumed to be direct translations of each other over all languages. We could demonstrate a pronounced increase in annotation quality for English and, arguably, for German and Spanish, as well as a moderate increase (~2\%) in annotation coverage for French and Dutch thanks to the operation of JuFiT.

**Methods**

All experiments were conducted based on an installation of the 2014AB UMLS (processing the MRCONSO.RFF and MRSTY.RFF files) with default settings and all sources. We applied both single rules and combinations thereof using appropriate JuFiT configuration files to produce dictionaries digestible by a LingPipe\(^e\) based gazetteer, suppressing terms marked as suppressible in the UMLS (the latter was also done for the baseline). Filtering was applied to prevent rules from producing duplicate strings, i.e., ones that were already contained in the UMLS for a term of the language under scrutiny. Whereas JuFiT is capable of preserving the original cases (helpful for blacklist-based rules), the gazetteer was configured to ignore them in order to increase recall (many UMLS terms reveal irregular capitalization).

Two types of rules can be distinguished, viz. deletion rules (removing terms) and rewrite rules (generating variants, while preserving the original term, with the exception of RewriteSemanticType). The basic principles underlying these rules are well-known in the literature\(^{2,4,10-12}\) yet, we differ from prior works in terms of increasing lexical coverage and handling multilingual phenomena.

**Deletion rules:**

- DeleteIfContainsAtSign: Deletion of terms containing “@”, such as “CASTOR OIL@@MISCELL@OIL”.
- DeleteIfContainsResiduals: Deletion of terms marked as unspecific through warning strings, e.g., “not elsewhere classified” or “other” for English, “no clasificados” (and other inflected forms) for Spanish. This rule combines the “Any classification”, “Any underspecification” and “Miscellaneous” rules from Hettne et al.\(^4\)
- DeleteIfContainsDosage: Deletion of terms containing dosages and other measurement information, covering, e.g., “5 ml”, “Milligram/Kilogram“, “per day” or “2 %“.
- DeleteIfContainsECNumber: Deletion of terms containing enzyme classifications, identified as terms containing “EC” followed by at least one digit and zero up to three combinations of a dot followed by a single or multiple digits.
- DeleteShortToken: Deletion of terms that do not contain at least one token with two or more letters, which is not a Roman numeral (between I and VIII) or a stop word (e.g., German “die” [English: “the”]). This rule removes terms such as “L.Q.; 20-34”.

\(^d\) https://github.com/JULIELab/jufit
\(^e\) http://alias-i.com/lingpipe/
Rewrite rules:

- RewriteApostropheS: Adds a variant without “’s” at the end of words. This results in variants without possessives in English, e.g., “Abelson virus” for “Abelson’s virus”, and plurals in Dutch, e.g., “Getto” [English: “ghetto”] for “Getto’s” [English: “ghettos”]. This rule was only used for English and Dutch.

- RewriteShortFormLongForm: Adds separate variants for terms containing both a long and a short form by using Schwartz and Hearst’s algorithm, resulting in new term variants like “child ADD” and “child attention deficit disorder” for “child attention deficit disorder (child ADD)”.

- RewriteSyntacticInversion: Adds a variant of terms in which syntactic inversions are reverted, e.g., “Adult Human” for “Human, Adult”. We provide special support for compounding according to German and Dutch orthographic conventions, i.e. “Berufsunfälle” [English: “work accidents”] is added for “Unfälle, Berufs-” instead of (orthographically false) “Berufs-Unfälle”.

- RewriteSemanticType: Replaces terms containing a semantic type in rounded, angular or square brackets by a variant where the brackets and their contents are removed. Separate lists are used to identify types contained in rounded, angular and square brackets for each language. These types are not identical with the UMLS semantic types (as in CASPER⁷), yet were manually extracted from frequent terms with brackets in several resources.⁷ We also added some rules to all languages, e.g. “SMQ” (for “Standardised MedDRA Queries”),⁸ as well as the language-specific names for the “Kiel Classification” (appearing in most terms describing non-Hodgkin lymphoma),⁹ after searching the UMLS for language-specific bracket content in German, French and Dutch. This rule yields terms like “injection of steroid into spinal canal” as a replacement for “injection of steroid into spinal canal (procedure)”, a typical example of a SNOMED CT Fully Specified Name.

Rule implementation is as generic as possible, language-specific variants or word lists, as well as the active rules themselves and their sequence order are configured via a file, allowing for easy adaptation to additional languages. These rules were organized in three different rule sequences, i.e. all rewrite rules, all deletion rules and a balanced sequence (following Hettne et al. who combined both types of rules). Rules can modify term variants generated by other rules in order to ensure that no new term would conflict with the constraints imposed by our deletion rules.

Evaluation

The evaluation was performed under three conditions, first, by looking at the number of dictionary entries produced or removed by each rule, second, by using these dictionaries to annotate EMA files and counting the number of matches and, third, by taking a random sample of terms only annotated or no longer annotated given our rules. The manual evaluation was performed on samples for English, Spanish, German and French for the balanced condition. As evident from Table 2, the balanced rule sequence resulted in an increase of dictionary entries for German and Dutch only, whereas English and Spanish lost 12.8% and 36.9% of their respective entries. One of the main reasons for this surprising effect is due to the application of the RewriteSemanticType rule—many of the terms affected by this rule exist both with and without the interfering semantic type metadata (removed by the rule). This is typical for SNOMED CT, which constitutes a substantial part of the UMLS’ English and Spanish contents. These terms are effectively removed by the rule, as no rule may produce a new variant which is indistinguishable from existing terms. This effect is far less pronounced in Hettne et al.’s study,⁴ due to their questionable semantic type selection. The highest number of additional term variants for all rules was provided by the RewriteSyntacticInversion rule, which is consistent with numbers reported by Hettne et al.⁴ (their data show an 8.6% increase, whereas we found a

⁸ http://www.meddra.org/standardised-meddra-queries

⁹ http://www.morbus-hodgkin.de/infoserv/kiel.htm

⁴ For the balanced condition, we executed the rules in the following sequence: DeleteIfContainsDosage, DeleteIfContainsAtSign, DeleteIfContainsECNumber, DeleteIfContainsResidual, DeleteShortToken, RewriteSemanticType, RewriteAngularBrackets, RewriteShortFormLongForm, RewriteApostropheS (English/Dutch only), DeleteIfContainsDosage, DeleteIfContainsAtSign, DeleteIfContainsECNumber, DeleteIfContainsResidual, DeleteShortToken; the deletion rules were applied twice to cover newly added variants as well.
10.9% increase, for English terms). Deletion rules had only minor effects, the strongest were seen for DeleteIfContainsDosage for Spanish and English, again consistent with results from Hettne et al.\(^4\)

Table 2. Number of terms in the gazetteer file produced by JuFiT per language for all tested rules and rule combinations. ‘Balanced’ combines the deletion and rewrite rules. Baseline numbers differ from the size numbers reported in Table 1 since suppressible terms, as well as identical term strings for the same CUI, were removed.

Table 3 depicts the number of entity occurrences in the EMEA corpus that were annotated with gazetteer dictionaries, filtered by different rules and rule sequences. The balanced rule sequence caused little deviation from the absolute number of German annotations, while for French we observed an increase of 2.1% and 2.4% for Dutch. By contrast, both English and Spanish lost several tens of thousands annotations, 3.2% and 1.6%, respectively. This drop is inconsistent with results reported by Hettne et al.,\(^4\) which showed a 2.8% increase.

Table 3
To better assess the differences between JuFiT and CASPER we used the latter to processes the UMLS version of the EMEA corpus (with LINGPIPE) used in our JuFiT experiments for English. The results of this experiment are listed in Table 4. CASPER’s rules can mostly be mapped 1:1 to JuFiT rules (only DeleteIfContainsResidual is a combination of CASPER’s “Any classification”, “Any underspecification” and “Miscellaneous” rules). Hence, we use JuFiT’s rule names for ease of comparison. The number of terms is counted after the removal of multiply identical terms for the same CUI. The number of annotations produced by a ‘balanced’ system is quite similar for both JuFiT and CASPER, thus the differences in UMLS versions or corpora must be the source of the aforementioned drop in comparison with the baseline. For the three tested rule combinations, JuFiT produces fewer terms, yet leads to slightly more annotations than CASPER. For single rules, the number of annotations differ only slightly between both systems, except for the DeleteIfContainsDosage rule where JuFiT’s implementation is more general and thus more effective. The number of terms produced by applying single rules differs strongly for two rules—JuFiT’s RewriteSemanticType rule produces only 90% of the terms generated by CASPER, which can probably be attributed to our finer grained list of semantic types (cf. rule description above for details). Meanwhile, for RewriteSyntacticInversion JuFiT produces 5% more terms, which may be due to our implementation that includes no checks for prepositions or conjunctions, whereas CASPER’s implementation does. These explanations are educated guesses, since CASPER is not available open source, in contrast to JuFiT.

We refrained from comparing JuFiT with METAMap because they markedly differ in design. METAMap is a full-blown lexical processing engine, whereas JuFiT is only a lexical pre-processor without, e.g., disambiguation or tagging functionality. Hence, a comparison of both would require embedding JuFiT into a more comprehensive text analysis pipeline. Still, such a comparison is badly needed and a topic of future research.

Table 4. Number of terms and annotations achieved by using CASPER (and LINGPIPE) on the 2014AB UMLS and annotating EMEA with the filtered terminology (English only due to CASPER’s monolingual nature).

Finally, we performed a manual review by comparing the terms annotated in the baseline with those annotated after balanced preprocessing. We sorted these terms in three categories, those annotated only in the baseline, those annotated only by JuFiT and those annotated differently by JuFiT, i.e. the baseline contained a term, yet a longer and overlapping term was found, e.g., “Stage 5 Chronic Kidney Disease” instead of the more general “Chronic Kidney Disease”. This analysis was performed for English, Spanish, German and French by taking the 10 most frequent changes for each language plus 50 randomly selected ones into consideration. These samples were annotated as positively, moderately or negatively effecting annotation quality, with results shown in Table 5. Removal of all annotations for measurements was intended and thus rated positively. According to our analysis, JuFiT was clearly helpful for English, and most likely also for German and Spanish, yet changes for French were about equally positive and negative. The differences between languages could point both towards additional efforts necessary for some languages (especially French), yet can also be explained by large, language-specific differences in terms of source vocabularies in the UMLS.
Table 5. Number of annotations positively, moderately or negatively affected when comparing baseline annotations with annotations generated after application of JuFiT’s balanced rule sequence; results are based on a sample of 60 changes per language.

Conclusions

While the UMLS is of central importance for numerous clinical and biomedical NLP applications, the structure of some of its entries, containing e.g., syntactic inversions (‘failure, renal’ instead of ‘renal failure’, the latter being recoverable by the RewriteSyntacticInversion rule), hampers these applications. We provide JuFiT, an open source tool for filtering and improving such entries, which extends prior solutions (such as METAmap and CASPER) by adding analytic capabilities for several non-English languages. The impact of JuFiT was tested in three kinds of evaluation experiments, one manual and two automatic ones. We could demonstrate a clear increase in annotation quality for English and arguably German and Spanish, as well as a moderate increase (~2%) in annotation coverage for French and Dutch with JuFiT’s balanced rule sequence.

Future work could be directed in several directions, e.g., adding additional rules for further phenomena, e.g., TNM classifications, improving existing rules to avoid false positives or increasing the number of languages for which specific rules exist. Furthermore, a comparison between METAmap and an analysis pipeline with JuFiT embedded in it is on the agenda. As mentioned before, one could also try to use the filtered UMLS for other applications besides information extraction, e.g., as a resource for machine translation.

Abstract
The Institute of Medicine (IOM) recommends that health care providers collect data on gender identity. If these data are to be useful, they should utilize terms that characterize gender identity in a manner that is 1) sensitive to transgender and gender non-binary individuals (trans* people) and 2) semantically structured to render associated data meaningful to the health care professionals. We developed a set of tools and approaches for analyzing Twitter data as a basis for generating hypotheses on language used to identify gender and discuss gender-related issues across regions and population groups. We offer sample hypotheses regarding regional variations in the usage of certain terms such as ‘genderqueer’, ‘genderfluid’, and ‘neutrois’ and their usefulness as terms on intake forms. While these hypotheses cannot be directly validated with Twitter data alone, our data and tools help to formulate testable hypotheses and design future studies regarding the adequacy of gender identification terms on intake forms.

Introduction
The LGBT community is subject to a variety of health disparities. This is a result of a lack of meaningful data on LGBT populations as well as a lack of training and resources for clinicians to provide culturally competent care. Recent Institute of Medicine (IOM) recommendations to address these health disparities include (1) gathering data on sexual orientation and gender identity in Electronic Health Records (EHR) as part of the meaningful use objectives in EHRs, (2) developing standardization of sexual orientation and gender identity measures to facilitate synthesizing scientific knowledge about the health of sexual and gender minorities, and (3) supporting research to develop innovative methods of conducting research with small populations and to determine the best ways to collect information on LGBT minorities.\textsuperscript{1}

While the IOM notes that data collection would be aided by standardized measures for sexual orientation and gender identity, their report also emphasizes that defining sexual orientation and gender nonconformity is a challenge since these are multifaceted concepts. The use of terminology that is familiar to the participant has been shown to improve response rates.\textsuperscript{1,2} However, based on the limited research available, there is some evidence\textsuperscript{3,5} to suggest that consumer vocabulary for self-identifying gender and sexual orientation varies by community. There is clear evidence of lexical variation associated with geography in linguistics studies.\textsuperscript{6,8} Also, through discussions with members of the trans* community and health care providers at LGBT clinics across the country, we have learned that new terms are frequently being coined to describe gender identity and that the connotations of existing terms may vary by community.

There is documented variation of terms to describe sexual orientation across communities.\textsuperscript{9} There is also variation in the meaning of terms between individuals who consider themselves part of the sexual minority (e.g., lesbian, gay, or bisexual) and those who do not (e.g., straight or heterosexual).\textsuperscript{10} For example, self-identifying members of a sexual minority use ‘lesbian’ to refer to women who are primarily attracted to other women, but others tend to use ‘lesbian’ more broadly to refer to a woman who has experienced any sexual attraction or sexual activity with another woman.\textsuperscript{10} This raises the question of whether there is similar variation in the meanings of terms used to describe transgender identity. However, data addressing variations of gender identity terms and their meanings is lacking. This is significant for the development of good intake forms; if there is significant lexico-semantic variation of gender identity terms, then a single, universal standard intake form may result in a lower response rate than intake forms that are community specific.
A number of organizations have attempted to address the question of how to ask patients about their gender identity. A summary of these approaches can be found in the GenIUSS Report by the Williams Institute. The most promising is a two-step format recommended by the UCSF Center of Excellence for Transgender Health. First patients are asked about their gender identity and then their sex assigned at birth. However, this research addresses the form of the question, not the specific items used to present gender-identity options that ought to be available on the form. The language used in the gender identity question varies across forms from different healthcare organizations. Table 1 contains the choices from the sample forms of three institutions: 1) Fenway Health, 2) UCSF, and 3) the Williams Institute. Although the two-step format has been field tested in Michigan by the Fenway Institute, it is not clear to what extent the terms on these forms represent the identity terms used by transgendered, non-binary, and/or gender-variant people (trans*) across the United States. For brevity we refer to transgendered, gender non-binary and gender-variant people by the term ‘trans*’. The result is that there are still outstanding questions regarding which terms are optimal for intake forms and whether a single, universal standard terminology will suffice for all trans* communities.

Table 1. Gender identity terms found on various intake forms.

User generated content on social media, such as Twitter, is a valuable resource because it can provide a source for gleaning information about people’s daily life to answer scientific questions. We believe this source can produce a data set that can contribute to the IOM priority area to study social influences on LGBT health and to the IOM recommendation to develop innovative methods for conducting research on small populations. Mining social networking resources produces data sets that can be used to investigate social influences of health concerns among transgender persons.

Our goal is to build a data set and visualization tools that can be used as a basis to generate hypotheses for further testing to guide the development of gender identity questions on intake forms. Our process for building these tools was as follows. We first examined which terms are currently used to describe transgender identity on Twitter. Based on existing research on linguistic variation in social media, we hypothesize that the usage of gender identification terms varies by geographical region. Then we geotagged the tweets by US state, classified tweets as authored by self-identifying transgender users, and created a co-occurrence network and term frequency counts to support hypothesis generation with data visualization tools. These co-occurrence counts and frequency counts will form the basis of distributional similarity metrics in future research to help determine a) whether different terms are synonyms; and b) whether some terms are polysemous, i.e., carry multiple distinct meanings. By ‘self-identifying’ we refer to people to have stated that they have a trans* identity in some context through their tweets.

Our approach is consistent with the intersectional perspective recommended by the IOM. The intersectional approach considers sub-populations of the LGBT community based on several orthogonal factors, such as ethnicity and geographical region. Furthermore, the resulting data set can be used to address demographic research, social influences on health, and transgender specific health needs — three of the five priority research areas.

Another goal of this paper is to establish a set of best practices for dealing with social media for extracting useful biomedical knowledge, which can help produce data on small populations through unfettered access to such a “Big Data” source (over 500 million tweets per day).
Methods

The general idea underlying our approach is to identify tweets that are relevant to the discussion of trans* related issues, and then examine the variations in language used for gender identification by different communities, that is, by population (trans* people vs. the general public) and by geographical location (U.S. states). The analysis workflow consists of five main steps, as depicted in Figure 1: 1) collect tweets that are potentially related to discussions about gender identification; 2) preprocess and geotag tweets with their corresponding U.S. state; 3) build supervised classification models based on textual features in the tweets to a) filter out irrelevant tweets and b) find people who are self-identified as trans*; 4) collect relevant (both self-identifying trans* users and users in the general public who discussed trans* related issues) users’ Twitter timelines which consists of all of their tweets in chronological order; and 5) compare the usage of gender identification terms by geographical locations (i.e., by U.S. states) and by population groups (trans* people vs. the general public). Some of the search terms are ambiguous and their meanings are context dependent. For example, the tweet “That Hot Pocket is full of trans fats” is not related to discussions of gender identification even through it contains the keyword. To account for this observation, we engineered a binary classifier to determine the likelihood that a tweet is relevant to the discussion of gender identification and remove those that are unlikely to be irrelevant from the corpus in step 3. We also leverage a number of visualization techniques to provide straightforward and easy-to-understand visual representations – word clouds, co-occurrence matrices, and network graphs – to substantiate our findings. In the following sections, we describe each step and the basic procedures in further detail.

![Figure 1](image.png)

**Figure 1.** The general analysis workflow consists of five steps: 1) collect relevant tweets using the Twitter search API with a search term list; 2) preprocess the collected data to filter out non-English tweets and geotag based on user profiles; 3) build classification models to identify relevant tweets and Twitter users; 4) collect relevant users’ Twitter timelines; and 5) analyze the usage of keyterms through comparing term frequencies and co-occurrences.

**a) Data collection through the Twitter search API**

We developed a set of Python scripts leveraging the twython\(^{15}\) library for accessing the Twitter APIs. We designed our Python crawler, `tweetfilter\(^{16}\)`, to handle various potential runtime exceptions (e.g., the crawler will recover from a system failure automatically and pause collection when it reaches the Twitter API rate limits\(^{17}\)) and distribute the workload across multiple Amazon EC2 instances. The data collection process began with a list of keywords (i.e., search terms) mainly related to gender identification such as ‘transwomen’, ‘genderqueer’, and ‘transmasculine’. We have also included a number of other keywords that could indicate relevance of the tweets to trans* discussions such as ‘testosterone’ (often used as part of the hormone replacement therapy for transgender individuals) and ‘gender reassignment surgery’. To ensure coverage, we considered the base forms of these terms as well as their spelling variations, such as ‘transwomen’, ‘trans-women’, and ‘trans women’.

613
Additionally, we found that a number of hashtags (i.e., patterns that start with ‘#’ to mark topics in a tweet and often used by Twitter users to categorize the messages), such as ‘#iamnonbinary’ and ‘#iamtrans’, are good search terms with a low false positive rate for identifying tweets relevant to our study. To develop a list of search terms, we started with ‘transgender’ and ‘trans’ as seed terms which we used as search terms on Twitter and manually compiled a list of co-occurring terms that are in the domain of trans* gender-identification. We next iterated this process until we were no longer accumulating new terms. Then we manually examined the collected tweets to determine the quality of these terms as search terms. Through an iterative process, we removed terms where the majority of the returned tweets were false positive and added new relevant keywords that discovered in the collected tweets.

b) Data preprocessing and geotagging

We preprocessed the collected data to eliminate tweets that 1) were not written in English or 2) those for which we could not determine the geographical location of the user. For language detection, we leveraged the Twitter API metadata directly, which includes a ‘lang’ attribute specifying the language that the tweet was written in. For geotagging, we extracted the ‘location’ field, part of a user’s profile, and attempted to assign a U.S. state to each tweet accordingly. Specifically, we searched each location field for a number of lexical patterns indicating the location of the user such as the name of a state (e.g., Arkansas or Florida), or a city name in combination with a state name or state abbreviation in various possible formats (e.g., “——, fl” or “——, florida” or “——, fl, usa”). Self-reported locations are often non-referring terms (e.g., “wonder land” or “up in the sky”), but strict patterns produced good matches and helped to reduce the number of false positives.

Notably Twitter also provides the ability to attach geocodes (i.e., latitude and longitude) to a user’s profile and to each tweet. Yet, since geolocation needs to be enabled explicitly by the user as well as requires the user to have a device that is capable of capturing geocodes (e.g., a mobile phone with GPS turned on), very few tweets we have collected have this information. This is consistent with findings from previous studies. If the ‘location’ field was missing in a user’s profile, but the ‘geo’ attribute was available, we attempted to resolve the location of the user through reverse geocoding via the publicly available GeoNames geographical database. In Twitter, geocoding can be either at the user-level or at individual tweet-level. However, we did not use the geocodes attached to each individual tweet since it is possible that a user was traveling away from their home state, in which case the geocodes attached to the tweets would be different from those on their profile. For our study, we geotagged the tweets based on where the user is from, not where the user is traveling temporarily. However, we do consider the scenario where a user permanently moved from one state to another reflected as a change in the ‘location’ field of a user’s profile.

We have also made a number of other efforts to clean up the tweets including: 1) fixing Unicode text using ftfy; 2) removing mentions (i.e., indicating conversations in a tweet, starts with ‘@’ followed by a username); and 3) eliminating hyperlinks. However, we did retain hashtags as they indicate topics and categories of the tweets and may contribute to the vocabulary of trans* related discussions.

c) Classification models for finding relevant tweets and Twitter users

Even though a tweet contains one or more of the search keywords, the tweet may not be relevant to our study due to the ambiguity of the search terms. The meanings of many search terms are context dependent. For example, the term ‘trans’ could also mean “trans fat” or “transmission”, depending on the context of the sentence. Since we are interested only in tweets where ‘trans’ means “transgender”, we built a binary classifier to distinguish tweets that are relevant vs. irrelevant to the discussion of gender-related issues. Further, we want to examine whether there are any differences in the terminology used across trans* communities. Thus, we built a second binary classifier to discover people who are self-identified as trans*.

The mechanisms of both classifiers are essentially the same. We first converted each tweet into a feature vector using the term frequency-inverse document frequency (tf-idf) scheme and then trained the classifiers using a random forest. We manually annotated 6,058 tweets to obtain a training sample. All tweets were read by three people and each tweet was assigned one of three labels: ‘irrelevant’ (661 tweets), ‘relevant but NOT self-identifying’ (4,619 tweets), and ‘relevant AND self-identifying’ (778 tweets). When disagreements between the three annotators occurred, we used the majority rule to determine the final label. Although the three labels are mutually exclusive in the sense that only one label is assigned to each tweet, self-identifying tweets are inherently relevant tweets. Therefore, in building the disambiguation classifier, we treated relevant tweets (both self-identifying and not self-identifying) as positive samples and irrelevant tweets as negative samples. In building the second classifier to identify the trans* population, we treated self-identifying tweets as positive and the remainder of the
relevant tweets as negative. We followed standard machine learning best practices (e.g., use 10-fold cross-validation to find the best model parameters—the number of trees in the forest for the random forest model, and for both classifiers the best parameters are 110) to ensure these classifiers are of high quality. The prediction accuracy for finding irrelevant tweets is 97.4% (precision: 0.970; recall: 0.766), and the accuracy for identifying trans* people is 87.8% (precision: 0.741; recall: 0.261).

d) Collect relevant users’ Twitter timelines

Further, we expanded our corpus to include all the tweets posted by the users who were classified as trans*. The motivation for collecting relevant users’ Twitter timelines is two-fold. First, the Twitter search API only returns recent tweets (Twitter does not release the details of their search algorithm, so we do not know exactly how many days of data will be returned prior to the day an inquiry is submitted, but an analysis of our data set suggests it is around 14 days.), and it is important to recognize that a user could have posted discussions related to trans* issues beyond the search limit. Second, our list of search terms does not contain all of the keyterms of interest such that a user could have posted discussions that contain one or more terms that are not search terms. Our search term list is rather restrictive, and does not contain all the gender identification terms that we are interested in to eliminate too many false positives. We removed a term from the search term list when the majority of the tweets it returned are irrelevant. For example, we found that “fm” (“female-to-male”, but could also mean “first time mom”) performed extremely poor. A user’s Twitter timeline can be collected using Twitter’s ‘statuses/user_timeline’ API. However, the Twitter user timeline API only return up to 3,200 of a user’s most recent tweets. Therefore, our crawling tool continuously monitors all relevant users’ timelines to collect data beyond the 3,200 limit. Note that our approach cannot go beyond the limit for historical data, but rather is a way to circumvent the limit for future tweets.

e) Generating term frequency and co-occurrence networks

From the collected tweets, we calculated the term frequency statistics of the keyterms that we are interested in at both national and state level. The list of keyterms includes not only gender identification terms but also terms that are relevant to the discussions of transgender issues such as ‘transphoa’ (i.e., a range of antagonistic feelings against trans* people based on the expression of their internal gender identity) and ‘HRT’ (i.e., an abbreviation for hormone replacement therapy often used in discussions of gender affirming medical procedures). Moreover, to provide a fair state-by-state comparison, the term frequency statistics were normalized by the number of total tweets of each state. Comparing the term frequency statistics can suggest regional differences in terminology, which in turn can lead to focused hypotheses for further investigations.

Furthermore, we produced co-occurrence networks of the keyterms hoping to discover semantic proximities and the latent structure among them.\textsuperscript{25-27} We formalize a key term co-occurrence network as an undirected weighted graph, \( G = (V, E) \), where each term is a vertex or node \((v_i)\). If two terms co-occurred (in any order) in the same Twitter message, we drew an edge or link \((e_{ij})\) between the two term nodes \((v_i \text{ and } v_j)\), such that the weight \((w_{ij})\) of the edge is set to the number of co-occurrences in all tweets posted by the users of interest. We constructed two co-occurrence networks for each state—one representing the trans* population and the other for the general public (including trans* people).

To assist in the presentation of the results, we built a number of web-based visualizations (http://bianjiang.github.io/twitter-language-on-transgender/). In particular, we used word clouds to depict the representative keyterms; and built interactive network visualizations using a physically-based force-directed graph layout with the Scalable Vector Graphics (SVG)—a language for building rich graphical content,\textsuperscript{28} and d3—a JavaScript library for manipulating SVG objects.\textsuperscript{29}

Results

We collected over 31 million tweets matching the search queries during a 49-day period from January 17, 2015 to March 6, 2015 inclusive. Out of the collected tweets, about 11 million tweets (36.1%) were in English. We were able to extract location information for 141,400 tweets (1.24% of English tweets from 57,997 unique users), which we retained for further processing. Next, we applied the two developed classifiers. We eliminated the tweets that were deemed irrelevant (5,685 tweets from 1,899 users). From the rest of the data set, 56,098 Twitter users were classified as relevant, of which 1,129 users were classified as self-identifying trans*. In addition to the data we collected using the search API, we crawled more than 154 million tweets from the 56,098 relevant Twitter users’ timelines. Out of the 154 million tweets, 532,682 Twitter messages contain one or more of the keyterms of our interest. These 500k tweets represent the corpus we used for language usage analysis.
Table 2 shows the top ten most frequently used keywords across the US on Twitter by trans* people vs. the general public. We present the data on the percentage scale to make the results comparable between the two population groups. In the table the term ‘trans’ occurs frequently because it is part of other keywords (e.g., ‘trans people’ and ‘trans woman’) that we are interested in. For the same reason, ‘trans’ co-occurred frequently with terms like ‘trans people’ and ‘trans woman’. For the purpose of better presentation, we removed any top ranked co-occurrence pairs that contain the term ‘trans’ in Table 2.

As reported in Table 2, the most frequently used terms are similar between users classified as trans* and the general public on the national level. The Spearman’s rank correlation coefficient of the term frequency lists (i.e., the general public vs. trans* people) yields a value of 0.943 (with a two-sided p-value of $8.38 \times 10^{-47} < .01$ significance level) indicating the two lists are highly correlated. On the national level there is a common vocabulary invoked to discuss gender-related issues online.

Table 2. The top ten terms and co-occurring terms tweeted across the United States by the general public vs. trans* for gender identification and discussions of gender-related issues. (*The number in the parenthesis corresponds to the percentage of tweets that contains the term.*)

However, for the sake of developing gender identity questions on intake forms we want to know whether there are reasons to suspect differences among terms used by trans* people at the regional level. Furthermore, since the same intake form is used for both trans* people and non-trans* people, we also want to be able to compare the terminology used by the trans* community with the general population to minimize non-trans* patients inadvertently indicating a trans* status. For further details on false negatives with respect to transgender identification, we direct the reader to The GenIUSS Group: Gender-Related Measures Overview. To gather data for distributional similarity measures, we performed the same term frequency and co-occurrence analysis for each state. Figure 2 compares the word clouds of the keywords used in Arkansas between trans* people and the general public; while Figure 3 depicts the word clouds of the keywords used by trans* people in Arkansas, Florida, Washington, and Kansas. Consider the term ‘genderqueer’ which appears on all three of the sample intake forms in Table 1. An examination of the word clouds in Figure 3 shows that in Arkansas the general public uses the term ‘genderqueer’ (0.46%) more frequently than the term ‘genderfluid’ (0.23%). In contrast, the trans* population uses the term ‘genderfluid’ (0.57%) more often than the term ‘genderqueer’ (0.28%) in Arkansas. Similarly, as shown in Figure 3, the term ‘genderqueer’ while present in Kansas (0.17%) among trans* people, is used less frequently than ‘genderfluid’ (0.34%) and ‘agender’ (0.43%). In Washington, ‘genderqueer’ (0.77%) and ‘genderfluid’ (0.80%) are used with about the same relative frequency. However, in Florida, we see usage that is the inverse of Arkansas and Kansas; ‘genderqueer’ (0.43%) is used more frequently than ‘genderfluid’ (0.25%). Further, ‘agender’ is used with less relative frequency in Arkansas (0.28%) and Florida (0.33%) than in Kansas (0.43%) and Washington (0.46%).

616
Further, consider the term ‘neutrois’, which describes individuals who feel that they have no gender or are gender neutral. This is an example of a regionally specific term whose meaning cannot be characterized as “not exclusively male or female” (similar to ‘agender’), and as such would not be captured by the options of the sample intake forms surveyed. We found that users classified as trans* used the term ‘neutrois’ in only twelve states: CA, FL, GA, LA, MA, MI, MN, NY, PA, TX, VA, and WA. That is, in addition to states such as CA, MA, VA, and WA that are known for having a large identified LGBT population, ‘neutrois’ appears in the Great Lakes states and some of the Southern states.

**Discussion**

*Generating hypotheses about language preference*

While there are no definitive conclusions that can be drawn from this data alone, the findings suggest the following conjecture: intake forms in the southern United States that use ‘genderfluid’ and ‘agender’ rather than ‘genderqueer’ may have better response rates than forms that use ‘genderqueer’.

Furthermore, in light of the findings of the term ‘neutrois’ in the Great Lake states and select southern states, another conjecture is that trans* populations in these states have a higher incidence of ‘neutrois’ in the free-text ‘please specify’ fields.
Similar conjectures can be generated by comparing the co-occurrence networks at the individual state-level. For example, Figure 4 shows the structures of the two co-occurrence networks around ‘genderqueer’ for trans* in Washington and trans* in Florida. Thicker arcs indicate more frequent co-occurrence.

These co-occurrence networks show regional variations in the co-occurrence of ‘genderqueer’. For example, in Washington ‘genderqueer’ co-occurs with terms ‘trans-boy’ and ‘demi-boy’ that fit the Fenway Health characterization of ‘genderqueer’ (“not exclusively male or female”), but also terms such as ‘agender’ and ‘non-binary’ which are gender identities that do not fit this characterization. On the other hand, in Florida, ‘genderqueer’ does not co-occur with terms favoring one end of a binary spectrum, but it does co-occur with ‘non-binary’. From these observations, we can generate the following conjectures: ‘genderqueer’ denotes a broader set of gender-identities in Washington than in Florida, and in both cases it denotes identities not adequately characterized by Fenway Health’s gloss.

These conjectures, however, stand in need of further testing using formal and controlled methods. One of the trouble spots for our research is that some states have very few relevant tweets collected and few users classified as trans*. Delaware, Montana, and Wyoming each only had one user classified as trans* while South Dakota and Mississippi each has only two. While it is likely that this is because there are relatively few trans* persons in these regions using Twitter to discuss issues related to gender identity, it is also possible that trans* related tweets are not captured in our data set because the language used to discuss these terms are not in our list of keywords. We reviewed the raw data captured to date with the current keyterms to find additional keyterms we have missed, but did not find any in this set. These gaps in data point to the need for tools and methods outside of those discussed in this paper for gathering data and testing hypotheses about variations in transgender identity terms and capturing those that are used by people who are less vocal about their gender identity.

Limitations

Our study suggests that social media data sources such as Twitter can expand the range of what can be easily measured and provide new types of information for mining health-related knowledge. However, in addition to big data challenges, Twitter data has its limitations and may not be reliable for answering certain questions. First, although Twitter has a set of feature-rich APIs and a relatively open policy for scraping, collecting relevant data to answer a specific scientific question is not easy. We collected over 154 million raw tweets in less than two months; however, only a fraction of the data (500,000 tweets) was deemed relevant to our study. Second, we found that even with a list of well-developed search terms, the returned data set had many false positives, which affirms the necessity of building classifiers to further narrow the search results. Nevertheless, the process of building classifiers is a tedious process involving manually annotating a large number of tweets to produce a gold-standard training data; and the accuracies of the classifiers were not perfect. In particular, the recall of the second classifier – finding self-identified trans* people – is low (0.261) indicating that we have missed many true positive cases. This might be the reason that we do not have a large enough corpus for trans* people. More sophisticated features\textsuperscript{30, 31} can be
incorporated into the classifiers to improve the performance. Third, the geographic analysis was coarse-grained, providing only statistics on the state level. Although we attempted to geotag tweets with more fine-grained location information at the city level, the result was not satisfactory due to common conflicts in city names (e.g., Springfield, SC vs. Springfield, MA vs. Springfield, IL). Even though Twitter added the capability to record geocodes (latitude and longitude) and introduced new geographic metadata (‘geo’ and ‘place’), there are very few tweets and user profiles we collected with geocodes available. One possible reason for this phenomenon is Twitter users having to give explicit consent to allow software vendors to record their geocodes. Another possible reason is that geocodes are only available if the tweets are sent from devices that have Global Positioning System (GPS) enabled. More sophisticated geocoding techniques20, 32 may be utilized to provide more accurate and finer grained location information. However, there is no direct way to integrate these techniques into our pipeline.

We note that our study is limited by the user demographics available on social media platforms. The users of social media tend to be younger (e.g., 37% of Twitter users are under 30, while only 10% are 65 or older, as of 201433); and there are power users who exhibit a substantially greater quantity of activity than the average user.34 These characteristics are likely to create sample bias and impose limitations on mining meaningful information that represents a broader population. For instance, Twitter data may not be reliable for mining information about senior citizens.

Finally, we recognize that our methods do not capture data from the trans* people who are less vocal about there gender identities on social media platforms. This is an inherent limitation of social media data sources and affects the coverage of the gender identification terms. However, does not affect our conclusion of the prevalence of differences in using gender identification terms in the public. Thus, we limited our investigation here to people who have made an explicit statement on Twitter about their identity. While the results from Twitter mining do not always yield language that is appropriate in the context of clinical care and research — for example, there is a significant quantity of advertisements for sex work on Twitter and discussions of gender-related slurs — Twitter has the potential to provide a comprehensive snap-shot of the language used by self-identified trans* individuals.

Conclusion

This research shows that mining information on social media platforms such as Twitter can yield valuable insights to guide hypothesis generation in the development of intake questionnaires. While the output of this pilot study is insufficient to guide the development of better intake forms, it can be used to generate hypotheses for further testing. Furthermore, this data set can form the basis of future research in transgender health care. By capturing terms in context, we have generated a data set that will allow us to look at contextually sensitive aspects of the term use such as sentiment analysis in future research. Utilizing social networking resources also produces a data set that will allow us to begin investigating the social influences related to health concerns among transgender persons, which is one of the priority research areas identified by the IOM. Finally, our experiences with mining Twitter data in this study yield a good process in dealing with large textual social media datasets.

mobile Digital Access to a Web-enhanced Network (mDAWN): Assessing the Feasibility of Mobile Health Tools for Self-Management of Type-2 Diabetes

Abstract
The mobile Digital Access to a Web-enhanced Network (mDAWN) program was implemented as an online, mobile self-management system to support patients with type-2 diabetes and their informal caregivers. Patients used wireless physiological sensors, received text messages, and had access to a secure web platform with health resources and semi-facilitated discussion forum. Outcomes were evaluated using (1) pre and post self-reported health behavior measures, (2) physiological outcomes, (3) program cost, and (4) in-depth participant interviews. The group had significantly decreased health distress, HbA1c levels, and systolic blood pressure. Participants largely saw the mDAWN as providing good value for the costs involved and found the program to be empowering in gaining control over their diabetes. mHealth programs have the potential to improve clinical outcomes through cost effective patient-led care for chronic illness. Further evaluation needs to examine integration of similar mHealth programs into the patient-physician relationship.

Introduction
Diabetes mellitus is a chronic illness which affects over 2.7 million Canadians1. 90% of those affected have Type-2 diabetes, a metabolic disorder characterized by the body’s inability to produce and/or use insulin effectively. In 2010, diabetes cost the Canadian health systems $11.7 billion. This number is expected to rise to $16 billion by 20201. The majority of these costs are attributed to health care costs (including those for complications such as cardiovascular disease, limb amputations and kidney disease), disability and work loss2, some of which could be delayed or avoided through improved diabetes management1

Though management can take a number of forms, a growing body of evidence suggests that technology-based outreach increases patient health literacy and access to quality care and there is specific evidence to demonstrate that self-management and monitoring can improve clinical outcomes as well as quality of life in patients with diabetes3-5. The extension from generalized technology to mobile technology is logical as almost 50% of Canadians are using mobile devices to access the internet, and an increasing amount of time is being spent on these devices as compared to traditional technologies such as computers or laptops6. Mobile technologies offer a number of benefits including portability and improved accessibility, and are a particularly interesting platform for health related uses due to their low cost relative to other health technologies and due to the availability of health related applications.

Mobile Health (mHealth) research has begun to document evidence of its potential for chronic disease and diabetes management7,8 and current literature demonstrates positive findings with respect to the use of mHealth tools in a variety of health contexts9-12 however a recent environmental scan of fully implemented mHealth programs in Canada that use remote tracking and analysis of clinical data for patients’ management of diabetes identified a scarcity of fully implemented or sustained programs. We therefore conducted a feasibility study, mobile Digital Access to a Web-enhanced Network (mDAWN), to examine the use of mobile technologies (wireless monitoring sensors, social media, and text messaging) in an attempt to address this gap and to better understand the potential of mHealth programs to support both individuals with type-2 diabetes and their caregivers.

Methods
mDAWN was conducted to determine the feasibility and potential benefits of using mHealth technologies to support patients with diabetes patients and their caregivers. The program included three different mHealth “tools”; SMS, an online community, as well as wireless and manual monitoring devices and participants were enrolled for a 3 month period. mDAWN used an iterative approach to examine the use of mHealth technologies from a patient/caregiver perspective, conducting a pilot study (December 1, 2013 to February 28, 2014) to enrolled a group of patients and caregivers to trial the system and refine our protocol and monitoring strategy and a full intervention with program evaluation from May 1st, 2014 to July 31st, 2014.
Participants were recruited from the general public using convenience sampling. The pilot study engaged 24 participants: 13 patients and 11 caregivers (family members or friends identified as health supporters). During the study, two dyads dropped out due to injury and a lack of interest due to technology delivery delays. The second study group was comprised of 43 participants, 26 patients and 17 caregivers.

In order to be eligible to participate in the mDAWN program, participants needed to be able to receive text messages and access the internet. They also needed to speak English and be at least 18 years of age. Patient participants were offered an honorarium of $100 and caregivers were offered an honorarium of $75. Initially, it was required that patients select a caregiver to participate with them in the study; however, this requirement was removed as potential participants reported that they did not necessarily view the presence of a caregiver as important to their type-2 diabetes management. All participants completed an informed consent process.

Participants took part in a 3-month study during which they received access to a website with health resources and a semi-facilitated discussion forum, bi-weekly text messages with health tips and challenges, and three monitoring devices including a wireless blood pressure monitor which measured systolic and diastolic blood pressure as well as heart rate, a wireless weight scale, and a manual blood glucose meter.

The blood pressure monitor and weight scale were purchased from blipcare (www.blipcare.com), a subsidiary of the Carematix company, as they fulfilled the study target of consumer-marketed technology with wireless connectivity capabilities. Measurements from these devices were automatically uploaded to a secure website, accessible to patients and their caregivers, when taken and could be viewed in a number of different graphical and report formats. The blood glucose meter was standard and patients were asked to measure their blood glucose twice daily and enter these results into an electronic tracking form designed by the study team. Patients and caregivers also had access to a web-portal with health resources and a semi-facilitated discussion board. Access to this webportal was limited to participants and study team members and discussion were started both by study team members and by participants. In addition to this, participants received text messages twice a week over the three month intervention period; the first message was designed to be informative, including a health tip and a link to a matching resource on the website and the following text provided a challenge or a question on the same topic, encouraging participants to interact with other study participants using the web-portal.

During the three month study period, evidence of the mDAWN’s impact was gathered from four sources:
1. Self-reported health measures
2. Physiological outcomes in weight, blood pressure, heart rate, and blood glucose
3. Program Cost and Feasibility
4. In-depth post-study interviews with participants

**Self-reported health measures**

Patients and caregivers were administered an online survey at the beginning and again at the end of the three month interventions. Nine different measures, selected by a literature scan of similar programs and through review by the clinicians on the research team, were administered to participants. We chose a large number of measures to scrutinize which ones could best reflect the impact of mHealth activities. A statistical and theoretical analysis led to the selection of the following measures for pre-post comparison:

Health Distress: measures how much distress a person experiences directly related to their health in the past month. It is more specific to distress stemming from health issues rather than a general measure of anxiety or depression. The lower the score, the less distressed a person is about their health.

eHealth Literacy (eHEALS): measures the ability to read, understand and communicate about health information in regards to internet resources to make informed health decisions. High eHealth literacy is indicated by a high score on this measure.

Diabetes Empowerment – Short Form (DES-SF): measures psychosocial self-efficacy of people with diabetes, dissatisfaction, readiness to change, and goal attainment. The higher score, the better the patients’ sense of empowerment when it comes to managing their diabetes.
Quality Adjusted Life Year (QALY) Index: a measure of disease burden that assesses the quality and quantity of life lived in one year ranging from 0 to 1.0, with 1.0 being a full quality life year lived. It is typically used in assessing the monetary value of a medical intervention. The Euroqol 5D-5L (EQ-5D-5L) and United Kingdom look-up table was used to obtain the QALY values for this study.

Two measures were not included beyond a preliminary analysis, the Patient Activation Measure (PAM) and Patient Health Questionnaire (PHQ-9) due to high correlations which indicated overlap with other measures. The PAM is a broad measure of confidence with health management and is not diabetes-specific. The PHQ-9 measures depression, but not in relation to a person’s current view of their health otherwise. Social support scales were excluded as patients did not identify with being in need of a caregiver. (Measures of social support that were considered: Multi-dimensional Scale of Perceived Social Support (MSPSS), Zarit Burden Interview, and Kingston Caregiver Scale).

Physiological outcomes in weight, blood pressure, heart rate, and blood glucose
Data was analyzed from patients’ weight, systolic blood pressure, and blood glucose measurements. Additionally, patients visiting their physicians before and after the study to provide a measure of HbA1c. Weight and systolic blood pressure data were automatically uploaded to the Carematix website when a patient took a measurement. The Carematix website had a patient facing site where the participants could securely sign-on and review their self-monitoring data as well as an administrative side where the research team could view data from all participants.

Participants were asked to obtain their glycated hemoglobin (HbA1c) from their physician prior to the mDAWN study and at the end of the three month program. Blood glucose measurements were collected by patients manually and then emailed to the research team. Patients were instructed to measure their blood glucose twice a day at alternating times every other day. Specifically, patients would measure when they woke up in the morning and before they went to bed on one day and then the following day they would measure before lunch and then again before dinner. This resulted in an aggregate view of blood glucose at four times a day: (1) at wake-up (morning), (2) before lunch time (midday), (3) before dinner (evening), (4) before bed (late evening).

Program Cost and Feasibility
An environmental scan was conducted to identify research or clinical programs similar to mDAWN for comparison in implementation and costs. The search was limited to programs in Canada that use technology to improve health outcomes for people with diabetes by enabling remote tracking and analysis of clinical data.

This scan focused on three information areas: peer-reviewed literature (from 2008 to 2014), grey literature and key informant outreach. Grey literature included a review of national and provincial health organization publications, press releases, internal reports and other online documentation. Sixty inquiries were made of key informants around organizational use of mHealth programs for diabetes management.

Patient participants were also given a cost-feasibility survey at the end of their post survey that asked about annual household income, what devices the participants’ were most likely to pay for, how much they would pay to use mHealth devices to manage their type-2 diabetes and the perceived value of an mDAWN-like program.

In-depth post-study interviews with participants
Patient and caregiver participants were invited to take part in a structured interview about their overall program experience with mHealth and how it could fit into their interactions with the health care system as well as specific experiences with the program content (resources, text messages, discussion board, and monitoring devices).

Results

Self-Reported Health Measures
Two pre and post-test comparisons were done, one for patients only, and one for patients / caregiver dyads. Patients’ pre and post test scores were compared on the selected self-report health measures, HbA1c, health distress, diabetes empowerment (DES-SF), and eHealth literacy (eHEALS). Dyads were analyzed for comparisons between patients and caregivers as well as pre and post-test measures on health distress, eHealth literacy (eHEALS) and QALY.

A one-way within groups multivariate analysis of variance (MANOVA) was conducted to assess patient pre and post - test differences on HbA1c, health distress, diabetes empowerment, and eHealth literacy. There was a
statistically significant difference between pre and post testing, Wilks’ Lambda = .391, F (4, 11) = 4.28, p = .025. The effect size for the overall model using partial eta squared was .61 indicating a very large effect. Each dependent variable in the model had a partial eta squared of over .138, which is a generally accepted criteria (Cohen, 1988) for a large effect. HbA1c, health distress and diabetes empowerment scores all saw changes in a positive direction, with HbA1c and health distress lowering and diabetes empowerment increasing. HbA1c decrease is not only statistically significant, but also clinically significant in dropping from 7.41 to 6.77 (see Appendix A, table 1), with 7 as the clinically acceptable upper limit of normal. eHealth literacy decreased from pre to post test. See Table 1 in Appendix A for the means, standard deviations, and partial eta squared of each variable.

A mixed within and between groups MANOVA was conducted to assess differences between caregivers and patients on pre and post-tests of health distress, eHealth literacy, and quality-adjusted life year (QALY). There was a statistically significant interaction between patients and caregivers across pre and post-tests, Wilks’ Lambda = .533, F (3, 12) = 3.5, p < .05. The partial eta squared was .467 indicating a large effect. Patients reported a significant decrease in health distress, whereas caregivers reported an increase with a large effect size of .405 (partial eta squared). Similarly, QALY scores increased for patients and decreased for caregivers with a moderate effect size of .079. Both patient and caregiver eHealth literacy scores decreased, but with no effect size to report (partial eta squared = 0). See Table 2 in Appendix A for patient and caregiver means and standard deviations.

Physiological Outcomes
Weight and systolic blood pressure were each analyzed with a one-way repeated measures analysis of variance (ANOVA) and blood glucose was analyzed using a two-way repeated measures ANOVA to examine measurement time and changes across the three months of the intervention.

There was no significant decrease in the group’s average weight (Wilk's Lambda = .859, F (2, 14) = 1.15, p = .346), though the group lost an average of 3.51 pounds. Additionally there was a significant negative correlation between number of weigh-ins a participant completed and their weight difference by the end of the study (r = -.69, p < .01) indicating that the more a participant weighed themselves, the more weight they could be expected to lose.

There was a significant decline in systolic blood pressure across the three months, Wilk's Lambda = .49, F (2, 11) = 5.7, p < .02. A multivariate partial eta squared .51 was found, indicating a large effect. Further examination using a trend analysis showed that the significant drop occurred from month 1 to month 2 with systolic readings climbing back up again slightly in the third month (quadratic trend F (1, 12) = 7.79, p < .016, partial eta squared = .394).

Blood glucose data was analyzed according to the four measurement times (morning, midday, evening, and late evening) across the three mDAWN months to elucidate if there was a difference over the three months in each of the four measurements. Data was analyzed using a two-way repeated measures ANOVA. There was no interaction effect for time and month (Wilk’s Lambda = .80 F (6, 60) = 1.15, p = .35).

Program Cost and Feasibility
The environmental scan of diabetes-focused mHealth programs revealed that there are very few published evaluations of remote monitoring programs- while a number of pilot programs featured remote monitoring, none appeared to have a mobile component or reported outcomes beyond the pilot stage. Outreach to key informants supported this finding, with most stating that they were unaware of any mobile health programs for diabetes being used within their organizations. Many were familiar with mobile apps for diabetes management, and multiple respondents expressed interest in learning more about the outcomes of mDAWN, however, no baseline was found to provide a cost comparison point for the mDAWN program.

Patient participants in the second study group also completed a cost survey at the end of the program. In this survey, participants were provided with information about the variable costs of the program and asked questions designed to help the study team understand the perceived value of a program such as mDAWN. 24 participants answered the cost survey, though not all respondents answered all questions. Key findings are illustrated in Table 4.
Household Income

The total cost per person of the mDAWN study is $25 per month for the monitoring service, $35 a month for blood glucose test strips, and $365 for the monitoring devices (weight scale, blood pressure monitor, and blood glucose meter). If you were to purchase an mDAWN-like system yourself, you would spend $365 at start-up and then $60 a month after that. Please choose the statement below that best describes how the program cost suits you.

Table 4. Cost Survey Results

**In-Depth Post Study Interviews with Participants**

All participants indicated an overall positive experience with the mDAWN program, finding their participation beneficial. Common themes that emerged from the participant interviews were the creation of self-care routines and habits, increased self-awareness, and participant empowerment. Participating in the mDAWN program increased awareness of diabetes and of the self, related to diabetes. Particularly, participants expressed an increased understanding of how their lifestyle can affect their glucose control, weight or blood pressure measurements. More importantly, through their experiences in the program participants were able to connect and apply the information provided to their own lives. In turn, making these connections allowed participants to effect positive changes in their lifestyle including exercise and eating habits and to achieve goals such as reducing HbA1c levels, weight or blood pressure measurements.

Participants’ experience in the program also increased their sense of empowerment. Throughout the program participants gained an appreciation that they were ultimately responsible in caring for their diabetes. Participants felt that the program provided the right amount of accountability, incentive, and support to allow them to achieve their goals. Some participants indicated that participating in the program increased their feelings of control and level of confidence in their ability to care for themselves. Being generally participant-led, the mDAWN program gave participants the tools and knowledge while still allowing considerable freedom. This allowed participants to take ownership over the positive changes they achieved while participating in the program.
This new sense of self-confidence carried over into their expectations of future interactions with their doctor, as patients noted that they were now able have a more knowledgeable conversation and were more confident in knowing which questions to ask. In essence, participants felt they were now more “activated” patients who would be more involved in making decisions about their care with their doctors.

Discussion

The mDAWN patient group was able to achieve lowered health distress, HbA1c, and systolic blood pressure as well as an increase in diabetes empowerment over the course of the 3 month study. During interviews, the group reported that they were able to achieve their health goals through a bolstered sense of empowerment. Additional findings in our study based on pre- and post-study self-report health measures are worthy of further consideration: the decrease in both patients’ and caregivers’ perceived eHealth literacy and the rise in caregiver distress. The study team can hypothesize that the decrease in eHealth literacy may be a case of participants ‘not knowing what they don’t know’ at the beginning of the study - feeling that they had a good handle on how technologies have then discovered new digital ways to improve health through the mDAWN program. This “broadening of horizons” could have affected their perception of their own eHealth literacy. The rise in caregiver stress found in the study might be caused by the more constant linkage of them with their patients with potential 24/7 connectivity, thereby triggering a sense of rising responsibility. Recent studies and news reports indicate that caregiver burden can be a source of negative health outcomes, and our current findings may suggest a more nuanced view: that taking on or imposing the role of caregiver may be a factor in negatively impacting health for the caregivers themselves. Further research should be conducted in order better understand these results.

In terms of cost, participants largely identified the mDAWN program as providing good value for money and indicated that hypothetically, they would be willing to pay the fees associated with a program like this. While willingness exists, more than half of the participants (56%) also indicated that based on their current income they would be either unable to afford the program, or that they would find it to be a significant financial burden. Questions regarding cost sharing between the patients and the health system funder, in our case the provincial medical program, found that 52% of participants interested in continuing the program would only find it feasible to do so if the cost was zero. It should further be noted here that over half of mDAWN participants had a household income of less than $60,000/year (below that of the national average). This suggests that in order for a program like this to be successful and feasible for all participants, cost-sharing with the health-system or subsidies must be considered. Cost considerations in future studies should include considering how to build a cost model comparison point which is flexible to changes in technology development that impact accessibility and price, as well as exploring strategies which support sustainable and affordable programs.

Results from the mDAWN feasibility study suggest that the mDAWN system, in the context of type-2 diabetes self-management, can improve clinical outcomes and overall wellbeing. Key aspects of the program’s success include the synergistic use of physiologic sensors and social media. This combination of monitoring devices and a secure social media platform empowered participants by providing them with a unique combination of autonomy and connectedness. The monitoring devices allowed patients to quantify their own health data and apply it recognize patterns in their health and understand how lifestyle choices were affecting their wellbeing. Sharing insights on the social media platform provided opportunities to learn from others, share and celebrate success, and created a sense of accountability to a community. This unique combination of autonomy and connection to a peer group was highly valued by participants and identified as a key part of increasing patient empowerment.

This finding supports the validity of the behavioral change model put forward by Bandura (1986) which asserts that that three key sequential steps are needed to affect behavior change, self-monitoring, self-evaluation, and behavior modification, and that these steps work in synchrony and in a continuous cycle of positive reinforcement. Our findings in this study may be applicable to not only diabetes self-management, but also chronic disease self-management in general.

Limitations

The mDAWN program explored the feasibility of a mHealth based program for type-2 diabetes. A convenience sample was used which resulted in a study group with high pre-study levels of motivation, eHealth literacy, and activation and relatively low levels of health distress and perceived burden. While the study has addressed the key
research questions, the findings of this study cannot at this point be generalizable to the general population. Further research needs to be conducted to fully understand:

- What value can a mHealth program provide to patients with low levels of motivation or health engagement? Recruitment for mDAWN attracted participants who were interested in improving their health. While mDAWN supported improved outcomes for these individuals, we are unable to say how this program might work with a less-motivated patient group.
- Can those who might not be as familiar with mobile health technologies still find this system useful for them? For those who use social media relatively less than the mDAWN study group, is the social media component of this program of value to help them connect with their peers?
- How can health professionals add value to this monitoring system? Our study did not include health professional participation and focused on the value of mhealth tools when used independently by patients. This is in contrast to many conventional remote patient monitoring studies which commonly put patients in a passive role of being managed by health professionals. While both strategies have benefit, there is a gap in knowledge regarding both the value that mhealth tools might offer to the health professional-patient partnership model, as well as a lack of information regarding what would be required to fit this sort of system into existing workflows. Further research is necessary to understand how health professionals can best support patients in the use of mHealth tools as part of an integrated self-management plan.

The next step in this evaluation would be to conduct a clinical trial to address the questions above, and also to allow for the quantification of the benefits seen in this feasibility study.

Uncertainty, Case Complexity and the Content of Verbal Handoffs at the Emergency Department

Jan Horsky, PhD,1,2 Edward H. Suh, MD,3,4 Osman Sayan, MD,3,4 Vimla Patel, PhD5

1Brigham and Women’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3New York-Presbyterian Hospital, NY, 4Columbia University Medical Center, NY; 5New York Academy of Medicine, NY

Abstract
Handoffs are known to increase the risk of medical error and adverse events. Few electronic tools can support this process effectively, however. Our objective was to describe the relationship between clinical complexity, diagnostic uncertainty, fit with illness script and the content of case presentations by physicians. We observed the handoff of care for 150 patients during eleven shift changes at a large urban emergency department (ED). Results indicate that as uncertainty about diagnosis and perceived illness script increased, more descriptive detail was conveyed to the incoming physicians. Physicians were concerned primarily with creating a shared mental model of a patient’s clinical state and with describing the expected path to disposition rather than simply passing on data and findings. Electronic tools for ED handoffs should allow adjustment of structure and content to capture complexity and uncertainty appropriately without requiring extra effort for more routine cases that better fit to more standard narratives.

Introduction
Physicians transferring the care of patients to another team at the end of a shift have the challenging task of collecting sets of clinical data with laboratory results, test findings, significant events and gathering other sometimes complex evidence that collectively characterize a patient’s course from complaints, problems and clinical decisions to disposition plans. All information needs to be presented to incoming clinicians as a succinct narrative of interconnected events that can be accurately interpreted in order to allow them to continue care without delay. Research evidence suggests that handoffs engender misinterpretations and omissions that may lead to medical errors and adverse events1,2 but that these discussions also afford the opportunity to consider alternative viewpoints, correct mistakes and propose new tests or interventions.3 Efforts to analyze and improve the process generally assume that its primary goal is a unidirectional and complete transfer of information between individuals and teams on adjoining shifts. However, it is also an opportunity for a dialog in which participants co-construct and negotiate a shared understanding of existing clinical issues and check the accuracy of medical reasoning and prioritize next steps.4

Developing a shared mental model of illness and care by the active involvement of both parties during a handoff is particularly relevant to emergency medicine where adequate and reliable information may not be available and where uncertainty about symptoms, presentation and several possible diagnoses create ambiguities that allow different interpretations.2,5 Interventions and strategies intended to make handoffs more robust and resilient toward misinterpretation and loss of important facts usually emphasize training, standardization and the use of checklists and structured forms as best practices.6 This approach has clearly reduced adverse events in some settings7 and has appropriate application in specific areas of care.

Intrinsic to emergency care, however, are frequently changing priorities, time limitations, the need to treat multiple patients concurrently and large variations in problem complexity and acuity that are encountered and treated on a single shift. When the incoming team takes over, patients are at very different points in their care trajectory. Uniform and inflexible handoff structure is therefore not likely to provide support to clinicians effectively and may even introduce costly unintended consequences.8 For example, in an environment where time and attention needs to be allocated to many patients simultaneously, detailed, exhaustive documentation of routine problems or standard treatments may in effect reduce the opportunity to discuss complex and uncertain conditions or unfolding events.

Theories of cognition distinguish between reasoning strategies that people use in ambiguous, complex and arbitrary situations to develop insight and understanding and those used in predictable or familiar conditions. Problems that can be articulated within clearly defined categories, relationships and hierarchical structures, such as a relatively uncomplicated or routine illness and care history, are generally best evaluated and resolved by the use of paradigmatic reasoning. Standardized handoff tools and templates will likely improve human performance and reduce the occurrence of errors for these cases. By contrast, a narrative mode of reasoning becomes more effective for complex
problems as it organizes knowledge into temporal plots, linking specific events into causal chains and emphasizes consequential connections among them.\textsuperscript{9} Highly structured, static forms of support will not align well with uncertain diagnoses and indeterminate illness scripts. Modern handoff tools will need to support both cognitive strategies equally well.

Current methods of coordinating handoff procedures and organizing communication provide an important foundation for tool development but may be conceptually limiting.\textsuperscript{10} Market innovation has not yet adequately addressed existing design challenges and electronic handoff modules often resemble or mimic paper forms,\textsuperscript{11} providing little meaningful support for diverse cognitive tasks. Studying handoffs from the perspective of uncertainty, complexity and perceived fit to illness script is in our opinion a productive approach to identifying and describing cognitive strategies that are used in different clinical situations and that may need different kinds of support. For example, new insights may inform the design of electronic tools that will be appropriate for the volume and character of information discussed between outgoing and incoming teams for patients with high and low levels of diagnostic certainty or who are at a different stage in their emergency department (ED) trajectory. The goal is to give clinicians the right information in a form that will allow them to make timely and effective interventions when needed and to sustain the care process uninterrupted across shift and unit boundaries.

Our objective was to observe discussions of physicians during handoffs and to analyze how case complexity, uncertainty and fit to illness script affect the content of their patient case presentations. This predominantly descriptive and exploratory study was intended to report findings from a research perspective not frequently present in publications and also to test our assumptions about the relationship between uncertainty levels, clinical complexity and different needs of cognitive support.

**Background**

There seems to be little convergence in clinical research literature on the characterization of a good handoff\textsuperscript{12} and little published evidence on what constitutes best practices.\textsuperscript{13} Many quality measures have been proposed although there is a general lack of consensus on the primary purpose of handoffs and how to best improve the process.\textsuperscript{14} For example, one rating scale assessed information transfer, shared understanding, working atmosphere, and overall quality\textsuperscript{15} and another rated, on a nine-point scale, performance in interviewing, physical examination, humanistic qualities and professionalism, clinical judgment counseling, and organization and efficiency.\textsuperscript{16} Recognizing that there are multiple purposes for handoffs that need to be addressed simultaneously is a critical precursor to quality improvement.\textsuperscript{17} Studies of uncertainty in clinical work also give a somewhat fragmented and incomplete account of its effects and important insights have not been translated to practice.\textsuperscript{18} One taxonomy conceptualizes uncertainty as a multi-dimensional phenomenon with theoretically distinct domains and constructs that are potentially measurable and related to different outcomes, mechanisms of action, and management strategies.\textsuperscript{19} A measure developed to study clinical reasoning strategies during patient visits and derived in part from a cognitive engineering framework includes assessment of uncertainty that refers to how well limitations of available information are recognized, explained and solutions are planned to adjust to the current situation.\textsuperscript{20} Our current framework uses uncertainty for this study in a similar way to analyze its relationship to reasoning and the amount of detail conveyed in narrative accounts of care during handoffs.

Cognitive and human-computer interaction studies in healthcare have shown that team and system interaction,\textsuperscript{21} staff workload,\textsuperscript{22} clinical workflow and the effects of technology on decision making and cognition\textsuperscript{23} need to be investigated if new information technology is to be meaningfully integrated into the process of care. A design paradigm that embodies this comprehensive approach and is employed routinely for the design of safety-critical systems (although still somewhat sporadically for health information technology) is User-Centered Design.\textsuperscript{24} The most common method for gaining insights and understanding of tasks and the environment is direct observation of work and ethnographic studies. Our investigation contributes to the body of knowledge about the handoff process in emergency care and can be used as a starting point in the design of new technology to support clinicians.

**Methods**

We observed clinicians during rounds in the ED and recorded their conversations concerning patient care handoffs. Eleven scheduled shift changes were studied on ten days over a four-month period. On each occasion, a group of two to three outgoing ED residents presented between seven and twenty-two patient cases to an incoming attending physician. The aggregated time of all recordings was 190 minutes (17 minutes on average) and contained conversations about 168 patients. Recordings were transcribed, de-identified (when names were audible) and reviewed by two physicians to correct errors and misinterpretations. Eighteen patients were excluded either because
they had not yet been formally seen or because of poor recording quality. The remaining 150 cases were analyzed in this study.

Setting

The study was conducted in the main adult ED of a large academic hospital in an urban area. The annual census is approximately 88,000 in three clinical districts and a separate fast-track area. Two of the districts have shift changes for all providers twice a day, at 8am and 8pm. The attending physicians and senior residents in the third district have three shifts a day, ending at 8am, 4pm, and at midnight. Emergency medicine residents, those rotating from different services and attending physicians will “round” as a group on all patients in the district. These rounds constitute the usual handoff process between the teams. At the time of data collection, no program for improvement of handoffs had been implemented. Rounds were primarily recorded at 8am and 4pm when the census tends to be significantly lower than when shift change occurs at 8pm and midnight. A fully integrated EHR system was used for virtually all clinical activity.

Analytical constructs and coding scale development

We operationalized the assessment of uncertainty along three axes with 3- and 2-point scales. The constructs were derived from established concepts in medical education and clinical care that are well described in literature and have generally accepted meanings. They were developed and refined iteratively in a series of meetings and conversations. For example, scales were initially proposed to have 5-points but were subsequently simplified so that they were more appropriate for describing variations encountered in the analyzed sample.

Apparent Diagnostic Uncertainty estimates the amount of confidence physicians seemed to have in their understanding of the disease process that lead to the acute presentation. The concept may be defined in ways that are specific to clinical context. In our interpretation, uncertainty about a diagnosis may originate from the lack of expert knowledge, level of training, experience with a particular disease and its presentation, and also from information conveyed by patients whose clinical history may contain ambiguity.

Apparent Fit with Illness Script to typicality of the presentation for a particular complaint or diagnosis is based on a theoretical framework describing how experts prioritize syndrome recognition through comparing and contrasting key clinical features in making a diagnosis. Expert clinicians use illness scripts most of the time in their clinical reasoning since it involves a highly efficient knowledge-driven model of pattern recognition.

Clinical Complexity was an assessment regarding the number of complicated elements and the overall extent of problem complexity classified on a 2-point scale. The complex patient has been described as “one for whom clinical decision-making and required care processes are not routine or standard.” Our characterization of the concept is...
somewhat qualitative as the definition is difficult to translate into quantitative terms. Definitions of each scale level are in Table 1. The acuity of each case and disposition status were also assessed as a secondary descriptive measure.

The amount of descriptive detail in communications about each patient as presented by the outgoing physician was classified into three categories: History of Present Illness and Physical Examination, Diagnostic Findings and Course of Treatment. The categories correspond to standard components of evaluation practice in the ED. They were aggregated into the Informational Content measure and scored on a three-point scale (Table 2). Assessment and classification definitions were developed by two physicians (authors) based on their clinical expertise and detailed knowledge of emergency care and further refined (originally from a 5-point scale) through consensus in a series of meetings and conversations. Audio recordings and their transcripts were scored by an ED physician (author) and results reviewed and revised in collaboration with another physician (author) to assure appropriate coding and classification.

The dataset was uploaded to SAS 9.3 statistical software111 and tests were performed on the Confidence and Informational Content sets of variables. Non-parametric analysis of variance for ordered values (Jonckheere–Terpstra Trend Test) was used as a measure of difference between groups with three levels of a predictor variable. The levels of Clinical complexity were analyzed using the Wilcoxon Score (Rank Sums) test.

Results

The assessed acuity of most cases (67%) was found to be of small to moderate likelihood of morbidity and mortality. Nine cases (6%) were considered more serious and for twenty-nine (19%) acuity was not possible to determine. Disposition status at the point of a handoff was to admit (including boarding) for 86 (58%), discharge for 13 (9%) and under evaluation for 51 (33%) patients. Informational detail conveyed by the presenting to the incoming physician increased with rising diagnostic uncertainty and case complexity. Results are provided below. Measures are compared to the History of Present Illness and Physical Exam, Diagnostic Findings and Detail of ED course.
Apparent diagnostic uncertainty

Two patients did not have any history or physical examination discussed and for 25 (17%) diagnostic uncertainty could not be determined from the recordings. The remaining sample of 123 patients was analyzed (Figure 1). Most patients (76, or 62%) either had a narrow differential diagnosis or the process for a workup was well defined. The extent of communicated history and physical exam detail was mostly minimal, with a smaller proportion of patients with a moderate or detailed description. Similar pattern was observed for patients with a presumptive diagnosis. This trend was reversed when the diagnosis was uncertain where most patients (42%) had a detailed description. We found the statistical difference between groups with Presumptive, Differential and Uncertain diagnoses for levels of informational detail about the history of present illness and physical examination to be significant (p=0.0009).

The quantity of Diagnostic Findings in the presentations was mostly minimal for all groups (Figure 2). Equal proportions of cases had no or moderate levels of descriptive detail, and patients with the most detailed explanations represented the smallest proportion in each group. This trend was most pronounced for differential diagnoses that were described only in minimal descriptive detail, for 43 patients (35%). Patients with uncertain diagnoses tended to have larger proportions of detailed description than other groups. Difference between groups with Presumptive, Differential and Uncertain diagnoses was statistically significant for levels of detail about diagnostic findings (p=0.024).

The Detail of ED course was described for all groups in a pattern similar to Diagnostic Findings although differences between the levels of detail were not statistically significant. The sample consisted of 125 patients: 25 (17%) were excluded because the ED course could not be determined from the recordings.
Two patients did not have any history or physical exam discussed and for 44 patients (29%) the fit to illness script could not be determined from the recordings. The remaining sample of 106 patients was analyzed (Figure 3). Most patients had a typical presentation of an illness (61, or 58% of total) and were most likely to have a minimal description of history and physical (29 or 48% of their group). Those with a variant or atypical presentation were most likely to have a moderately detailed description (16, 55% in group) and those with no apparent fit to an illness script a detailed description (8, 50% in group). Statistical difference between groups with a Typical Presentation, Variant and No Fit with illness script was significant for levels of informational detail about the history of present illness and physical exam (p=0.01).

Diagnostic findings were communicated mostly at a minimal level of description and with a higher level of detail for only three patients (2%) (Figure 4). However, patients with no apparent fit of presentation to an illness script tended to have more information conveyed during the handoff. Statistical difference between groups with a Typical Presentation, Variant and No Fit with illness script was significant for levels of informational detail about Diagnostic Findings (p=0.02).

The Course of Treatment in the ED was communicated in a pattern similar to Diagnostic Findings with a slightly larger proportion of detailed descriptions for all groups. Differences in the amount of descriptive detail between groups with different uncertainty levels were not statistically significant, however. The sample consisted of 106 patients as 44 (30%) were excluded because fit with illness script could not be determined from the recordings.
Clinical complexity

Two patients did not have any history or physical exam discussed, for 30 patients (20%) clinical complexity could not be determined from the recordings and five patients with simple problems were excluded as the group was too small for analysis. The remaining sample of 115 patients was analyzed (Figure 5). Clinical complexity was moderate for 53 patients (46%) and 62 (54%) had more complicated problems. Both groups had about the same proportion of minimal and moderately detailed descriptions of history and physical exam but complex patients had more detailed narratives. Observed statistical difference between groups of clinically moderate and complex patients in levels of informational detail about the history of present illness and physical exam approached significance (p=0.058).

Trend patterns and the distribution of descriptive detail in communication was similar for diagnostic findings and course of ED treatment, with higher proportions of detailed descriptions for more complex cases. The difference between groups of clinically moderate and complex patients in levels of informational detail about diagnostic findings was significant (p=0.001) and approached significance for levels of detail about course of ED treatment (p=0.051).

Discussion

This preliminary investigation shows an association between the extent of descriptive content in verbal communication during handoffs and the level of confidence in diagnosis and probable course of further care that the outgoing physician has. As diagnostic uncertainty rises and the fit of the illness to a recognized script is less typical, the amount of detail in the history of present illness, physical examination, diagnostic findings and the course of care increases.

We have observed several trends in the way diagnostic uncertainty changed during a typical ED course. For many patients, there was initially a high degree of uncertainty about the cause of the presentation and about best ways to evaluate before deciding on disposition. As information was gradually gathered a corresponding reduction in the degree of uncertainty usually ensued but could also rise again when new data did not confirm expectations and hypotheses or new complications arose. A scheduled handoff could happen anywhere on this trajectory and clinicians would need to reason about the same patient differently. An innovative handoff tool would allow them to select the right modality to support the creation of their report or guide their discourse. Patients can be signed out from one provider to the next at virtually any point along the course of evaluation and treatment, at points when uncertainty may be at its peak, its lowest level or anywhere in between. Our analysis has demonstrated that there is a tendency towards giving fuller and more complete accounts of information when the degree of uncertainty is higher.

Diagnosing a patient with a high degree of confidence is generally of less concern to ED clinicians than the process of reaching a disposition. In the context of emergency care, a definitive diagnosis is often elusive, and the constant influx of potentially critically ill patients makes time and cognitive resources precious commodities. There is rarely a complicated plan for treatment that needs to be conveyed, as priorities are in addressing immediate, most critical and time-sensitive needs of new patients seeking care. Incomplete information is a routinely expected condition as are rapid changes and new developments and physicians typically view their role as stabilization and disposition rather than securing definitive diagnosis and management. It is therefore important to emphasize in the handoff process the aspect of collaborative discussions and review. Our contention is that ED physicians are not primarily concerned with transmitting sets of data about patients from one to another in handoffs. Rather, they engage in the process of
developing a shared mental model of each patient’s current state and expected path that can be quickly and accurately adopted for care. These mental models function similarly to individual illness scripts, but encapsulate the entire process of evaluation and disposition, including the prospects of multiple possible outcomes.

When the presenting physician feels uncertain about which pre-defined ED “process script” is appropriate for a patient, the handoff cannot consist only of heuristics but is necessarily more detailed. This allows the incoming team to more explicitly contribute to the understanding of the patient’s state and invites their input into the current plan of management. The narrative of the patient encounter becomes much more valuable to the incoming physicians in constructing their own understanding of the situation, especially where there is asymmetry between the roles of those giving and receiving a report, as it exists for example in teaching hospitals. A form of a handoff decision support would help both parties to navigate through this situation and perhaps provide patient-specific advice to guide their discussion. However, when patients do fit well onto an established process script and expected trajectory, the value of adding additional detail to the handoff is questionable. Required data are usually available in the EHR already.

Rounds were conducted by walking from patient to patient, carrying printouts of the ED status board that includes the patient name, age, and chief complaint as documented in triage and boxes that indicate if laboratory tests, radiology studies and nursing orders are completed or pending. However, these indicators were quickly out of date and were considered unreliable. There were also columns that show the current disposition, and if planned for admission, the assigned admitting team. This information is also not reliable and is usually verbally reviewed. Only one ED attending routinely conducted rounds with a mobile computer workstation. Mobile technology such as tablet computers may serve as a convenient technology platform for handoff tolls so that all parties have access to updated, shared information that is unobtrusively present during discussions.

Our emphasis on the changing rather than stable components of a handoff process is not contrary to the current effort to standardize handoffs in order to achieve more successful transfer of information. Consistency and predictability are core design principles that have been known improve communication speed, clarity and to reduce errors of omission. Checklists or other structural constants would be essential in the ED to quickly and accurately document routine cases with low complexity and high levels of certainty in diagnosis and disposition plans. We are proposing that often the ebb and flow of information is a meaningful variation and when the reasoning of clinicians follows a strategy that needs to account for ambiguous, missing or uncertain information, standardization would not adequately fit the model. Designers would need to include this source of variation into their tools to make them more flexible in supporting the sharing of mental models in authentic conditions of emergency care delivery.

We are not aware of any published tools or programs that explicitly address this understanding of the handoff and believe that a valuable direction for future investigation would be continued research into the nature of the types of information conveyed in the handoff and their usefulness. However, it seems apparent that one size does not fit all, as it were, when sign-out tools and processes are concerned.

Limitations

We did not have access to written and electronic information that was used many physicians during rounds and for documentation of care. Verification and comparison of verbal and written communication was therefore not possible which sometimes limited our insight into the clinical cases that were discussed. The study design was somewhat limited by our focus on the verbal report of the outgoing physician and did not capture the understanding of the incoming physician. This would be an important aspect of the mental model sharing description and would need to include interviews with physicians and other forms of data collection.

Observations were limited to one institutions so the findings may not be directly relatable to other emergency departments, particularly in non-teaching hospitals. Our exclusive priority was on physicians and relevant communication between nurses and other clinical staff in the ED that is also critical to the process was not captured. Our estimates of the stage of the ED process care in which a particular patient was at the time of handoff are often not accurate. This knowledge would be important to validate our assumption about variations in uncertainty along the course of care.

Conclusion

Evidence supporting medical decisions is often shared among clinicians in a written form (electronic or otherwise) as a part of diagnostic and care planning documentation. In the time-constrained environment of emergency care, verbal presentations and discussions during rounds and handoffs are essential for developing a more comprehensive understanding of findings and symptoms and for increasing confidence and certainty through consensus, especially in
the absence of complete information or distinct manifestations of known illness trajectories. Both forms of communication are necessary as they seem to have complementary roles in refining and sharing knowledge that will be the basis for further treatment decisions and interventions. Electronic handoff tools that could direct and focus verbal discourse by allowing clinicians to identify and point out missed or possibly misinterpreted evidence from notes or to elicit opinions and clarifications from other parties may be more effective in safeguarding the integrity of communicated information than a simple demand for completeness regardless of case complexity or apparent good understanding of the patient case by those involved. This view is framed in theories of cognition and management of uncertainty under time-constrained conditions and situated in a larger socio-technical context. Better understanding of the process will have positive implications for both training and design of rounding and handoff tools specific for emergency care physicians.

The importance of understanding handoffs is well recognized by the clinical research community. A well-executed handoff, in our view, is not necessarily one with the most details or high levels of completeness. Rather, the ability of the incoming clinician to make well informed and timely interventions when a patient’s state suddenly changes is seen as a high benchmark of safe and quality handoff process. We hope that our work will provide insight and guidance for the development of modern electronic support tools and best practices for effective and safe handoffs of care in the ED.

Acknowledgements

Our thanks are due to the many clinicians who let us observe their work on numerous occasions and were generous with their insights and expert advice, and to our research associates who recorded their conversations. We are also grateful to the James S. McDonnell Foundation for funding this study.

Surgical Duration Estimation via Data Mining and Predictive Modeling: A Case Study

N. Hosseini, PhD¹, M.Y. Sir, PhD¹, C.J. Jankowski, MD², K.S. Pasupathy, PhD¹

Abstract
Operating rooms (ORs) are one of the most expensive and profitable resources within a hospital system. OR managers strive to utilize these resources in the best possible manner. Traditionally, surgery durations are estimated using a moving average adjusted by the scheduler (adjusted system prediction or ASP). Other methods based on distributions, regression and data mining have also been proposed. To overcome difficulties with numerous procedure types and lack of sufficient sample size, and avoid distributional assumptions, the main objective is to develop a hybrid method of duration prediction and demonstrate using a case study.

Keywords
Classification, prediction, hybrid method, regression, surgery times

1. Introduction
Accurate prediction of the duration of surgical procedures is necessary to meet the needs of stakeholders. The duration of the procedure is critical in determining optimal schedules, and to reduce delays for patients and providers as well as reducing overtime and under-utilization of operating rooms (ORs) for administration. As surgeries get scheduled, the surgery duration is estimated and an appropriate day is selected to schedule the surgery. Currently most hospitals use software designed by commercial surgical scheduling systems from EMR vendors such as Cerner, Epic, etc. Both traditional method of surgery prediction and those used by commercial software used in most hospitals is based upon a moving average of previous cases, based on surgeon and procedure codes. This warrants the need for a scientific method to predict duration. With the increasing amount of data in healthcare and the need for making improvements in the hospital industry, it is critical to use more efficient methods of surgery prediction that can improve system performance and encourage physicians and hospital staff to not only think about the success of their own practice as an individual surgeon but also think of improving the performance of the hospital as a system. In this study, we consider data from a large hospital and propose a hybrid method for predicting surgery duration times. Our method is consisting of two steps 1) classification and 2) prediction. In prediction portion, we explore two different methods and discuss the performance of each method.

2. Literature Review
To provide a more scientific mechanism for prediction, various approaches have been proposed. While predicting surgical durations, there are two main streams of research. The first stream attempts to find the best fit among known distributions (most commonly normal [1] and lognormal [2]–[6]) and use these fitted distributions in order to characterize variability in surgical procedures and predict durations. In the second approach, researchers build statistical models to predict surgical procedure durations and identify critical factors that influence variability in these durations.

Among those studies relating to distributions, Strum et. al. analyzed a large dataset of clinical cases and concluded that fitting a log-normal model for each Current Procedural Terminology (CPT) code-anesthesia combination provides accurate predictions for procedure duration [7]. In a follow-up study, Strum et. al. showed that the lognormal distribution provides a better fit than normal distributions for modeling procedure durations having exactly two CPT codes [8]. With such an approach, the distribution is used in scheduling instead of a single value. This approach is good because it considers stochasticity by using distribution, however it is clear that there is a lot of variability within procedures of a certain CPT code in terms of complexity and that the single criteria CPT code is not an accurate indicator of surgery prediction. Relying on the lognormality assumption for procedure durations, Dexter, and Ledolter develop a Bayesian method to calculate prediction bounds for procedure durations [9]. Stepaniak et. al. use a three-parameter lognormal model for predicting the procedure durations of CPT-anesthesia
combinations including surgeon effects and show that their model can significantly reduce prediction errors and therefore operating room (OR) inefficiency [10].

On the other hand, with model building, due to the large number of CPT codes, Strum et. al. built a separate five-factor main-effects linear model for each CPT code [11] using logarithm of surgical time (i.e., the time from incision to closure) or the logarithm of total procedure time (i.e., the time from when the patient enters the OR until he/she emerges from anesthesia) as the response variable and surgeon, anesthesia type, American Society of Anesthesiologist (ASA) risk class, patient gender, and patient age as the explanatory variables. Eijkemans et. al. developed a regression-based prediction model with the logarithm of the total OR time, defined as the time from patient entry into the OR room until the patient is moved out of the OR, as the response variable [12]. Besides the surgeon’s estimate, they considered a large set of additional factors, divided into three classes, including operation characteristics (e.g., the number of separate procedures and whether it is a laparoscopic procedure), team characteristics (e.g., number and experience of the surgical team), and patient characteristics (e.g., age, sex, body mass index, previous hospital admissions) and determined their significance when added as a single factor to the base model, which only included the procedure type as a random effect. Motivated by the fact that CPT codes are among the factor with the highest predictive power for procedure durations, Li et. al. developed a general regression-based predictive model with multiple CPT codes as dependent variables [13]. They developed a grouping procedure to identify CPT codes that always appear together in order to construct a full-ranked design matrix for the regression model. Kayis et. al. developed a regression model, which adjusts a commonly used base estimation method using procedure-surgeon specific last five cases, using operational (e.g., order of surgery, OR assignment, surgical staff) and temporal factors (e.g., day, month, time of day) [14]. Due to the larger number of explanatory variables, they used an elastic-net regularized generalized linear model. Their model results in improved mean absolute deviation, especially for cases with long durations.

Some authors investigated use of data mining techniques to predict procedure durations. Combes et. al. proposed a knowledge discovery in databases (KDD) framework. Within the data mining step of this framework, they developed and compared two data mining methodologies, namely rough sets and neural networks, using patient related factors (e.g., administrative data, previous medical history) and surgical environment (e.g., surgeon, type of anesthesia) as explanatory variables [15]. Based on factors related, the patient and surgical environment (including patient age, experience of surgical staff, type of anesthesia) within an ophthalmology department, Devi et. al. developed and compared the performance of three methods: 1) adaptive neuro fuzzy inference systems (ANFIS), 2) artificial neural networks (ANN), and 3) multiple linear regression [16]. Using duration estimates, they solved a mixed-integer programming problem to optimize surgery schedules with an objective of minimizing overall completion time (i.e., make span). Their numerical experiments indicated that ANFIS outperforms other methods. Instead of predicting duration of individual surgical procedures, some authors study the completion time of a series of surgical procedures (also referred to as operating list) in the same operating room on a given day. Dexter et. al. proposed a regression model to predict the completion time of a list with the number of surgeon-procedure combinations with the list as independent variables [17]. Pandit and Carey used a questionnaire of surgical staff (including surgeons, anesthetists, and senior nurses) to estimate the duration of procedures and subsequently applied the average of these estimates to predict the completion time of historical lists. They concluded that even though estimates from surgical staff are accurate in predicting the completion time of operating lists, a substantial number of lists were overbooked [18]. In a related work, Pandit and Tavare developed a method for calculating the probability that a list will finish within its scheduled time [19].

3. Method and Case Study
As previous research suggests there are several factors that impact surgical times. In this study we received data from a large hospital system. The data includes several fields including some general fields and some patient specific information (we discuss the details related to the data in next section). One of the fields that show to be impacting surgery duration is procedure code. Our data shows the record of 2000 procedure codes during the study period. Therefore, the first step in our proposed method is to statistically reduce the number of sub factors for this field. Our proposed method consists of two steps as part of the model and an evaluation to assess the performance of the model (as shown in Figure1). In first step, we use classification to group procedure codes and to reduce the number of sub-factors for the field of procedure code. The next step is prediction; in this step we develop two separate regression models for procedure duration prediction using classical least square linear regression with main factors included (LIN) and stepwise regression (STEP) where main factors and second level interactions are included (we note that the stepwise with more levels of interaction did not add value, therefore were not considered).
We then evaluate the model by comparing prediction results from LIN and STEP against the baseline. The hospital system prediction (baseline) currently uses the moving average of 5 to 10 previous cases of same surgeon for that procedure code. The system then allows the scheduler to adjust this value. Therefore, the recorded value for procedure time in the system is the adjusted system prediction (ASP) and that is the value we use as baseline. The adjustment scheduler makes to the moving average value is reflected by clinical situation of patient (such as preexisting conditions, etc.) and the complexity of the surgery which we do not have any fields available for that in electronic data. This may seem that we set an unfair baseline to compare with. However, we feel confident that if our model can outperform this baseline, then with additional data fields that will be added in future, our model can perform even better.

### 3.1. Data Structure
A total of 63,254 surgical procedures performed by 234 surgeons over 39 months at a large academic health system with a total of 60 ORs were included. The data fields that show to impact surgery times and are included as part of the electronic data records are specialty, priority, ASA class (American Society of Anesthesiologists score – preoperative evaluation of patient physical status), age, encounter class, and procedure code. We also use fields such as actual surgery start and stop times, actual OR start and stop times, and scheduled OR start and stop times for evaluation purposes. Tables 1 and 2 show how the patients are distributed in relation to factors priority class and ASA code. We also note that there are total of 2000 procedure codes, and 30 specialties associated with the data. The patient class consist of 41% inpatient and 59% outpatient cases. Figure 2 shows how patients were distributed among different age groups.

Table 1. Cases by Priority Class

Table 2. Cases by ASA Class
Although surgeon name was available as part of the data, however, this field was not considered as a factor, because a surgeon based model makes the model not to be used for surgeons who just join the practice or those who start performing a new surgery. Data was split with 85 percent for training and the remaining for the test set. The analysis was performed using JMP PRO 10 software. We also note that all time units throughout the paper are in minutes.

3.2. Classification
The dataset shows record of 2000 different procedure codes performed over the period of 39 months. The analysis indicates that procedure code is highly significant factor in both surgery time (ST) and ASP. However, some of the procedure codes are very rare and there are not enough records of these surgery types available. Also there are procedure codes that are very similar in terms of duration. In order to consider the effect of procedure code while fixing some of the issues with rare cases, we decide to define a new variable based on the grouped procedure codes. In order to do that, we use data mining technique, particularly classification to categorize the 2000 different procedure types in new groups. Classification or decision tree is a platform that recursively partitions data according to a relationship between certain independent and dependent variables, creating a tree of partitions. It finds a set of cuts or groupings of independent variables that best predict a dependent variable. These splits of data are done recursively forming a tree of decisions until the desired fit is reached. There are several heuristic algorithms used to build classification and decision trees [21,22]. Some of these algorithms are ID3, and CART [21]; in this study we used CART. The proposed work uses classification to group different procedure codes based on their length of OR time. This allows reduction of the number of categories of procedure codes. This reduction needs to be validated by using cross-validation. We use a 10 fold cross validation to validate the categorization at 95% confidence. The new categorization then can replace the variable procedure code in our regression model. This new variable called adjusted procedure code. The classification method categorizes 2000 procedure types to 49 distinct groups. Therefore, nominal variable adjusted procedure code has 49 levels instead of the initial 2000 levels. The $R^2$ value for the classification is 0.65. We apply Tukey Kramer HSD test with $\alpha=.05$ to test that these categories represent statistically different groups in terms of mean procedure times. The results of this test are very lengthy and therefore are omitted.

3.3. Prediction
Once the procedure category variable is created, regression models are developed to predict the duration. A multi regression is a regression with more than one independent variable or factor and is one of the common methods of prediction. The two of the most common techniques used in multiple regressions are least square regression and stepwise regression. These methods are applied to predict surgery duration. We note that the stepwise regression and linear least square regression are very similar in nature. The difference is mainly in the way significant variables selected. For stepwise regression we use the combination of backward elimination and forward selection.
According to the Gauss–Markov theorem, there are a few conditions to be satisfied such that the least square estimator will be the best linear unbiased estimator. We notice that validation of these conditions is often ignored in many previous studies, resulting in poor or invalid outcomes. In practice, there are rarely situations that all these conditions hold; therefore, there is often need for adjustments and changes in the data that can help to satisfy these. These conditions are:

1. Relationship between dependent and independent variables should be linear
2. The residuals are normally distributed with mean close to zero
3. There is no heteroscedasticity which means that residuals have a constant variance
4. There is no autocorrelation, that is successive residuals are not correlated
5. There is no multi-collinearity

In preparation for use of regression model, all above assumptions have been verified. Due to the length of results related to these assumptions, here only the method that applied to test each of the assumptions has been listed in Table 3.

</tr>
</tbody>
</table>

Also regression factor statistical analysis indicates that all main factors shown in Table 4 are significant factors for least square prediction model with p-value<0.0001. Although we admit that these are not the only factors influencing OR times however the statistical results show that all of these factors significantly affect OR times. For the stepwise regression we not only consider these main factors but also the two level interactions of these factors to start the stepwise regression. The stepwise method however enters only those factors that have a significant impact on the result. We also tested the stepwise with three levels of interaction; however, no improvement has been reported from this model compared to the model with only two levels of interaction. Therefore, in result section only the stepwise method with two levels of interaction has been discussed.

As we are predicting duration of times, we also need to make sure that the values reported as output of the regression model are greater than zero. Plotting the distribution of duration of surgeries, it could be seen that the distribution is very much skewed to the left. We expect this to cause the prediction values to occasionally get values of zero or even negative. To prevent that, we use log transformation as predictor in regression model. This
transformation has been widely used in literature to prevent the output of time predictions from falling to negative numbers. After applying the regression model, inverse transformation needs to be applied before statistical results are gathered. Figure 3 shows the distribution of case durations in train set before and after transformation.

![Figure 3. Case Distribution Before and After Transformation](image)

4. Results
The results of the three predictions (ASP, LIN, and STEP) are compared against each other. Multiple performance measures such as $R^2$, RASE, and AAE which are coefficient of determination, root square average error, and average absolute error respectively, are reported for both train and test sets (due to respective strengths [23, 24]). Table 5 shows the comparison statistics of the three methods. As can be seen, STEP prediction is better than LIN, and each outperforms ASP.

Table 6 shows the comparison of the three prediction values by specialty, for most frequent specialties with at least 100 cases. STEP is the best model for the most frequent specialties (orthopedics and general surgeries, surgical oncology). LIN is better for urology, ophthalmology, thoracic, vascular, GYN oncology, and gynecology. ASP outperforms both STEP and LIN for otolaryngology, plastic, and GYN oncology procedures. Neuro surgery, obstetrics, and acute care procedures have mixed results. For Psychosurgery cases, the $R^2$ values for ASP and LIN are negative (these values for psychology is not shown in table as this specialty did not have many cases), suggesting that the mean of the group is a better representative of the predicted values. Even though the $R^2$ values for STEP is positive (yet very small), none of the prediction models can accurately estimate the procedure durations of this specialty. The t-test performed with alpha=0.05, suggests that LIN and STEP are significantly different from ASP in terms of the mean residuals.

5. Discussion
Both LIN and STEP show moderate improvement over ASP. This is not surprising since ASP prediction is often adjusted by the scheduler and/or the surgeon. These adjustments are typically based on intuitive consideration of patient characteristics and clinical factors and surgery complexity (12). There is no indication in the data set of any of these variables however about how often the moving average has been adjusted and by how much to determine reported scheduled duration. We believe that additional factors such as those considered by scheduler to adjust the value of the moving average if available can potentially make LIN and STEP even more accurate. The STEP regression model includes two-level interactions (inclusion of three-level interactions gives only slight improvement). The performance of LIN and STEP is dependent on the choice of independent variables and the size of the data set. While having additional factors and interaction of factors can potentially increase $R^2$ value in the training set indicating a better model, corresponding performance in the test set needs to be evaluated.

The independent variables considered in this study are general factors available across all specialties, and hence ensures ease of scalability. If more clinical factors are added to the model, then the interaction of factors will add more value to the accuracy of the prediction. These clinical factors however may not be available in structured data format. In some situations these factors could be observed by applying text mining on pre and post diagnostic notes if these notes are recorded electronically in unstructured form. However, in some situations such data is not available electronically. In such case there is need for manual observation of factor from notes by reading hand written charts by experts. We also note that each specialty has several meaningful variables which are specific to their practice, to add all these factors into a single model, care needs to be taken since this will create an uneven spread of factors among data due to the fact that some practices perform more surgeries than others. For instance, our data shows an indication that there is more of general and orthopedic surgery compared with other specialties; this however should not be used against accuracy of the prediction of duration of specialties with lesser number of cases. Further, individual specialties tend to show variation in performance based on the type of regression. STEP performs best with fewer specialties but those that account for more than half of the procedures. LIN performs best with specialties that account for a third of the procedures. Psychosurgery as a specialty is not predicted well by any of the models, and hence needs further investigation.

6. Conclusion
Prediction of OR times is very important as these times are used to assign time and day of the surgery. Accurate predictions are necessary to prevent over- and under-utilization. We proposed and evaluated a hybrid method with two steps 1) creation of a new variable to categorize procedures across all specialties and 2) development of regression models to predict procedure duration using the procedure category variable from the first step along with other factors. Evaluation shows that both regression models (LIN and STEP) result in better predictions compared to the current state-of-the-practice. The hybrid method with STEP regression gives a better prediction for orthopedics and general surgeries and surgical oncology specialties, which constitute more than half of the procedures. The proposed hybrid method can effectively deal with the heterogeneity problem, and further improvements can be obtained through inclusion of additional clinical factors.

Abstract
Modeling and clustering medical inpatient journeys is useful to healthcare organizations for a number of reasons including inpatient journey reorganization in a more convenient way for understanding and browsing, etc. In this study, we present a probabilistic model-based approach to model and cluster medical inpatient journeys. Specifically, we exploit a Bayesian Hidden Markov Model based approach to transform medical inpatient journeys into a probabilistic space, which can be seen as a richer representation of inpatient journeys to be clustered. Then, using hierarchical clustering on the matrix of similarities, inpatient journeys can be clustered into different categories w.r.t their clinical and temporal characteristics. We evaluated the proposed approach on a real clinical data set pertaining to the unstable angina treatment process. The experimental results reveal that our method can identify and model latent treatment topics underlying in personalized inpatient journeys, and yield impressive clustering quality.

1. Introduction
In recent years, healthcare process management is increasingly being used in healthcare organizations to provide standardized and normalized health services in medical inpatient journeys [1, 2]. Different from common business processes in commercial and industrial environments, healthcare processes are highly dynamic, context sensitive, event driven, and knowledge intensive such that they often bear no relation to the ideal as envisaged by the designers of healthcare processes [3]. To this end, healthcare organizations need to analyze and improve healthcare processes continuously [4].

Regarding healthcare process analysis and improvement, process mining, as a valuable set of techniques in business process management, has achieved emerging attention in clinical settings [3, 5, 6]. Process mining techniques use event logs to record business process execution information, to mine the actual behaviors in business processes, and to discover business process models from event logs [7]. Shifting to clinical settings, process mining can be an objective way of analyzing healthcare processes as it is not biased by perceptions or normative behaviors [5]. Applying process mining in clinical settings, non-trivial information about healthcare processes can be extracted from electronic medical records (EMRs) that contains the execution results of inpatient journeys, such as latent treatment patterns [3], treatment performance metrics [8], and performance characteristics [9], etc.

However, the diversity of treatment behaviors in healthcare processes is far higher than that of common business processes [5]. Healthcare processes are typically dynamic, complex, and loosely-structured, such that traditional process mining techniques have many problems and challenges when applied for healthcare process analysis and improvement [3, 10]. In fact, the diversity of healthcare processes, i.e. each inpatient journey has different kind of treatment events as well as difficult sequences of treatment events, causes the mining results often complicated and difficult to understand.

As a fundamental research problem, clustering actual medical inpatient journeys plays an important role in assisting healthcare process analysis and improvement. Indeed, a key step for healthcare process analysis is to cluster similar inpatient journeys into homogeneous subsets (clusters) [5, 11]. This helps clinical analysts locate treatment information of interest and capture an overview of healthcare processes easily and quickly. It must mention that, in contrast to static health data clustering, the clustering of medical inpatient journeys needs to be performed for each type of healthcare processes and be limited to the number of patients following a particular healthcare process protocol (e.g., a specific clinical guideline or pathway to a specific disease, etc.). This adds extra requirements to clustering, i.e., the clustering algorithm should group similar inpatient journeys together, and separate relevant
inpatient journeys from irrelevant ones in order to support medical staff to efficiently understand and browse these journeys for the further tasks on healthcare process analysis and improvement.

The requirements above in general introduce several challenges to modeling and clustering of medical inpatient journeys. In contrast to structured business process execution traces, an inpatient journey is described as a series of clinical epochs/stages in the patient’s hospitalization, and each epoch consists of a set of treatment events which may occur arbitrarily without a particular order [12]. Thus, one has to incorporate such loosely-structured treatment event sequence in the clustering process for good similarity measure. To the best of our knowledge, most of the approaches developed so far try to modify the existing algorithms to handle sequential business process data [6, 13, 14]. In order to have benefits, the data sources should be in fine structures. Unfortunately, such types of data sources are not available or rich enough for healthcare processes [5, 6].

In consideration of informal structures and the modelling of non-stationary data on inpatient journeys, we present a new approach for modeling and clustering medical inpatient journeys in this article. The proposed approach combines the model-based method provided by a well-known Bayesian Hidden Markov Model (B-HMM) [15] and a hierarchical clustering procedure. More specifically, we develop a clustering process that incorporates the medical behavior dependency observed in inpatient journeys and transforms inpatient journeys into a probabilistic space, where a symmetric similarity between inpatient journeys can be measured. Then, we resort to hierarchical clustering on the matrix of similarity in order to cluster the data sequences into homogenous groups according to both their characteristics and dynamics. In this sense, our approach provides an intuitive organization of the inpatient journey repository. Experiments on a real clinical data set collected from a Chinese hospital show that our proposal outperforms traditional approaches on medical inpatient journey modeling and clustering.

2. Methods

This section introduces a probabilistic model-based approach for medical inpatient journey modeling and clustering. The proposed approach combines both model-based and hierarchical clustering procedures, as shown in Figure 1. We first introduce the basic concepts and notations.

![Figure 1](image)

**Figure 1.** The proposed approach for medical inpatient journey clustering.

2.1 Representation of a Medical Inpatient Journey

In this study, we make an assumption that treatment events in medical inpatient journeys are regularly recorded in EMRs, which effectively reflects real executing conditions in inpatient journeys. Each treatment event refers to a well-defined step in inpatient journeys. Additional information such as the occurring time-stamp of the event is used in this study. To explain the kind of input needed for the proposed approach, we first define the following concepts.

Let $A$ be a finite set of treatment event identifiers (clinical terms describing activities), and $T$ the time domain set (set of time point primitives). A treatment event $e$ is a pair $e = (a, t)$ where $a \in A$ and $t \in T$. We denote by $E = A \times T$ the set of all valid events of a particular domain. Note that treatment events could be characterized by various properties, e.g., an event has an occurring time stamp, it corresponds to an event type, it is executed for a particular patient, has associated cost, etc. We do not impose a specific set of properties, however, given the focus of this study, we assume that the event type and occurring time stamp of the event are present. For convenience, let $e, a$ and $e, t$ denote the event type and occurring time stamp of $e$, respectively. For example, $e = (admission, 1)$ is a treatment event where $e, a = admission$ is the admission type, and $e, t = 1$ is the occurring time of the event. A medical inpatient journey is a series of treatment events $\sigma = (e_1, e_2, \ldots, e_n)$, observed on a particular patient in his/her hospitalization.

For a particular medical inpatient journey $\sigma = (e_1, e_2, \ldots, e_n)$, we have $e_1, t \leq e_2, t \leq \cdots \leq e_n, t$. In general, an inpatient journey consists of different categories of treatment events, and certain temporal dependencies exist between the events for a particular inpatient journey. Figure 2 depicts examples of medical inpatient journeys.

2.2 Medical inpatient journey modeling
In this section, we present a probabilistic model to recognize medical inpatient journeys by considering the sequential and dependency characteristics of treatment information in the journeys. As we mentioned above, inpatient journeys are dynamic, flexible, and loosely-structured. Although there are temporal dependencies between some critical events in different clinical epochs of inpatient journeys, treatment events in one time epoch might occur arbitrarily without a strict order. In this sense, we segment an inpatient journey $\sigma$ as a series of $M$ clinical epochs $\sigma = \{\sigma(1), \sigma(2), \ldots, \sigma(M)\}$, and each epoch has a specific time duration, e.g., a hospitalization day, etc. For example, inpatient journey $\sigma_2$ shown in Figure 2 consists of 5 epochs sequentially, in which each epoch records typical treatment events occurring on a particular hospitalization day. For example, the first clinical epoch of $\sigma_1$ consists of 26 treatment events, i.e., $\sigma_1(1) = \{(A01,1), (A11,1), (A21,1), \ldots\}$, and the last epoch of $\sigma_1$ has one treatment event, i.e., $\sigma_1(5) = \{(A17,5)\}$.

In addition, we assume that each clinical epoch of a particular inpatient trajectory has a specific treatment topic (e.g., “Admission”, “Prepare Surgery”, “Surgery”, “Post-surgery recovery”, etc.). Formally, we use $z_{\sigma(t)}(t)$ to denote the underlying treatment topic in the $t$th epoch of a particular inpatient journey $\sigma$. Thus the objective of inpatient journey modeling is to identify the latent treatment topics and their transitions in a particular inpatient journey.

To this end, we propose a Bayesian Hidden Markov Model (B-HMM) [15] based medical inpatient journey model (IJM) to identify inpatient journeys. The proposed IJM has the structure of a standard HMM that contains symmetric Dirichlet priors over the transition and emission distributions for modeling the sequential treatment information in an individual inpatient journey. Formally, given an inpatient journey $\sigma = \{\sigma(1), \sigma(2), \ldots, \sigma(M)\}$ with a series of $M$ clinical epochs, the dependency relationships of IJM are represented as follows:

$$z_{\sigma(t)}(t) \sim \text{Multinomial}(\theta_{z_{\sigma(t-1)}}(t-1)) \quad (1); \quad e_{t} | z_{\sigma(t)}(t), \Phi \sim \text{Multinomial}(\phi_{z_{\sigma(t)}}(t)) \quad (2)$$

$$\theta_{z_{\sigma(t-1)}}(t-1) | \alpha \sim \text{Dirichlet}(\alpha) \quad (3); \quad \phi_{z_{\sigma(t)}}(t) | \beta \sim \text{Dirichlet}(\beta) \quad (4)$$

Where $z_{\sigma(t)}(t) \sim \text{Multinomial}(\theta_{z_{\sigma(t-1)}}(t-1))$ means $z_{\sigma(t)}(t)$ follows multinomial distribution $\text{Multinomial}(\theta_{z_{\sigma(t-1)}}(t-1))$, $\theta_{z_{\sigma(t-1)}}(t-1)$ is the topic transition distribution over the $t$th clinical epoch $\sigma(t)$ when the treatment topic of the previous epoch $\sigma(t-1)$ is $z_{\sigma(t-1)}$. $z_{\sigma(t)}(t)$ indicates the treatment topic in $\sigma(t)$. $e_{t}$ is the $t$th treatment event recorded in $\sigma(t)$, and $\phi_{z_{\sigma(t)}}(t)$ is the emission distribution of treatment events in $\sigma(t)$. Particularly, $\alpha$ and $\beta$ follow the Dirichlet distribution with parameters $\alpha$ and $\beta$. Figure 3 shows the graphical representation of IJM.

In summary, the processed IJM assumes the following generative process for an inpatient journey $\sigma$:

1. Draw treatment topic proportions $\theta_{z} \sim \text{Dirichlet}(\alpha)$
2. For each treatment topic $z = 1, \ldots, K$, draw treatment event probability $\phi_{z} \sim \text{Dirichlet}(\beta)$
3. For each clinical epoch $t = 1, \ldots, M$ of $\sigma$:
   3.1 Draw treatment topic $z_{\sigma(t)}$ from $\theta_{z_{\sigma(t)}}$ w.r.t the previous treatment topic $z_{\sigma(t-1)}$, $z_{\sigma(t)} \sim P(z_{\sigma(t)} | z_{\sigma(t-1)}, \theta_{z_{\sigma(t)}})$
   3.2 For each treatment event $e_{t} \in \sigma(t)$, $t = 1, \ldots, |\sigma(t)|$, draw $e_{t} \sim \text{Multinomial}(\phi_{z_{\sigma(t)}}(t))$.

Given the generative process of IJM, we can calculate the joint distribution of all observations and hidden variables in IJM by the following equation:

$$P(z_{\sigma(t)}, \sigma(t), \theta, \Phi | z_{\sigma(t-1)}, \alpha, \beta) = P(\theta | \alpha)P(z_{\sigma(t)} | z_{\sigma(t-1)}, \theta)P(\Phi | \beta) \left( \prod_{i=1}^{\sigma(t)} P(e_{t} | z_{\sigma(t)}(t), \Phi) \right) \quad (5)$$

Therefore, the likelihood of a medical inpatient journey $\sigma$ can be calculated as follows:

$$L(\sigma) = \int \prod_{t=1}^{K} P(\theta_{z} | \alpha) \prod_{t=1}^{M} P(e_{t} | z_{\sigma(t)}, \Phi_{z_{\sigma(t)}}(t)) \, d\theta \int \prod_{t=1}^{K} P(\phi_{z} | \beta) \prod_{t=1}^{M} \prod_{i=1}^{\sigma(t)} P(e_{t} | z_{\sigma(t)}, \Phi_{z_{\sigma(t)}}(t)) \, d\Phi \quad (6)$$

We developed a Gibbs sampling approach to get the to maximize the likelihood in Equation (6), with the time complexity for a particular inpatient journey $\sigma$ being $O(LKM)$, where $L$ is the number of iterations, $K$ is the number of treatment topics, and $M$ is the number of clinical epochs in $\sigma$.

2.3 Medical inpatient journey clustering

---

4 In this study, we set the time range of each clinical epoch in an inpatient journey $\sigma$ as a hospitalization day, which records a set of treatment events observed on a particular day in the patient’s length of stay.
The second step of our hybrid clustering method exploits the information provided by the probabilistic space obtained in the first step to define the clusters of medical inpatient journeys characterized by similar treatment behaviors. Based on the generated IJM models of inpatient journeys, we measure the similarity between the journeys. Specifically, we use Monte Carlo sampling to compare two IJM models. Formally, let $M_i$ and $M_j$ be the learned IJM for inpatient journeys $\sigma_i$ and $\sigma_j$, respectively. The similarity between any two IJM models is defined as

$$ Sim(M_i, M_j) = \frac{\log p(\sigma_i|M_j) + \log p(\sigma_j|M_i)}{2} $$

Where $\log p(\sigma_i|M_j)$ and $\log p(\sigma_j|M_i)$ are a measure of how well model $M_j$ matches observations generated by model $M_i$, relative to how well $M_i$ matches the observations generated by itself. $\log p(\sigma_i|M_j)$ and $\log p(\sigma_j|M_i)$ are in the same spirit and make the similarity $Sim(M_i, M_j)$ symmetric. Equation (13) can be rewritten in terms of inpatient journeys as

Figure 2. Examples of medical inpatient journeys
\[
Sim(\sigma_i, \sigma_j) = Sim(M_i, M_j) = \frac{1}{2} \sum_{t=1}^{M_j} \log P(\sigma_i(t) | M_i) + \frac{1}{2} \sum_{t=1}^{M_i} \log P(\sigma_j(t) | M_j)
\] (14)

Where \(\sigma_i(t)\) is the \(t\)-th clinical epoch in \(\sigma_i\), \(\sigma_j(t)\) is the \(t\)-th clinical epoch in \(\sigma_j\), and the log-likelihood for each inpatient journey given the IJM can be obtained from Equation (8). This similarity measure is well suited to large collection of inpatient journeys, as it only requires the storage of the IJM parameters for each piece rather than the original patient’s EMR data itself.

In order to make no assumption on the number of medical inpatient journey clusters that are to be extracted, we use hierarchical clustering, which builds a hierarchy of clusters rather than treating all clusters as distinct, equal entities, such as in K-Means clustering.

A reasonable similarity measure \(Sim(\sigma_i, \sigma_j)\) for medical inpatient journeys \(\sigma_i\) and \(\sigma_j\) is critical for inpatient journey clustering. In Equation (15), we have presented how to measure \(Sim(\sigma_i, \sigma_j)\) between inpatient journeys \(\sigma_i\) and \(\sigma_j\), which defines the similarity matrix used for grouping the collected journeys into a tree of clusters through the hierarchical clustering procedure [16]; the dendrogram is achieved starting from \(C\) clusters, one for each inpatient journey \(\sigma\), and iteratively aggregating pairs of clusters until one single clusters is obtained. This agglomerative strategy is defined using complete linkage, i.e., similarity between clusters is measured on the basis of the similarity between the two furthest data points in two clusters. The hierarchical clustering allows us to easily obtain an informative data structure without having to specify a priori the number of clusters.

3. Experiments

In this case study, a collection of EMRs consisting of 9944 medical inpatient journeys following the unstable angina treatment process (from 2004 to 2013) was extracted from hospital information systems of Chinese PLA General Hospital to demonstrate the feasibility of the proposed approach. The collected data-set have 704004 treatment events within 606 event types. The average length of stay (LOS) recorded in the collection of EMRs is 8.30 days, which some inpatient journeys take a very short time, e.g., only 1 day in hospital, and other trajectories take much longer, e.g., more than 3 months in the hospital, which implicitly indicates the diversity of inpatient journeys in the unstable angina treatment process.

The case study was performed in the Cardiology Department at the Chinese PLA General Hospital. Prior approval was obtained from the data protection committee of the hospital to conduct the study. We state that the patient data was anonymized in this study and in this paper. All experiments were performed on a Lenovo Compatible PC with an Intel Pentium IV CPU 2.8 GHz, 4G byte main memory running on Microsoft Windows 8.1. The algorithm was implemented using Microsoft C#.

To evaluate the proposed IJM, we also developed a traditional sequence alignment based inpatient journey clustering method, and a variation HMM to model and cluster inpatient journeys. For the variation HMM, it can label the \(t\)-th clinical epoch of a particular inpatient journey \(\sigma\) by

\[
P(z_t = z | \sigma(t)) \propto P(\sigma(t) | z_t \equiv z)P(z_t | z_{t-1}) \propto P(z_t | z_{t-1}) \Pi_{i=1}^{\alpha(t)}P(e_i | z_t \equiv z)
\] (15)

Based on the suggestion of our clinical collaborators, the number of latent treatment topics for both IJM and HMM was chosen as 5, which is the general number of clinical stages of the unstable angina treatment process. For the other parameters of the proposed IJM, we used the following values: \(\alpha = 0.1, \beta = 0.01\), and the number of Gibbs iterations \(L=1000\).

**Modeling performance.** In this subsection, we evaluate the proposed IJM on modeling medical inpatient journeys. To this end, we randomly picked up 10 sample inpatient journeys from the collected dataset, as shown in Figure 2. Since the whole time period of the collected EMRs is across 10 years (i.e., from 2004 to 2013), we randomly selected one piece of EMRs in the dataset segment of a particular year. Each selected sample records typical
treatment behaviors occurred in a particular inpatient journey.

To investigate the problem of how to know the learned treatment topics are meaningful or not for a given medical inpatient journey, we adopted a hypothesis testing in which we used the derived treatment topics to describe each clinical epoch of an inpatient journey, and then conducted statistical tests to know whether the derived treatment topics from IJM can better represent the treatment topical information of a particular clinical epoch than that of the variation HMM on a given inpatient journey. The null hypothesis assumes that “both IJM and HMM have no difference in treatment topical representation in inpatient journeys”. The process to test the significance of violating the null hypothesis is given as follows:

(1) Firstly, we labeled each clinical epoch $\sigma(t)$, $(1 \leq t \leq M)$ of a sample inpatient journey $\sigma$ with the recognized treatment topic $z$ which is derived from either IJM or HMM. In particular, we chose the treatment event types $e$, $a$ with $P(e, a | z) > 0.01$ to represent the derived treatment topic $z$.

(2) Secondly, we asked 3 clinicians from the Cardiology department of the hospital to evaluate that to what extend the derived treatment topic correctly represents the actual treatment information in each clinical epoch of a sample inpatient journey. To ensure the evaluation quality, we did not inform evaluators that a given learnt treatment topic is learned by which model. The answer was given on a particular label, i.e., “Bad”, “Fair” or “Good” (i.e., “Bad” represents “does not represent at all”, “Fair” represents “fairly represent the treatment information in a specific clinical epoch”, and “Good” represents “perfectly represent the treatment information in a specific clinical epoch”, respectively). Note that we obtained the evaluation result of 3 evaluators based on a major voting strategy.

Figure 4 shows the results of human judgment for both IJM and HMM. From Figure 4, we can observe that the proposed IJM outperforms HMM in terms of “Good” cases and positive cases (“Good” + “Fair”), which indicates that treatment topics learned by our IJM is more reasonable because our model can represent loosely-structured inpatient journeys into the learning process.

(3) We performed both cohen’s Kappa test and $t$-test on the human evaluation results for both IJM and HMM. (i) The Kappa test is used to calculate inter-judge reliability between IJM and HMM. For the good cases, the obtained kappa value for Kappa test is 0.053, which is slightly larger than 0 and indicates the poor agreement between IJM and HMM. For the positive cases, the obtained kappa value for Kappa test is 0.167, indicating slight agreement between IJM and HMM. (ii) The $t$-test is used to evaluate the human understandings on the derived treatment topics and their assignments on clinical epochs of medical inpatient journeys. For the good cases, the obtained $t$ statistic is 6.020, which is larger than 3.250 (the confidence value of 99.5%). It indicates that the proposed IJM achieves the better understanding of human evaluators on the discovered treatment topics and their assignments on clinical epochs of inpatient journeys than that of HMM. For the positive cases, the obtained $t$ statistic is 2.756, which is less than 3.250 (the confidence value of 99.5%), and indicates that there are statistically no differences between IJM and HMM on positive cases.

![Figure 4](image.png)

Figure 4. Spherical comparison in terms of human evaluation. (A) Percentage of good cases; (B) Percentage of positive cases.

To illustrate the quality of inpatient journey modeling more intuitively, we take the inpatient journeys $\sigma_1$ and $\sigma_2$ (as shown in Figure 2) as examples. In particular, we manually checked the learned treatment topics with their representative treatment events for $\sigma_1$ and $\sigma_2$. In consideration of treatment topic and their transitions for both examples, clinical evaluators think that all these transitions are reasonable and easy to understand.
For example, the patient with $\sigma_1$ is an aged male patient. He has high-risk level of unstable angina and his LOS is 5 days. With IJM, a typical treatment topic transition pattern for the unstable angina treatment process is generated:

**Topic 1 (Admission, day 1)** → **Topic 2 (Prepare surgery, day 2)** → **Topic 3 (Surgery, day 3)** → **Topic 4 (Post-surgery recovery, day 4)** → **Topic 5 (Discharge, day 5)**

To look insight into the learned treatment topics, clinical evaluators think that most of treatment event types of each learned topic underlying in $\sigma_2$ are reasonable, except for one irrelevant treatment event type in the learned topic “Prepare surgery“ of $\sigma_1$, which is shown in bold in Table 1. As a result, 4 out of 5 clinical epochs are labeled as “Good” and 1 clinical epoch ($t = 2$) is labeled as “Fair”.

</table>

The patient with $\sigma_2$ is an aged female unstable angina patient. Her LOS is 8 days. This patient also has a common comorbidity of unstable angina, i.e., “Diabetes”, such that anti-diabetes treatments, e.g., “Diabetes check”, “Glucose regulating treatment”, etc., were performed during her LOS (shown in bold in Table 1). In clinical practice, conservative treatments are performed in $\sigma_2$. The proposed IJM generates the following treatment topic transition pattern:

**Topic 1 (Admission, day 1)** → **Topic 2 (day 2)** → **Topic 3 (day 3)** → **Topic 4 (Surgery, day 4)** → **Topic 3 (days 5-7)** → **Topic 5 (Discharge, day 8)**
To look insight into the learned treatment topics of $\sigma_2$, clinical evaluators find that most of treatment event types in the derived topics of $\sigma_2$ are reasonable. In particular, they point out that our approach cannot only discover typical medical interventions on unstable angina treatment and therapy, but also disclose typical medical interventions on Diabetes treatment for the patient, such as “Blood sugar regulation”, and “Anti-diabetes treatment”, etc., as shown in the derived topics of $\sigma_2$. Regarding discovered topics for each clinical epoch, clinical evaluators think it would be better to label the third clinical epoch of $\sigma_2$ as “Topic 2” than “Topic 3”. As a result, clinical evaluators labeled 7 clinical epochs as “Good”, and the other one as “Fair” for $\sigma_2$.

Figure 5. Part of the cluster hierarchies obtained by applying the proposed IJM (A), a variation HMM (B), and sequence alignment (C). Every node represents a cluster and reports the number of traces in the cluster itself, and their average normalized similarity (in brackets).

Clustering performance. The hierarchical clustering on the experimental dataset was performed based on the similarity matrix using Equation (14). Since the similarity measure is the key of clustering techniques, we compared the presented IJM-based similarity measure with the variation HMM-based similarity measure, and the classical sequence-alignment-based (SA) similarity measure [16].
To evaluate the proposed approach in a quantitative manner, we measured the cluster homogeneity, which is a widely used measure for the quality evaluation of clustering [22, 43]. A classical definition of cluster homogeneity is as follows:

\[ H(C) = \frac{\sum_{i,j \in C} \text{sim}(\sigma_i, \sigma_j)}{|C|^2} \]  

(16)

Where \(|C|\) is the number of inpatient journeys in cluster \(C\), and \(\text{sim}(\sigma_i, \sigma_j)\) is the similarity between any two inpatient journeys \(\sigma_i\) and \(\sigma_j\) in \(C\). The higher the homogeneity value, the better the quality of clustering results.

Figure 5 shows parts of the cluster hierarchies we obtained by applying the proposed IJM, HMM, and SA, respectively, on the experimental dataset. The structure of the hierarchies and the content of the resulting clusters are very different between the proposed approach and the baseline methods. As shown in Figure 5(B) and (C) the hierarchies built by both HMM and SA are a bit friable: the root node has a lot of children. It indicates that both HMM and SA resort to a large amount of clusters (117 and 188 for HMM and SA, respectively). In addition, the generated hierarchies by both HMM and SA are very unbalanced: one of these children corresponds to a very big cluster, while the others contain only one or just a few inpatient journeys. In comparison with the benchmark methods, the hierarchy generated by our approach is not sparse, and each node is normally split into few clusters of more comparable dimensions (cc. Figure 5(A)).

In addition, the average homogeneity \(H\) were calculated on the obtained clusters from data to assess its quality [11]. Average cluster homogeneity allows to compare the output of different clustering techniques on the same dataset. Figure 5(A) shows that the proposed approach had an average homogeneity of 0.54. On the other side, using HMM and sequence alignment, they reached an average homogeneity of 0.04 and 0.13, respectively. These indicate that the proposed method outperforms the benchmark methods based on medical inpatient journey clustering.

As shown in Figure 5(A), three clusters in the second level generated by our approach define the cut of the cluster tree that corresponds to the maximum split between clusters, which allow us to obtain some relevant insights on the dynamics of the unstable angina treatment process:

**Table 2.** Clustering results on the unstable angina dataset using IJM. 25 top-ranked treatment activities are listed to refer to clusters at level 2 in the hierarchies. Unique treatment activities of each cluster are marked with bold type.

Cluster 1, which corresponds to 50.3% inpatient journeys, collects typical treatment behavior of unstable angina patients who have been performed PCI surgery in their treatment processes. A closer analysis shown on Table 2 indicates that cluster 1 contains typical treatment interventions (e.g., “Coronary angiography”, “Stent implantation”, etc.) for unstable angina. There is little variation occurred and common treatment events are carried out smoothly. In clinical practice, patients who are categorized into cluster 1 have shorter LOS (on average 5.79 days) than the others.

Cluster 2, which collects about 32.2% samples, contains typical conservative treatments of unstable angina. In clinical practice, patients in cluster 2 have either low risks or specific physical problems, e.g., coronary stenosis such that they prefer conservative treatments instead of PCI surgery. As a result, the average LOS of patients in cluster 2
(i.e., 8.91 days as shown in Figure 5(A)) is longer than patients in cluster 1.

Cluster 3 has captured typical treatment behaviors of unstable angina patients who have more complex conditions than others such that many treatments on the comorbidities of the patients, e.g., “Glucose regulating treatment”, “Tumor markers checks”, “Consultation”, etc., can be found in this cluster (as shown in Table 2). Note that several patients in cluster 3 are transferred to Cardiac Surgery department for the further surgical thoracotomy, such as “Coronary artery bypass graft (CABG)”, etc. Note that this variant cluster is a bit normal in the unstable angina treatment process (17.5% patients in the collections of EMRs). The average LOS of patients in cluster 3 is about 14.35 days, which is much longer than the other clusters.

4. Conclusions

In this paper, we propose a novel approach for medical inpatient journey modeling and clustering, which first collects critical treatment events in inpatient journeys from EMRs, and then develop a probabilistic model-based approach to group inpatient journeys characterized by similar treatment behaviors. To this end, we present a Bayesian HMM-based representation method, i.e., inpatient journey model, to transform the collection of medical inpatient journeys into a probabilistic space defined by the estimated posterior probabilities without losing information related to the dynamics and dependency in the data. Based on the constructed probabilistic space, similarities between inpatient journeys are calculated and the homogenous ones are grouped into the same cluster.

Abstract

Domain-specific common data elements (CDEs) are emerging as an effective approach to standards-based clinical research data storage and retrieval. A limiting factor, however, is the lack of robust automated quality assurance (QA) tools for the CDEs in clinical study domains. The objectives of the present study are to prototype and evaluate a QA tool for the study of cancer CDEs using a post-coordination approach. The study starts by integrating the NCI caDSR CDEs and The Cancer Genome Atlas (TCGA) data dictionaries in a single Resource Description Framework (RDF) data store. We designed a compositional expression pattern based on the Data Element Concept model structure informed by ISO/IEC 11179, and developed a transformation tool that converts the pattern-based compositional expressions into the Web Ontology Language (OWL) syntax. Invoking reasoning and explanation services, we tested the system utilizing the CDEs extracted from two TCGA clinical cancer study domains. The system could automatically identify duplicate CDEs, and detect CDE modeling errors. In conclusion, compositional expressions not only enable reuse of existing ontology codes to define new domain concepts, but also provide an automated mechanism for QA of terminological annotations for CDEs.

Introduction

Domain-specific common data elements (CDEs) are emerging as an effective approach to standards-based clinical research data storage and retrieval. Notably, the National Cancer Institute (NCI) has implemented the Cancer Data Standards repository (caDSR) that adopted the ISO/IEC 11179 Metadata Registry (MDR) standard¹-². ISO/IEC 11179 defines a standard model of a meta-data registry - a registry of information about data models*. Along with the expected provenance and workflow information such as the creator, owner, workflow state, etc., part 3 of the ISO/IEC 11179 model also describes a model for formally associating data model elements with their intended meaning. It is the common meaning aspect of the 11179 standard that allows one to determine that two data elements from two different models are alternative representations of the same real world entity.

The caDSR repository has attempted to record the intended meaning of many of the data elements that support cancer study data collection and reporting which, in turn, are used to identify data elements used in relevant domains, an example of which is the Cancer Genome Atlas (TCGA) Biospecimen Core Resource (BCR) data dictionary, which is used to create clinical data collection forms for a number of clinical cancer genome study domains³. The viability and usefulness of this approach depends on the quality of the reference caDSR elements themselves. Earlier studies⁴,⁵ have uncovered serious issues with at least some of the caDSR definitions and have highlighted a need for robust, principled and automated quality assurance (QA) tools for the CDEs in cancer study domains.

Date element meanings, as recorded in the caDSR frequently use a simple form of "post-coordination", where a primary (focus) concept is identified along with one or more secondary identifiers that modify or qualify the intended target meaning. When taken on its own, this approach does not lend itself to automated validation and consistency checking. If, however, the constellation of identifiers were to be assembled into a compound expression of the sort that is used in SNOMED CT and OWL, it would then be possible use a description logic (DL) classifier to evaluate the various definitions for completeness and consistency. As an example, consider a data element about "joint pain in the hands". This could be assembled as a simple collection, with a focus concept of "pain" juxtaposed

* The 11179 standard is about metadata, not the actual data models. This is sometimes a source of confusion, as, in order to record metadata about an artifact, you also need a good idea of the type and purpose of the artifact itself. 11179 is about how one describes the provenance and purpose of a given element of a given type in a given data model and how it relates to similar elements with different types in different models.
with "joint" and "hand" or it could be constructed as a formal DL construct of "pain AND finding_site SOME hand AND finding_site SOME joint" (meaning the set of all things that simultaneously instances of (1) pain (2) have a finding_site of a hand and (3) have a finding_site of a joint). The latter form allows an automated reasoner to determine the relationship of the target data element with similar constructs. A DL reasoner would be able to determine that this data element described "hand pain" and "joint pain", was related to, but more specific than a data element that was just about "joint pain" (which could be describing ankle pain, knee pain, etc). Given sufficient information, a DL reasoner would also be able to determine that a data element about, say "joint pain in the eyebrow" was most likely nonsensical, as there was no possible instance that could simultaneously be both. While the above example may seem contrived, mistakes of this sort can and do occur in data element definitions. As an example, a data element that confuses "apoptosis" as a process with "apoptosis" as a morphological abnormality may, in turn, confuse data elements that describe genetic processes with descriptions of dead cells themselves.

DL-based mechanisms allow ontology curators to formally and unambiguously represent concept meanings and relationships, and to use off the shelf reasoning tools such as HermiT to automate the computation of the relationship between two class expressions and consistency checks. Rector, et al. developed an effective quality assurance mechanism using reasoners to incorporate qualifiers (e.g., acute or chronic) in the post-coordination in SNOMED CT. The editors of the National Cancer Institute Thesaurus (NCIt) use a DL reasoner to check the terminology completeness and consistency, and the Thesaurus is distributed as a DL based terminology. Horridge, et al. demonstrated how automated DL reasoning, along with a Justification Finding Service can be used as a QA technique for the development of large and complex ontologies such as ICD-11. The post-coordination approach using compositional expressions has been used to build a common ontology to harmonize ICD-11 and SNOMED CT. In an earlier study, we audited the semantic completeness of the SNOMED CT content using a formal model of the normal forms of SNOMED CT expressions.

The objective of the present study to design, develop and evaluate a quality evaluation tool for cancer study CDEs using a post-coordination approach. We propose a compositional expression pattern based on a modified SNOMED CT observable model, which renders the Data Element Concept model structure informed by ISO/IEC 11179. We then developed a transformation tool to convert the pattern-based compositional expressions into the OWL syntax. The OWL-based constraints are designed and the reasoning and explanation services are invoked to detect CDE modeling errors and duplicate CDEs. We then test the system utilizing CDEs from two TCGA clinical cancer study domains.

Materials and Methods

Materials

NCI caDSR CDEs, TCGA Data Dictionary and NCI Thesaurus (NCIt)

We downloaded an XML rendering of all non-retired production CDEs as of August 7, 2014 from the NCI caDSR website and an XML rendering of the snapshot of the publicly available TCGA BCR data dictionary from the TCGA website. We also downloaded the asserted (i.e. the inputs to a DL reasoner vs the conclusions) version 15.01d of NCIt in OWL format from the NCI Enterprise Vocabulary Services (EVS) website.

Semantic Web Applications and Tools

We used 4store, an open source RDF triple store as the back end for data integration and query and Protégé, an open source editor and knowledge acquisition system developed by the Stanford University in combination with HermiT version

\[\text{\textsuperscript{†}}\] "Sufficient information" in this context assumes that the reasoner would be able to process statements about negation and/or disjointness and that it its set of known facts included an axiom that explicitly or implicitly asserted that the set of things that are parts of the ear are disjoint (no pun intended) from the set of things that are joints.

\[\text{\textsuperscript{‡}}\] See: 20663007 | Apoptosis (morphological abnormality) | in the January 2014 edition of SNOMED CT.
1.3.8.3, a DL reasoner.

Methods

Figure 1 shows the architecture used in our evaluation. Module 1, Data Integration and Services combines the information from the caDSR Common Data Elements and the TCGA data dictionary as a cohesive unit, which allows the SPARQL query services to access the contents of both resources as a single unit. Module 2, Compositional Expression Transformation converts the data element meaning definitions recorded in the caDSR elements into DL expressions which become the inputs to Module 3, OWL-based Quality Assurance which uses the combination of the NCI Thesaurus and additional disjointness axioms to detect potential errors and duplications in the data element definitions. Each of these modules is described in more detail in the following sections.

Module 1: Data Integration and Services

The caDSR CDEs and TCGA data dictionary were converted from XML into RDF using the XML2RDF tool that was developed for the Redefer project. The output was loaded into the 4Store RDF triple store instance and a SPARQL endpoint was added to enable the actual SPARQL query services. The original XML files and transformed RDF files can be found at the project github website (https://github.com/caCDE-QA/owl-qa).

Figure 2 shows a SPARQL query that retrieves all CDEs from the domain “clinical pharmaceutical” and their data related to data element concept, object class and property recorded in caDSR.

Module 2: Compositional Expression Transformation

ISO/IEC 11179 identifies a basic model of a definition of a Data Element Concept, "A concept that is an association of a property ("a quality common to all members of an object class") with an object class ("set of ideas, abstractions or things in the real world that are identified with explicit boundaries and meaning and whose properties follow the same rules")². The data element definitions in the NCI caDSR separated the property and object class concept references, an aspect that we were able to take advantage of in an earlier study. One of the defining concepts in both the property and object class definitions were identified as the "focus concept" (i.e. one focus property and one focus object class). The relationship between the remaining concepts and the focus was left unspecified. Figure 3 shows the 11179 Data Element Concept model region and Table 1 shows two sample Data Element Concepts as defined in the NCI caDSR, with the primary or focus concept of each definition in bold. The first definition asserts that the object of the data element was Internal Radiation Therapy and the property being measured was the "Technique" qualified by "delivery". In the second example, the object is asserted to be "blood pressure", qualified by "person" and the property of the blood pressure was "assessment".

It became apparent that we were dealing with two levels of modeling. On the most fundamental level, we were working with data elements as defined in ISO 11179 ("unit of data that is considered in context to be indivisible")². In this context, the data elements "Adjuvant Postoperative Pharmaceutical Therapy Administered Indicator" (3397567), "Year of Death" (2897030) and "Initial Pathology Diagnosis Method" (2757948) all have the

[Diagram of Data Element Concept Definition]
same object class/property definitional structure. Considerable value could be added, however, if the data elements could be correctly positioned in more sophisticated model such as the proposed SNOMED CT observables model\textsuperscript{18} as shown in Figure 4, which would allow the various property and object class modifiers to be correctly identified by the role they played in context of the data element itself. One of the challenges in doing this, however, is that not all of the data elements in the caDSR can be treated as observation results. As an example, "Tumor Tissue Site" (CDE 3427536) is not an observation unto itself but would instead serve as a direct site or (inherent) location in a more complete location.

The remainder of this paper focuses on the first and more abstract model level, where every CDE is treated as complete "observation" unto itself -- either as a property of an object (independent continuant) or as characterizing a process.

Figure 5 shows a diagram illustrating the mappings between a modified version of the SNOMED CT observable model and the ISO/IEC 11179 model implemented in the NCI caDSR. As illustrated in the figure, a data element concept is mapped with an observable entity; a data element concept property is mapped to the target (i.e., range class) of the predicate “is about”; a primary property is mapped to the target (i.e., range class) of the predicate “property type”; a data element object class is mapped to the target of the predicate “inheres in or characterizes”. Note that we combined two predicates “inheres in” and “characterizes” into a single predicate “inheres in or characterizes” as NCI caDSR does not directly provide the distinction between independent continuants and processes (see the section Discussions for more details). Within the NCI caDSR model, a primary object class is the target of the predicate “object class type” and a primary property is the target of the predicate “property type”.

We created a transformation tool using the Jena Java API\textsuperscript{19} that takes the input from the results of a SPARQL query described in the previous section and renders the data recorded for the data element concept of a CDE into an OWL-based compositional expression. Table 2 shows two compositional expressional examples transformed to represent the semantics for the data element concept, object class and property of the CDEs “Clinical Trial Drug Classification Name” and “Agent Administration Total Dose Code”.

Module 3: OWL-based Quality Assurance

Module 2 transforms the CDE definitions into OWL compositional expressions. We are now in a position that we can use a DL reasoner to validate the expressions against the underlying ontology.

Checking for duplicate data elements

A DL reasoner can find equivalent (duplicate) definitions. This provides an automated mechanism for checking potential duplicate data elements that have the same meanings.

Mechanism for detecting data element modeling errors

With the OWL rendering of compositional expression patterns based on the SNOMED CT observable model, we can add constraints to the patterns that will allow a DL reasoner to detect potential data element modeling errors. The first constraint is to assert that instances of Object Class and Property are disjoint -- that nothing can simultaneously be a thing or process and attribute or characteristic of the thing or process.

A second constraint is an assertion about the subjects (domain) and objects (range) of the :is_about, :property_type, :measures, and :object_class_type predicates. The domain/range constraint restricts each object property linking between the instances of asserted classes. Table 3 shows two types of the OWL constraints asserted in the compositional patterns.

Explanation of detected inconsistencies or errors

We used the Protégé 5.0 beta version and the HermiT reasoner which can explain the possible reasons for inconsistencies or errors. Figure 6 shows a screenshot of illustrating the explanations for the class “C1708:Agent” violating the disjointness constrain asserted between the classes “Observable Entity Object Class” and “Observable Entity Property”.

Case study of CDEs from two TCGA cancer genome study domains

We used the configuration above perform a quality evaluation of the CDEs from two clinical cancer domains in TCGA data dictionary: Clinical Pharmaceutical and Clinical Shared. CDEs from each domain along with the data element concept, object class and property assertions were retrieved using the SPARQL query in Figure 2. The results were converted compositional expressions and classified using the Protégé based DL reasoner. We were able to identify the equivalent CDEs and the CDEs violating the reasoning constraints. To verify the modeling errors, four co-authors (GJ, HS, CT, CW) reviewed the detected CDEs by checking the definitions of the CDEs recorded in the NCI caDSR to verify whether there is a modeling error or not.

Results

In total, TCGA data dictionary contains 775 CDEs for 38 clinical cancer domains, which cover 21 cancer types. In the present study, we performed a case study of two clinical cancer domains: Clinical Pharmaceutical and Clinical Shared, which contain 18 and 98 CDEs respectively.

The reasoning services identified 6 CDEs with equivalent CDEs from the domain Clinical Pharmaceutical and 29 CDEs with equivalent CDEs from the domain Clinical Shared. In total, there are 12 groups of equivalent CDEs. Human-based review shows that among 12 groups of equivalent CDEs identified, the CDEs in 2 groups had modeling errors, indicating that they should not be considered as the equivalent CDEs. Table 4 shows the equivalent CDE groups identified with errors from the domain Clinical Shared.

</tr>
</tbody>
</table>

Table 5 shows the results of CDEs violating constraints from two TCGA domains by reasoning services. In total, there are 19 CDEs (out of 116 CDEs) identified with constraint violations. Human-based review shows that all 19 CDEs had modeling errors in their asserted primary properties. Table 5 provided the suggested primary properties for the 19 CDEs.

Discussion

In a previous study, we analyzed the terminological concepts associated with the standard structure of the caDSR CDEs using the UMLS Semantic Network. We found out that the semantic annotations of a CDE that did not observe the overall pattern of disjointness between dominant semantic types of primary object class/property, had a high probability to have modeling errors. Although the ISO/IEC 11179 specification states that it provides a semantically precise structure for data elements, the standard does not specify disjointness constraints between
object class concept and property concept. In the present study, we designed a compositional expression pattern to post-coordinate the data element concept of a CDE and transformed them to the Semantic Web OWL-based expression. The transformation allows us to take advantage of the built-in feature of OWL in expressing the disjointness and domain/range restrictions among a set of OWL classes, and subsequently invoke the reasoning services provided in existing OWL-DL reasoning tools (e.g., the HermiT reasoner used in this study) to check the inconsistencies and violations. This approach has proven to be very useful in identifying potential modeling errors. With the case study of the CDEs from two TCGA clinical cancer study domains, we reviewed those CDEs violating the constraints (n=19) and found that all of them had incorrect property concepts asserted.

While the domain expertise would be definitely helpful in evaluating whether an object class/property concept is correctly asserted or not, the challenging question is how to make the system to tell automatically that a terminological code could only be used for annotating an object class not a property. We consider that the approaches leveraging the upper level ontologies such as UMLS Semantic Network, basic formal ontology (BFO)\(^{20, 21}\) or BioTop ontology (a top-domain ontology for the life science)\(^{22, 23}\) would potentially provide a formal approach to define the constraints for supporting the CDE modeling applications. Linking to ISO/IEC 11179 model, a
constraint can be made like “an object class concept has to be an independent continuant or processual entity whereas a property concept cannot be such entity”. Actually, the SNOMED observable model we referenced in this study has been developed using such principles. As we are using a modified version of SNOMED observable model to post-coordinate the data element concepts, we plan to look into the upper level ontology-based approaches further in our future study.

With the compositional expressions coded for the data element concepts representing the meaning of CDEs, the Semantic Web reasoning services can be invoked to automatically identify semantically equivalent CDEs. On the one hand, this powerful feature could be used to detect potential duplicate CDEs as well as the modeling errors. As demonstrated in our case study (in Table 4), among 12 groups of equivalent CDEs are identified, the CDEs in 2 groups had modeling errors, meaning that they should not be considered as the equivalent CDEs. For example, reviewing the definition for the CDEs “2181650|Patient Smoking History Category” and “2228604|Started Smoking Year”, their primary property concept are all assigned as the “Patient Medical History” which is not correct. If we correct the primary property concepts for the two CDEs as “C25372|Category” and “C25164|Date” respectively, they will be no longer inferred as the equivalent CDEs. On the other hand, the post-coordination approach could be used to harmonize and standardize the data elements collected from different study groups or sites. Specifically, if we could use the compositional expression pattern to post-coordinate these data elements using standard ontologies such as NCIt, we would be able to accurately identify the data elements with the same meanings and easily harmonize the data element and enable data integration. This is exactly the very goal the ISO/IEC 11179 standard would like to achieve. Leveraging the SNOMED CT observable model would help make the compositional expression pattern user-friendlier. For example, the notion of Observable Entity is user-friendlier to clinical study researchers than the notion of “Data Element Concept”.

We have demonstrated the value of using Semantic Web technologies in building our QA tools for cancer study CDEs. First, we developed a semantic metadata repository using an open source RDF triple store. The RDF-based data model not only provides a scalable and powerful framework for data integration, but also provides standard SPARQL query services that allow us to easily retrieve the preferred set of CDEs in a particular TCGA clinical cancer study domain. In a separate study, we demonstrated that such Semantic Web-based metadata repository could also be used to support authoring detailed clinical models (DCMs) in clinical cancer study domains 24. In the present study, the framework enables us to build a domain-specific QA mechanism. Although we focused on the two TCGA domains as a case study, the approach could be easily generalized to any other TCGA domains. Second, we developed a compositional expression transformation tool that transforms the data structure of a data element concept informed by ISO/IEC 11179 into an OWL-based representation. The compositional expression is based on a modified version of SNOMED CT observable model. We consider that the syntax of SNOMED CT’s compositional expression grammar 25 may be useful as an intermediate layer in our transformation tool, which will provide a human readable format and potentially improve the usability of authoring a post-coordination expression. Third, as the NCI Thesaurus is distributed in the OWL format, we can easily integrate the compositional expressions generated for the CDEs in each domain with the NCIt using the “owl:imports” mechanism. As the latest version of the NCIt has marked all its retired concepts using the deprecated annotation “owl:deprecated”, we were able to detect retired concepts out of the compositional expressions that are originally based on the annotations using the NCIt codes. Fourth, Semantic Web reasoning services are a critical component of our QA tool. We used the latest version of HermiT reasoning plugin in Protége 5 environment in this study. We found that incremental reasoning and explanation services are very helpful in detecting and explaining the CDE modeling errors and duplicate CDEs. However, further studies will be needed in transforming the reasoning results into the well-formed report to inform the decision-making of CDE curators. In addition, integration of compositional expressions with the large-scale ontology such as NCIt will make the reasoning services more complicated and also require high performance. There already have a number of high-performance reasoners such as Snorocket 26 available in the Semantic Web community, and we will compare and test out such reasoners in the future.

There are a number of limitations in the study. First, our QA tool is based on the CDEs from a particular domain. While the domain-specific approach has advantage of making the auditing results more interpretable, some of the modeling errors may not be able to be detected. The systematic solutions would include 1) enabling the violation checking globally on CDEs across domains; 2) implementing the upper level ontology-based approach as discussed above. Second, we used a simplified compositional expression model that captures main constructs of a data element concept informed by ISO/IEC 11179 standard. For example, for an object class concept “Adjuvant Hormone Therapy”, it is recorded as “C2140:C15445”. The primary object class “C15445|Endocrine Therapy” has been captured in our model but the semantic relationship between “C2140|Adjuvant” has not been captured. We plan to
look into the approach for post-coordination such expressions in the future. Third, the QA of the data structure describing the meaning of a value domain is out of scope in the present paper and will be conducted in a separate study.

Conclusion

In this study, we developed and evaluated a QA tool for cancer study CDEs using a post coordination approach. We designed a compositional expression pattern based on a version of SNOMED CT observable model, which is used to represent the data structure of a data element concept (i.e., the meaning of data element) informed by the ISO/IEC 11179 metadata standard. Leveraging the existing Semantic Web tools, we demonstrated that the post-coordination approach could enable an effective and automated mechanism in detecting potential CDE modeling errors and duplicate CDEs. Future work will be focused on 1) developing a systematic QA approach leveraging upper level ontologies; 2) refining the compositional expression model by aligning with SNOMED observable model; 3) making the reasoning-based explanation more user-friendly; and 4) incorporating the value domain in the scope.

Abstract

Communication and information sharing are critical parts of teamwork in the hospital; however, achieving open and fluid communication can be challenging. Finding specific patient information within documentation can be difficult. Recent studies on handoff documentation tools show that resident handoff notes are increasingly used as an alternative information source by non-physician clinicians. Previous findings also show that residents have become aware of this unintended use. This study investigated the alignment of resident note updating patterns and team note viewing patterns based on usage log data of handoff notes. Qualitative interviews with clinicians were used to triangulate findings based on the log analysis. The study found that notes that were frequently updated were viewed significantly more frequently than notes updated less often \(p < 2.2 \times 10^{-16}\). Almost 44% of all notes had aligned frequency of views and updates. The considerable percentage (56%) of mismatched note utilization suggests an opportunity for improvement.

Introduction

Care teams require communication and information sharing to coordinate and provide care for patients in the hospital¹⁻³. However, poor communication is frequently associated with errors and sentinel events⁴. Studies on improving patient outcomes and care processes after the implementation of electronic health records (EHRs) have shown both positive and negative results⁵⁻⁸. Critical patient information is often difficult to obtain quickly or is simply missing in the EHR⁹,¹⁰. Moreover, team member information needs differ according to clinician training and specialization¹¹. Clinical documentation, a common form of team communication, often contains out of date information or is simply not read¹²,¹³. These and other problems pose a challenge to adapting EHR based tools to facilitate team-based communication and information sharing.

There is, however, emerging evidence that new electronic tools for facilitating handoffs, handoff documentation tools, are increasingly used as a source of patient information¹⁰,¹³,¹⁴. Schuster et al. found that despite handoff notes being written by and for residents, other services, such as ancillary services, also consulted these notes for information¹⁰. Furthermore, Vawdrey et al. demonstrated that despite its original intent to facilitate transitions of care for resident physicians, non-physician services, such as nursing and pharmacy, make up more than half of all views of handoff notes¹³.

In a follow-up study to Vawdrey et al., residents, the primary authors of handoff notes, acknowledged team members reading their notes¹⁴. Some even acknowledged a change in the frequency of updates to their handoff notes based on how others in the team incorporated handoff notes into their daily workflow¹⁴. However, many questions still remain about using handoff documentation as a way to disseminate information to other care team members. One such question is to what degree are residents’ expectations and practices in regards to updating handoff notes aligned with other team members? In this study, we examine the patterns of updates and views for electronic handoff notes (handoff notes from this point forward) at a large tertiary care hospital. Specifically, this study investigates the degree with which users are aligned in their viewing and updating practices and focuses on the following question: Are more frequently updated notes also viewed more frequently?

Materials and Methods

Handoff Tool

Handoff Tool is a custom-designed module included in the commercial EHR system (Sunrise Eclypsis). At the time the study data was collected, Handoff Tool included 9 free text boxes: Active Issues, Consult Notes, Contact Information, Coverage To Do List, Discharge Planning, Hospital Course, Notes and Comments, Patient Summary, and Primary To Do List. The tool also provided the functionality to produce a printable report that included structured data, such as labs and medication. Furthermore, users could choose to print a cover sheet that summarized
selected patients. At the time of the study, only physicians, physician assistants, and nurse practitioners could make edits to the handoff document, but all members of the care team could access and view the document. In contrast to traditional notes, such as the daily progress notes, which started blank each shift, handoff notes were updated from the last save iteration of the note. The tool is described in further detail in[1].

Dataset

To examine updating and viewing practices related to handoff notes, we collected the document-updating and document-viewing event logs for all of October 2013 at Columbia University Medical Center campuses of NewYork-Presbyterian Hospital, a large urban, academic medical center. The document-editing event log contained the date and time of each edit event, along with which free-text box was edited, the patient medical record number, the patient bed location, the clinician user ID, and the care provider role. The document-viewing event log contained the date, time, and duration of each handoff document access. Additional information in the log included the patient medical record number, the patient bed location, the clinician user ID, and the care provider role. The dataset was then divided into individual notes for each patient. Each unique handoff document was identified by the patient medical record, and each shift was defined as being either from 7am to 7pm (day shift) or 7pm to 7am the next day (night shift). For each document, the number of updates and views were tabulated. An update was defined as an event when the handoff document was edited. A view was defined as instance when a clinician, other than the primary author of the note, opened and closed the note. The primary author for a note was defined as the clinician who made the most edits to the handoff note during a particular shift. Furthermore, the frequency of views for each clinician role for each note during each shift was also calculated. To correlate the frequency of views and updates, each document was assigned an activity level score, which reflects the relative frequency of the views and updates for each document (see Table 1).

</table>

Quantitative Analysis

To identify temporal patterns of viewing, the hour of each view was extracted and plotted. To identify the relationship between updates and views, a linear regression was fitted on the frequency of views and updates for each patient’s note per shift. Then each note was stratified into one of three categories based on the frequency of updates according to the schema found in Table 1. An ANOVA (and Kruskal-Wallis) test was then performed to identify if there was a difference in frequency of note views between the three levels of note updates.

The statistical packages pandas, numpy, and scipy for Python were used to analyze the data, and ggplot2 for R was used to visualize the data.

Qualitative Analysis

To triangulate the finding from the quantitative analysis, interviews were conducted, transcribed, and analyzed for common themes. In total, 3 interviews were conducted. Two residents from the adult general medicine department, and one nurse practitioner from a pediatric hematology/oncology unit were interviewed. All clinicians were consented prior to interview. This study was approved by the Columbia University Medical Center Institutional Review Board (CUMC IRB).

Results

Description of Handoff Note Views

In total, 70,042 handoff notes were included in the analysis. Handoff notes were viewed an average of 2.34 times per shift. When aggregated among all notes, physicians viewed handoff notes most frequently (207,849 times), followed
by physician assistants (46,792) and nurses (40,593). A complete breakdown of the frequency of views by common clinical roles can be found in Figure 1. The data shows that while physicians account for the majority of note views, all other roles combined account for 36.41% of views. During the interviews, all participants explained that their handoff notes were written primarily for clinicians who are covering during the evening shift. However, all three participants also acknowledged that others, such as consulting physicians or bedside nurses also read the note.

![Note Views Among Clinical Roles](image)

**Figure 1.** Monthly Handoff Note Views Among Common Clinical Roles.

Temporally, 38.70% of handoff views occurred during handoff periods (6am to 8am and 5pm to 7pm) as shown in Figure 2. This shows that while handoff notes are most frequently viewed during handoff periods, most views do not actually occur during time periods commonly associated with handoff.

**Relationship Between Views and Updates**

To analyze the data using linear regression and ANOVA, three outlier data points (notes where updates were greater than 50 during a shift), were removed. As shown in Figure 3A, notes with more updates were also viewed more frequently. In Figure 3A, the $R^2$ value is 0.2611 with a p-value $< 2.2 \times 10^{-16}$. The data was then stratified into three groups by updates (no updates, minimal updates, and frequent updates). The ANOVA test showed that notes in the different groups had significantly different frequency of views ($F = 12893$, $p < 2.2 \times 10^{-16}$). Post-hypothesis testing using Tukey’s HSD test reveals that all three groups are significantly different from each other ($p < 2.2 \times 10^{-16}$ for each instance). The greatest mean difference between groups is between frequently updated notes and notes not updated during that shift (difference = 3.39 views per shift). The mean difference in note views between notes that are minimally updated and frequently updated is also similarly large.
Given that notes in the frequently updated group were viewed more frequently than notes in the other two groups, those notes were analyzed further. In this analysis, the focus shifted from the frequency of note views to the frequency of updates. Table 2 shows the frequencies of note updates for different units of the hospital. The left hand
side of the table shows the top 15 units that contributed the most frequently updated handoff notes. The table shows that frequently updated notes come from many different units. The right hand side of the table shows the top 15 units where a high proportion of the handoff notes were frequently updated. Notably, several of these units are intensive care units (B09N, B09S, MICA, M8GS, M4SI, AICU) that provide care for complex and unstable patients. This finding indicates that use of handoff notes as part of the clinical workflow may be at least partially dependent on unit practices and norms and patient severity.

**Matched Utilization of Handoff Notes**

To further analyze the use of Handoff Tool from the team perspective, the relative note activity level was coded according to the schema in Table 1. Tables 3 and 4 show that matched cases of handoff views and updates are the most prevalent (43.44%). Within matched utilization, notes were most likely to be either not used in a shift at all (0
updates and views) or used frequently during a shift (Table 3). Between the two types of mismatched utilization, notes were more likely to have relatively more views than updates during a shift (Table 4).

Qualitative Analysis

The qualitative interviews provided much insight into log data findings. All three interview participants explained that they primarily wrote handoff notes to provide information for night coverage teams and consulting physicians. Participant 3 expressed that bedside nurses frequently read the participant’s handoff notes at the beginning of the shift and often asked her follow-up questions based on the handoff note. This is consistent with qualitative findings from previous work by Jiang et al. showing that intensive care unit residents are aware that other team members, such as bedside nurses, are reading their handoff notes. Participant 2 explained that, “I think that if there had been a greater awareness of others reading [the handoff note], it would have been updated more.” This suggests that awareness of other’s actions acts as a positive feedback loop in regards to updating. However, participants 1 and 2 described little to no interactions with other clinicians prompted by the handoff note, suggesting that unit practice variations impacted the use of handoff note for information sharing. Expounding further upon the differences in units, participant 2 explained that ICU teams and general medicine teams operated differently. ICU teams often operated closely, while general medicine teams operated in a more diffuse manner. This difference may also provide one explanation for why frequently updated notes are also viewed more often.

Discussion

Previous studies have suggested that nurses and ancillary services used resident handoff notes as information sources. Further pursuing this line of investigation, this study investigated how handoff notes are used from a team perspective, and on their possible role in facilitating team communication. To complement previous qualitative studies on handoff notes, this study took a quantitative focus. The findings showed that handoff notes are read throughout the day by multiple care team members. Most of these note viewers were physicians or physician assistants; however, nurses also made up a noticeable number of the user base. As highlighted by the interviews, the frequency of notes updates is at least partially due to the awareness that other team members, such as consulting physicians or nurses are referring to them for information.

Currently, many clinicians rely on verbal communication in transmitting or obtaining patient information because documentation is not updated sufficiently quickly. This study found that units with the almost critical patients tend to have notes that are frequently updated and viewed. A possible interpretation of this finding is that those units are most likely to include Handoff Tool as one method to disseminate patient information to the rest of the team. This conclusion is mirrored in the interviews, which revealed that teams in ICUs often rely on Handoff Tool for documenting and sharing information more than general medicine units. This finding suggests a possible shift towards greater utilization of documentation, particularly electronic handoff notes, to pass on patient information.

Overall the study revealed that there exists a high degree of alignment in editing/viewing practices for electronic handoff notes. This is particularly the case for intensive care units, where patients’ conditions often change rapidly throughout a shift, and where members of patient care teams must work in close alignment with each other. Previously, researchers used the term social translucence to describe the degree of awareness between individuals about their respective practices in social settings. According to Kellogg et al, being aware of intentions and actions
of others helps individuals to maintain a high degree of cohesion and coordination. This study suggests that across the hospital, and particularly for intensive care units, electronic handoff tools are contributing to social translucence among members of patient care teams. Residents update their notes more frequently knowing that others refer to these notes for updated patient information, and other members of the teams view these notes more frequently with the expectation that they are updated. Handoff notes at our institution are carried over from the previous version and act more similarly to a single note that evolves over time; rather than traditional notes which are more similar to a collection of individual notes about a patient over time. Because of this difference, alignment of note update and view frequencies is an important indicator that note writers are providing and note viewers are reviewing updated information. However, the study also showed that there are cases when these practices are not aligned, suggesting an opportunity for improvement. For example, currently, clinicians are not informed of new updates to handoff notes that might indicate important changes in patients’ conditions. One possible solution to this limitation is the addition of an RSS-style subscription of handoff note updates that could help clinicians more reliably disseminate new patient information and maintain higher level of awareness within patient care teams.

Limitations
A key limitation to the study is that it only captured views of the electronic version of the handoff note, but not the views of its printed version. During the interviews clinicians repeatedly expressed that they frequently consulted the printed version of the handoff note throughout the day in lieu of the electronic version. Another limitation in the study is the small sample of participants in the interviews. However, these interviews were primarily conducted to help interpret the quantitative findings, rather than to draw novel conclusions. Lastly, this dataset represents a small temporal period within a single academic medical center. Handoff practices constantly evolve, and not all variations of these practices were captured with the current dataset.

Conclusion
This study examined and compared patterns of updates and views of electronic handoff notes based on the usage log data. The study revealed that use of handoff notes was commonly aligned between care team members, with frequently updated notes being also frequently viewed. Moreover, frequently updated notes commonly originated from one of the intensive care units. This indicates that the electronic resident handoff note is emerging as a new method for disseminating patient information, in addition to facilitating transitions of care. Given that there is a large proportion of mismatched utilization of handoff notes, more work can be done to help teams reach a consensus about using handoff notes as an alternative information source.

Abstract

The rapid growth of digital health databases has attracted many researchers interested in using modern computational methods to discover and model patterns of health and illness in a research program known as computational phenotyping. Much of the work in this area has focused on traditional statistical learning paradigms, such as classification, prediction, clustering, pattern mining. In this paper, we propose a related but different paradigm called causal phenotype discovery, which aims to discover latent representations of illness that are causally predictive. We illustrate this idea with a two-stage framework that combines the latent representation learning power of deep neural networks with state-of-the-art tools from causal inference. We apply this framework to two large ICU time series data sets and show that it can learn features that are predictively useful, that capture complex physiologic patterns associated with critical illnesses, and that are potentially more clinically meaningful than manually designed features.

1 Introduction

The increasing volume, detail, and availability of stored digital health data offers an unprecedented opportunity to learn richer, data-driven descriptions of health and illness.1 This principle has driven the rapid development of computational phenotyping, a broad field encompassing a variety of efforts to apply modern computational methods to increasingly large and complex medical data sets. These efforts are further unified by a common goal: to not only build successful predictive models but also to learn and recognize clinically meaningful descriptors of health. Computational phenotyping has attracted many researchers in machine learning and data mining, who apply many different techniques (ranging from Gaussian processes to tensor factorization) to extract meaningful representations from a variety of data sources and types (e.g., clinical time series, text, event counts, etc.).1,2,3,4,5,6,7

Some of the most interesting phenotyping work involves phenotype discovery, i.e., learning latent representations that capture structure in data and may represent real patterns of illness. Such techniques have the potential to become powerful tools for clinical research. For example, Schulam, Wigley, and Saria used a Bayesian framework to find patient clusters that may represent previously unknown subtypes of Scleroderma.6 However, phenotype discovery from physiologic data poses significant challenges because human physiology is immensely complex and nonlinear, and illnesses often span a large number of body systems and processes. Acute respiratory distress syndrome (ARDS), for example, involves an acute failure of the respiratory system but may manifest with circulatory, excretory, and even neurological symptoms. What is more, its causes range from injury from inhalants to infection to overdose of antidepressants.8 This complexity suggests that such diseases have many latent factors of variation, and modeling and disentangling these factors is essential to successful analysis.9 One potential solution to this problem is deep learning (e.g., multilayer neural networks), which has led to major breakthroughs in speech recognition10 and computer vision11.

However, despite rapid advances in methods12 and software,13,14,15,16 there has been comparatively little formal research on interpretation of deep learning architectures.17,18 This becomes an especially critical question when applying deep learning to health and medicine. Neural networks are classically viewed as "black box" models that may achieve high predictive accuracy but are uninterpretable by humans and unsafe for use on clinical problems. One solution for unraveling the complex representations produced by deep learning is to apply ideas and tools from causal inference.19 Feed-forward architectures are in fact directed acyclic graphs (DAGs), in which inputs cause higher layer activations, which in turn cause outputs. Thus, they may be thought of as causal models, which makes them amenable to causal analysis. This likewise provides an motivation for phenotype discovery, in which we seek to learn representations that are potential causes of outcomes, rather than merely correlated or predictive.

There is a growing body of research on discovering causal relationships among variables from observational data under a variety of assumptions and settings.20,21,22 In particular, we can identify potential causal relationships among the variables if noise is not Gaussian distributed.21,22 This is frequently the case for neural networks with, e.g., sigmoid hidden units and binary outcomes. In this paper, we present a first step toward automatic discovery of causal phenotypes and for cracking open the black box of neural networks, making them more readily applicable to medical
data. Our frame is a two-stage process. First, we use a simple deep neural network architecture to learn latent representations of physiology from clinical time series. Then we use a state-of-the-art causal inference algorithm called Pairwise LiNGAM\(^22\) to analyze the relationships between these learned phenotypes and patient outcomes and diseases of interest. Finally, we use common deep learning heuristics to visualize and interpret the learned phenotypes. We show that this algorithm discovers intuitive patterns of physiology known to be associated with acute illnesses. We also propose an informal causality-based framework for measuring the causal power of learned representations.

### 1.1 Related Work

While a young field (at least by that name), computational phenotyping is advancing rapidly, spurred on by the increased adoption of electronic health records (EHRs) and the growing interest from data mining and machine learning researchers. There is already a large body of excellent research, much of it published in just the last five years or so.

One popular approach to computational phenotyping is to construct a large multi-dimensional array (i.e., matrix or tensor) view of clinical data and then apply dimensionality reduction or feature selection techniques to learn a lower-dimensional set of latent bases that can be treated as phenotypes. Each basis can be seen as a combination of observations (from the original tensor), while each patient becomes a sparse set of coefficients representing her projection onto the phenotype bases. Such work can be seen as a much more powerful generalization of classic techniques such as principal components analysis. Two primary examples of this paradigm include Zhou, et al.,\(^4\) and Ho, Ghosh, and Sun,\(^5\) which apply such frameworks to outpatient disease data and medicare claims, respectively, with very interesting results. Such an approach could be applied to physiologic time series, as well.

An alternative phenotyping paradigm includes probabilistic models, which assume a generative process and then fit the model to data using, e.g., maximum a posteriori inference. Such models can be robust to uncertainty, noise, and some types of missing values and are often interpretable. Marlin, et al., used a Gaussian mixture model with a temporal smoothness kernel prior to discover meaningful physiologic patterns (or physiomes) in multivariate time series from acute care settings similar to ours.\(^1\) Saria, et al., proposed a Time Series Topic Model (TSTM) that can learn bag-of-AR (autoregressive linear models) representations from dense time series (e.g., ECG waveforms) and has been used to develop a novel severity of illness score for neonatal patients.\(^7\) Schulam, Wigley, and Saria recently proposed the Probabilistic Subtyping Model, a Bayesian framework that combines splines and Gaussian processes to cluster longitudinal data from chronic Scleroderma patients and discover potentially novel subtypes.\(^6\)

To our knowledge, work by Lasko, Denny, and Levy represents one of the first applications of modern deep learning to clinical time series.\(^3\) They train stacked autoencoders on 30-day windows of uric acid readings to learn features that are competitive with expert-designed features for classifying gout versus leukemia. They handle irregular, biased sampling by warping their time series and then sampling from a fitted Gaussian process. This framework successfully learns time series features that are both visually intuitive and useful for discerning the two phenotypes. Kale, et al., and Che, et al., recently demonstrated that neural networks (unsupervised and supervised) can be used to discover and detect interpretable subsequences in multivariate physiologic time series that are useful for classifying acute illnesses.\(^23,24\) Given that deep learning approaches have achieved breakthrough results in language modeling,\(^25\) speech recognition,\(^10\) and music transcription,\(^26\) we expect similar results (with time and effort) in health and medicine.

In deep learning research, feature analysis is often secondary to, e.g., prediction performance, and focuses on visualization. Strategies include sampling from generative models and optimizing (using, e.g., stochastic gradient ascent) over inputs rather than parameters.\(^17\) Each method has strengths and weaknesses (e.g., simplicity, computational efficiency, local optima), but they share several properties: they work best for data that are easily interpreted by human beings (e.g., images\(^27\)); they employ heuristics and approximations; and they analyze each hidden unit independently. However, recent research has begun to provide a more rigorous understanding of the representations learned by deep architectures. Szegedy, et al., showed that the semantics encoded by hidden unit activations in one layer are preserved when projected onto random bases, instead of the next layer's bases.\(^28\) This implies that the practice of interpreting individual units can be misleading and that the behavior of deep models may be more complex than previously believed.\(^29\)

One solution for unraveling the complex representations produced by deep learning is to apply ideas and tools from causal inference.\(^19\) Chalupka, Perona, and Eberhart recently proposed a theoretical framework that reformulates image classification as a causality problem (i.e., an image causes an agent to label it as a 7 or 9) and uses active learning to perform interventions that can separate causal features from spurious correlations.\(^30\) This idea offers a partial solution to the problems described above\(^28\) but requires the ability to perform interventions that may not be possible in clinical data analysis. Alternatively, there is a growing body of research on discovering causal relationships among variables...
from observational data under a variety of assumptions and settings,\textsuperscript{20,21,22} which we discuss in detail later.

2 Methods

In this section we describe our two-stage framework for discovery and analysis of causal phenotypes from clinical time series data uses deep neural networks. We first describe the background of feature (i.e., phenotype) extraction from time series in Section 2.1. We then demonstrate how deep neural networks can be used to perform both unsupervised (Section 2.2) and supervised (Section 2.3) discovery of latent representations of physiology (i.e., phenotypes) from clinical time series. Finally, we show in Section 2.4 how state-of-the-art causal inference algorithms can be used to analyze the learned phenotypes and to identify potential causal relationships between phenotypes and critical illness.

2.1 Background: feature extraction from time series

Given a multivariate time series with $P$ variables and length $T$, we can represent it as a matrix $X \in \mathbb{R}^{P \times T}$. We denote the time series of the $p$th variable as a row vector $x_{p, \cdot} \in \mathbb{R}^T$ and the $t$th time as a column vector $x_{\cdot, t} \in \mathbb{R}^P$.

A feature map for time series $X$ is a function $f : \mathbb{R}^{P \times T} \rightarrow \mathbb{R}^D$ that maps $X$ into a $D$-dimensional feature space, which can be used for machine learning tasks like classification, segmentation, and indexing.\textsuperscript{31} In a medical context, we can think of features as phenotypes. These can take the form of extreme measurements (as in severity of illness scores), thresholds, or important patterns. In multivariate time series, features become increasingly complex to design, so automated feature discovery is an attractive proposition. Given the recent success of deep learning in a variety of applications, it is natural to investigate its effectiveness for feature learning from clinical time series data.

![Image](image1.png)

Figure 1: Deep neural networks for phenotyping from clinical time series.

2.2 Deep unsupervised autoencoders for phenotyping clinical time series

We explore several deep neural network architectures for automatic discovery and detection of important physiologic patterns. We begin with a simple denoising autoencoder (DAE).\textsuperscript{32} This is a one layer unsupervised model that simultaneously learns paired encoding and decoding functions, similar to sparse coding but easier to optimize and incorporate into deep architectures. Figure 1a shows a simple illustration of the DAE.

We encode and decode $x$ using rules similar to making a prediction using a logistic function:

$$h = g(Wx + b), \quad \hat{x} = g'(W' h + b')$$

where $h \in [0, 1]^D$ is the latent representation, $\hat{x}$ is the reconstruction, and $g$ and $g'$ are elementwise nonlinearities (a common choice is the sigmoid function $g(z) = 1/(1 + \exp\{-z\}$). The choice of $g'$ depends on the type of input $x$. As described later, in this work we scale all variables to fall between 0 and 1, so we can use a sigmoid for decoding as
well. As is typical, we also tie the weights, letting \( W' = W^T \). Finally, in DAEs we actually add random corruption to the input before encoding, sampling \( \hat{x} \sim P_{corr}(\hat{x}|x) \). In our case, \( P_{corr} \) applies a binary masking to \( x \), zeroing out each entry independently with some probability \( p \).

We train the weights by minimizing the reconstruction loss for each training example. For \([0, 1]\) inputs, we use cross entropy loss

\[
\mathcal{L} = - \sum_{d=1}^{D} (x_d \log \hat{x}_d + (1 - x_d) \log(1 - \hat{x}_d)),
\]

where \( x_d \) is the \( d \)th dimension of \( x \). Note that for a DAE, \( \hat{x} = g'(W^T g(W \hat{x} + b) + b') \), i.e., the reconstruction of the corrupted input \( \hat{x} \). We use standard (stochastic) gradient methods to minimize the reconstruction error with respect to \( W, b \) and \( b' \) for all training examples.

We can construct a deep autoencoder by stacking multiple DAEs, forming a stacked denoising autoencoder (SDAE).\(^{33}\) SDAEs are typically trained using greedy layer-wise training,\(^{34}\) as shown in Figure 1b. Once the weights for layer \( \ell \) have been trained, we can map each training example into its feature space, producing \( h^{(\ell)} \). This then becomes the input for training the \((\ell+1)\)th layer. Note that \( h^{(0)} = x \), the input.

In our setting, \( x = \text{vec}(X) \), a vectorization of our \( P \times T \) time series. We can then use an SDAE of any number of layers as a feature map \( f \) for time series, as shown in Figure 1c. Each element of \( h^{(\ell)} \) is a nonlinear function of the SDAE’s inputs, meaning that it can capture complex correlations across both time and variables. This makes it well-suited tool for phenotyping from clinical time series, especially when working with relatively small data sets with few or unreliable labels.\(^3\)

### 2.3 Deep supervised neural networks for phenotyping clinical time series

We can convert a deep autoencoder into a deep feed-forward neural network by adding an additional output layer to make predictions, as shown in Figure 1c. For binary classification, we typically use a sigmoid nonlinearity applied to a linear activation, i.e., a logistic regression:

\[ y_k = \sigma(\beta^T_k h^{(\ell)}) \]

where \( y_k \) is the \( k \)th output unit and \( h \) are the hidden unit activations (we omit the bias for brevity). Neural networks lend themselves naturally to multi-output prediction problems (also called multi-label or multi-task learning), and training such neural networks can often improve prediction performance by enabling the neural network discover shared features that are useful across a range of tasks. In a medical context, this approach can be used to train a single model to predict multiple outcomes or diagnoses.

A neural network with \( L \) hidden layers and an output layer has hidden layer parameters \( \{ (W^{(\ell)}, b^{(\ell)}) \}_{\ell=1} \) and output parameters \( \{ \beta_k \}_{k=1}^K \) for \( D^{(L)} \) hidden units in the \( L \)th layer and \( K \) outputs. For \( K \) binary classification tasks, the loss function during supervised training also uses cross-entropy but with the true labels (vs. reconstruction, as in the SDAE):

\[
\mathcal{L} = - \sum_{k=1}^{K} \left( y_k \log \sigma(\beta^T_k h^{(L)}) + (1 - y_k) \log(1 - \sigma(\beta^T_k h^{(L)})) \right)
\]

where \( h^{(L)} = g(W^{(L)} h^{(L-1)} + b^{(L)}) \) and \( h^{(0)} = x \). Again, we minimize the loss with respect to all model parameters using (stochastic) gradient descent and backpropagation.

### 2.4 Discovery of causal phenotypes from clinical time series

One of the main advantages of deep learning is its ability to disentangle factors of variation that are present in the data but unobserved.\(^9\) This makes subsequent learning (i.e., training a classifier) much easier since it counteracts the curse of dimensionality.\(^{35}\) In addition, knowledge about one factor usually improves estimation about another.\(^{36}\)

However, it can often be difficult to analyze and understand the learned latent representations and to understand whether the model is learning truly important relationships or spurious correlations. One way to explore and demonstrate this fact is to perform causal analysis of the features extracted by the hidden layers of a deep neural network. Disentangled representations should have clearer and stronger causal relationships with other variables of interest (e.g., mortality) than raw outputs and other choices of features. Additionally, causality is of primary interest in medicine and health, especially if analytics will contribute to decisions about treatment and care, which can significantly impact patient lives and outcomes. Thus, discerning correlation from true causal relationships is of vital importance.
Given a set of features denoted by $\mathbf{h} \in \mathbb{R}^{D(L)}$ and a response variable $y$, we investigate the causal relationship between each feature $h_j$, $j = 1, \ldots, D(L)$, and the response variable $y$. There are two options: either the direction of the edge is from feature to the response variable $h_j \rightarrow y$ or vice versa $h_j \leftarrow y$. We are interested only in the former case where the features are causally predictive of the response variable. Thus, we need to use a causality discovery procedure to find the direction of causation between the features and the response variable.

Classic causal inference algorithms require a set of causal priors to be available for the variable to be able to cancel out the impact of spurious causation paths. While we often do not have such priors available for our outputs, we can still identify causation among the variables if they are not distributed according to a Gaussian distribution. Binary labels (e.g., mortality prediction) satisfy the requirements of many causal inference frameworks. We apply a state-of-the-art causal inference algorithm Pairwise LiNGAM, based on DirectLiNGAM, in order to discover the causal edges between each feature and response variable. The key idea of this algorithm is to compute the likelihood ratio of the two models $h_j \rightarrow y$ and $h_j \leftarrow y$ for $j = 1, \ldots, D(L)$ and select the direction that makes the log-likelihood ratio positive. In particular, we have

$$R = \frac{1}{n} \mathcal{L}(h_j \rightarrow y) - \frac{1}{n} \mathcal{L}(h_j \leftarrow y) \quad \Rightarrow \quad \begin{cases} h_j \rightarrow y & \text{if } R > 0, \\ h_j \leftarrow y & \text{if } R < 0. \end{cases}$$

where $n$ denotes the number of observations. The log-likelihood values are computed using the non-parametric entropy estimation techniques. Pairwise LiNGAM requires that the two variables be non-Gaussian distributed, which makes it especially useful for analyzing deep neural networks with nonlinear activation functions in hidden layers and logistic outputs. This is the case in our setting.

It is important to emphasize that causal inference algorithms do not necessarily select those features that are most correlated with the response or most useful in predicting it. Our goal in causal analysis, rather, is to discover a subset of features that are the best candidates to be true causes of the response and which may provide insight (not necessarily more predictive power).

Next we propose an informal method for quantifying the causal power of features (derived or learned). After learning the causal features, we follow the recommendation, we fit a logistic regression model to the features selected by the causality discovery algorithm as follows:

$$\hat{\alpha}, \hat{\alpha}_0 = \arg \max_{\alpha, \alpha_0} \left\{ \sum_{i=1}^{n} [y_i \log \sigma(\alpha^\top \hat{\mathbf{h}}_i + \alpha_0) + (1 - y_i) \log(1 - \sigma(\alpha^\top \hat{\mathbf{h}}_i + \alpha_0))] \right\}$$

where $\hat{\mathbf{h}}$ represent the set of features selected by the causality discovery algorithm and $\alpha, \alpha_0$ denote the prediction vector and the intercept, respectively. We treat the resulting weights as the magnitude of each variable's causal relationship. Finally, we use the $L_2$ norm of the regression coefficient vector $\|\alpha\|_2$ to quantify the overall causal power of the features being analyzed. We can use this to compare the causal power of different representations.

3 Experiments

In order to demonstrate the effectiveness of our framework, we performed a series of phenotype experiments using two clinical time series data sets collected during the delivery of care in intensive care units (ICUs) at large hospitals. After describing our data and experimental set up, we briefly present quantitative results for several classification tasks, in order to demonstrate the predictive power of features discovered by neural networks (Section 3.1). Then in Section 3.2, we apply causal inference tools to the learned features in order to discover the most clinically meaningful features and to analyze the quality of the learned phenotypes. We also provide example visualizations of causal features learned by neural networks that capture clinically significant physiologic patterns.

**Physionet Challenge 2012 Data.** The first data set comes from PhysioNet Challenge 2012 website which is a publicly available collection of 8000 multivariate clinical time series from one ICU and three specialty units, including coronary care and cardiac and general surgery recovery units. As with the competition, we focus on mortality prediction (from the first 48 hours of each episode) as our main prediction task. This is a challenging problem: no competition entry scored precision or recall higher than 0.53. We used both Training Subsets (A and B) for any unsupervised training but only the labeled Training Subset A for supervised training and evaluation (to our knowledge, labels are not available for Subset B). Each episode is a multivariate time series of roughly 48 hours and containing over 30 variables. While each episode also has a variety of static variables available (e.g., age, weight, gender), we focus our experiments
on just the time series. In all supervised learning experiments, we use label stratified 10-folds cross validation when estimating performance scores.

**PICU Data.** The second data set consists of ICU clinical time series extracted from the electronic health records (EHRs) system from Children's Hospital LA (CHLA), previously described in Marlin, et al, and Kale and Che, et al. The original data set includes roughly ten thousand episodes of varying lengths, but we exclude episodes shorter than 24 hours, yielding a data set of roughly 8500 multivariate time series of thirteen physiologic variables. Each episode has zero or more associated diagnostic codes from the Ninth Revision of the *International Classification of Diseases*, (ICD-9). We aggregate the five-digit ICD-9 codes according to the standard seventeen broad category codes (e.g., 460-519 for respiratory diseases) and supplementary V and E groups. We then treat predicting each category code as a distinct binary classification task. The sparse multi-label nature of these data prevents us from applying cross-validation; we instead create five 80/20 random splits of the data, ensuring that each split has a minimum number of positives examples for each ICD-9 label.

**Preprocessing.** We perform three steps of preprocessing to both data sets before analysis. First, we scale each variable to a $[0, 1]$ range. Where variables have known ranges (e.g., Total Glasgow Coma Scale or binary variables), we use these. Otherwise, we treat the 1st and 99th percentiles of all measurements of a variable as its minimum and maximum values. Outliers are truncated to 0 or 1. This is applied to both time series and static variables. Next, we resample all time series to a fixed hourly sampling rate using a simple bucketing procedure: we divide each time series into 48 non-overlapping hour-long windows. When a window includes more than one measurement, we take the mean. Where this creates missing values, we propagate forward the previous measurement. This makes a reasonable assumption that each time series is relatively stable and that important changes are observed and recorded. Finally, we handle entirely missing time series (e.g., a patient may have zero measurements of end-tidal CO$_2$ if she is not ventilated) by imputing a `normal` value. For variables without known normals, we use the median of all measurements in the data set. This strategy the fact that missing time series are typically not missing-at-random but rather are missing because clinical staff decided not to measure a particular variable. Often this is because they also assume it is normal.

**Neural network training.** We implemented all neural networks in Theano as variations of a multilayer perceptron with 3-5 hidden layers (of the same size) of sigmoid units. The input layer has $PT$ input units for $P$ variables and $T$ time steps, while the output layer has one sigmoid output unit per label. We initialize each neural network by training it as an unsupervised stacked denoising autoencoder (SDAE). We found this helps significantly because our data sets are relatively small and our labels are quite sparse. We use minibatch stochastic gradient descent to minimize cross-entropy loss during unsupervised pretraining and logistic loss during supervised finetuning. We use ten-fold cross validation, and both neural networks and classifiers are not trained on the test folds. Additionally, we use grid search and one training fold to tune parameters (e.g., the strength of the L1 penalty).

### 3.1 Classification performance

We first present a quantitative evaluation of the predictive performance of different types of features, both hand-designed and learned, on the Physionet Challenge 2012 data set. To ensure a fair comparison, we use the same type of classifier in all experiments: a linear support vector machine (SVM) with hinge loss and a designed and learned, on the Physionet Challenge 2012 data set. To ensure a fair comparison, we use the same type of cross validation, and both neural networks and classifiers are trained on the test folds. Additionally, we use grid search and one training fold to tune parameters (e.g., the strength of the L1 penalty).

We do not use our neural networks to make predictions. We select the strength of the L1 penalty by performing a grid search over the range $[10^{-2}, 10^{2}]$ and choosing the value that maximizes the Area Under the Precision-Recall Curve (AUPRC) on a held-out subset of our training data. We report both Area Under the Receiver Operator Curve (AUROC) and AUPRC, as well as the Precision when Recall is 90%. All three metrics are more robust to the class imbalance of our label than accuracy and give us an idea of the trade-off between false negatives and false positives.

Our baselines include the raw data and hand-designed features that capture the extremes, central tendency, variation, and trends within the entire time series. While relatively simple from a machine learning perspective, these features are often quite effective for clinical predictive modeling and similar to those used in classic severity of illness scores. Table 1 shows the mortality prediction performance for the Physionet Challenge 2012 data for our best-performing baselines and neural network features. We see that features learned using a 3-layer neural network beat the raw data fairly substantially and are competitive with the hand-designed features. Given the success of neural networks in other domains, it is somewhat disappointing that the learned features do not beat the hand-engineered features soundly. However, we offer several observations to temper this disappointment: first, we invested minimal time in tuning hyperparameters of the neural network, including hidden layer sizes, learning rate, and early stopping criteria. Additional experiments (not reported here) suggest that our neural network underfit the training data due to insufficient size and training epochs.
Second, as shown in the bottom two rows of Table 1, we found that we could substantially improve performance by combining the neural net and hand-engineered features. This suggests that in fact the neural net learns features that contain information that does not overlap that captured by the hand-engineered features and may capture different physiologic patterns. What is more, as shown in Section 3.2, they have increased causal power.

Interestingly, we found minimal difference between the performance of features learned using unsupervised and supervised neural networks. We speculate that this has two causes. The principle reason, we speculate, is the class imbalance in our labels, which we did not attempt to handle in any way during neural network training. Second, mortality prediction from early admission data is a difficult problem, and it may not be possible to do substantially better (our results are similar to those from the competition).

### 3.2 Causal analysis

Next, we perform causal inference on the hand-designed and learned features using the framework described in Section 2.4. Table 2 shows the per-feature causal power (i.e., the $L_1$ norm of the coefficient vector divided by the number of features with nonzero weights) of the raw data, hand-designed features, and neural network features for Acute Respiratory Distress Syndrome (ARDS) in the PICU data. We see the the neural network features have, on average, a much larger magnitude than either of the baselines.

</tr>
</tbody>
</table>

Table 1: Classification performance on the Physionet Challenge 2012 data set. We report mean and standard deviation (across 10 folds) for each metric. We use the following abbreviations: $R$: raw time series, $H$: hand-designed features, $NNet(I,L)$: L-layer neural network with input $I$

Figure 2 shows visualizations of two the significant physiologic patterns learned by the neural networks. For each we used causal inference to discover the subset of features with the strongest causal relationship with our outcome of interest. Then we found the 50 input subsequences with the highest activations in those units and plotted the mean trajectories for some or all physiologic variables. Figure 2a visualizes features that were found to be causally related to the ICD-9 circulatory disease category from the PICU data. We see these features detect highly elevated blood pressure and heart rate, as well as depressed pH. The features also detect elevated end-tidal CO2 (ETCO2) and fraction-inspired oxygen (FIO2), which likely indicate ventilation and severe critical illness. Interestingly, these features also detect elevated urine output, and thus it is not surprising that these features are also correlated with diagnostic labels related to urinary disorders. Figure 2b visualizes the First-48-hour physiologic patterns detected by features that are causal of mortality in the Physionet Challenge 2012 data.

### 4 Discussion and Conclusion

We have presented a simple, two-stage framework for discovering latent phenotypes from clinical time series that have strong causal relationships with patient outcomes and critical illness. Our framework combines feature learning using neural networks with causal inference tools to discover latent phenotypes that are causally predictive of clinical outcomes. While our results are preliminary, we believe that this general line of research will help us discover more clinically meaningful representations of health and illness and to eventually develop tools for automatic discovery of causal phenotypes.
(a) 12-hour causal phenotype for ICD-9 circulatory disease category (390-459), learned from the PICU data.

(b) 48-hour causal phenotype for mortality, learned from the Physionet Challenge data.

Initial Readability Assessment of Clinical Trial Eligibility Criteria

Tian Kang, BS, Noémie Elhadad, PhD, Chunhua Weng, PhD
Department of Biomedical Informatics, Columbia University, New York, NY 10032

Abstract

Various search engines are available to clinical trial seekers. However, it remains unknown how comprehensible clinical trial eligibility criteria used for recruitment are to a lay audience. This study initially investigated this problem. Readability of eligibility criteria was assessed according to (i) shallow and lexical characteristics through the use of an established, generic readability metric; (ii) syntactic characteristics through natural language processing techniques; and (iii) health terminological characteristics through an automated comparison to technical and lay health texts. We further stratified clinical trials according to various study characteristics (e.g., source country or study type) to understand potential factors influencing readability. Mainly caused by frequent use of technical jargons, a college reading level was found to be necessary to understand eligibility criteria text, a level much higher than the average literacy level of the general American population. The use of technical jargons should be minimized to simplify eligibility criteria text.

Introduction

As the gold standard for generating the most rigorous medical evidence regarding the effectiveness and efficacy of new medical therapies, clinical trials are fundamental for advancing medical research and public health. However, recruitment has remained the biggest persistent obstacle. With the pervasive Internet access, the rise of web-based patient-trial matching and patient-screening methods presents great opportunities to overcome recruitment barriers. There is an increasing need to engage the general public in participating in clinical trials through “active matching,” where patients or health consumers are empowered to review clinical trial eligibility criteria and select clinical trials to participate in. According to the search logs of popular online clinical trial search engines, in addition to researchers, patients and health consumers have been increasingly searching and browsing clinical trials.

The success of active patient-trial matching hinges on the readability of clinical trial summaries, particularly the eligibility criteria language that clinical trial seekers use for determining their match to a trial. Because of the different professional training levels between patients and the researchers who wrote the clinical trial summaries, we hypothesize that required reading level of the trial texts are higher than the health literacy of out-of-domain readers. In particular, eligibility criteria, which determine the potential match for a patient, contain complex, specific content primarily written for researchers. In this paper, we examine the readability of clinical trial eligibility criteria.

Text readability assessment is an established field of research. As defined by Dale and Chall et al., readability is “the sum total (including all the interactions) of all those elements within a given piece of printed material that affect the success a group of readers have with it. The success is the extent to which they understand it, read it at optimal speed, and find it interesting”. Most readability measures have been established as assessment of shallow features of text, such as the number of words per sentence and the number of syllables per word. The SMOG readability assessment formula, which measures the percentage of polysyllables in texts, is a popular method for semantic assessment. These widely adopted assessments are easy to compute on any text but lack the ability to represent the complexity of a text accurately, as this requires the use of both semantic and syntactic features. Measures of readability, which do assess both semantic features and syntactic features, have also been adopted to achieve more accurate assessment results. The New Dale-CHALL formula uses a combination of average sentence length and the proportion of the words in the text deemed “difficult” based on a 3000-word list containing what have been identified as the most commonly used English words. As an added benefit, Natural Language Processing (NLP) enables automated readability assessment. For instance, Yngve measures the depth of nodes in the parse tree using NLP methods as the indicator of structure complexity. These well-accepted methods for readability assessment have been validated in general reading materials and have been in use for years. Feng et al. performed a readability measurement for people with intellectual disabilities (ID) using a linear regression model to fit a set of cognitively motivated features. Methods like Support Vector Machine were also popular in this kind of research. However, supervised learning approaches constantly suffer from one big limitation, the need for large-scale labeled corpora.

Compared to what is known about general English’s readability, our understanding of biomedical text’s readability, especially that of clinical trial summaries, remains limited. Many studies of medical texts focus on online health-related materials and evaluate if these texts’ readability meets the recommendations of NIH, AMA and USDHHS.
standards (less than 6 grade) using general readability formulas. A review of all readability and comprehension instruments used for print and web-based cancer materials concluded that although readability formulas are predictive measures of text comprehensibility, they have been criticized for “only relying on word and sentence factors and for ignoring possible effects for reader motivation, design, and graphics on readability and comprehension”. Kim et al. developed a new health text-specific readability measurement, which is based on the distance of text features from the health related material to the predefined “easy” and “difficult” documents. It takes both syntactic features and semantic features into consideration and generates a sum of those distances as the indicator of readability. This method has been applied to several studies since its inception.

Since clinical trials constitute a critical part of the biomedical domain, the readability of clinical trials has started to receive attention. For example, Wu et al. conducted a readability assessment for description text in clinical trials from ClinicalTrials.gov using both general purpose and medical specific readability assessment measures. They concluded that the descriptions were the most difficult to read when compared to other corpora e.g. electronic health records, MedlinePlus Health Topics articles. Ross et al. conducted the first formal analysis of computer-interpretations of eligibility criteria complexity in clinical trials in order to facilitate phenotype studies. They randomly selected 1000 clinical trials from ClinicalTrials.gov and manually analyzed their complexity and semantic patterns. The results concluded that 93% of these free-text criteria were mainly comprehensible for professionals and 85% had significant semantic complexity for computational representations. Still, little is known about the readability of eligibility criteria and its impact on clinical trial recruitment and evidence adoption. Aiming to fill this knowledge gap and guide future improvement of consumer-facing clinical trial search engines, this paper contributes the first comprehensive readability assessment of clinical trial eligibility criteria text. In this study, we measured the human reading level necessary to understand the eligibility criteria in ClinicalTrials.gov. We measured both general readability and health-domain specific readability of eligibility criteria and discussed the implications of our findings for clinical trial designers and clinical trial search engine developers.

**Methods**

**Datasets**

Three corpora were used for comparison in this project. We retrieved clinical trial summaries from the world’s largest clinical trial registry, ClinicalTrial.gov, as our target corpus. To generate a better understanding of the results, we also performed assessments on two health-related corpora, i.e., Reuters News and PubMed. Reuters News is intended for lay people. PubMed is intended for technical readers. Samples taken from the three corpora are shown in Table 1. We select a set of disease topics to include disease-specific descriptions from the three corpora. We downloaded the flat file of the database from the ClinicalTrials.gov website using their API and extracted trial summary text for the same list of health topics in two health-related corpora (e.g., Alzheimer, Type 2 Diabetes Mellitus, and Cardiovascular Diseases). We matched these disease topics to the condition field of clinical trial summaries supplied by ClinicalTrials.gov. We extracted 120,977 clinical trials on the aforementioned health topics. Then we collected 3,144 Reuters stories along with their corresponding PubMed articles.

**Table 1. Sample text on the topic of “lung cancer” from the three corpora**

| PubMed articles | ...Marijuana smoke contains many of the same constituents as tobacco smoke, but whether it has similar adverse effects on pulmonary function is unclear...The Coronary Artery Risk Development in Young Adults (CARDIA) study, a longitudinal study collecting repeated measurements of pulmonary function and smoking over 20 years...
 |
| --- | --- |
| Reuter News | ... A few hits on the bong now and then don't seem to have any detrimental effects on lung health, suggests a new study. Researchers found that multiple measures of lung function actually improved slightly as young people reported using more marijuana ...
 |
| Eligibility Criteria | Ages Eligible for Study: 18 Years and older  
Genders Eligible for Study: Both  
Inclusion Criteria:  
• Pathologically confirmed, by biopsy or cytology, non-small cell lung carcinoma diagnosed within 3 months prior to study enrollment.  
• T1, N0, M0 or T2, N0, M0.  
• ...  
Exclusion Criteria:  
• Evidence of distant metastasis (M1) and/or nodal involvement (N1, N2, N3). |
The new Dale-Chall formula was also used. This measurement is considered more accurate than the original formula as it is based on the use of “easy” and “difficult” words rather than syllables or simply letter counts. It labels words found on an established word list containing 3000 statistically common-used English words as “easy” word if the word is not included in the word list, then this word is labeled as “difficult” and a corresponding penalty is added to the final score. The final score can then be mapped to the grade level and the required grade reading level for readers can be determined. The mapping from SMOG grade to U.S. standard educational level and the mapping from final score to education levels are shown Table 2.

The calculation method is as follows:

Raw score = \(0.1579 \times \) percentage of “difficult words” + average sentence length

If percentage of “difficult words” >5%

Adjusted score = Raw Score + 3.6365,

Otherwise Adjusted score = Raw score

Table 2. Mapping of Readability Levels across Standards
2. Term familiarity prediction

We hypothesized that the technical terminology used in eligibility criteria might be one of the major obstacles preventing lay readers from fully understanding the content. Thus, a health-domain specific method published by Elhadad [2] was applied to evaluate the familiarity of words used in EC texts based on word frequency. The words with high frequencies in “easy” texts are usually found to elicit a higher recognition than words with lower frequencies. We know that the Reuter Health news stories are targeted at lay readers, thus when a word shows a high frequency (in its all morphological variants) in this corpus, we can define it as “familiar” (“easy”) for lay readers. In contrast, the words with high frequencies in PubMed articles, but rarely seen in the news stories, are more likely to elicit a higher requirement for professional knowledge, then this word tends to be more “unfamiliar” (“difficult”) for lay readers. Therefore, if the term usage in EC texts is more similar to Reuter News, then we could conclude that the terms used in EC texts are generally not difficult for lay readers; otherwise, the demands of the EC texts are more like technical papers. Figure 2 illustrates the 3-step approach we applied to evaluate term familiarity.

![Figure 2. Our analysis schema for familiarity evaluation of terms](image)

concept to contain several lexical variants mapping to the same CUI (e.g. CUI: C0027051, lexical variants: heart attack, myocardial infarctions). We generated a frequency distribution of all lexical variants for each CUI in each corpus and then applied Kullback–Leibler divergence to evaluate pairwise differences between Reuter news/ EC texts, and PubMed articles/ EC texts. When the difference between eligibility criteria texts and news was smaller, we defined the word usage in EC texts as relatively “easy” for lay readers. For example, for CUI C0027051, we determined the frequency of use of “heart attack” and “myocardial infarctions.” Commonly, the latter is a more technical term used in the health domain and so we expect a lower frequency in the Reuter news corpus, e.g. 0.01. Say we found that the frequency distribution of C0027051 in the news corpus was (0.99, 0.01); then we would calculate the frequency of the same CUI in the PubMed article. We expect that the frequency of “myocardial infarctions” would be much higher in technical papers than in the news corpus, e.g. (0.5, 0.5). When we apply KL divergence between the two distributions of the compared (news and article) and the test (clinical trials) corpus, those having similar distributions of word frequency can be detected. After manually filtering the concepts detected by HealthTermFinder that were not discriminative enough to be distinguished as technical or general text, such as C0014522 - "at any time," and also those not existing in our selected eligibility criteria texts, 90 UMLS concepts were finally selected. The KL divergence of Q from P is defined as:

$$D_{KL}(P||Q) = \sum P(i) \ln \frac{P(i)}{Q(i)}$$

3. Stratified analysis using clinical trial metadata

Considering that context may help with comprehension, we also took the complete text of each clinical trial into consideration. Besides the eligibility criteria, ClinicalTrial.gov has also archived the background information, the purpose, and some other detailed metadata of each clinical trial. To examine clinical trial metadata associated with readability of eligibility criteria, we classified the selected trials by their recruitment conditions and study results and chose SMOG and Dale–Chall scores as the indicators of required reading level. Further, we investigated clinical trial metadata that might be associated with a variance in reading levels. We tried to classify the trials using some other metadata (e.g., country that submitted the trial, the year that the trial was started). We selected two lexical features as indicators for the stratified analysis in that, 1) they are easy to compute, and 2) though the general readability formulas suffer from a lack of ability to precisely measure biomedical text readability, they are still able to indicate the discrepancies in required readability among different texts and enable stratified analyses. The text processing was carried out in Perl (v5.18.2), and the statistical analysis was performed using R 3.1.1.
Results

1. Features Evaluation

The overall readability measurement results are shown in Table 3. The first two columns reflect the results for the two standard corpora used for comparison with the EC texts. Examining the shallow features, we can see that generally PubMed articles are more complex than their corresponding news stories, using longer sentences and more complex words. This is consistent with our intuition about scientific papers. A more in-depth look at the syntactic features reveals that the PubMed articles tend to use more nouns in each sentence while Reuter news stories tend to use more verbs and subordinate clauses. This result also is consistent with the characteristics of each type of literature. The news style, used for news reporting in mass media, tends to use subject-verb-object construction and vivid, active prose, to inform the public compared to the corresponding scientific papers, which follow the style of technical writing, having longer sentences including a series of nouns or noun phrases. Also, at the word level, as a rule, journalists try not to rely on jargon and will not use a long word when a short one will work the same, because their readers are the masses and so have completed various levels of education. Scientists, however, are more likely to use professional terminology. These contrasting features are reflected in the lexical feature results – both methods used graded PubMed articles much higher than the news. For Reuter news, according to Table 1 and 2, both SMOG and Dale-Chall grades indicate a reading level requirement of around grade 13-14, reflecting the consistency of the two kinds of measurement. However, discrepancy regarding the reading grade level exists between the measurement results (grade 13-14, college) and the claim made by Reuter news (grade 12, high school). This can be explained by the findings in a review of readability16 -- SMOG usually results in a score one or two grade levels higher because it is based on stricter criteria for readability, like other similar assessment methods. Overall, PubMed articles tend to use longer and more unfamiliar terms than the news, requiring readers to have at least a college degree to fully comprehend them.

* The 95% Confidence Interval for averages of the scores of eligibility criteria from the entire database were calculated using 1000 bootstrap

After ensuring that we had a full understanding of the results for the two standard corpora, we interpreted the corresponding results for the EC texts. Two kinds of EC texts were assessed here. As mentioned above, we were also concerned whether other parts of the trials documents might help readers to understand the EC of clinical trials besides the EC texts we were focusing on. Thus, the third column in Table 3 represents the assessment results for the complete document text of the clinical trials (including purpose, detailed description, eligibility criteria, etc.), which we refer to as “CT texts” here. Finally, the fourth column is the assessment results for the eligibility criteria text (“EC text”) alone. Compared to the Reuter and PubMed corpora, EC texts tend to use much shorter sentences (aWPS) and all 3 syntactic features indicate a particularly simple syntactic structure, especially in the EC text.

The reason for these results can be explained by the sample texts in Table 1. Eligibility criteria basically consist of short descriptions or the constraints for the characteristics of the target cohorts, and most of time they are not even a complete sentence, leading to particularly low results for aNP, aVP, and aSBr. In contrast, the syntax of the CT text is closer to that of the standard corpora and the assessment results with respect to lexical aspects (aSPW, aPPS, SMOG and Dale-Chall) further indicate that the CT texts are more similar to PubMed articles, indicating a college reading level requirement. However, discrepancy appeared between the results for the EC text in SMOG and those in Dale-Chall. The SMOG grade indicated that this corpus requires only a high school reading level, even lower than that of Reuter news, while the Dale-Chall grade indicated that it needs at least college level reading skill to understand, meaning the EC text is as difficult as that in the PubMed corpus. The most likely explanation for this result is that while EC text uses many short terms, they are unfamiliar to the public, but this cannot be accounted for when using SMOG methods, because SMOG only takes the number of polysyllables into consideration. For
example, some technical terms, e.g. “heparin”, are much shorter than some familiar words, e.g. “characteristics”, but are more difficult to understand for lay readers. Moreover, we also observed a large amount of professional abbreviations present in EC texts (e.g. “AD”, “KPS”), which also have fewer syllables, but present more difficulties for readers with low health literacy. The Dale-Chall scoring system, in contrast to SMOG, takes familiarity of the words into major consideration, perhaps explaining why it determined EC texts to be as difficult to read as scientific papers. Thus, in conclusion, for EC texts, the syntactic structure may not cause problems for readers, but the large number of unfamiliar terms (e.g. technical jargon) used can be a major obstacle for lay readers, who lack a high level of health literacy. The other parts of the text in clinical trials literature were found to require an even higher reading level (see Figure 3). Each dot represents a clinical trial. Most of the dots are above the diagonals, consistent with the recent results for the readability assessment of the detailed descriptions in CT texts from clinicaltrials.gov by Wu et al. Specifically, in their paper, they reported that detailed descriptions required an education level of grade 18 to understand. Therefore, it seems that other parts of the CT texts cannot offer much help to readers with respect to understanding eligibility criteria.

Figure 3. Lexical feature comparison between eligibility criteria and the according whole documents. Left: SMOG Grade; Right: Dale-Chall Grade. The x-axis is the SMOG grade of the whole clinical trial summary and the y-axis is the SMOT grade of the eligibility criteria text.

2. Term familiarity evaluation

The results for lexical features in Table 3 have led us to conclude that the terms used in EC texts are as unfamiliar for the public as those used in scientific papers, even though sometimes the words or terms are not that long and complex. Those findings agree with our hypothesis that technical jargon is one of the major obstacles to lay readers comprehending EC texts. To further confirm this hypothesis, we performed a term familiarity evaluation. As described in the methods section, we chose 90 UMLS concepts to evaluate for term familiarity by computing the KL divergence of the EC texts from both the PubMed and the Reuter corpora. If the divergence of term usage between EC texts and PubMed articles is smaller than that of the news articles, then the conclusion would be that EC are organized and composed with unfamiliar and more technical terms like professional papers. Otherwise, the reverse would be true. For instance, CUI C0027051 has the lexical variants “heart attack” and “myocardial infarction.” In our eligibility criteria text, “heart attack” occurred 434 times while “myocardial infarction” occurred 5810 times, accounting for 7% and 93% of the text, respectively. In Reuter, this set of frequencies was 100% and 0%; while in the PubMed corpora, it was 50% and 50%. The results for KL divergence showed that for this set of lexical variants, the eligibility criteria text was closest to PubMed articles. The 90 comparison results after 180 times performing KL divergence are shown in Figure 4. Only eight sets of lexical variants from the same CUI could not determine which

Figure 4 Results of KL divergence for 90 chosen UMLS CUIs to perform word familiarity prediction.
corpus our eligibility criteria was closer to. Among the rest of the valid values obtained, about 60 % of the concept usage results indicated a more technical lexical variant of the same concept was likely to be chosen to elaborate the EC. Again, this kind of term usage pattern is likely to increase the difficulty for out-of-domain readers to understand the criteria.

3. Clinical Trial Stratification analysis

The readability assessment of the EC texts from clinicaltrials.gov has come to a conclusion, but in order to make use of our results to improve the readability of clinical trials, we extended our research one step further and did a series of preliminary analyses to guide future work and in the hopes that we could find factors related to the changes in required reading level. We stratified the trials according to different features: source country, study type, recruitment conditions and whether they had final results. From all 120,977 files used for general analysis, we filtered out the data that had missing records for these features, which left 46,137 trial files to be examined in our stratified analysis.

Start year and study results.

Only 4,449 of the 46,137 files, less than 1/10 of all the clinical trials examined, included final study results. This is depicted in Figure 5 – where one dot represents one documented trial. There are several possibilities that may lead to no result being recorded. Often it’s either because the trial was not completed yet or the studies were terminated halfway. As the graphs also show, the red dots (trials with recorded results) are all located on the right side, indicating that the clinical trials with recorded results are more likely to be the trials started more recently. One way to explain this fact could be that the related knowledge and findings have grown tremendously in recent years, or the technology to document related records has advanced. For this reason, we were not surprised to observe a significant increase in numbers of records in the early 21st century, with the variance in required reading level of the eligibility

![Figure 5](image.png)

**Figure 5.** Distribution of lexical features among years according two readability measures. The red dots present the trials with final results, and the green points represent this without results records criteria being enlarged since then as well.

Study type.

The two graphs in the upper row describe the readability of lexical features for eligibility criteria, and show no significant distinction among the different types of trials. However, when evaluating the whole documents (CT texts; two graphs in the lower row of **Figure 5**), the red and purple dots clearly split into separate groups, with the group of purple dots, representing interventional trials, clearly requiring above-average literacy to comprehend. This separation indicates that the discrepancy in required reading levels between the two major kinds of trials is more distinct than when considering EC texts alone. The results also show that, the observational studies were much easier to read than the interventional studies, which is consistent with the internal complexity of the interventional studies. However, as the number of submitted clinical trials began to increase rapidly, the readability of the two types converged to be more similar.

This very interesting phenomenon requires further study to determine what factors influenced this convergence. In comparing the results for EC texts alone (upper row in Fig 5) and the whole trial documents (lower row), it’s obvious that the complexity of the interventional studies with respect to reading is not mainly caused by the eligibility criteria text but by other parts of the trial documents, e.g., detailed descriptions of the studies. Figure 6
reveals that observational (purple) and interventional (green) studies comprise the majority of the documents. It also shows that, as the 21st century approached, the number of interventional studies increased dramatically, a reasonable result given the advances made in medical science.

Source country.

Before the study, we hypothesized that whether English was the first language for the researchers who wrote those trial summaries might also influence the readability of the trial documentations. Since the number of U.S. and Non-U.S studies in the corpus were relatively equivalent (39% and 45%), we were able to classify trials for source
country into one of only two groups: U.S. or non-U.S. (includes many non-English speaking countries, e.g. Germany, China, Japan). We then explored the differences in the readability of the trials according to country where the trial was being performed. It’s interesting to notice that when stratified the whole documents (the two graphs in lower row of Figure 7), the trials with no location recorded showed either much higher or lower readability than the average level. We sorted all the trials by their startyears and noticed that most of the trials short of country information were started before 2000, and account for a large part of all documents before 1990s. We manually reviewed some trial documents with extrem readability scores and noticed that the low scores (easy to read) were always gained because the incompleteness of the trial documents, while the extremely high scores (difficult to read) were caused by multiple reasons, e.g. internal complexity of the study disease. One intersting thing we also found is that most of the low-readability trials without country information while started in recent year (after 2000) were those sponsored by large international pharmaceutical companies (which cause no country information recorded), and this kind of trials tend to be more difficult for readers compared to those conducted by federal-funded research institutes, universities or hospitals.

**Discussion**

**Implications of the findings**

According to our results, to gain a full comprehension of contents of EC, the readers have to be at least college education level, which is higher than the average American, who has achieved a high-school level. Therefore, in order to allow the many kinds of people who are looking for information in this online database, especially out-of-domain readers, to understand EC, there is a need for the website and researchers to be more careful in expressions and take those health consumers who are at a lower education level into consideration. Particularly, it was found that the main difficulty in understanding the contents is not a result of the syntactic features, but of the lexical ones, meaning that it is not a lot of long, complex sentences confusing people, but rather, the technical terms frequently used that increases the reading level required for target readers. Hence, the readability problem might be solved by using fewer technical jargons including clinical terminology and abbreviations, and instead considering lexical variants designed for patients, like consumer health vocabularies.

To realize this goal, we need to establish a comprehensive consumer health dictionary. However at present, no existing consumer health terminology can be called comprehensive or complete. It is a non-trivial effort to develop a comprehensive terminology that can keep up with the face pace of the constantly evolving consumer vocabulary. Most of the existing consumer vocabulary lists are based in a particular disease domain or user community. Given this situation, using existing consumer terminology to translate from clinical terminology is not realistic. Therefore, for further development, either existing “partial” consumer health vocabulary lists could be used to translate clinical trials in different fields, which lists could then be linked together, or an attempt could be made to find a method to establish a new comprehensive consumer health terminology, which would be a huge, long-term research effort.

**Limitations**

This study has several limitations. First, we only used computational measures to estimate readability. In the future, it would be valuable to engage enough real users, including both patients and clinicians, to validate our computational results and to obtain their feedback on their real-life experience. Second, the stratified analysis only serves as preliminary work for future guidance. The interpretation of the stratified analysis results here is just some reasonable guessing and is one of many possibilities without solid statistical tests to confirm. In the future, more relative study should be carried out based on refined stratification to find more interactive information.

**Conclusions**

In this study we presented an initial assessment of the readability of clinical trials eligibility criteria in ClinicalTrials.gov. We used both general popular readability formulas and health-domain specific methods, covering three aspects of readability: the unit length of a text, the syntactic complexity, and the lexical complexity. Moreover, we also conducted a comparison with two other health-related corpora to assess the term use tendency of the clinical trials. The overall results showed that eligibility criteria texts are beyond the comprehension capacity of the general American population, and the main reason for that is the frequent use of professional terminology and technical jargons. To guide future works on improvement, we also classified the trial texts by different factors and study the readability, trying to find some properties of the trials that might impact the readability. In the results, we found that in the beginning of the 21st century, the number of documented clinical trials increased greatly. Of all the properties we have studied, different study types of clinical trials might result in different levels of readability: generally, interventional studies require a higher education level to understand than observational studies. We also found that
clinical trials sponsored by pharmaceutical companies tend to have higher reading level requirement compared to federally-funded studies. Overall, our study presented a systematic evaluation and analysis of this online clinical trials database and contributed evidence for future improvement.

Automatic Assignment of Non-Leaf MeSH Terms to Biomedical Articles

Abstract

Assigning labels from a hierarchical vocabulary is a well known special case of multi-label classification, often modeled to maximize micro $F_1$-score. However, building accurate binary classifiers for poorly performing labels in the hierarchy can improve both micro and macro $F_1$-scores. In this paper, we propose and evaluate classification strategies involving descendant node instances to build better binary classifiers for non-leaf labels with the use-case of assigning Medical Subject Headings (MeSH) to biomedical articles. Librarians at the National Library of Medicine tag each biomedical article to be indexed by their PubMed information system with terms from the MeSH terminology, a biomedical conceptual hierarchy with over 27,000 terms. Human indexers look at each article’s full text to assign a set of most suitable MeSH terms for indexing it. Several recent automated attempts focused on using the article title and abstract text to identify MeSH terms for the corresponding article. Despite these attempts, it is observed that assigning MeSH terms corresponding to certain non-leaf nodes of the MeSH hierarchy is particularly challenging. Non-leaf nodes are very important as they constitute one third of the total number of MeSH terms. Here, we demonstrate the effectiveness of exploiting training examples of descendant terms of non-leaf nodes in improving the performance of conventional classifiers for the corresponding non-leaf MeSH terms. Specifically, we focus on reducing the false positives (FPs) caused due to descendant instances in traditional classifiers. Our methods are able to achieve a relative improvement of 7.5% in macro-$F_1$ score while also increasing the micro-$F_1$ score by 1.6% for a set of 500 non-leaf terms in the MeSH hierarchy. These results strongly indicate the critical role of incorporating hierarchical information in MeSH term prediction. To our knowledge, our effort is the first to demonstrate the role of hierarchical information in improving binary classifiers for non-leaf MeSH terms.

1. Introduction

Indexing biomedical articles is an important task that has significant impact on how researchers search and retrieve relevant information. This is especially essential given the exponential growth of biomedical articles indexed by PubMed®, the main search system developed by the National Center for Biotechnology Information (NCBI). PubMed lets users search over 22 million biomedical citations available in the MEDLINE bibliographic database curated by the National Library of Medicine (NLM) from over 5000 leading biomedical journals in the world. To keep up with the explosion of information on various topics, users depend on search tasks involving Medical Subject Headings (MeSH®) that are assigned to each biomedical article. MeSH is a controlled hierarchical vocabulary created by the NLM and consists of medical subjects that form a directed acyclic graph (DAG). Once articles are indexed with MeSH terms, users can quickly search for articles that pertain to a specific subject of interest instead of relying solely on keyword based searches.

Since MeSH terms are assigned by librarians who look at the full text of an article, they capture the semantic content of an article that cannot easily be captured by keyword or phrase searches. Thus assigning MeSH terms to articles is a routine task for the indexing staff at NLM. This is empirically shown to be a complex task with 48% consistency because it heavily relies on indexers’ understanding of the article and their familiarity with the MeSH vocabulary [1]. As such, the manual indexing task takes a significant amount of time leading to delays in the availability of indexed articles. It is observed that it takes about 90 days to complete 75% of the citation assignment for new articles [2]. Moreover, manual indexing is also a fiscally expensive initiative [3]. Due to these reasons, there have been many recent efforts to develop automatic ways of assigning MeSH terms for indexing biomedical articles including an on-going indexing challenge (http://www.bioasq.org/). However, automated efforts (including ours) mostly focused on predicting MeSH terms for indexing based solely on the abstract and title text of the articles. This is because most full text articles are only available based on paid licenses not subscribed by many researchers.

Many efforts in MeSH term prediction generally rely on two different methods. The first method is the $k$-nearest neighbor ($k$-NN) approach where $k$ articles that are already tagged with MeSH terms and whose content is found to be “close” to the new abstract to be indexed are obtained. The MeSH terms from these $k$ articles constitute candidate terms for the new abstract [2]. A second method is based on applying machine learning algorithms to learn and
index the best binary classifier models for each MeSH term. A new candidate abstract would then be put through all these classifiers and the corresponding MeSH terms of classifiers that return a positive prediction are chosen as candidate terms for the abstract. This approach has been termed as meta-learning and researchers at the NLM [4] have demonstrated that depending on the individual terms different classifiers might yield different results thus justifying the approach.

In one of their recent results, Jimeno-Yepes et al. [5] identify six MeSH terms that have been found to be difficult to predict using existing indexing approaches at the NLM. Out of these, two terms, hormones and infection, were shown to have unusually high numbers of false positive instances (with existing classification approaches) that are actually tagged with the descendants of the corresponding terms in the MeSH hierarchy. That is, there were many citations (abstract and title text) that were originally assigned a more specific descendant of an ancestor term but where the ancestor term classifier has classified each of them as a positive instance. Using this as motivation, in this paper, we explore classification methods that utilize training examples from the descendants as a way of improving non-leaf MeSH term prediction.

The rest of the paper is organized as follows. In the rest of this section, we first discuss the essential background on the size and structure of the MeSH terminology and discuss some related efforts. We also discuss a motivating scenario for incorporating descendants of non-leaf terms in building non-leaf term binary classifiers. In Section 2, we discuss our main methods that exploit descendant training instances to reduce false positive errors. We present our experiments using a large dataset and the corresponding results obtained with associated discussion in Section 3.

1.1. Background and Related Work

MeSH’s main purpose is to index biomedical articles and hence strict notions of meronymy were not used in its design; the hierarchical relationships are actually guided by “aboutness” of a child to its parent\(^1\). Hence a term could be a descendant of multiple other terms whose least common consumer is not one of them. That is, a term could have multiple paths from the root. In the 2013 version of MeSH, there are 26,578 main subject headings. The scatter plot of number of descendants and depth of the term is shown in Figure 1. Note that there are 16 individual hierarchies in MeSH but the machine processable UMLS Metathesaurus\(^2\) files combine these hierarchies with additional placeholder nodes to have a unified root. In the figure, the depth of the root is taken as 0 and the first valid MeSH nodes for each of the 16 hierarchies start at depth 1. From the figure, we can see that the number of descendants is in hundreds for many nodes at depths \(\leq 4\). By analyzing the MeSH hierarchy (Figure 2), we also found that there are at least 15,000 MeSH nodes with depth \(\leq 4\).

![Figure 1: Scatter Plot of Term Depth and Number of Descendants](image)

NLM initiated efforts in automatic MeSH term extraction with their Medical Text Indexer (MTI) program that uses a combination of \(k\)-NN based approach and named entity recognition (NER) based approaches with other unsupervised clustering and ranking heuristics in a pipeline [6]. MTI recommends MeSH terms for NLM indexers to assist in their efforts to expedite the indexing process\(^3\). Another recent approach by Huang et al. [2] uses \(k\)-NN

---

\(^1\)http://www.nlm.nih.gov/mesh/meshrels.html
\(^2\)http://www.nlm.nih.gov/pubs/Factsheets/umlsmeta.html
\(^3\)For the full architecture of MTI’s processing flow, please see: http://skr.nlm.nih.gov/resource/Medical_Text_Indexer_Processing_Flow.pdf
approach to obtain MeSH terms from a set of $k$ already tagged abstracts and use the learning to rank approach to carefully rank the MeSH terms. They use two different gold standard datasets one with 200 abstracts and the other with 1000 abstracts and achieve an F-score of 0.5 and recall 0.7 on the smaller dataset compared to MTI’s F-score of 0.4 and recall 0.57. Vasuki and Cohen [7] also use the $k$-NN approach but employ reflective random indexing to find the nearest neighbors in the training dataset and use the indexing based similarity scores to rank the terms from the neighboring citations.

Several other attempts incorporated different machine learning approaches with novel feature selection [8] and training data sampling [9] techniques. In our earlier effort, we also explored purely unsupervised approaches that rely on term co-occurrence counts and named entity recognition [10], which we subsequently extended [11] to a supervised framework exploiting latent associations between MeSH headings based on reflective random indexing. A recent effort by Jimeno-Yepes et al. [4] uses a large dataset and uses meta-learning to train custom binary classifiers for each MeSH term and indexes the best performing model for each label to be applied on new abstracts; we request the reader to refer to their work for a recent review of machine learning methods used for MeSH term assignment. In a related effort [5] they identify six MeSH terms that have been found to be difficult to predict using existing indexing approaches at the NLM. In this work, we look at all non-leaf nodes ($8756 \approx 33\%$ of all MeSH terms) in the MeSH hierarchy with varying number of descendants For these terms we develop and evaluate binary classifiers that utilize examples of their descendants. Given recent efforts [4, 12] that heavily rely on accurate binary classifiers for each term, we believe our work is very relevant to further the state-of-the-art in automated indexing of biomedical articles.

1.2. Motivating Scenario & Baseline Approach

In this section we demonstrate the presence of false positives arising from descendant nodes using the following six terms with varying descendant counts.

1. **Membrane Proteins**: 971 descendants
2. **Neoplasms**: 663 descendants
3. **Hormones**: 221 descendants
4. **Infection**: 154 descendants
5. **Mutation**: 47 descendants
6. **Plasmodium**: 10 descendants

Here *Hormones* and *infection* are from the challenging terms used in experiments in [5]; among the terms considered in these related efforts, these two had many descendants and high descendant attributable FPs. In addition to these, we chose four other terms arbitrarily with varying numbers of descendants. For our motivating scenario, we built training and testing datasets for each of these terms by extracting positive and negative examples from over 20 million Medline citations that are already fully tagged with MeSH terms by trained coders at the NLM. We made sure that our training and testing examples both had a non-empty abstract field as books and other artifacts indexed might not have an abstract. The number of positive and negative examples for each of the terms in the training and testing data are shown in Table 1.

In Table 1, the sum of positive examples in both training and testing sets for each term is equal to the total number of citations (with a non-empty abstract field) tagged with that term in the Medline citation database (2014 Baseline).
We randomly selected approximately 5% of the available citations for each term to be included as the corresponding positive examples in the testing data. Most MeSH terms are tagged for very few citations and hence, we chose a very high number of negative examples as shown in the negative testing instance count column; the positive examples constitute a maximum of around 2% of the total testing dataset for each term.

For our experiments, we chose as baseline the LIBLINEAR [13] logistic regression implementation through the scikit-learn [14] framework. We used unigrams and bigrams, with a minimum frequency of five citations per n-gram, as our binary features. After applying the classifiers on the corresponding testing sets for each of the six terms, we looked at the number of FPs that can be attributed to descendants of the six terms under consideration. These observations are shown in Table 2 from which we notice that a significant number of FPs (more than 40% for four terms) are due to misclassification of descendants. Based on these observations, we set out to design and evaluate classification approaches that exploit descendant instances.

2. Methods: Hierarchical Strategies to Handle Descendant FPs

Motivated by observations in Table 2, we proceed to exploit instances of descendants terms in building better binary classifiers for non-leaf MeSH terms. Here, the descendant set of a given MeSH term is defined recursively as the union of the set of its children and all their descendants in the MeSH hierarchy. The baseline method is simply building binary classifiers with unigram and bigram features using support vector machines (SVMs). Next, we outline the five different methods that incorporate descendant instances to be compared with the baseline approach. We eventually use a dataset of one million biomedical citations and all non-leaf terms that are assigned to at least 100 citations in this dataset. Details of dataset and results achieved using our methods will be elaborated in Section 3.

Before we proceed, we first note that it is a valid indexing approach to assign a term and one or more of its descendants to the same biomedical article. NLM’s multi-label assignment process allows this when the content of the article warrants such an assignment. As such, the task of assigning MeSH terms is a relaxation of the non-mandatory leaf node prediction [15, Section 4.4] scenario encountered in hierarchical classification. Given this, to best differentiate a term’s instances from its descendants’ instances, we curate training data of ancestor terms that are not tagged with any of their descendants. Similarly, we curate training instances of descendant terms that are not tagged with the corresponding ancestors. If \( T \) is the size of the training set of a given ancestor term selected as explained above, we randomly pick \( T/d \) training instances for each of its \( d \) descendant terms to approximately create equal
sized datasets. While we allow appropriate data imbalance to persist in our main experiments, we selected balanced datasets to distinguish between main terms and their descendants, with equal contribution from each descendant. This is due to the presence of extremely large number of instances when summed over all descendants of a given term. Because of the way we incorporate these descendant instances into our methods (the rest of the section), we believe this descendant specific instance selection is appropriate given the testing data set is chosen randomly while preserving realistic imbalance. Next, we describe each of the five methods that employ descendant training instances.

2.1. **Multiclass Prediction with a Third Descendant Class**

Unlike the binary classification approach used in our baseline method, in this approach, for each term we model the prediction as a multiclass text classification problem with three classes: 1. main non-leaf term class of interest to us, 2. its descendants class, and finally 3. the ‘other’ class that has negative examples of all other non-descendant instances. The non-descendant ‘other’ instances are citations in our dataset that are not tagged with the non-leaf term of interest or its descendants. The positive class instances are those that are tagged with the non-leaf term but none of its descendants. The descendants’ training instances are curated as explained in the beginning of this section with equal contributions from each descendant. We used the built-in one-vs-all approach in LIBLINEAR with the same set of features used for our baseline method in Section 1.2.

2.2. **Two Stage Hierarchical Prediction**

Here we follow the conventional hierarchical approach and build two different classifiers. The top level binary classifier combines instances of either the main term or any of the descendants as one positive class, the negative class being the ‘other’ class from Section 2.1. Intuitively, this classifier is expected to identify testing instances of a candidate term or its descendants. Once an instance is predicted as positive with this classifier, a second binary classifier that distinguishes between the main term and its descendants’ instances is applied. This second classifier is built using the main non-leaf term class and the descendants class from Section 2.1.

2.3. **Baseline Result Filtering using Descendant Classifier**

Instead of applying the second stage classifier in Section 2.2 to the positive instances of the top level classifier in the hierarchical approach, we simply use it to filter the positive instances output by the baseline classifier from Section 1.2. Given the high proportion of FPs attributable to descendant instances (Table 2) and the reasonably high performance we observed in the 2nd stage classifier in the two stage hierarchical approach, we chose to do this filtering.

2.4. **Baseline Filtering with Descendant Classifier and FN recovery**

Our primary focus thus far has been on minimizing FPs. In this context, clearly, the percentages of total FP reduction should be looked at in the context of the recall loss due to new false negatives (FNs) induced. Just as many FPs can be attributed to descendant instances, it is also possible that several FNs can be attributed to descendants. This is because of the multi-label indexing nature where both a term and any of its descendants can be assigned to a given article as discussed in the beginning of this section. That is, many negative predictions that end up in the descendant class in Section 2.1 or of the second stage classifier in Section 2.3 could actually be positives. To reduce these descendant attributable FNs, we propose to move several of these positives from the incorrect descendant predictions to their correct ancestor predictions using a binary FN recovery classifier that distinguishes between instances that are tagged with “only descendants” (negative class) and instances that are tagged with “both the ancestor term and at least one descendant” (positive class). We apply this binary classifier to the negative predictions from the second stage classifier of the baseline filter approach (Section 2.3). Those that are classified as belonging to the class “both the ancestor term and at least one descendant” are considered positive instances of the non-leaf ancestor term in the end. To build this binary classifier, we obtain the positive instances by considering all citations tagged with the non-leaf term and any of its descendants. The negative instances dataset is again a subset of the descendant-only examples as explained at the beginning of this section.

2.5. **Combining NER and Supervised Classification**

Our final approach involves combining named entity recognition with supervised classification. It is also essentially a filter on positive classifications of the baseline classifier from Section 1.2. In this method, we first use a state-of-the-art biomedical named entity recognition tool, MetaMap [16], on the input citation of each positive instance output.
by the baseline classifier to identify MeSH terms mentioned in its title and abstract. If any of these MeSH terms is actually a descendant of the candidate term, we subject it to a corresponding new binary classifier that distinguishes between instances that are tagged with only descendants and those tagged with both a main term and at least one of its descendants (from Section 2.4). Those that are classified into the “only descendants” are treated as negatives in this filter. Intuitively, since the input instances to this filtering approach are already deemed positive for the main term (since they are the positives from the baseline classifier), we only need to identify those instances that should be exclusively tagged with descendant terms only. However, just because a citation contains a descendant MeSH term does not necessarily mean it can only take a descendant MeSH term as a tag, although it could be a candidate for further analysis. Hence we apply the supervised classifier to those that contain a descendant term.

2.6. Summary of Our Approaches

Some of our methods in Sections 2.1–2.5 involve multiple classifiers that use different training data subsets. For clarity, here we summarize all the classifiers involved and how they are used in different methods using the corresponding section numbers. We use the following notation to represent different training data subsets for our classifiers.

- **A**: set of all training examples annotated with the main non-leaf term but none of its descendants
- **D**: set of examples not tagged with the main non-leaf term but with at least one of its descendants
- **AD**: examples tagged with both the non-leaf term and at least one of its descendants
- **O**: training examples that are not in sets A, D, or AD.

### Table 3: Classifiers Used in Different Methods

<table>

Based on this notation, in Table 3(a), we identify the five different types of classifiers L1–L5 used in our methods and the corresponding training data subsets used. All classifiers are binary except L2, which is a three-way classifier. For L4 and L5, the D set is sampled as elaborated in the second paragraph of Section 2. In Table 3(b), we specify the classifiers used for the baseline approach (Section 1.2) and our proposed FP handling methods in Sections 2.1–2.5.

3. Results and Discussion

To ensure a natural distribution of terms, we chose a set of 1 million already annotated citations with dates of publication between 2005–2014 from around 1900 well known journals used in the BioASQ competition to index biomedical articles. Out of this dataset, 850,000 citations were used for training, 100,000 were used for validation, and the remaining 50,000 were used for testing. The testing dataset instances’ dates of publication are chronologically later than the training and validation dataset instances. Among all non-leaf terms in the MeSH hierarchy, we chose those that had at least 100 instances in the training dataset, which resulted in 4395 non-leaf terms that we considered for our experiments. Before we proceed we outline the performance measures used.

3.1. Performance Measures

Since the task of assigning multiple MeSH terms to a citation is the multi-label classification problem, there are multiple complementary methods [17] for evaluating automatic approaches for this task. Here, we focus on label based measures since we are only concerned about the performance of non-leaf MeSH terms.
For each MeSH heading $T_j$ in the set of terms $T$ being considered, we have label-based precision $P(T_j)$, recall $R(T_j)$, and $F_1$-score $F(T_j)$ defined as

$$P(T_j) = \frac{TP_j}{TP_j + FP_j}, \quad R(T_j) = \frac{TP_j}{TP_j + FN_j}, \quad \text{and} \quad F(T_j) = \frac{2P(T_j)R(T_j)}{P(T_j) + R(T_j)}$$

where $TP_j$, $FP_j$, and $FN_j$ are true positives, false positives, and false negatives, respectively, of term $T_j$. Given this, the label-based macro average $F_1$-score is

$$\text{Macro-F} = \frac{1}{|T|} \sum_{j=1}^{|T|} F(T_j).$$

The label-based micro precision, recall, and $F_1$-score are defined as

$$P_{\text{mic}} = \frac{\sum_{j=1}^{|T|} TP_j}{\sum_{j=1}^{|T|} (TP_j + FP_j)}, \quad R_{\text{mic}} = \frac{\sum_{j=1}^{|T|} TP_j}{\sum_{j=1}^{|T|} (TP_j + FN_j)}, \quad \text{and} \quad \text{Micro-F} = \frac{2P_{\text{mic}} \cdot R_{\text{mic}}}{P_{\text{mic}} + R_{\text{mic}}}.$$  

While macro measures consider all labels as equally important, micro measures tend to give more importance to more frequent labels. Here we are interested in improving both the micro and macro averages over non-leaf terms.

### 3.2. Application of Hierarchical Classifiers

We first applied our hierarchical strategies (Section 2) to the set of six terms in the motivating scenario in Section 1.2. All approaches showed some improvement except the two-stage hierarchical approach in Section 2.2, which suffered a major loss in precision. This is not surprising given recent attempts by other researchers [18] also show that top-down hierarchical approaches may not be very suitable with very large terminologies with thousands of labels. Hence all our large scale experiments described in this section are conducted with all the methods except the two-stage approach. We note that all approaches we consider here are thus essentially filters on the positive instances of the baseline. That is, we are not attempting to obtain better recall than baseline but are willing to trade off some recall for precision increases that could yield us better micro and macro $F$-measures.

Instead of using the default approach of making predictions based on SVM scores, we use a more suitable approach for multi-label classification based on the meta-labeler [19] method where, in addition to a ranked list of labels (based on probability estimates) for each artifact to be classified, a threshold on the number of labels is also predicted using the same set of features used for predicting the labels. This generally helps because some binary classifiers for labels with low frequencies do not always produce high scores for the positive class. We used this approach and built over 27,000 binary classifiers (one for each MeSH term even if it is not a non-leaf term) using the training dataset. We also developed another model that predicts the number of terms for an input citation based on the training dataset. Next, we applied each of these classifiers to each instance in the validation dataset. We ranked the MeSH terms for each instance based on the corresponding SVM classifier scores and chose the threshold for the number of terms to retain based on the thresholding model. Next, for each of our hierarchical strategies, if one of the 4,395 non-leaf terms that we consider in our experiments shows up in the top terms predicted using the baseline approach and the thresholding, we apply the hierarchical strategy as an additional filter. If the output of the hierarchical strategy also ends up in the positive class, we take it as a positive classification for the non-leaf term. If the strategy outputs a negative prediction, we treat the prediction to be negative for the non-leaf term. Thus, we reverse some positive non-leaf term predictions by the base classifier using the hierarchical strategies.

### 3.3. Results on Validation Dataset

We used the validation dataset to identify non-leaf MeSH terms for which we notice an improvement over the baseline when the hierarchical strategies are used. We then applied the strategies for only such non-leaf terms on the test dataset. This is to ensure that our choice of the terms is not influenced by the test data. Here we present our results on the validation dataset. In Table 4, for each strategy (first column, indicated by the section number), we show how many terms had better $F_1$-score (compared with the baseline), the average increase in macro-$F_1$ and micro-$F_1$ over such terms, and average number of descendants and average depth for such terms. The final row is a hybrid classifier that chooses the best hierarchical strategy over the baseline for each non-leaf term.

From the table, we see that the FP filtering approach with a descendant classifier and an FN recovery classifier (Sec 2.4) had the largest improvement when considering both macro and micro averages. Although the NER based approach (Sec 2.5) improved results for over 300 terms, the improvement is smaller compared to other methods. The average depth of the full MeSH hierarchy is 4.5 with an average of 17 descendants per non-leaf term. From Table 4, it is evident that the hierarchical strategies seem to do well when the terms are slightly higher in the hierarchy with
many descendants. The absolute improvement is around 1.5% in both micro and macro averages for a total of 536 terms, which constitute about 12% of the set of non-leaf terms we considered. We will now apply the hierarchical approaches as discussed in Section 3.2 to the test dataset.

### 3.4. Results on Test Dataset

The test set results in Table 5 are obtained by considering all those non-leaf terms that had at least 1% improvement in $F_1$ score in the validation dataset and ranking them in the descending order of their frequency in the validation dataset. This is to analyze if we can find a large set of terms for which the performance holds across different datasets. From the table it is clear that both micro and macro averages increase for the top 500 non-leaf terms. We also display relative improvements ($\frac{(\text{hybrid} - \text{baseline})}{\text{baseline}}$) in the table which become prominent at the macro level as we consider fewer frequently occurring terms. But overall were able to identify 500 terms for which we improved micro-$F_1$ score by 1.6% and macro-$F_1$ score by 7.5% relative to the baseline scores. These results indicate the strong potential of exploring hierarchical information in improving the state-of-the-art in automated indexing of biomedical articles.

### 3.5. Remarks on Class Imbalance

As noted in Section 1.2, there is extreme imbalance between the positive and negative instances of MeSH terms, a situation which is more prominent in non-leaf terms. We conducted additional experiments with different class weighting schemes for all the strategies discussed in Section 2. To handle high negative class bias in a methodical way we also tried a combination of boosting and random under sampling [20]. Although there were marginal improvements for a few terms, we do not think they warrant reporting in this manuscript and so we leave them out. However, this also leads us to believe that this problem is not only important but also very difficult to solve, especially under the assumption that only the abstract and title are available. There is some evidence [21] that points to small improvements if additional sections of the article full text, when available, are considered. The class imbalance in the MeSH training data can also result from the so called “Rule of Three”\(^5\) for indexing biomedical articles – “If more than 3 related concepts are discussed in an article but are not a major topic, the more general MeSH heading under which they are all treed is usually indexed. The specific headings usually are not indexed." Due to this rule, some of the false positives could have been due to more than three specific MeSH headings predicted for a citation with a common immediate parent. So we conducted additional experiments where we replaced such term sets with their immediate ancestor in the final candidate set of predicted terms (an extension to the method in Section 3.2).

However, we observed only marginal improvements; incorporating this particular manual indexing guidance into the automation process did not seem to help. The rule-of-three also states that when three or more related concepts are identified as major MeSH terms (terms that are deemed central to the article), their immediate common ancestor is coded as a major topic, while the descendants are retained but not as major terms. Thus this aspect of the rule-of-three is also essentially responsible for situations where both a non-leaf term and several of its descendants are assigned to an article.

For our initial study we used a dataset of one million citations although there are currently about 21 million citations made available through NLM for training purposes. Although we chose the smaller dataset for computational tractability in building over 27,000 baseline models and four sets of 4,395 hierarchical models for non-leaf terms, increasing the dataset size to 22 million citations may not necessarily yield improved performance. This is because of the extreme class imbalance that will persist given the unusually high number of negative examples for each non-leaf term. In such cases, it is not clear whether rare event adjustments to supervised learning approaches [22, 23] will help the situation for MeSH term prediction because of the limitation of considering only the title and abstract. However, there is recent evidence that micro averages (over all MeSH terms) can be improved by using more efficient learning methods and considering all available citations [24]. Our main purpose in this paper is to show that descendant instances play an important role in improving results for many MeSH terms. We believe their role will only increase in relevance, if extreme class imbalances are handled, because of the hierarchical nature of MeSH.

4. Conclusion

Assigning MeSH headings to biomedical articles is an important task at the NLM due to the search flexibility it gives biomedical researchers in satisfying their information needs. Many automated attempts have been developed in the recent past to predict MeSH terms from the title and abstract text of an article. In this paper, we focus on the problem of building binary classifiers for terms corresponding to non-leaf nodes in the MeSH hierarchy. Based on the observation that many false positives for terms with several descendants could be attributed to the descendants, we experimented with approaches that exploit descendant training instances. To our knowledge, this is the first effort to investigate the suitability of hierarchical information toward improving MeSH term prediction. Our results show good promise with a relative improvement of 7.5% in macro-\(F_1\) score and 1.6% in micro-\(F_1\) score over the baseline non-hierarchical approach for a set of 500 non-leaf terms that occur at least 100 times in our training dataset of one million citations.

Given that there are over 23 million citations and the recent evidence [24] of computational tractability for learning using all citations, we will conduct additional experiments to identify other non-leaf terms whose performance can be improved using hierarchical approaches. We will also conduct additional error analysis to identify factors that make certain non-leaf terms more suitable for hierarchical classification compared to others. Our current effort in this paper, nevertheless, demonstrates that hybrid hierarchical approaches that exploit descendant instances play a key role in assigning MeSH terms to biomedical articles.

Acknowledgments

We are grateful to anonymous reviewers for their careful assessment and constructive criticism of the manuscript, which helped improve it for the final camera-ready version. Challenges and Insights in Using HIPAA Privacy Rule for Clinical Text Annotation

Mehmet Kayaalp, MD, PhD, Allen C. Browne, MS, Pamela Sagan, RN, Tyne McGee, BS, Clement J. McDonald, MD

U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD

Abstract
The Privacy Rule of Health Insurance Portability and Accountability Act (HIPAA) requires that clinical documents be stripped of personally identifying information before they can be released to researchers and others. We have been manually annotating clinical text since 2008 in order to test and evaluate an algorithmic clinical text de-identification tool, NLM Scrubber, which we have been developing in parallel. Although HIPAA provides some guidance about what must be de-identified, translating those guidelines into practice is not as straightforward, especially when one deals with free text. As a result we have changed our manual annotation labels and methods six times. This paper explains why we have made those annotation choices, which have been evolved throughout seven years of practice on this field. The aim of this paper is to start a community discussion towards developing standards for clinical text annotation with the end goal of studying and comparing clinical text de-identification systems more accurately.

1. Introduction
The Privacy Rule of Health Insurance Portability and Accountability Act (HIPAA) requires that clinical documents be stripped of personally identifying information before they can be released to researchers and others. The Rule indicates 18 pieces of personally identifiable information (PII) that need to be de-identified in order to protect patient privacy. Our particular interest in the Privacy Rule is to use it as our guideline for preventing unintended privacy breaches during the secondary use of patient health information for clinical research. Although it is very clear what each piece of PII is, conceptually, it may not be so straightforward when we try to do so manually in a clinical narrative report. The Privacy Rule has been designed mainly with the structured tabular data in mind. When we attempt doing the same with text, we are faced with a number of difficulties that arise due to the nature of English, or any other natural language.

For example, the Privacy Rule requires de-identification of personal names but does not say anything about personal name initials (e.g., JFK). While U.S. District Courts impose restrictions on the use of personal names of minors and require their names in all hearing transcripts to be de-identified by converting them into personal name initials,1-3 the Office of Civil Rights of the Health of Human Services interprets the Privacy Rule in such a way that equates personal name initials with personal names.4

It is unreasonable to expect from any piece of legislation or set of rules to spell out every imaginable version or combination of entities that could occur in a clinical narrative report or patient record. Our approach is to take the Privacy Rule as a model, interpret its language, understand its aim, and in ambiguous cases, make decisions whether we ought to de-identify those particular pieces of information in order to fully comply with the Privacy Rule to the best of our abilities.

To this end, we have been developing annotation guidelines, which basically are a compendium of examples, extracted from clinical reports, to show what types of text elements and personal identifiers need to be annotated using an evolving set of labels. We started annotating clinical text for de-identification research in 2008, and since then we have revised our set of annotation labels (a.k.a. tag set) six times. As we are preparing this manuscript, we are working on the seventh iteration of our annotation schema and the label set, and will be making it available at the time of this publication.

Although the Privacy Rule seems pretty straightforward at first glance, revising our annotation approaches so many times in the last seven years is indicative of how involved and complex the task is. We don’t believe that publishing the guidelines would suffice by themselves, since the guidelines only tell what needs to be done. In this paper, we try to address not only what we annotate but also why we annotate the way we do. We hope that the rationale behind our guidelines would start a discussion towards standardizing annotation guidelines for clinical text de-identification. Such
standardization would facilitate research and enable us to compare de-identification system performances on an equal footing.

Before describing our annotation methods, we provide a brief background on the process and rationale of manual annotations, discuss personally identifiable information (PII) as sanctioned by the HIPAA Privacy Rule, and provide a short overview of approaches of how various research groups have adopted PII elements into their de-identification systems. We conclude with Results and Discussion sections.

2. Background

Manual annotation of documents is a necessary step in developing automatic de-identification systems. While de-identification systems using a supervised learning approach necessitate a manually annotated training set, all systems require manually annotated documents for evaluation. We use manually annotated documents both for the development and evaluation of NLM-Scrubber. 5-7

Even when semi-automated with software-tools, 8 manual annotation is a labor intensive activity. In the course of the development of NLM-Scrubber we annotated a large sample of clinical reports from the NIH Clinical Center by collecting the reports of 7,571 patients. We eliminated duplicate records by keeping only one record of each type, admission, discharge summary etc. The primary annotators were a nurse and linguist assisted by two student summer interns. We plan to have two summer interns each summer going forward.

These annotators used NLM’s Visual Text Tagging tool, VTT. VTT allows annotators to select and annotate strings of text by swiping the cursor over them and choosing a tag from a pull-down list of annotation labels. The application displays the annotation with a distinctive combination of font type, font color and background color. Tags in VTT can have sub-tags which allow the two dimensional annotation scheme described below. VTT saves the annotations in a stand-off manner leaving the text undisturbed and produces records in a machine readable pure-ASCII format. A screen shot of the VTT interface is shown in Figure 1. VTT has proven helpful both for manual annotation of documents and for displaying machine output. As an end product the system redacts PII elements by substituting the PII type name (e.g., [DATE]) for the text (e.g., 9/11/2001), but for evaluation purpose tagged text is displayed in VTT.

![Figure 1. VTT Window Showing a Hypothetical Annotated Report](image)

The Privacy Rule guidelines published by the Office of Civil Rights of the Health and Human Services (HHS) say that “The importance of documentation for which values in health data correspond to PHI, as well as the systems that manage PHI, for the de-identification process cannot be overstated.” 4
Most studies in the area of automatic de-identification only indicate the set of PII items they redact in the course of de-identification. In their review, Meystre et al. mapped the personal identifiers that were de-identified by the 18 different systems into seven categories: patient names (or both patient and provider names), ages greater than 89, geographical locations, hospitals and healthcare organizations, dates, contact information (phone numbers, pager numbers, fax numbers, and e-mail addresses), and IDs (Social security number, medical record number, driver’s license number, and other identifiers).

The i2b2 challenge uses a list of eight identifier types: patient, doctor, location, hospital, date, ID, phone, and age. Studies based at the Veteran Administration Health System treat a different list of items more in line with their particular needs adding four non-PII categories of clinical eponyms to the i2b2 list. They annotate medical procedure names, medical device names, disease names, and anatomic structures. By supplying the annotations of significant clinical information, they could train their supervised learning system so that it could recognize these entities in text and then evaluate how well the system performs in preserving such clinical information at the end of the de-identification process.

Separating doctor names from patient names is another move in this direction. Although the names of doctors and other medical personnel are not PII, they could not be distinguished with a high level of confidence by automatic de-identification systems and might be redacted inevitably.

In most cases, the details of the annotation scheme are not published. The i2b2 efforts publicly provide their corpus with a data use agreement. This is only possible through an automatic de-identification process followed by an extensive multi-round process of manual validation by human experts. In the resulting corpus the PII elements are substituted with pseudonyms, a surrogate text that looks like the original.

This emphasis on annotation of PII alone overlooks a need for more elaborate annotation, including non-PII items and specific sub-parts of PII items that contribute to evaluation and error analysis and the need to explicitly publish the guidelines used to annotate documents. This paper discusses the annotation scheme we use in the NLM Scrubber project detailing the annotation guidelines and the reasoning behind the decisions that led to this annotation schema.

3. Methods

As mentioned in the previous sections, we have been annotating clinical text since 2008. Our main goal in this effort has always been to develop a set of standards so that we can evaluate the performance of our clinical text de-identification system, NLM Scrubber. Both our annotation and de-identification studies have been influencing and informing each other. While the availability of a standard text has been helping us to test new ideas and monitor the de-identification performance of our system as we modify existing modules, evaluation of the updated de-identification system has also made the shortcomings of our annotation methods explicit. In the following subsections, we describe our annotation methods and explain why we annotate the way we do.

3.1. Annotations on two dimensions

We perceive the annotation space in two orthogonal dimensions. The first dimension denotes personal identifiers. We established a total of 12 personal identifier categories: Address, Personal Name, Personal Name Initials, Organization, Occupation, Telecommunication, Date, Age, Time, Numeric and Alphanumeric Identifiers, Personally Identifying Context, and Role.

The second dimension is personhood, which associates the identifier with an identity. We define 5 personhood categories: Patient, Relative, Employer, Provider, and Other. For example, we would annotate the word “John” in the following two dimensions: It is a personal name and may denote (say) the patient. If the latter is true, we would use the following label PersonalName::Patient. If “John” is the name of the health care provider, we would label it PersonalName::Provider.

We use the personhood category Relative broadly, which includes family members as well as the members of the household of the patient—the Privacy Rule mentions them separately. Given that a family member mentioned in a clinical report is frequently a household member as well, categorizing them separately would be problematic, since we would have to annotate the same word with two distinct personhood labels. Although technical challenges are not insurmountable, it would be conceptually too complex for the annotators to distinguish whether the family member mentioned in the clinical text was also living with the patient in the same house.
Although the Privacy Rule dictates that personal identifiers of the patient’s employer must be de-identified, it does not clarify what constitutes an employer. It could be the owner, president, or the CEO of the company. Could it be the supervisor of the patient? How about their supervisors? In many workplace accident cases, the patient is accompanied to the health care facility by a co-worker. In a re-identification attempt, the co-worker’s identity could be linked to the company and through which, indirectly, to the patient; thus, we use the personhood category Employer to annotate all types of co-workers and supervisors of the patient.

The Provider category denotes every type of healthcare professional who takes part in the health care of the patient. Note that information about the provider was not defined by the Privacy Rule as PII. We use the category Other to denote other personhood identities that are not patients, relatives or providers and there is no apparent method to link that particular person or personal identifier to the patient. For example, we annotate the word Obama in “the patient cited Obama as our president” with the label PersonName::Other. Disclosures of identifiers associated with Provider or Other usually do not pose any significant privacy risk to the patient, since they are not directly linkable to the patient.

How should we annotate girlfriend, partner, and neighbor? We annotate partner as, since it may indicate some kind of formal union and/or household membership, and can be linked to the patient. We use the label Other for friends and other informal relations who may not be linked to the patient directly and as easily as a household member—in the age of social networks, we are not sure how long this assumption would be holding! Although neighbor seems fitting to the label Other at the very first glance, the neighbor information is actually akin to that of the household member, since their residence information could be identifying the address of the patient; thus, we annotate it as Relative.

By reserving the label Other for information that cannot be linked to the patient directly (or indirectly) and by not using it for sensitive information such as information about neighbors, we may prevent significant complications with respect to the evaluation of the de-identification system in case of any unintended disclosure.

In the following subsections, we discuss 12 personal identifier categories, what subcategories, if any, they consist of and how they are related to identifiers mentioned in the HIPAA Privacy Rule. Some entities in these categories may not be personal identifiers. In those cases, we discuss why we chose to introduce and annotate them.

3.2. Address

The Address category comprises a number of entities such as street name, number and types. Table 1 shows which labels we use to annotate such entities. A mention of address may contain a subset of these entities.

<table>
<thead>
<tr>
<th>Label</th>
<th>Entity</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Street</td>
<td>Street name</td>
<td>Pennsylvania Ave</td>
</tr>
<tr>
<td>Location</td>
<td>Street number, apartment, suite or office number; floor or room number inside an office building, hospital or clinic including a bed number, P.O. Box</td>
<td>Station 10-Room 33-A</td>
</tr>
<tr>
<td>Building</td>
<td>Building name</td>
<td>Woodward Building</td>
</tr>
<tr>
<td>City</td>
<td>Village, town or city</td>
<td>Bethesda</td>
</tr>
<tr>
<td>County</td>
<td>County</td>
<td>Montgomery County</td>
</tr>
<tr>
<td>State</td>
<td>State, US district, territory, province or region</td>
<td>D.C. Metro Area, Guam, East Coast, Alberta, Western Pennsylvania</td>
</tr>
<tr>
<td>Country</td>
<td>Country</td>
<td>United States</td>
</tr>
<tr>
<td>Zip</td>
<td>Five or nine digit US ZIP code or foreign postal equivalent</td>
<td>20894-3828, SW1A 2AA</td>
</tr>
</tbody>
</table>

Why do we use eight different address labels, instead of using a single label, to annotate all address tokens? Using a single, common address label sounds quite practical at the first glance, esp. during the annotation process. However, if one needs to assess the performance of a de-identification system that may inadvertently reveal some address information, uniform address labels would be very inadequate for estimating the level of risk to the potential breach
of patient privacy. Note that revealing certain address elements, e.g. a rare street name and number, could pose significantly more risk than revealing more common or widely shared address elements such as an apartment number or name of the city where the patient resides.

HIPAA Privacy Rule makes a distinction between different types of address information. The Privacy Rule states that information about all geographic subdivisions smaller than state, except the first two digits of the zip code, must be de-identified. The third digit of the zip code can be left intact, only if the size of the population in the area of the censored two digits is greater than 20,000 according to the most recent census data. In other words, the Privacy Rule indicates certain address tokens are more informative than others in identifying an individual. If we visualize the address elements on a line ordered from the most granular or specific elements (such as street name and number) towards the most widely shared element (i.e., country), the Privacy Rule puts the threshold between County and State.

If the user intends to fully de-identify patient data, then s/he needs to use the above threshold. However, the Privacy Rule also offers a lower threshold in its Limited Data Set provision, which allows the user to preserve city and town information as long as such information is necessary for the study and the user signs a data use agreement with the provider of the data.

These two thresholds divide the address elements into three parts: If using the Privacy Rule, (A) information more specific than town or city needs to be eliminated under any circumstances; (B) state and country information can be preserved even in a fully de-identified set of data; and (C) information whose specificity lies between these two thresholds that can be preserved only within the boundaries of the Limited Data Set provision. In other words, one needs to use at least three distinct labels to differentiate these three parts in an address. Furthermore, a separate label for ZIP codes is also necessary since ZIP code information crosses these two boundaries.

We could merge State and Country labels into one State/Country label and merge City and County labels into City/County label but we chose not to do so for various reasons. The first reason is practicality—annotating these four types of address elements separately does not impose undue burden onto our annotators. Distinguishing these labels can also be useful under certain situations. For example, in an epidemiologic study in which preserving county information may be necessary and sufficient, de-identifying city information could better protect patient privacy. Unless the user requires state information, NLM Scrubber de-identifies it by default. Although HIPAA does not sanction state information to be de-identified, we choose to do so, since many re-identification algorithms rely on address information and the more unnecessary address information we could de-identify, the more difficult the re-identification would be. Since it is usually difficult to distinguish country of residence from the country of origin, we annotate the residence of a foreign national and the country of the origin of an individual (e.g., “40yo Ethiopian man”) with label Country. We believe a de-identification system ought to preserve ethnicity and country of origin information, since some diseases are more prevalent in certain groups and geographical locations globally.

We distinguish three distinct address elements below the town or city level: Street name, location information such as house or apartment numbers, which further qualify the local address, and building name. Note that inadvertently revealing a street (i.e. house) number without disclosing the street name would not jeopardize privacy of the patient—it would be truly nonspecific. Revealing a street name without the street number however poses a more serious risk, especially if the street name is not a very common one. In that scenario, the privacy risk would be inversely proportional to the size of the household population on all streets with that street name in the country. If on the other hand, the de-identification system inadvertently discloses both street name and number, re-identifying the individual along with age and gender information may not be too difficult. We separated building names from street and location categories, because a building name alone can be more informative than either of them. Note that a building name is at least as informative as the combination of both the street name and the street number. Since it is not customary to name residential units in the US, a building name, as rare as it is, could be quite identifying.

3.3. Personal Names and Personal Name Initials

The Privacy Rule states that names (of the individual or of relatives, employers, or household members of the individual) should be removed. If one has a tabular data where the columns are well defined, it would be easy to distinguish personal names from other identifiers. But when the data in question is text, the seemingly obvious de-identification task can be quite complicated. For example, questions like “would it be okay to leave single letter middle initials intact?” or “would personal name initials constitute a name?” can be difficult to answer.

Clearly, personal name initials like JFK are not as revealing as corresponding full names. In fact, converting names into initials is a widely used practice to protect identities of the minors in reports of the court hearings.1-3 So, we
categorize personal name initials separately from personal names. According to the Office of the Civil Rights, however, personal name initials are considered as personal names and ought to be de-identified.\(^4\) We reserve personal name initials only for the full set of name initials (i.e., when first, middle, and last names are initialized altogether as in JFK) but annotate middle and/or first name initials, as in “James T. Kirk” or “J.K. Rowling,” as parts of the personal names.

Although we annotate suffixes such as Jr. and Sr. as parts of personal names, we do not extend it to professional and academic titles, for some of which we use the label Occupation.

### 3.4 Occupation and Organization

Occupation information is not one of the 18 pieces of PII, sanctioned by HIPAA, to be de-identified. However, especially if it is a rare occupation (e.g., clinical computational linguist, Supreme Court justice), the information may be used to re-identify the patient. Up to date, we have not come up with an easily implementable annotation method to differentiate rare occupation information from the common ones. We have to separate the wheat from the chaff for each piece of occupation information at the evaluation phase of our de-identification studies. Note, however, the personhood dimension that we introduced in this paper for the first time (see Section 3.1) can be helpful when occupation information is associated with Provider or Other, which usually would not pose any privacy risk to the patient.

Most professional titles indicate the occupation of the person. Although we annotate provider occupations (e.g., dermatologist) whenever it is explicitly stated in the text, we have not been annotating their titles (e.g., Dr., M.D., etc.) due to their sheer number of occurrences and the difficulty that it would impose on our annotation team. We are currently studying the feasibility of the issue in a pilot.

We also annotate past occupation information but not the future ones. The former can be linked to the patient but the latter (e.g., “the patient plans to open a car dealership”) is mostly hypothetical. Similarly, we do not annotate hobbies as occupations since they would rarely be unique and linkable to the patient. In such rare scenarios, however, we have other methods to employ (see Section 3.7).

Occupation (e.g. a cook) does not specify the employer like where the person works (e.g., “… at Acme Restaurant”), but sometimes, they are very closely linked together. For example, “he is an Army Master Sergeant,” where we annotate Army with label Organization::Employer and Master Sergeant with Occupation::Patient or Occupation::Relative, depending on whom “he” denotes. If the title were Admiral, for which we would use label Occupation::Patient, it would also implicitly reveal the employer’s organization, Navy.

We reserve the personhood label Employer only for the patient’s employer and do not extend it to the employer of the relative, since there is no apparent direct link from the employer to the patient. In the example, “The patient’s mother is a math teacher at Takoma Park Middle School,” math teacher is Occupation::Relative and Takoma Park Middle School is Organization::Relative. Between the school and the patient, there is two degrees of separation, which is implied by the label Organization::Relative—the linkage for re-identification is possible but the link is weaker than the link between the patient and their employer.

Although we do not annotate hobbies, we do annotate organizations that individuals can be associated with (e.g., “the patient is a member of the Rotary Club” or “…presented his findings during the AMIA Symposium last year”).

### 3.5 Age, Date and Time

Similar to category Address, Age and Date are categories, each of which comprises multiple labels. By mandating that ages over 89 be de-identified, HIPAA separates age into two categories: (1) ages 90 and above are considered PII, which we annotate with label AgePII, and (2) ages that are below 90, which HIPAA considers as non-PII. We split the second group into two additional separate groups: (2A) ages that are mentioned as whole numbers, which we annotate with label AgeNPII, and (2B) ages that are mentioned as fractions of whole years (e.g., “Patient is a 4 and 11/12 month old boy”), which we annotate with label AgeFraction.

Without an anchor to a fixed date AgeFraction is not very useful to re-identify the patient; thus, it should be considered as non-PII. However, it is possible that a de-identification system might miss a mention of the report date, which, along with the age information in fractions (e.g., “he will be 11 months old in two days”), one may be able to identify
the birth date of the patient. In other words, label AgeFraction could pose privacy risk only in conjunction with an inadvertently revealed full-date within the text.

If the patient’s current age is 90 or older and the narrative report provides indirect reference to the patient’s age such that re-identification can be done through a simple arithmetic (e.g., “Twenty years ago, at the age of 75, he had an ischemic attack”), we would annotate the earlier age references (i.e., 75 in the example above) as AgePII as well.

We do not annotate other “age” types such as gestational age, bone age (unless identical to the chronological age), school grade level (10th grade) or age periods such as teenage, middle-aged, etc., since they are not as identifying as chronological age found in formal records.

The category Date comprises six labels: Year (e.g., 2001), Month (e.g., September), Day (e.g., 11th), DayOfWeek (e.g., Tuesday but not Tuesdays), SpecialDay (e.g., 9/11, Hurricane Sandy, Katrina, Cinco de Mayo, New Year), and Period (e.g., flu season, Monsoon, Ramadan, winter, second trimester).

We annotate not only those special days that are fixed in history such as Pearl Harbor, 2008 Market Crash but also those special days that occur every year such as New Year, whose exact dates can be construed when combined with year information, which taken alone is not PII under HIPAA. We also label personal special days such as birthday or Bar Mitzvah, not only due to potential privacy concerns as they may be available from external sources, but also due to their potential importance in reference to other events in the narrative text.

We use the label Period to annotate any time period longer than a day of which begin and end dates are not explicitly stated. We use this label to annotate periods in the patient’s medical history such as pregnancy, puberty, hospitalization period, and menstruation as well as calendar periods such as early 2001 or in the 90s. Most age references in the medical history are periods. For example, “when the patient was 5 years old …” or “spoke at 5–5 ½ years old”. Note that age references in these examples do not denote the patient’s current age but if such age references in the past reveal that the patient’s current age is 90 or older, we would have to use label AgePII instead.

If a period of two days or longer is described in terms of an interval or a range with explicit begin and end date identifiers (e.g., 1995–97, between next Tuesday and Friday), we separately annotate begin and end points with the appropriate date label. If it is an age range, we label each age separately. In the example, “had hearing loss from 85-97 years old”, we annotate 85 with AgeNPII and 97 with AgePII.

Recall that we define the Period as a subcategory of date; therefore, we use it only if the period can be stated relative to a date. In example, “when the patient was 5 years old”, we perceive a period of one year, starting 5 years after the birth date. If the period is stated using terms like last year, last month, last week, and last weekend, the period is defined relative to the date of the report. We do not annotate (hence do not use the label Period) cyclical temporal references such as daily, Tuesdays or every Tuesday or other temporal references described in sequence of events without any apparent date to anchor (e.g., “completed 2 weeks of antibiotics”).

We annotate last Christmas or Christmas last year as SpecialDay since the terms last and last year further qualify the special day, but when the year is explicitly stated as in Cinco de Mayo 2000, we annotate Cinco de Mayo as SpecialDay and annotate 2000 as Year, because in this example, the date term refers to a full date May 5, 2000.

We do annotate time of the day using the label Time, but we also believe that it is too general to link to the patient for re-identification. Since we do not classify it under the Date category, we do not annotate time periods within a day as Period (e.g., noon-4:30pm); instead, we use label Time to annotate noon and 4:30pm, separately.

3.6. Telecommunication and Alphanumeric Identifiers

Telecommunication identifiers are the most straightforward and the least ambiguous identifiers since they are well defined engineering objects. Of the 18 personal identifiers defined by the HIPAA Privacy Rule, five of them are telecommunication identifiers to be de-identified: telephone numbers, fax numbers, electronic email addresses, web universal resource locators (URLs), and Internet protocol (IP) address numbers. As new telecommunication modes and media emerge, new telecommunication identifiers (e.g., Twitter usernames such as @BarackObama) appear, but they too are covered by the last (18th) catch-all identifier of the Privacy Rule: “any other unique identifying number, characteristics, or code” must be de-identified.

Numeric and Alphanumeric Identifiers consist of four labels: MedicalRecordNo, ProtocolNo, HealthRecordID, and AlphanumericID. The first two are very specific identifiers denoting medical record and protocol numbers,
respectively. Medical record number is one of the 18 HIPAA identifiers. Since protocol numbers are very important entities for clinical researchers, who are the intended users of NLM Scrubber, we annotated them separately. We use the label HealthRecordID for all other alphanumeric identifiers issued by health care and insurance providers uniquely to the patient; e.g., hospital account number, health plan beneficiary number and lab specimen number. MedicalRecordNo, ProtocolNo and HealthRecordID are almost always associated with the patient—only in a handful of cases did we observe mentions of such identifiers for the relatives.

We use the label AlphanumericID for all other numeric and alphanumeric identifiers that are not issued by the provider, including those five identifiers defined by the Privacy Rule: social security number, account numbers, certificate/license numbers, vehicle identifiers, and device identifiers. Note for hospital account numbers we use the label HealthRecordID.

Sometimes, names of some lab materials and experimental drugs may contain some numbers (e.g., drug 123-ABC or instrument QRS-40). We do not annotate such health information, as they are neither unique to the patient nor personal identifiers.

3.7. Personally Identifying Context

So far, we discussed how we annotate entities that were mentioned in the HIPAA Privacy Rule along with a few other closely related entities, some of which can be PII in certain contexts. We are aware of the fact that due to the intricacies of natural languages, it is possible to specify a context in which the person could be identified indirectly such that no labels we discussed so far would be appropriate to use. In those cases, we label the tokens with PIC, denoting Personally Identifying Context.

In the hypothetical example, “received his injuries while he was reporting from Tahrir Square”, we would annotate reporting with label Occupation::Patient and Tahrir Square with PIC::Patient, since the latter would provide context so specific that along with the occupation information would probably identify the person directly.

In the example “the patient was deployed to Iraq”, the reader may presume that the patient is in the military, but the deployment to Iraq is not an occupation—equipment could be deployed to Iraq as well as other types of personnel such as reporters could be deployed to a war zone. However if the example provides an occupational context that is so specific that it might tighten the circle of potential candidates, we would label those tokens as PIC. But in this example, even if we presume that the context alludes that the subject is a military person, the circle of military personnel remains too broad to label the phrase as PIC.

3.8. Role

In order to associate a personal identifier with a person, automatic de-identification system needs to recognize a reference to that person. We define such a reference as Role, which can denote the patient, mother, father, daughter, supervisor, physician, boyfriend, and others. We annotate those roles in order to evaluate and monitor our system’s performance. Although they too are roles, we do not annotate pronouns such as he, she, him, hers, their, themselves etc. We use the label Role only if no other label is suitable for that annotation. For example, if the provider’s occupation is more specific than the role of physician or nurse, such as cardiologist or physical therapist, then we annotate it as Occupation. If the reference specifies a personally identifying context, instead of using the label Role, we would annotate it as PIC.

The role information is quite important in the context of the deceased patient records as well, because even though health records of the deceased patient may not constitute protected health information, health information of their living relatives does. Fortunately, such information is quite rare. Recognizing such roles in the narrative reports of the deceased helps prevent such privacy breaches.

4. Results

Our annotation label set and methods of annotating text elements that we described in this paper are the results of the seven years long evolution of annotation, de-identification, and evaluation. By defining the annotation labels on two dimensions and associating identifiers with personhood, Patient, Relative, Employer, Provider, and Other, we can easily stratify the importance of text elements in terms of high, medium, low, and no privacy risks.
We divided some identifier categories such as Address into subcategories, each with a distinct label. Even though
some information (e.g., house or street numbers labeled with Location) seem more granular or specific than others
(e.g., town labeled with City), inadvertently revealing them would pose little or no privacy risk; however such
identifiers (e.g., house number and street name) become very significant only if they are revealed in combination with
certain other elements of the same category (e.g., house number and street name together). The same is true for the
subcategories of Date; i.e., day, month, or year information alone has no significance until they are revealed together.

The newly introduced special subcategories and associated labels such as Period, SpecialDay, and AgeFraction enrich
our label set and provide clarity and direction to our annotators when faced with non-standard and borderline cases.
For example, “at age 3, the patient started…” may seem to contain a piece of information about the patient’s age at
the very first glance, but “age 3” actually outlines a period in the medical history of the patient and does not identify
how old the patient currently is. In short, these new labels yield a corpus with more accurate annotations.

Personally Identifying Context labeled with PIC is a very important new category since we no longer need to say
“There could be some information identifying the patient indirectly without using any explicit PII elements in this
report.” Now, if we encounter such information, we have the tool to annotate it.

5. Discussion

In this paper, we introduced a new annotation schema that extends the identifier elements of the HIPAA Privacy Rule.
In this schema, we annotate text elements on two dimensions: identifier type and personhood denoted by the identifier.
The personhood can take one of the following type values: Patient, Relative, Employer, Provider and Other. We
extended identifier types both in terms of scope and granularity.

Our annotation label set is based first and foremost on the PII elements defined by the HIPAA Privacy Rule. However,
being aware of other annotation efforts, we tried to design a broad spectrum of annotation labels so that we can
establish a common ground for our community. Standardization of annotation schemas is a very important goal that
we all should strive for; otherwise, an effective evaluation and comparison of our study results would be too difficult.
We believe this is the first step towards that ambitious goal.

The concepts and annotation methods defined and described in this paper could be best understood if studied along
with a number of good examples. We are currently working on finalizing our annotation guidelines containing a rich
set of examples most of which are extracted from actual reports. The guidelines will be publicly available by the time

Acknowledgements

Clinical Predictive Modeling Development and Deployment through FHIR
Web Services

Mohammed Khalilia, Myung Choi, Amelia Henderson, Sneha Iyengar, Mark Braunstein, Jimeng Sun
Georgia Institute of Technology, Atlanta, Georgia

Abstract
Clinical predictive modeling involves two challenging tasks: model development and model deployment. In this paper we demonstrate a software architecture for developing and deploying clinical predictive models using web services via the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) standard. The services enable model development using electronic health records (EHRs) stored in OMOP CDM databases and model deployment for scoring individual patients through FHIR resources. The MIMIC2 ICU dataset and a synthetic outpatient dataset were transformed into OMOP CDM databases for predictive model development. The resulting predictive models are deployed as FHIR resources, which receive requests of patient information, perform prediction against the deployed predictive model and respond with prediction scores. To assess the practicality of this approach we evaluated the response and prediction time of the FHIR modeling web services. We found the system to be reasonably fast with one second total response time per patient prediction.

Introduction
Clinical predictive modeling research has increased because of the increasing adoption of electronic health records\(^1\)\(^-\)\(^3\). Nevertheless, the dissemination and translation of predictive modeling research findings into healthcare delivery is often challenging. Reasons for this include political, social, economic and organizational factors\(^4\)\(^-\)\(^6\). Other barriers include the lack of computer programming skills by the target end users (i.e. physicians) and difficulty of integration with the highly fragmented existing health informatics infrastructure\(^7\). Additionally, in many cases the evaluation of the feasibility of predictive modeling marks the end of the project with no attempt to deploy those models into real practice\(^8\). To achieve real impact, researchers should be concerned about the deployment and dissemination of their algorithms and tools into day-to-day decision support and some researchers have developed approaches to doing this. For example, Soto \textit{et al.} developed EPOCH and ePRISM\(^7\), a unified web portal and associated services for deploying clinical risk models and decision support tools. ePRISM is a general regression model framework for prediction and encompasses various prognostic models\(^9\). However, ePRISM does not provide an interface allowing for integration with existing EHR data. It requires users to input model parameters, which can be time consuming and a particular challenge for researchers unfamiliar with the nuances of clinical terminology and the underlying algorithms. A suite of decision support web services for chronic obstructive pulmonary disease detection and diagnosis was developed by Velickovski \textit{et al.}\(^10\), where the integration into providers' workflow is supported through the use of a service-oriented architecture. However, despite these few efforts and many calls for researchers to be more involved in the practical dissemination of their systems, little has been done and much less has been accomplished to utilize predictive modeling algorithms at the point-of-care.

An important missing aspect that retards bringing research into practice is the lack of simple, yet powerful standards that could facilitate integration with the existing healthcare infrastructure. Currently, one major impediment to the use of existing standards is their complexity\(^11\). The emerging Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) standard provides a simplified data model represented as some 100-150 JSON or XML objects (the FHIR Resources). Each resource consists of a number of logically related data elements that will be 80% defined through the HL7 specification and 20% through customized extensions\(^12\). Additionally, FHIR supports other web standards such as XML, HTTP and OAuth. Furthermore, since FHIR supports a RESTful architecture for information and message exchange it becomes suitable for use in a variety of settings such as mobile applications and cloud computing. Recently, all the four major health enterprise software vendors (Cerner, Epic, McKesson and MEDITECH) along with major providers including Intermountain Healthcare, Mayo Clinic and Partners Healthcare have joined the Argonaut Project to further extend FHIR to encompass clinical documents constructed from FHIR resources\(^13\). Epic, the largest enterprise healthcare software vendor, has a publicly available FHIR server for testing that supports a subset of FHIR resource types including Patient, Adverse Reaction, Medication Prescription, Condition and Observation\(^14\) and support of these resources is reportedly included in their June 30, 2015 release of Version 15 of their software. SMART on FHIR has been developed by Harvard Boston Children’s Hospital as a
A universal app platform to seamlessly integrate medical applications into diverse EHR systems at the point-of-care. Cerner and four other EHR systems demonstrated their ability to run the same third party developed FHIR app at HIMSS 2014. Of particular importance to our work is the demonstrated ability to provide SMART on FHIR app services within the context and workflow of Cerner’s PowerChart EHR.

As a result of these efforts, FHIR can both facilitate integration with existing EHRs and form a common communication protocol using RESTful web services between healthcare organizations. This provides a clear path for the widespread dissemination and deployment of research findings such as predictive modeling in clinical practice. However, despite its popularity, FHIR currently is not suitable to directly support predictive model development where a large volume of EHR data needs to be processed in order to train an accurate model. To streamline predictive model development it is important to adopt a common data model (CDM) for storing EHR data. The Observational Medical Outcomes Partnership (OMOP) was developed to transform data in disparate databases into a common format and to map EHR data into a standardized vocabulary. The OMOP CDM has been used in various settings including drug safety and surveillance, stroke prediction, and prediction of adverse drug events. We utilize a database in the OMOP CDM to support predictive model development. The resulting predictive model is then deployed as FHIR resources for scoring individual patients.

Based on these considerations, in this paper we propose to develop and deploy:

- A predictive modeling development platform using the OMOP CDM for data storage and standardization
- A suite of predictive modeling algorithms operating against data stored in the OMOP CDM
- FHIR web services, that use the resulting trained predictive models to perform prediction on new patients
- A pilot test using MIMIC2 ICU and ExactData chronic disease outpatient datasets for mortality prediction.

Methods

Overview and system architecture

Figure 1 shows how our architecture supports providing predictive modeling services to clinicians via their EHR. On the server side, the model development platform trains and compares multiple predictive models using EHR data stored in the OMOP CDM. After training, the best predictive models are deployed to a dedicated FHIR server as executable predictive models. On the client side, users can use existing systems such as desktop or mobile applications within their current workflows to query the predictive model specified in the FHIR resource. Such integrations are done by using FHIR web services. Client applications use FHIR resource to package patient health information and transport it using the FHIR RESTful Application Programming Interface (API). Once the FHIR server receives the information, it passes it on to the deployed predictive model for the risk assessment. The returned result from the predictive model will be sent to the client and also stored into a resource database that can be accessed by the client to read or search the Risk Assessment resources for later use.

![Figure 1. System Architecture](image-url)
The common data model

Developing a reliable and reusable predictive model, requires a common data model into which diverse EHR data sets are transformed and stored. For the proposed system we used the OMOP CDM designed to facilitate research using some important design principles. First, data in the OMOP CDM is organized in a way that is optimal for data analysis and predictive modeling, rather than for the operational needs of healthcare providers and other administrative and financial personnel. Second, OMOP provides a data standard using existing vocabularies such as the Systematized Nomenclature of Medicine (SNOMED), RxNORM, the National Drug Code (NDC) and the Logical Observation Identifiers Names and Codes (LOINC). As a result predictive models built using data in an OMOP CDM identify standardized features, assuming the mapping to OMOP is reliable. The OMOP CDM is also technology neutral and can be implemented in any relational database such as Oracle, PostgreSQL, MySQL or MS SQL Server. Third, our system can directly benefit the existing OMOP CDM community to foster collaborations.

The OMOP CDM consists of 37 data tables divided into standardized clinical data, vocabulary, health system data and health economics. We only focused on a few of the CDM clinical tables including: person, condition occurrence, observations and drug exposure. As we enhance our Extract, Transform, Load (ETL) process and the predictive model, we can incorporate additional data sources as needed. Figure 2 shows a high level overview of the ETL process in which multiple raw EHR data are mapped to their corresponding CDM instances. In the transformation process, EHR source values such as lab names and results, diagnoses codes and medication names are mapped to OMOP concept identifiers. The standardized data can then be accessed to train the predictive models.

Predictive model development

The CDM provides the foundation for predictive modeling. As various datasets are transformed and loaded into the OMOP CDM predictive modeling training can be simplified because the OMOP CDM instances all have the same structure. For instance, one can equally easily train a model for predicting mortality, future diseases or readmission using different datasets. Figure 3 provides an overview of predictive model training.
The predictive models are trained offline and can be re-trained as additional records are added to the database. Training consists of three modules: 1) **Cohort Construction**: this is the first step in the training phase. At this stage the user specifies the OMOP CDM instance, prediction target (i.e. mortality) and the cohort definition. Based on the specified configuration the module will generate the patient cohort. 2) **Feature Construction**: at this stage the user specifies which data sources (e.g. drugs, condition occurrence and observations) to include when constructing the features. Additional configurations can also be provided for each data source. The user can include the observation window (e.g. the prior year, to utilize only patient data recorded in the past 365 days). Other data source configurations include the condition type concept identifier to specify which types of conditions to include (i.e. primary, secondary), observation type concept identifier and drug type concept identifier. The final configuration is the feature value aggregation function. For example, lab result values can be computed using one of five aggregation functions: sum, max, mean, min, and most recent value. 3) **Model Training**: This module takes the feature vectors constructed for the cohort and trains multiple models using algorithms such as Random Forest, K-Nearest Neighbor (KNN) and Support Vector Machine (SVM). The parameters for each of these three algorithms are tuned using cross validation in order to select the best performing model. The best model will be deployed as a FHIR resource. In the next section, we will describe how to deploy such a predictive model for scoring future patient in real time.

**FHIR web services for model deployment**

Our approach is focused on API based predictive modeling services that can be easily implemented in thin client applications, especially in the mobile environment. FHIR defines resources represented as JSON or XML objects that can contain health concepts along with reference and searchable parameters. FHIR further defines RESTful API URL patterns for create, read, update, and delete (CRUD) operations. In this paper, we propose to use the RiskAssessment resource defined in the FHIR Draft Standard for Trial Use 2 (DSTU2) for our predictive analysis. Readers should note that this particular FHIR resource is still in the draft stage. The current approved DSTU1 version of FHIR does not have a RiskAssessment resource. However, our development version of FHIR is currently being balloted on by HL7 members and should be approved soon. Detailed information about the FHIR development version for RiskAssessment can be obtained from Ref. 20.

A prediction request to the FHIR server starts by forming the CREATE operation, which is used to request for scoring specific patients in real-time using the deployed predictive model. This creates RiskAssessment resources at the server. Client applications then receive a status response with a resource identifier that refers to the newly created resource. Clients can use this resource identifier to read or search the resource database via a FHIR RESTful API. For this paper, we used a SEARCH operation as we need to retrieve more than one result. Groups of FHIR resources are called a bundle and there is a specified format for that. As all performed analyses are stored in the resource database, additional query types can be implemented in the future. The operation process is depicted in Figure 4.

![Figure 4. Operation Process](image)

During the process, clients and server need to put appropriate information into elements available in the RiskAssessment resource. However, most of the data elements in the RiskAssessment resource are optional for predictive modeling which gives us flexibility in choosing the model output. For the CREATE operation, the RiskAssessment resource is constructed with subject, basis, and method elements as shown in Figure 5(a).
Subject is used to define a group identifier, which we also refer to as the resource identifier. Basis can contain information used in assessment, which are the patient identifiers. All patients included in basis are bound to the group identifier specified in the subject element. Therefore, the results of assessment for patients will be grouped in the resource database by the group identifier at the FHIR server. Subject or group identifier provides a simple mechanism for users to specify a group of patients, whose prediction score can be retrieved from the resource database.

Predictive model scoring creates feature vectors (one for each patient), which are derived from the patient’s health information. The FHIR Patient resource can be referenced by either the patient identifier or by a collection of resources such as MedicationPrescriptions, Conditions, Observations, etc. In our initial implementation we used patient identifier. Using the patient identifier, the predictive model constructs feature vectors by pulling the appropriate information from various resources that contain each patient’s clinical data occurring within the specified observation window. In our implementation the clinical data is stored in the OMOP database. This all happens during the predictive analysis period in Figure 4. In the future, we will construct features directly from EHR databases through querying other FHIR resources in real-time.

Results from the predictive analysis are sent back to the FHIR server in JSON format and the FHIR server stores the information in a resource database. If the CREATE operation is successful, the server will send a 201-status created message. In case of any errors, an appropriate error status message will be sent back to the client with the OperationOutcome resource, if required.

Clients can query the prediction results using the resource identifier returned in the CREATE response (i.e. group identifier under subject in this case). This resource identifier can be used to query the stored prediction results using the SEARCH operation. Recall that the resource identifier is bounded to a list of patient identifiers. Once the SEARCH operation request is received with the resource identifier, the FHIR server constructs a response FHIR resource for each patient. In the RiskAssessment resource, the prediction element contains the risk score for a patient, as shown in Figure 5(b). When the SEARCH operation is completed, the RiskAssessment resources are packaged into a bundle and sent to the client. For example, the resource contains an identifier that represents the patient for whom the predictive analysis is performed. In our experiments, mortality prediction was performed and risk scores are returned. The mortality scores are populated in the probabilityDecimal sub element of the prediction element, as shown in Figure 5(b).

Experiments

We tested our implementation using two datasets: Multiparameter Intelligent Monitoring in Intensive Care (MIMIC2) and a dataset licensed from ExactData. MIMIC2 contains comprehensive clinical data for thousands of ICU patients collected between 2001 and 2008. ExactData is a custom, large realistic synthetic EHR dataset for
chronic disease patients. Using ExactData eliminates the cost, risk and legality of real EHR data. Table 1 presents key statistics about the two datasets.

Table 1. Key ExactData and MIMIC2 Dataset Statistics

</table>

Two ETL processes were implemented to move the raw MIMIC2 and ExactData datasets into two OMOP CDM instances. From each instance a cohort was generated for mortality prediction. The cohort for ExactData is limited to the 53 patients with death records matched with 53 control patients to keep it balanced. The MIMIC2 cohort is somewhat larger with 500 case patients and 500 control patients. To generate the control group we performed a one-to-one matching with the case group based on age, gender and race. As illustrated in Figure 3, the feature vectors for each cohort are generated using these MIMIC2 and ExactData cohorts. The features include condition occurrence, observation and drug exposures. The observation window was set to 365 days for both cohorts and the feature values for observations were aggregated by taking the mean of the values.

For each cohort three mortality predictive models were trained offline using Random Forest, SVM and KNN. After performing cross validation and parameter tuning for each algorithm, the model with the highest Area Under the Receiver Operating Characteristic curve (AUC) was deployed. This results in three final models, one for each algorithm, allowing clients to specify which algorithm to use to predict new patients. The predictive models were trained using Python scikit-learn machine learning package. The final model training runtime, AUC, accuracy and F1 score are reported in Table 2.

Our entire software platform was evaluated and tested on a small Linux server with 130GB hard drive, 16GB memory, and two Intel Xeon 2.4GHz processors with two cores each. FHIR web services were built on the Tomcat 8 application server using the HL7 API (HAPI) RESTful server library. The FHIR web service expects a request from the client to perform patient scoring (in our case mortality prediction) with patient data or patient identifier contained in the request body. We evaluated the performance of the web service in two ways. The first evaluation method measures the response time from the client’s request to the web service until a response is received back from the server. This is an important measure since a very slow response time makes the system unusable for practical applications including at the point-of-care where busy clinicians demand a prompt response. A single API request to score a patient is a composite of two different requests: 1) CREATE request made to the FHIR server that sends the data in the JSON format. The data comprises of resource type, a set of patient identifiers, classification algorithm to be employed (e.g. KNN, SVM or Random Forest) and the OMOP CDM instance to be used (e.g. MIMIC2 or ExactData). The response time of this request increases with the number of patients (as can be observed from Figures 6 and 7). SEARCH request is made by passing the patient group identifier as a parameter to obtain the prediction for the patients. Similar to the CREATE request, a larger number of patients increases the response time of the SEARCH request.
Figure 6 shows the FHIR web service response time using KNN and MIMIC2 datasets as we vary the number of patients to score in the request. For a single patient, a typical point-of-care scenario, the response time is around one second. The CREATE request consumes most of the time and the response time increases with the number of patients. This could become an issue in an application such as population health to identify those chronic disease patients most likely to be readmitted or screening an entire ICU to identify patients most in need of immediate medical attention. The SEARCH request has a relatively constant response time and does not change significantly as the number of patients increases.

The actual scoring or prediction of the patient is performed in the CREATE request. There are two major tasks that take place in this CREATE request. First is the feature construction that is performed for each patient included in the request. This requires querying the OMOP CDM database, extracting and aggregating feature values, which can be an expensive operation when scoring a large number of patients. The second task is the actual prediction operation which takes the least amount of time. Figure 7 shows the response time (after subtracting the feature construction and prediction time), feature construction time, and prediction time as we increase the number of patients. As the number of patients increases the prediction time does not increase much compared to the response time or the feature construction time. For instance, a request for scoring 200 patients takes about 23 seconds, out of which 8 seconds were spent constructing features and only 16 milliseconds were spent on the actual predictions.
The second web service performance evaluation measures the amount of load that the service can handle within some defined time interval. As this service handles multiple clients it is important to guarantee that it is available and able to respond in a timely manner to requests as the number of clients increases. However, keep in mind that our evaluation is only a proof of concept done on a moderate server. Figure 8 shows the average response time when 1000 clients send CREATE requests (one patient in each request) to the FHIR server within a minute. Figure 8 is generated by the Simple Cloud-based Load Testing tool and has three axes: response time on y-axis, number of clients on secondary y-axis and time on x-axis, where 00:05 indicates the fifth second from the start of the test. The green curve (upper curve) shows the number of simultaneous clients sending the requests at some point in time. For instance, on the fifth second, about 50 clients were sending simultaneous requests. The blue line shows the average response time for those clients (on the fifth second, the average response time for 50 clients was about 1800 milliseconds). Overall, the average response time for the 1000 clients is 1506 milliseconds (about 1.5 seconds). A 1.5 second response time is acceptable when the task is performed at the point-of-care.

![Figure 8. Average response time as 1,000 clients send CREATE request within one minute](image)

**Conclusion and Discussion**

In this paper we presented a real-time predictive modeling development and deployment platform using the evolving HL7 FHIR standard and demonstrated the system using MIMIC2 ICU and ExactData chronic disease datasets for mortality prediction. The system consists of three core components: 1) The OMOP CDM which is more tailored for predictive modeling than healthcare operational needs and stores EHR data using standardized vocabularies. 2) Predictive model development, which consists of cohort construction, feature extraction, model training and model evaluation. This training phase is streamlined, meaning that it will work for any type of data stored in an OMOP CDM. 3) FHIR web services for predictive model deployment that we use to deliver the predictive modeling service to potential clients. The web service takes a prediction request containing patient identifiers whose features can be extracted from the OMOP database. The prediction or the scoring is not pre-computed but is performed in real-time. Our future work on the FHIR web services will enhance the feature extraction by accessing EHR data over FHIR Search operations. In this case, our predictive platform will become a client to the FHIR-enabled EHR. Recent FHIR ballot for DSTU2 includes a Subscription resource. This resource, if included in the standard, can be utilized in our platform to subscribe the patient’s feature related data from their EHR. The Subscription resource uses Search string for its criteria, thus our future work will comply with this new resource with only a few modifications. Even if this resource couldn’t be included, our future platform will use a pull mechanism to retrieve EHR data for feature extraction.

A total of six predictive models were trained on MIMIC2 ICU and ExactData chronic disease datasets from which we generated cohorts based on patients with a death event and a matched set of control patients. The FHIR web service routes the incoming requests to the desired predictive model, which is usually a client specified parameter. For a practical, real-time web service it is important to achieve a fast response time. The observed response time for scoring one patient was around one second, of which the actual prediction took only few milliseconds. The total response time increases with the number of patients in a single request, but the actual prediction time remains very
small, reaching 16 milliseconds when scoring 200 patients. However, scoring many patients in one request is not always desired or needed. For instance, in many cases providers are only interested in querying one patient at a time from the point-of-care. In such a direct care delivery scenario only a single request containing one patient’s information would be sent to the server with an expected response time of one second. Additionally, this response time can be easily reduced by expanding the server hardware and optimizing the implementation.

We present a prototype with much work and many needed improvements yet to be done. First, additional predictive algorithms should be added. We demonstrated Random Forest, SVM and KNN, but others such as Logistic Regression and Decision Trees could be added. Second, the system should allow for updating the predictive model as new patients get scored. This requires using the patient EHR data passed into the web service for retraining the predictive model. For this to take place, the web service should allow the provider to give feedback on the patient scoring, which can then be used to improve future predictions. Third, the system needs to be scalable and should handle larger datasets to train the predictive models. This can be done by utilizing big data technologies such as Hadoop or Apache Spark. Fourth, the response time needs to be improved especially for requests that contain large numbers of patients, which can be done by allocating more resources and improving the FHIR web service software. Additionally, the response time can be decreased if the client includes patient EHR data in the request, thus avoiding expensive database querying. Fifth, the web service must have privacy and security protocols implemented such as OAuth2, which has been already implemented in the SMART on FHIR app platform.

The proposed approach in this paper assumes that the client that is deploying our predictive model stores the patient data in an OMOP CDM model and the CREATE request contains the identifier for the patient for which the analysis is to be performed. Any ETL process for moving data from EHR to OMOP model is outside the scope of this paper. However, FHIR resources such as MedicationPrescriptions, Conditions, Observations can be included in the body of the CREATE request instead of the patient identifier. This allows for performing analysis for patients not included in the database. Additionally, two processes can be performed on the FHIR resources, if passed in the CREATE request: 1) perform prediction using the patient data (resources) in the request and 2) subscribe the patient’s features related data from EHR to the predictive platform.

In conclusion, we have demonstrated the ease of developing and deploying a real-time predictive modeling web service that uses open source technologies and standards such as OMOP and FHIR. With this web service we can more easily and cost effectively bring research into clinical practice by allowing clients to tap into the web service using their existing EHRs or mobile applications.

Abstract

Orthographic and grammatical errors are a common feature of informal texts written by lay people. Health-related questions asked by consumers are a case in point. Automatic interpretation of consumer health questions is hampered by such errors. In this paper, we propose a method that combines techniques based on edit distance and frequency counts with a contextual similarity-based method for detecting and correcting orthographic errors, including misspellings, word breaks, and punctuation errors. We evaluate our method on a set of spell-corrected questions extracted from the NLM collection of consumer health questions. Our method achieves a $F_1$ score of 0.61, compared to an informed baseline of 0.29, achieved using ESpell, a spelling correction system developed for biomedical queries. Our results show that orthographic similarity is most relevant in spelling error correction in consumer health questions and that frequency and contextual information are complementary to orthographic features.

1 Introduction

Orthographic errors are pervasive in informal writing. The questions that consumers ask about their or someone else’s health often contain many misspellings\textsuperscript{[1]}. Misspellings may not pose a significant cognitive burden for a human reader, but they can severely limit the effectiveness of an automated system. At the National Library of Medicine (NLM), we have been building a system to assist customer service staff in answering health questions received from consumers. In 2014, we received more than 40K questions, approximately 15% of which sought health-related information. Our system currently uses a combination of rule-based and supervised machine learning techniques for question understanding. More specifically, we extract focus (generally a disease)\textsuperscript{[2]} and question type (e.g., treatment, prognosis)\textsuperscript{[3]} from the question and construct a semantic frame\textsuperscript{[4]}, which is then converted to a search engine query. These techniques assume well-written questions; thus, orthographic errors significantly hinder their performance. For instance, consider the following question:

(1) My mom is 82 years old suffering from anixity and depression for the last 10 years was dianosed early on set deminita 3 years ago. Do yall have a office in Greensboro NC? Can you recommend someone. she has seretona syndrome and nothing helps her.

Four disorders are mentioned in the question, three of which are misspelled (anixity for anxiety, deminita for dementia, and seretona syndrome for serotonin syndrome). Another, perhaps less central but potentially important, misspelling is dianosed for diagnosed. On the other hand, the misspelling of the colloquial yall (y’all) and nothing (nothing) may be less significant for interpretation of this question. In contrast to such non-word spelling errors, the spelling of onset as on set constitutes a real word spelling error as well as a word break error, since both on and set are valid words. Real word spelling errors can be even more problematic, as in the question “What can I do to lesson the severity of the adema?”, where the underlined words, both crucial for understanding the question, are misspelled. Without detecting and correcting these...
types of errors, there is little hope of extracting the information needed from this question to answer it automatically.

Punctuation errors can also have an impact on question understanding. Omitting sentence-ending periods or space after punctuation, for example, are likely to cause syntactic parsing errors and, consequently, errors in extracted information. A request, particularly rich in such errors, is given below. Unable to identify sentence-ending periods, Stanford syntactic parser has difficulty parsing this request.

(2) chromosome 3 found in the bloods between the father and son,, would this mean that my son,s blood is not the same as mine,, i was told it was all about learning problems,, but i am worried that there is more involved,, can you send me a chart or something describing ch 3 is all about and too what area of the body its being tested on espically a 9 year old child , thanks

In this paper, we present a method for detecting and correcting orthographical errors in consumer health questions. At this time, we do not attempt to correct grammatical errors. The method follows a pipeline architecture and consists of several modules: a) a pre-processing module that specifically focuses on errors involving punctuation and numbers, b) a misspelling detection module that relies on an expanded English dictionary, c) a spelling suggestion module that uses phonetic and orthographic distance, and d) a re-ranking module that uses a linear-weighted ensemble of several algorithms that score these suggestions. The scoring algorithms rely on orthographic, phonetic and contextual similarity as well as corpus frequency. We calculate contextual similarity using word embeddings, a recent natural language processing technique based on the distributional hypothesis. To evaluate our method, we developed a dataset that consists of 472 consumer health questions received by NLM, which we manually corrected for spelling errors. We compared the performance of our method against a strong baseline that relies on the ESpell algorithm, developed for PubMed query correction. Our results demonstrate the varying degrees of difficulty in correcting specific subtypes of spelling errors: while spelling errors in question elements most salient for question understanding (e.g., disorders) can be corrected to a large extent, real word spelling errors remain challenging.

2 Related Work

The approaches to correcting non-word spelling errors are reviewed by Kukich and Mitton. These approaches often rely on the availability of a comprehensive spelling dictionary and use edit distance and phonetic similarity between the misspelled word and the candidate suggestion. More recent approaches incorporate word frequency data collected from large corpora as well as contextual information. Flor and Futagi use word frequency data as well as orthographic and phonetic similarity, and re-rank the candidate suggestions using context, achieving very good correction results in correcting misspellings in non-native student essays. They report local error density (misspelling of adjacent words) and competition among inflectional variants as the main sources of their errors.

Real word spelling errors (also called malapropisms) are more challenging, because it is impossible to detect such errors in isolation. Thus, they often go undetected by spell checkers. Methods for real word error correction have used semantic information from lexical resources or relied on machine learning techniques and language models, all essentially taking some form of contextual information into account. The first approach is based on the hypothesis that the more distant a word is semantically from the other words in a text, the more likely it is a real word error. WordNet has often been used for calculating word distance. Machine learning techniques often use pre-defined confusion sets (e.g., \{their,there\}, \{principal,principal\}) and attempt to learn the typical context for each member using features from adjacent words. Language model-based approaches rely on n-gram probabilities generally drawn from web-scale data, such as
Google Web 1T dataset\(^1\). Syntactic and distributional information has also been used for this task\(^{[18]}\). While syntactic information based on parse features proved useful, the contribution of distributional information based on word cooccurrence was found to be limited.

In the biomedical domain, Crowell \textit{et al.}\(^{[19]}\) use a frequency-based technique to improve on existing spelling correction tools, ASpell and GSpell, for non-word spelling correction of consumer health information queries. They use MedlinePlus queries to generate word-frequency statistics. Their results show the significant contribution of frequency-based re-ranking for health information retrieval. Wilbur \textit{et al.}\(^{[7]}\) focus on spelling correction in the PubMed search engine. Their approach is based on the noisy channel model and makes use of statistics harvested from the user logs to estimate the probabilities of different types of edits that lead to misspellings. Word frequency counts in the PubMed database are used for computing prior probabilities. They apply different constraints based on the edit distance between the misspelling and the candidate suggestion. Ruch \textit{et al.}\(^{[20]}\) use the syntactic and semantic context to improve correction accuracy in clinical records. A simple, edit distance-based correction strategy is augmented with ranking via morpho-syntactic and word sense disambiguation. A named-entity extractor is used to avoid correcting physician and patient names. Patrick \textit{et al.}\(^{[21]}\) use a combination of a rule-based suggestion generation system and context-based and frequency-based ranking algorithm for spelling correction in clinical notes. Context-based ranking uses a trigram language model with the 3-word window around the misspelling. Each ranking method achieves the best result on one of the two test corpora. They also report inflectional variants as a challenge in spelling correction.

Word embeddings (also known as context-predicting models or neural language models\(^{[6,22]}\)) are a recent development in distributional semantics research, where the paradigm is to use vectors to represent the contexts that a word appears in and to apply vector algebra techniques to measure similarity between word vectors. In contrast to the more traditional distributional methods that rely on word counts, context-predicting models cast the problem as a supervised learning task and try to maximize the probability of the contexts that the word is observed in the corpus. The technique has been applied successfully to various word similarity tasks (e.g., semantic relatedness, analogy).

\section{3 Methods}

We begin this section by discussing our spelling correction dataset. We then explain the modules that comprise our spelling error detection and correction pipeline.

\subsection{3.1 Dataset}

We manually annotated and corrected 472 health-related questions posed to NLM by consumers for orthographic and punctuation errors. We considered the following types of errors in annotation:

- **NON-WORD**: the misspelled word does not appear in the dictionary (e.g., \textit{physians} for \textit{physicians})
- **REAL-WORD**: the misspelled word appears in the dictionary (e.g., \textit{leave} for \textit{live})
- **PUNCTUATION**: a spelling error caused by absence of punctuation or a spurious punctuation (e.g., \textit{I've} for \textit{I've})

\footnote{http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2006T13}
• **TO-MERGE:** a word break error, where a spurious space is introduced to a word (e.g., *during* for *dur ing*)

• **TO-SPLIT:** a word break error, where two adjacent words run together (e.g., *knowabout* for *know about*)

In addition, we annotated whether the error occurred in a *focus* element of the question (**IMPORTANT-FOCUS**) or whether it was important for extracting the semantic frame (**IMPORTANT-FRAME**). All errors annotated as **IMPORTANT-FOCUS** can also be considered **IMPORTANT-FRAME**, since one major element of a frame is the disease in focus. A misspelled word may be annotated with multiple types of errors. For example, *onset* misspelled as *on set* is a case of both **TO-MERGE** and **REAL-WORD** errors. In Example 1, *serotonin* misspelled as *seretona* is annotated as **IMPORTANT-FOCUS**, as well, since *serotonin syndrome* is the focal disease in the question.

The annotation was carried out by one of the authors of this paper (MF). 1008 spelling errors were annotated on a total of 1075 tokens. Of these 1008 errors, 39 were labeled as **IMPORTANT-FRAME** and 96 as **IMPORTANT-FOCUS**. The distribution of error types annotated in the dataset is given in Table 1.

### Table 1: Distribution of spelling error types

3.2 **Pipeline**

The spelling error detection and correction pipeline, illustrated in Figure 1, consists of four modules. The *preprocessor* uses simple heuristics to correct punctuation and splitting errors that occur frequently and are difficult to correct using the methods applied to non-word or real word errors. For example, consumer health questions contain many contractions (e.g., *i’m*, *there’s*) and they are often spelled without the apostrophe. These are usually short words and most systems do not attempt to correct them, since the number of candidates based on edit distance and phonetic similarity is generally high. Therefore, we simply substitute such errors in preprocessing. For this purpose, we used Wikipedia’s list of English contractions[^2]. We also correct some informal expressions, such as *plz* for *please* and *u* for *you*. Additionally, we attempt to correct punctuation errors that could cause downstream tokenization or parsing errors, such as a punctuation without a space following it. In the example below, *male.reading* is taken as a single token, which would lead the system to miss the important information about the patient (*male*).

(3) *hi im a support worker for a 46 yr old autistic male.reading your info provided about wolfram syndrome ,he matches alot of the symptoms.*

Finally, we split tokens with leading or trailing digits, when we recognize that such a split would eliminate the spelling error (e.g., 4.5. Doctors for 4.5. Doctors, but not 2nd for 2nd).

The second step is to detect misspellings. As most other spelling error detection systems, we use a simple dictionary lookup. Our dictionary is based on the comprehensive English dictionary that is distributed with the Jazzy spell checker\(^3\), an open-source Java implementation based on ASpell. We expanded this dictionary with tokens extracted from the UMLS\(^23\), resulting in a dictionary of 450K tokens, including inflectional variants. Needless to say, misspelling detection step skips real word errors, which are both detected and corrected in the subsequent steps.

In the third step, we generate phonetic and edit distance-based spelling suggestions. We ensure that each suggestion is a valid word with dictionary lookup. For non-word spelling errors, tokens of length two or less, and for real word errors, tokens of length three or less, are skipped, unless they can be merged with the next token to form a valid word. Phonetic suggestions are obtained using the Double Metaphone algorithm\(^24\). We also compute suggestions using Levenshtein distance. The maximum number of edits is taken as the minimum of the half length of the token and 5.

The next step is to rank all generated suggestions using a set of algorithms. Three of these address the orthographic similarity between the misspelling and the suggestion:

- **Token similarity**: This measure is based on the cost of converting the misspelling to the suggestion, in terms of the number of edits required. Deletion and insertion operations have a higher cost than transposition and a lower cost than substitution. For example, the token similarity scores between the misspelling *dianosed* and the suggestions *diagnosed* and *deionized* are 0.91 and 0.61, respectively. Splitting the misspelling incurs an additional penalty.

- **Phonetic similarity**: Similar to token similarity, it uses the phonetic representation of the misspelling and the suggestion. The phonetic similarity between *dianosed* and *diagnosed* is 1.0, while it is 0.91 between *diagnosed* and *diagnose*.

\(^3\)http://jazzy.sourceforge.net/
• **Leading/trailing character overlap**: This measure calculates the overlap between the misspelling and the suggestion in terms of the number of matching characters at the beginning and the end. For example, the overlap score between *dianosed* and the word *diagnosed* is \((3+5)/9=0.89\), where the denominator corresponds to the length of the longer token.

In addition to these similarity measures, we score the suggestions by their frequency in consumer health-related corpora. To create the word frequency list, we used health-related articles in MedlinePlus Medical Encyclopedia\(^4\), MedlinePlus Drugs\(^5\), Genetics Home Reference\(^6\), Genetic and Rare Diseases (GARD) frequently asked questions\(^7\), NHLBI Health Topics\(^8\), NINDS Disorders\(^9\), and NIH Senior Health\(^10\), resources targeted at the public that we use for answering health-related questions. The number of articles from each resource are given in Table 2. We ignore numbers, URLs, and email addresses. The resulting word count list consists of more than 50K words. The corpus frequency score of a suggestion is calculated as

\[
freq\_score(s) = \ln(C_s/N)/\ln(C_{\text{max}}(w)/N)
\]

where \(C_s\) is the frequency of the suggestion, \(C_{\text{max}}(w)\) the maximum frequency count and \(N\) the number of tokens in the corpus, the score essentially corresponding to normalized unigram probability. Among the suggestions for *dianosed*, the score for *diagnose* is highest with 0.58; *deionized*, on the other hand, has a score of 0.

Finally, we calculate a contextual similarity score using word embeddings, taking context around the token into account. For this purpose, we used the same corpora that we used to calculate word frequency counts. We used the *word2vec* toolkit\(^11\) with the CBOW (continuous bag-of-words) model and hierarchical softmax options with window size of 5 to generate word vectors of 200 dimensions. CBOW, unlike the traditional bag-of-words model, uses the continuous distributed representation of the context. Hierarchical softmax is a computationally efficient way to estimate the overall probability distribution. To calculate the contextual

\(^10\)http://nihseniorhealth.gov/
\(^11\)https://code.google.com/p/word2vec/
similarity score for the suggestion, we compute the context vector by averaging the vectors associated with the words in a predefined window around the token under consideration and then compute the cosine similarity between the context vector and the suggestion vector. If there is no word vector corresponding to the suggestion or if the resulting cosine similarity is less than 0, we take the contextual similarity as 0. As context, we use two tokens before and after the token in consideration. If a token in the context does not have a corresponding vector, we move to the next token in the same direction. The contextual similarity score computed in this way is 0.69 for diagnosed for the context given in Example 1 and 0.51 for diagnose.

Scores calculated by these methods are then combined using a linear-weighted ensemble, similar to Flor and Futagi\cite{12}, taking the suggestion with the highest score as the correct spelling. Using the training set, we empirically determined the best weights to be 0.6 for orthographic similarity, 0.15 for contextual similarity, and 0.25 for frequency score.

For real word spelling errors, the methodology is essentially the same. We mentioned above that we skip valid tokens with three or less characters, unless they can be merged with the next token to form another valid token. In addition, for a valid token to be considered a real word error, we stipulate that: a) the difference between the contextual similarity of the suggestion and that of the original token be greater than a threshold value (taken as 0.2 in our experiments), b) the Levenshtein distance between the suggestion and the original token be equal to or less than 2, and c) the suggestion not be an inflectional variant of the original token and vice versa.

3.3 Evaluation

We used 372 questions for training and the remaining 100 for testing. As an informed baseline, we used the ESpell algorithm\cite{7}, designed for biomedical queries and used in the PubMed search engine. For non-word error correction, we used the Jazzy spell checker to filter out correctly spelled words for both ESpell and our ensemble method. For real-word correction, no such filtering was performed. We assessed the effect of preprocessing and each of the similarity measures on the system performance. We used precision, recall, and F1 score as the evaluation metrics.

4 Results and Discussion

The evaluation results obtained with the system are given in Table 3. Considering the non-word spelling errors only, the baseline, ESpell with non-word tokens as input, yields a F1 score of 0.29, whereas the best weighted combination of ranking methods yields a score of 0.61. The preprocessing module is able to correct a significant number of spelling errors, providing a solid foundation which the ranking methods improve on. Orthographic similarity seems to contribute most to the prediction of the correct spellings, providing a 12% increase in F1 score alone. Ignoring orthographic similarity and using only contextual similarity or corpus frequency diminishes the results. On the other hand, each of these methods complement orthographic similarity and together yield better precision and recall, pushing the overall F1 score to 0.61. When the system attempts to correct real word errors as well, the baseline, in this case ESpell without any filtering step, yields a F1 score of 0.25. This score is improved by more than two-fold to 0.58, when we use the setup that yields best results for non-word spelling errors with additional constraints. When we take into account only the spelling errors that were deemed to be important for focus or frame extraction, we obtain a F1 score of 0.76, in comparison to the baseline score of 0.57.

The corrections made with preprocessing may seem unimportant; however, we believe these corrections...

will contribute to better tokenization and parsing, ultimately leading to better performance in information extraction. The results confirm that orthographic similarity is the best predictor of correct spellings. In general, edit distance of 2 or 3 is considered sufficient for successful spelling correction, based on the observation of Damerau\cite{10} that 80% of spelling errors are caused by a single edit. Our dataset provides evidence that spelling correction in consumer health questions may require considering suggestions with a higher edit distance (for example, in Example 1, *seretona* has an edit distance of 3 from its correct spelling, *serotonin*). This may be partly due to the fact that NLM receives questions from non-native speakers and partly due to the complexity of spelling of long medical terms.

We find that corpus frequency and contextual similarity contribute to spelling correction, though not as significantly as orthographic similarity. This may be partly due to the coverage of the corpora we considered. Their total size (approximately 5.8M tokens) is small, relative to the much larger corpora often employed in spelling correction. We experimented with larger corpora, such as one based on Wikipedia articles; however, we found that they did not make a significant difference, possibly because they are better written than health questions and are not health information-specific. To calculate contextual similarity, we use word embeddings, which, to our knowledge, is the first application of this technique to spelling correction. While the performance improvement due to word embeddings was relatively small, we believe it is a promising avenue to explore further. In its application to spelling correction task, one open question is how to best calculate contextual similarity using word vectors. We experimented with several measures and found that cosine similarity between the spelling suggestion and the average context vector yielded the best result; however, other measures (e.g., the maximum cosine similarity between the suggestion and a vector for any of the words in context) or a combination thereof could prove more beneficial.

The system, not unexpectedly, has more difficulty with real word spelling errors than with non-word errors. Our pipeline for real word errors differs little from that for non-word errors; it only incorporates several additional constraints. The results indicate that a more nuanced approach, probably with a different weighting scheme, may be necessary. It is worth noting that most systems focusing solely on real word spelling errors build on specific confusion sets\cite{15,18} or datasets to which real word errors are artificially introduced\cite{13,16},
and assume that the context around the error contains no spelling errors. We did not make such assumptions for the real word errors in our somewhat noisy dataset, and thus a fair comparison may be difficult.

Using a comprehensive, well-curated dictionary is critical for identifying misspellings. To have a better coverage of the biomedical domain, we extended an existing general English dictionary automatically with term tokens from UMLS, resulting in a comprehensive, albeit somewhat noisy, dictionary. Some errors were due to the noise in the dictionary. For example, the token Peyronies was simply skipped, since the word existed in the dictionary, although its canonical form, and the correct spelling in our dataset, is Peyronie’s.

Misspelling of adjacent words is a well-recognized problem in spelling correction and we observed errors due to this problem, as well. In Example 1, we are able to correct on set to onset based on contextual similarity when the following token is corrected from deminita to dementia; otherwise, we get a recall error.

5 Conclusion

We presented a spelling correction system for consumer health questions that takes into account orthographic features as well as corpus frequency information and contextual similarity. We did not attempt to use any semantic information (e.g., UMLS) beyond that obtained in an unsupervised manner from corpora. Our results show that all the components contribute to non-word spelling error correction, while real word errors remain challenging. Since the system is designed as part of a larger information extraction system, it is encouraging that it is able to recognize and correct the majority of spelling errors most relevant to information extraction.

The future work involves using more suitable corpora as the basis of frequency counts and word embeddings. We believe that a corpus that specifically focuses on text from online health forums would be more appropriate, since the questions we receive are probably closest to such text. We are currently incorporating such a corpus into our system. We are also planning to explore ways to better rank the similarity scores, probably in a machine learning framework. Another possible direction is to explore joint spelling correction, since misspelling of adjacent words is common in consumer health questions.

Abstract
Our research investigates methods for creating effective concept extractors for specialty clinical notes. First, we present three new “specialty area” datasets consisting of Cardiology, Neurology, and Orthopedics clinical notes manually annotated with medical concepts. We analyze the medical concepts in each dataset and compare with the widely used i2b2 2010 corpus. Second, we create several types of concept extraction models and examine the effects of training supervised learners with specialty area data versus i2b2 data. We find substantial differences in performance across the datasets, and obtain the best results for all three specialty areas by training with both i2b2 and specialty data. Third, we explore strategies to improve concept extraction on specialty notes with ensemble methods. We compare two types of ensemble methods (Voting/Stacking) and a domain adaptation model, and show that a Stacked ensemble of classifiers trained with i2b2 and specialty data yields the best performance.

Introduction
Medical notes provide detail on patient encounters. Written by clinicians primarily for clinicians, they document (e.g., progress notes) or summarize (e.g., discharge summaries) patient care. They come in a variety of note types and are entered by health care professionals from varying backgrounds.

Information extraction from medical texts is a challenging problem of growing interest to both the natural language processing and medical informatics communities. Medical concept extraction (MCE) is one such task, which seeks to identify specific types of information such as medical problems, treatments, and tests. Previous research on this task has primarily focused on discharge summaries and progress notes [1-4], which we will refer to as broad medical texts because they describe a patient’s overall care and their content can cover a diverse set of topics cutting across many areas of medicine. Most publicly available corpora of clinical medical notes consist of broad medical texts (e.g., i2b2 Challenge Shared Tasks [5-10] and ShaRe/CLEF eHealth Shared Tasks [11-12]). There has been relatively little research on medical concept extraction for more specialized clinical texts. Studies focused on Radiology and Pathology reports are an important exception, but we would argue that they also cover a broad set of clinical conditions. Broad medical texts have the advantage of being relatively well formatted, and they typically follow general documentation standards. In contrast, specialty notes conform to varying documentation standards, with little overlap between specialties. Patterson and Hurdle [13] and Friedman et al. [14] demonstrated that clinicians in different clinical domains use specific sublanguages. Still, given the general nature of broad medical notes, we speculate that their content could enrich MCE systems targeted at specialized note types and our work offers a practical way forward for clinical information extraction despite the common use of sublanguages.

Our research investigates methods for creating medical concept extraction systems that will perform well on specialty area notes. For this research, we created three new text corpora consisting of medical notes from three specialty areas: Cardiology, Neurology, and Orthopedics. We present an analysis of how they differ in content (semantic concepts and formatting) from each other and from i2b2 medical notes. We then examine a variety of information extraction (IE) models, and evaluate their performance on all of these data sets. The contributions of our work are twofold. First, we investigate how well MCE models perform on specialty notes when trained on a broad medical corpus and then when trained on the same type of specialty data. When training with a comparable amount of annotated data, we find that training with specialty texts outperforms training with broad medical texts. However, we achieve better performance for all three specialty areas by using a combination of both broad medical i2b2 data and specialty area data for training.

Second, we explore Voting and Stacked Learning ensembles to combine multiple MCE models. The ensemble architecture can be beneficial in two ways: (1) it can exploit multiple models that use different extraction techniques, and (2) it can exploit multiple models trained with different types of data (in our case, some trained on broad medical notes and some trained on specialty notes). To our knowledge, this is the first work that combines broad medical components and specialty area components in a single ensemble for MCE. Our results show that a stacked ensemble consisting of both types of components achieves the best balance of precision and recall.
Background

Medical concept extraction has been the focus of several shared tasks, such as the i2b2 Challenge Shared Tasks and the ShARe/CLEF eHealth Shared Tasks [8, 11-12]. Our work uses the annotated data set provided for the 2010 i2b2 Challenge [8]. In this challenge, machine learning approaches [15-16] showed superior results over hand-crafted rule-based systems. de Bruijn et al. [15] incorporated syntactic, orthographic, lexical, and semantic information (from various medical knowledge databases) and their system performed best in the i2b2 concept extraction challenge task with 83.64% recall, 86.88% precision, and 85.23% F1 score. Jiang et al. [16] implemented an ensemble method to combine concept extraction models trained with local features and outputs from different knowledge databases. In 2013, Tang et al. [17] extended their work using clustering and distributional word representation features, achieving 84.31% recall, 87.38% precision, and an F1 score of 85.82% on the i2b2 test set.

Our work is closely related to the classic task of Named Entity Recognition. In both newswire and biomedical texts, many types of supervised learning and sequential tagging methods have been used to extract specific types of entities [18-22]. In Clinical NLP (Natural Language Processing), several systems have been developed to process medical notes or biomedical texts. MedLEE [23] has been applied to chest radiology reports, discharge summaries, and operative reports to extract and encode medical information. MPlus [24] was used to extract medical findings, diseases, and appliances from chest radiograph reports. LifeCode [25] was developed to extract demographic and clinical information on emergency medicine clinical specialty and radiology reports.

Ensemble methods that combine multiple classifiers have been widely used for many NLP tasks. Voting strategies [26-28] and statistical approaches including stacked generalization [29-30] have generally shown better performance than individual classifiers. Our work is also related to supervised domain adaptation, which can be applied when some labeled data for the target domain is available. Many algorithms for efficient domain adaptation have been proposed, and domain adaptation-based models have been shown to improve performance for some tasks when limited annotated data is available for the target domain [31-35].

Methods

Data Sets and Annotated Concepts

Our research starts with the medical concept extraction (MCE) task defined for the 2010 i2b2 Challenge [8]. This task involves extracting three types of medical concepts: Problems (e.g., diseases and symptoms), Treatments (e.g., medications and procedures), and Tests. The 2010 i2b2 corpus consists of 349 training documents and 477 test documents manually annotated by medical professionals. This test set contains 45,009 annotated medical concepts.

For our work, we created new text collections representing three specialized areas of medicine: Cardiology, Neurology, and Orthopedics. We annotated 200 clinical notes from the BLULab corpus\(^1\) for each specialty area. Each specialty data set consists of different subtypes of notes. Table 1 shows the five most prevalent subtypes in each specialty data set.

\(^1\) The BluLab corpus is a collection of de-identified clinical notes drawn from multiple clinical settings at the University of Pittsburgh. The dataset was available for research to investigators with local Institutional Review Board approval, but unfortunately the University of Pittsburgh has withdrawn the corpus for new studies. However interested researchers can collaborate with previously approved sites.
Two people with medical expertise manually annotated the specialty notes using the 2010 i2b2 Challenge guidelines. One annotator had previously annotated data for the official 2010 i2b2 Challenge data and the other annotator had equivalent medical knowledge. We measured their inter-annotator agreement on 50 documents annotated by both annotators during the pilot phase using Cohen’s kappa [36] and their IAA was \( \kappa = .67 \). Each of the annotators then labeled 100 new documents for each specialty area, producing a total of 600 annotated specialty area texts. These texts contain 17,783 annotated concepts for Cardiology, 11,019 concepts for Neurology, and 12,769 concepts for Orthopedics.

Table 2 shows the number of annotated concepts of each type in the i2b2 test data and our three specialty data sets, as well as the average number of concepts per document. For example, the Cardiology data contains 7,474 Problem concepts and the average number of Problem concepts per text is 37, which is similar to the i2b2 data (39). However, the Neurology and Orthopedics data sets contain only 25 Problem concepts per document, on average. For Treatment concepts, the Neurology notes contain fewer than the i2b2 data but the Orthopedics notes contain more. The prevalence of Test concepts varies greatly: the i2b2 and Cardiology texts have many Test concepts per document, but they are much less common in the Neurology notes (11 per text) and Orthopedics notes (6 per text).

<td>89</td>
</tr>
<tr>
<td># Sentences</td>
<td>45,052</td>
<td>94</td>
<td>21,255</td>
<td>106</td>
</tr>
</tbody>
</table>

The last row of Table 2 compares the number of sentences in the data sets. The i2b2 test data contains 45,052 sentences (94 per file, on average). The Cardiology notes were generally longer with 106 sentences per text, while the Neurology and Orthopedics notes were generally shorter.

We also examined, qualitatively, the types of sections in each data set to gain more insight about content differences between specialist notes and the more general i2b2 notes. Table 3 shows the five most frequent section titles in each data set. Many section titles, such as ‘Hospital course’, are common across all of the data sets. However, we found section titles that are much more frequent in some types of specialty area notes. For example, sections related to ‘Procedures’ and ‘Operations’ occurred most frequently in Orthopedics notes. ‘Consultation’ sections were common in the Cardiology notes, but rare in the i2b2 notes.

Table 3. Five most frequent section titles in each data set

<table>
<thead>
<tr>
<th>Data</th>
<th>Section Titles</th>
</tr>
</thead>
<tbody>
<tr>
<td>i2b2 Test</td>
<td>Hospital course, History of present illness, Physical Examination, Past medical history, Allergies</td>

<td>Neurology</td>
<td>Hospital course, Reason for admission, History of present illness, Discharge medications, Discharge instructions</td>
</tr>
<tr>
<td>Orthopedics</td>
<td>Hospital course, Procedures, Discharge instructions, Description of Operation, Complications</td>
</tr>
</tbody>
</table>

Although some of the same section titles occur in both broad medical notes and specialty notes, their contents can differ. For example, in the sections titled ‘Procedures,’ Orthopedics notes typically contain more detailed information than discharge summaries. Figure 1 illustrates an Orthopedics note that is similar to the ones in our collection.

Information Extraction Models

We developed four types of information extraction models that use a diverse set of extraction techniques.

**Rules:** We created a simple set of rules by harvesting information from the annotated training data. First, for each word in the training data we computed Prob(concept | word) and Prob(category | word). Next, we selected words that had frequency $\geq 3$ and Prob(concept | word) $\geq .80$. For each selected word, we chose the category with the highest probability and created a rule (e.g., `diabetes` $\rightarrow$ `Problem`). Given a new text, we then found all words that matched a rule and labeled them as concepts using the category assigned by the rule. When two or more labeled words were contiguous, we treated them as a single concept. For multi-word concepts, we calculated the average Prob(category | word) across the words in the concept. The category with the highest average probability was assigned to the concept.

**MetaMap:** We used a well-known knowledge-based system, MetaMap [37], that assigns UMLS Metathesaurus semantic concepts to phrases. We identified UMLS semantic type identifiers, using the UMLS Semantic Lexicon, that covered the types of medical concepts required for our task. We only used the final mappings of MetaMap to avoid generating nested terms because the i2b2 guidelines do not permit nested concepts. Table 4 shows the semantic types that we used for concept extraction. We used MetaMap 2013v2 with the 2013AB NLM relaxed database.

2 Excerpted from http://www.mtsamples.com/
3 Refer to http://metamap.nlm.nih.gov/Docs/SemanticTypes_2013AA.txt for the mapping between abbreviations and the full semantic type names.
SVM: We trained a multi-class Support Vector Machine (SVM) classifier with a linear kernel using the LIBLINEAR software package [38]. We applied the Stanford CoreNLP tool [39] to our data sets for tokenization and part-of-speech (POS) tagging. We defined features for each medical concept’s lexical string, POS tag, affix(es), orthographic features, and pairwise combinations of these features. We also extracted these features for the three words before and after the concept. To identify multi-word concepts, we reformatted the training examples with IOB tags (B: at the beginning, I: inside, or O: outside of a concept) and then trained the model to produce IOB labels as output. We trained a single SVM model to produce labels for all three concept types (Problem, Treatment, and Test).

CRF: We trained two types of sequential taggers using linear Conditional Random Fields (CRF) models [19]: models with forward transitions (CRF-fwd) and models with backward transitions by reversing the word sequence (CRF-rev) [40-41]. The CRF models used the same feature set as the SVM models. A single CRF model produces labels for Problem, Treatment, and Test.

We performed 10-fold cross validation on the i2b2 training set to optimize the parameters of the SVM and CRF classifiers for F1 score maximization. For the SVMs, we tuned the cost parameter (c = 0.1) of LIBLINEAR. For the CRFs, we used Wapiti [42], a simple and fast discriminative sequence labeling toolkit. We set the size of the interval for the stopping criterion to be $e = .001$. For regularization, $L_1$ and $L_2$ penalties were set to 0.005 and 0.4 respectively. These parameter settings were kept the same throughout all of our experiments.

Ensemble Methods

We explored two types of ensemble architectures that have performed well for other NLP tasks: Voting ensembles and Stacked Learning ensembles [29]. Each ensemble consists of a set of MCE components. The general architectures of the Voting and Stacked ensembles are described below. In the Results section, we present experimental results for ensembles consisting of different mixtures of component systems.

Voting Ensemble: This ensemble collects the phrases labeled by a set of MCE components and outputs all phrases that received at least three votes (i.e., were labeled by at least three components). In the case of overlapping phrases, we choose the one with the highest confidence, based on the normalized confidence scores of the MCE models. For each MCE model, each confidence score was divided by the highest score produced by that model for normalization.

Stacked Learning Ensemble: This ensemble consists of a set of MCE components as well as a meta-classifier, which is an SVM classifier trained on the predictions of the individual MCE models. To create training instances for a document, we first aggregated all of the concept predictions into sets of unique predictions. For example, one aggregated prediction set might indicate that an instance of “acute renal failure” was labeled as a Problem by models $M_1$, $M_3$, and $M_4$. Each concept predicted by an MCE model was then compared with all concepts predicted by the other MCE models. For each pair of concepts, the following eight matching criteria are applied to create binary features:

- If the text spans match
- If the text spans partially match (any word overlap)
- If the text spans match and concept types match
- If the text spans partially match and the concept types match
- If the text spans have the same start position
- If the text spans have the same end position
- If one text span subsumes the other
- If one text spans is subsumed by the other

For an ensemble with $k$ MCE models, $k \times 8$ features are defined so that each matching function is replicated for each MCE model. Each feature indicates whether Concept$_1$ and Concept$_2$ satisfy a specific matching function, given that Concept$_1$ was produced by a specific model. In addition, features are defined that count how many different models produced a predicted concept, and features are defined for predictions produced by just a single model (indicating which model produced the predicted concept). In a previous study [43], this type of Stacked ensemble architecture achieved performance comparable to the state-of-the-art on the i2b2 test data with 83.4% recall, 87.9% precision, and 85.6% F1 score.

Results

We conducted an extensive set of experiments to evaluate the performance of each individual MCE model and Voting and Stacked Learning ensembles. We also experimented with models trained using the broad medical (i2b2) texts, using our specialty area texts, and using a mixture of both. We evaluated performance using the i2b2 test set as
well as our three sets of specialty area notes: Cardiology, Neurology, and Orthopedics. The specialty area models (Sp) were trained and evaluated using 10-fold cross validation on our specialty notes data. A labeled phrase was scored as correct if it was assigned the correct concept type and its text span exactly matched the gold standard text span, disregarding articles and possessive pronouns (e.g., “his”).

Performance of Individual MCE Models

Table 5 shows the performance of each MCE model based on Recall (Rec), Precision (Pr), and F1 score (F). The Rules (i2b2) row shows results for the simple rules harvested from the i2b2 training data. Not surprisingly, these rules performed better on the i2b2 test set than on the specialty notes, but the scores were low across the board. The Rules (Sp) row shows results (averaged during cross-validation) for the rules harvested from the training folds and evaluated on the test folds for the specialty area data. These rules also performed poorly. The MetaMap row shows similarly low scores for MetaMap on all data sets. One reason for its low performance is that the concept and phrase boundary definitions of MetaMap’s semantic categories are not perfectly aligned with i2b2’s concept definitions.

The machine learning classifiers performed substantially better. The SVM (i2b2) row shows results for the SVM model trained on i2b2 data, which produced an F1 score of 78.7% on the i2b2 test set but substantially lower F1 scores on the specialty datasets. The SVM (Sp) row shows results for the SVMs trained on specialty area data. Performance substantially improved on the Orthopedics notes (from 43.5% to 52.6% F1 score), but did not change much for the other specialty areas.

</table>

Both the CRF-fwd and CRF-rev models trained on i2b2 data performed better than the SVM models. Performance on the Cardiology and Neurology notes was similar when trained on specialty (Sp) data, but performance on the Orthopedics notes substantially improved. Since the i2b2 training data is much larger than our specialty area training data, we performed another experiment using only 180 randomly selected i2b2 training texts, to match the amount of specialty area training data (under 10-fold cross-validation, each fold trains with 180 documents). The performance of this model, shown in the CRF-rev (i2b2,180) row, is lower than when using all of the i2b2 training data. We can now see that training on specialty area data consistently performs better than training on i2b2 data when using comparable amounts of training data. The last row of Table 5 shows the results for training the CRF-rev model using all of the i2b2 training data as well as the specialty area training data. Performance improved for all three specialty areas by training with the combined data sets. The broad i2b2 data clearly provides added value. However, the F1 scores for the three specialty areas ranges from 60.9% to 69.5%, which is substantially lower than the 84.3% F1 score achieved for the i2b2 test set.
Performance of Voting and Stacked Ensembles

We also evaluated the performance of the Voting and Stacked ensemble architectures, which were populated with all five types of MCE components: Rules, MetaMap, SVM, CRF-fwd, and CRF-rev models. For both the Voting and Stacked architectures, we created three different types of ensembles: i2b2 ensembles consisting of MCE models trained on the i2b2 data, Sp ensembles consisting of MCE models trained on specialty data, and i2b2+Sp ensembles consisting of MCE models trained on i2b2 data and MCE models trained with specialty data. Consequently, the i2b2+Sp ensembles include nine different classifiers (two models each of Rules, SVM, CRF-fwd, CRF-rev, and one MetaMap model, because it does not use training data).

Table 6 shows the performance of these ensembles, as well as the EasyAdapt domain adaptation method [34], which we implemented as another point of comparison. For EasyAdapt, we used a CRF-rev classifier with the feature set augmented for broad medical (i2b2) notes as the source domain and specialty area notes as the target domain. For the sake of comparison, the first row of Table 6 displays again the results obtained for the best individual MCE model from Table 5, which was the CRF-rev classifier trained with both i2b2 and specialty data. Comparing the first two rows, we see that training a CRF-rev model with combined i2b2 and specialty area data outperforms the domain adaptation model on all three data sets.

For the Voting ensembles, the i2b2+Sp ensemble produced the best \( F_1 \) scores, but did not outperform the CRF-rev (i2b2+Sp) model. However, the Voting ensemble trained only on specialty notes (Sp) produced much higher precision than the CRF-rev model. A Voting ensemble appears to be an effective way to improve precision on specialty notes when a limited amount of annotated specialty data is available, although with some cost to recall.

For Stacked Learning, every Stacked ensemble outperformed its corresponding Voting ensemble. The best Stacked ensemble (i2b2+Sp) included MCE models trained on i2b2 data as well as MCE models trained on specialty data, producing slightly higher \( F_1 \) scores than the CRF-rev models for all three specialty areas. Using a paired t-test to measure statistical significance, the \( F_1 \) score performance of the i2b2+Sp Stacked ensemble is significantly better than EasyAdapt and all of the Voting ensembles at the \( p < .05 \) significance level, but not significantly better than the CRF-rev (i2b2+Sp) model. However, the results show that the Stacked ensemble produces higher precision than the CRF-rev model (70% → 75% for Cardiology; 67% → 72% for Neurology; 63% → 71% for Orthopedics), with correspondingly smaller decreases in recall (69% → 66% for Cardiology; 65% → 62% for Neurology; 59% → 55% for Orthopedics).

**Discussion and Analysis**

The main conclusion of our research is that models trained with a combination of broad medical data and specialty data consistently perform better than models trained on either type of data alone when the amount of specialty data is limited. In addition, we find that a Stacked ensemble consisting of a diverse set of MCE models using different types of extractors achieves overall performance comparable to the best individual classifier in our experiments, but
offers two advantages. First, the Stacked ensemble yields a recall/precision balance that favors precision, which may benefit applications that place a premium on high precision. Second, the Stacked ensemble can be easily augmented with additional components as new resources become available, because the meta-classifier automatically learns how to use them simply by re-training the meta-classifier component. In contrast, adding new components to Voting ensembles can require a change in voting strategies, and Voting ensembles do not provide a way to learn weights to optimally control the influence of different component models.

However, performance on all three types of specialty areas is much lower than performance on the broad medical (i2b2) texts. Clearly there is ample room for improvement for medical concept extraction from specialty area clinical notes and more work is needed on this topic. To better understand the strengths and weakness of our models, we manually inspected their output. We observed that our ensemble methods are particularly successful at identifying more accurate concept boundaries than the individual MCE models (e.g., identifying “severe chest pain” as a Problem concept instead of just “severe” or “chest pain”). We also analyzed the false negative errors by the CRF-rev models trained with i2b2 data and those trained with specialty data. Table 7 shows the results of this manual analysis, which were based on one test fold (20 notes) for each specialty area. The first row of Table 7 corresponds to errors due to unseen vocabulary. These concepts were misclassified when none of the words in a concept occurred in the training data. For example, the Cardiology concepts ‘thoracoscopy’ and ‘cardioplegia’ never appeared in the i2b2 training data. Unseen concepts accounted for roughly the same percentage of errors when training with i2b2 data or specialty data, but note that the i2b2 training set is roughly twice as large as each specialty area training set.

Table 7. False negatives errors by CRF-rev (i2b2) and CRF-rev (Sp) models

<table>
<thead>
<tr>
<th>Error types</th>

<td>70 (14%)</td>
</tr>
<tr>
<td>All seen</td>
<td>213 (48%)</td>
<td>279 (56%)</td>
<td>211 (43%)</td>
</tr>
</tbody>
</table>

The second row of Table 7 corresponds to false negatives for concepts containing at least one seen word and one unseen word. We see more false negatives in this category for the models trained with i2b2 data than the models trained with specialty data. For example, for the Treatment concept ‘aortic crossclamping’, ‘crossclamping’ never appeared in the i2b2 training data but it did appear in the Cardiology training data. This type of error was most common in the Orthopedics data (51% of the errors), which suggests that the Orthopedics notes contain many vocabulary terms that are not present in the i2b2 data.

The third row of Table 7 corresponds to false negatives for concepts containing all seen words, but at least one rarely seen word (frequency <= 3). For example, in the Cardiology data, the concepts ‘psa data’ and ‘r-wave’ were not identified by the i2b2 trained model. The model trained with Cardiology data could not extract ‘nystatin’ and ‘oximeter’, even though they occurred (infrequently) in the Cardiology training data.

The last row of Table 7 corresponds to false negatives for concepts consisting entirely of words that occurred > 3 times in the training data. Many false negative errors fell into this category. Generally, there were more false negative errors of this type for the models trained with specialty data than those trained with i2b2 data, presumably because the vocabulary is more homogenous in the specialty areas so more words simply fall into the seen category.

Finally, we observed that many errors were due to incorrect phrase boundaries of medical concepts. For example, only the word “hepatitis” was labeled in the phrase “hepatitis c”. We also witnessed some tricky errors due to contextual differences in the words surrounding medical concepts. For example, a Treatment concept ‘lidocaine’ is often prescribed for usage on skin (“treated with lidocaine jelly for pain control”). However, in the Cardiology data, it is usually applied by infiltration (“Lidocaine 20 cc was infiltrated into the tissues”).

Conclusion

We analyzed the differences in content between broad medical and specialty area notes, confirming prior research showing that specialty notes exhibit sublanguage behavior that requires rethinking the use of NLP tools developed.
on broad medical notes. We found that even though the CRF-rev (i2b2+Sp) and Stacked ensemble produce similar F_1 scores, they exhibit different behaviors with respect to the underlying recall and precision of their output. Consequently, our results suggest that the CRF-rev (i2b2+Sp) model may be preferable for applications where recall is more important than precision, while the Stacked ensemble may be preferable for applications where precision is more important than recall. Interestingly, Orthopedics specialty notes exhibit the most unique language when compared to other specialty notes or to broad medical texts. When a limited amount of annotated specialty area data is available, our research shows that training concept extractors with both broad medical data and specialty area data produces MCE models that achieve better performance on specialty notes than training with either type of data alone. In addition, our research found that a Stacked ensemble with a mixture of MCE components, including different types of MCE models as well as models trained on different types of data, achieves good performance and offers some advantages over other approaches. However, we also observed that MCE performance on specialty texts is substantially lower than state-of-the-art performance on broad medical texts. A promising direction for future work is to explore semi-supervised methods to exploit larger collections of specialty area notes for training.

Abstract
Postmarketing drug surveillance is critical to assessing adverse events associated with medications, because prelaunch clinical trials frequently miss negative drug effects. The Informatics for Integrating Biology and the Bedside platform (i2b2) has been used effectively for this. However, previous work suffers from incomplete medical data present in electronic health record (EHR) systems. Here, we develop a system to integrate non-traditional data sources with EHR data: pharmacy dispensing information and patient-reported data. We implement and validate a toolset to gather medication data from a Pharmacy Benefit Manager network, import it into an i2b2 EHR repository using a standard data format, merge it with the EHR data, and present it to for annotation with results returned to i2b2. This toolkit is enabling studies on medication list data quality, adherence, and adverse event detection.

Introduction
Postmarketing drug surveillance is critical to assessing adverse events associated with medications, because prelaunch clinical trials frequently miss negative drug effects. Such clinical trials have limitations in population size, diversity, disease comorbidities, and concurrent medication use. [1] Incident Reporting Systems, such as FDA MedWatch, are used to manually report postmarketing adverse events. However, their utility is limited by underreporting and poor compliance by physicians. [2] The Informatics for Integrating Biology and the Bedside platform (i2b2) has been used effectively for postmarketing drug surveillance. [3,4] i2b2, the output of an NIH National Center for Biomedical Computing grant, is an open source medical data analytics platform which is in use at over 100 sites nationwide that have data on over 90 million patients.

However, incomplete medical data is rampant, and because i2b2 relies on the "ambient" data generated by the electronic health record systems, it suffers as well. Medication histories are frequently poorly maintained, which is not aided by the significant fragmentation of care across sites (increasing the likelihood of incomplete data at any given site). [5–7]

We hypothesize that it is possible to improve the medication list by enlisting nontraditional data sources. We have begun to explore two sources thus far.

First, medication dispensing information, recorded by pharmacies when patients pick up medications, is fueled by the pharmacy supply chain. The pharmacy supply chain already has rather advanced data networks, traditionally used for payments, claim adjudications, and inventory management. [8] These data can be used as a source for postmarket drug surveillance. [9]

Second, the importance of patient reported data is increasingly becoming recognized. [10,11] Such data have been found to be timely and reliable, and patients are frequently willing to share and participate in their healthcare. [12,13] Along these lines, the Patient Centered Outcomes Research Institute recognizes and emphasizes patient centered research. They are leading “a national movement that meaningfully involves patients and incorporates their voices in producing trusted, evidence-based information, promoting better decisions and ultimately better health for all.” [14]

We previously developed the i2b2 Standards-based Extract, Transform, and Load (SETL) tool, which integrates i2b2 data with data in a standardized format, the Consolidated Clinical Document Architecture (C-CDA). [15] This work was timely because an embodiment of C-CDA is required by Meaningful Use and is therefore becoming widely available. [16,17] Our previous work supports import of medication prescribing events in C-CDA, which originate from the EHR. However, C-CDA can also represent many types of medication events with high granularity, including prescribing, billing, and dispensing events.

In this manuscript, we leverage our previous work on the SETL tool to develop a patient-centered medication annotation platform for i2b2 that can import granular medication information from a C-CDA source, combine it with
existing EHR data stored in i2b2, and enable multi-source patient medication annotation via a mobile app. We validate this platform by capturing pharmacy-benefit-manager-derived (PBM) data from a commercial PBM that is a major source of pharmacy dispensing data into i2b2 on an on-demand basis. We transfer PBM data into the i2b2 clinical instance at Boston Children’s Hospital alongside EHR data, and validate the app’s ability to interpret these data for patient action. This platform will enable forthcoming research in medication data quality, adherence, and adverse event detection. Presently, researchers are preparing to use this platform to study medication adherence by assessing the discordance between the clinical medication list and a patient-generated list.

Methods

Design

C-CDA. The C-CDA is a rich but complex XML document language for healthcare derived from the Health Level Seven (HL7) Reference Information Model. [16] It is elegant but so expressive that differences of opinion arise on the best way to represent healthcare events. A great deal of work has gone into defining Meaningful Use templates for the Continuity of Care Documents required by that program. However, no such templates exist for the differentiation of medication prescribing, dispensing, billing, and patient-provided medication data. We augmented the Meaningful Use templates with existing C-CDA templates to support the complete scope of medical data required for this study.

HL7v2 and PBM. PBM data is conveyed in record-based HL7 version 2 format (HL7v2), which is a declining but still predominant format for the exchange of healthcare data. Although used as foundation for most older interoperable healthcare systems, its record-based format is recognized as limited and many data sources that use HL7v2 add custom extensions to the format in order to achieve expressiveness; this can be a hindrance to interoperability. We developed a mapping from the PBM elements of HL7v2 to C-CDA.

i2b2 and Patient Data Objects. The i2b2 software is compartmentalized into functional units known as cells. These cells, which collectively make up the i2b2 hive, interact through web service calls. Clinical data is exchanged with these web services in the i2b2 Patient Data Object format, which is a denormalized data structure that reflects the underlying star schema design of the i2b2 database. [18] The atom of a PDO is the observation. Fact observations record clinical information associated with the patient, such as a medication he/she is taking. Modifier observations are linked to fact observations and provide additional information, such as medication route, dose, and information source (e.g., medication list, dispensing event, or patient report). The set of possible observations are defined as trees of facts and modifiers through i2b2 ontology services. Although some standard ontology trees are emerging as i2b2 is increasingly used for interoperable networks (for which a standardized ontological information model must be defined) [19], i2b2’s general position has been to leave development of the ontology trees to individual use cases, thus maximizing flexibility. We expanded our previous C-CDA to PDO mapping to include the more complex C-CDA documents used here.

System description

The architecture of the platform is outlined in Figure 1. This necessitated development of three new software components:

- A new i2b2 cell, the i2me2 cell. It includes two main functions, which are similar conceptually to previous work, but with important differences:
  - The first function is similar to the SETL cell previously described: transform data in a standard format (C-CDA) into i2b2 PDO format. [15] Like the SETL cell, the i2me2 C-CDA transformation functionality relies on the Model Driven Message Interoperability (MDMI) toolkit, and it loads data into the i2b2 EHR repository using the i2b2 Clinical Research Chart (CRC) Loader web service. Unlike the SETL cell, the i2me2 cell supports the more complex medication C-CDAs developed here.
  - Second, the i2me2 cell manages authentication, authorization, and communication with the medication annotation app. Authentication and authorization are accomplished separately from i2b2 in order to accommodate the enhanced granularity of access control and auditing required.
This additional layer of authorization augments i2b2's access controls, which offer access levels (such as full access or aggregate counts only) only across the entire repository, due to its cohort study focus. The i2me2 authorization schema enables subjects full access to only their own data, augmented by personally identifying information not available to i2b2. This is accomplished through an Identity and Demographics Module (IDM) within i2me2. The cell transmits a subject-specific token to the annotation app that is first used to request limited demographic data (e.g. name) to confirm the identity of the subject. This token is then passed back to i2me2 with a request for the subject's medication data. Upon receipt of this token, the i2me2 cell obtains medication data from i2b2 and transmits it to the app, possibly requesting medication information from RxConnect if PBM data has not already been imported into the i2b2 EHR repository. Finally, following use of the app, the updated medication list is transmitted from the app to i2me2 in PDO format. This is added to the i2b2 repository by i2me2 using the CRC Loader service. This follows a similar approach to the previously described i2b2-SMART cell, which uses the SMART RDF format to provide medical apps with subject-specific i2b2 data. [20] Because the i2b2-SMART cell presently supports neither bi-directional communication nor differentiation of medication event type (e.g., prescribing or dispensing), we currently use this more direct PDO approach.

A software component, RxConnect, provides a synchronous interface to the PBM web service. RxConnect receives patient demographic information from the IDM module via i2me2, which is used to identify a subject in the PBM patient index. The PBM then asynchronously returns medication dispense and claims information for the respective subject. RxConnect receives the HL7v2 response message from the PBM, parsing this using the HAPI open-source toolkit (http://hl7api.sourceforge.net). The returned message is processed, filtered of personally identifying information, and then converted to C-CDA via MDMI.

- A patient-facing application enabling patient input into the i2b2 medication data model. The app consumes an i2b2 PDO for a single subject that can reflect medication data from multiple sources. A list of de-duplicated medications is generated for presentation, one medication at a time, to the subject performing medication self-validation. Using a two-step process, the subject indicates if and how often a medication is taken. Missing medications may also be added. The patient-annotated medication list is then added back to the i2b2 repository to as patient reported data, which exists alongside (and not in replacement of) other sources of medication data in the repository. This multi-sourced data is then available to researchers for analyses.

The data conversions from the record-based HL7v2 format to the document based C-CDA format were developed with the MDMI toolkit, which is an open source project in the Open Health Tools (OHT) consortium that seeks to make interoperability a commodity. [21] MDMI provides a graphical data-mapping tool that supports rapid design and iterative development and can move data in any arbitrary data format to and from the MDMI model, known as the Referent Index. This Referent Index is an evolving standard that attempts to represent all possible healthcare data using a common semantic structure based elements identified in the C-CDA specification. By divorcing semantics from data structure, MDMI provides a unique approach to move data between different types of formats (in this case, record based, document-based, and denormalized).

These software components enable nontraditional data sources (pharmacy dispensing data and patient annotation information) to be added to an i2b2 EHR repository of medication data in five steps (shown in Figure 1).

1. Subject information is requested from the PBM network, which asynchronously provides dispensing and insurance claims information for a particular subject in HL7v2 format. This may be scheduled or on-demand.
2. RxConnect processes the message, converts it to C-CDA, and sends it to the i2me2 cell.
3. The i2me2 cell converts the incoming message from C-CDA to i2b2 PDO format as needed, and loads this data into the i2b2 repository alongside the pre-existing EHR data.
4. When a subject is ready to annotate their medication information, the i2me2 cell requests a combined PDO containing both dispensing data (from the PBM) and prescribing data (from the i2b2 EHR repository). The PDO is then forwarded securely to the app.
5. Subjects use the app to construct a current medication list that is added back to the i2b2 EHR repository as patient reported data to exist alongside (and not in replacement of) other sources of medication data in the repository.

749
The output of the five steps is a rich database of medication information containing prescribing, dispensing, and patient-reported medication data, as well as other i2b2 data sources including EHR and disease registry medication data. This will enable more accurate adverse drug event research. All data in the i2b2 repository can be studied via the i2b2 web client query tool, which supports dimensional data queries using the ontology hierarchies.

This patient annotation platform is not intended for clinical use at this time – the required quality testing would be a costly and time-consuming endeavor that is unnecessary for research use. The platform is research-focused and its usage will vary depending on the study question. Patients must be recruited for a particular IRB-approved study question before the five steps above can be performed.

Results

![Diagram of the i2me2 architecture](image)

**Figure 1**: The “i2me2” architecture, outfitted to combine i2b2 EHR medication data with PBM dispensing and claims data, as well as patient-reported medication information. Data flows from the PBM into i2b2 (steps 1-3), then to the subject for annotating corrections, and finally back to the i2b2 data repository. (Steps 4-5) The data are transformed from HL7v2 to the standard C-CDA to i2b2 Patient Data Objects.

Implementation

In this proof-of-principle, we implemented the architecture in Figure 1 at Boston Children’s Hospital and obtained 11 messages from the PBM corresponding to 11 synthetic patients intended for testing. We used these cases to develop our HL7v2 to C-CDA to PDO mappings, using the graphical MDMI Map Editor.
Our approach to constructing valid C-CDA and PDO messages involved a number of considerations due to complexities in data transformation.

First, the meaning of the HL7v2 medication order segment (i.e. dispensing vs. payment event) is determined by a custom element defined by the PBM. Although the MDMI specification is designed to support such overloaded fields through “linked data” functionality, the current MDMI transformation engine did not provide this functionality, as MDMI’s focus is declarative transforms. Declarative transforms encourage map developers to adopt straightforward designs that only rely on the semantic meaning of each individual element in hierarchical data and not the content of sibling elements. In this case, however, the sibling directly determines the semantic meaning. We worked with the MDMI group to implement this “linked data” functionality.

Second, MDMI was designed to expect both source and target messages to follow roughly the same hierarchy (e.g., all information on a medication is a child of that medication). C-CDA employs hierarchical information to embed observation details (e.g., medication dose and frequency), whereas PDO is a flat structure that uses a sequence of linked observations (a fact and its modifiers). In order to support modifiers, we worked with the MDMI group to add a feature to ‘flatten’ hierarchical information. Presently this feature is only supported uni-directionally, so it is not possible to move from PDO to other more compact formats using MDMI at present.

Third, the complexity of tracking and testing transformations between three different formats mandated improvements in existing debugging tools and techniques. Using MDMI’s new end-to-end traceability application, we produced traceability reports for these maps. This application takes maps and generates a report on how each data element in the various formats can be traced to the other data elements in the other formats. This tool should be valuable in future MDMI i2b2 projects.

A simplified example of a single medication dispense event in the three formats is shown in Figure 2. The example includes data elements needed to create a valid i2b2 observation as well as information on dispense quantity and instructions. The HL7v2 format is structured around “segments”: the PID segment provides patient information, the RDS segment provides pharmacy dispensing data, the ORC sub-segment provides metadata about the order, and the RXD subsegment provides data on the drug being dispensed. The C-CDA is a deeply nested XML structure that puts all information under a “substance administration supply” event (except the patient ID, which is not shown for compactness). Notice that some pieces of information require even more deeply nested structures under the supply event (e.g., patient instructions are four levels deeper). In contrast, the i2b2 format is a nearly flat structure organized into a sequence of observations. This example shows two linked modifier observations: dispense quantity and instructions. The core components of the observation are repeated for each modifier.

The C-CDA and PDO mappings will be released open source in Open Health Tools with the enhanced MDMI toolkit, which includes the transformation engine and the graphical map editor (http://sourceforge.net/projects/mdmi). [21] The HL7v2 mappings reference proprietary PBM data structures and cannot be released.

Finally, we developed i2b2 ontologies necessary for querying the prescribing, dispensing, and payment data. Because these ontologies are based on the C-CDA, we believe these are the beginning of standards-based medication ontology for i2b2. The medication tree was based on our previously developed RxNorm tree organized by Veteran’s Administration (VA) drug class. [15] Because the dispensing data is in National Drug Code (NDC) format, we used the linkage information present in the Unified Medical Language System (UMLS) to augment our ontology. Specifically, NDC codes for specific drugs are placed as children of the RxNorm drug formulation they are associated with. The ontology for modifiers is a list directly derived from the modifier codes in the PDO. Moreover, the PDO modifier codes are themselves derived from the MDMI Referent Index names. Once the Referent Index is an approved standard, this provides one path toward canonical naming of i2b2 modifiers. Because such a vast amount of medication metadata is included in the dispensing data, for this initial version we prioritized the modifiers most important in obtaining accurate patient medication information: detailed information on the drug, what was dispensed, and refills remaining. Not included are many of the details on credentials, such as NCPDP number (national pharmacy identifier code). More detail on the modifier codes in the ontology is shown in Table 2.

**Validation**

We deployed i2b2 1.7.04 with our i2me2 cell and the RxConnect tools at Boston Children’s Hospital. The patient annotation app was deployed as a web application that can interact with the i2me2 cell. To validate the patient annotation process shown in Figure 1, we loaded synthetic test data in HL7v2 format into i2b2.
We manually augmented the loaded data with prescribing information provided by the i2b2 demo data and used the patient annotation app to view a patient’s combined medications. We also verified our ability to run patient count queries on the imported data in the i2b2 Query Tool.

Discussion

This represents a successful validation of an approach to integrate important non-traditional data sources to enhance medication lists for post-market drug surveillance. In this work, we described the successful end-to-end tests of a toolset that combines PBM data with i2b2 data, which is presented to patients for corrections via tablet-based patient annotation. This study also describes how complex medication information can be represented in three very different data formats.

The project team is presently recruiting patients for studies that examine the data quality of the medication list using this toolset. The current goal is to identify discordance between the clinical medication list and the patient-generated list (the output of the annotation app). Then, techniques will be developed to assess adherence from the discordance.

This is a generalizable approach to importing a variety of medication data into i2b2 via C-CDA messages. Our inclusion of PBM data enables a novel data source for patient-performed medication list annotation. Also, the enhanced MDMI toolkit and the maps developed for this project offer a starting point for data interoperability between i2b2 and a variety of standardized or custom data formats. The MDMI toolkit and maps for i2b2 and C-CDA will be released open-source shortly on the Open Health Tools website, and non-PBM-specific components of the i2me2 codebase will be released open source by the completion of the project.

Limitations and Future Directions

The patient-facing app functionality for loading reconciled medication data into i2b2 remains under active development. A standard ontology for patient reported medication information is being developed. The initial version of the app app uses i2b2 PDO format, but the final version will use the Fast Healthcare Interoperability Resources (FHIR) format, which is considerably more compact as well as more efficient to transmit and parse. Upon completion of full end-to-end testing using synthetic data, we will proceed to test our approaches using real-time data from consented subjects.

Perhaps the greatest technical limitation of this toolset at present is the reliance on PDO format for client-facing transactions. While PDO format is flexible, the inherent denormalization creates highly verbose output. Therefore it is not an efficient transmission format between the app and i2b2. In the future, we will be leveraging previous work in implementing SMART on i2b2, including addition of FHIR-based SMART messaging.

Conclusion

We have demonstrated the ability to incorporate a novel data source (pharmacy dispensing data) into the medication list of the i2b2 EHR data warehouse. The C-CDA approach is generalizable and uses standard data transmission format. This combined list is then presented to patients for annotation, adding a second novel data source (the patient). These tools will be released open source and they are currently being used at Boston Children’s Hospital to
power studies on the concordance of medication lists across data sources. This work enables important research to improve medication list quality for drug surveillance and to improve patient drug adherence.

Acknowledgements

Thanks go to: Lori Phillips on the i2b2 team for contributing her expertise in ontology design and development; to Florence Bourgeois in the Children’s Hospital Informatics Program for her leadership of study design and research applications of the i2me2 platform; and, to the MDMI team (Ken Lord, Sean Muir, Sally Conway, and Gabriel Oancea) who worked closely with us to make sure all needed functionality was available to us. Long-Term Engagement with Health-Management Technology:
 a Dynamic Process in Diabetes

Abstract

Diabetes management is a complex, dynamic process that is largely incumbent on patient choices and behavior. We explore how health-management needs—and the needs for technological support—change over time for individuals with diabetes. Through interviews and a focus group, we found that after initial diagnosis, individuals face acute information needs and chiefly turn to mobile applications and Internet resources to help understand the diabetes-specific factors that affect their health. Over time their focus shifts from highly regimented routines to more flexible ones that enable them to maintain a quality of life. Our results suggest that long-term engagement with health technology does not necessarily require continuous, sustained use: routine disease management could lead to a decrease in use, until a new event occurs. Our findings point to a need for tools that help patients with diabetes to effectively manage their health as their bodies, treatment and circumstances change over time.

1. Introduction

Diabetes is a common, chronic disease that affects 346 million people worldwide, and is predicted to become the seventh leading cause of death by 2030¹. There are two main types of diabetes: Individuals with type 1 diabetes (T1D) have a deficit in insulin, whereas those with type 2 diabetes (T2D) have an increased resistance to insulin. Diabetes leads to increased risk of cardiovascular events, is the leading cause of kidney failure and amputations, and is a major cause of blindness. Patients that can reduce their average blood glucose level (HbA1c), control their blood pressure, and treat their cholesterol can delay the onset of these complications. Yet only one in eight individuals achieves these three goals². Such low rates of adequate self-management suggest that the standard model of care delivery consisting of short, infrequent visits with care providers conveys insufficient support for effective health management, including managing medications, improving diet, controlling weight, increasing physical activity, and smoking cessation³.

In recent years, mobile technology has emerged as a promising way to provide additional support for self-management⁴. Adoption of smartphones and other mobile devices has grown exponentially in all age groups and socioeconomic classes⁵ and applications for diabetes and wellness have flourished⁶. The available smartphone applications for diabetes are diverse, and allow individuals to track activities, medications, or diet, as well as to visualize the results in graphs. These types of applications offer new ways of supporting the challenge of diabetes self-management, and they have shown promise in clinical trials. A meta-analysis of 22 trials assessing the effect of mobile phone interventions on glycemic control showed a reduction of HbA1c of 0.5% over a median of 6 months’ follow-up duration⁷. This effect was shown to be greater in individuals with T2D than in T1D⁸. Early work on the use of mobile phones for diabetes management studied the use of phone calls or text messaging⁹. Recent studies focused on tracking applications (insulin, diet, blood glucose, and weight, for example), educational content, or integration with other systems, such as personal health records and social media⁶. Ralston et al found that the use of secure messaging with providers improved HbA1c results by 0.7%¹⁰. Combining mobile device and provider support, a randomized controlled trial with WellDoc Diabetes Manager™, a FDA-approved application that offers automated clinical coaching based on the data that patients track and supports sharing of that information with care providers, showed a 1.2% decrease in HbA1c with web- and mobile-based tools compared to usual care over a year⁶. This result suggests that mobile technology might be even more effective as a part of a comprehensive suite of technological tools.

Whether these preliminary efficacy results are an accurate picture of the benefits that mobile technology could have on diabetes self-management is unclear. In studies with a longitudinal design to assess the clinical impact of technological interventions for diabetes self-management⁷, researchers often classify irregular use of technology as a failure in use. However, the lack of use could be due to a number of factors, including a mismatch between the evaluated technology and the current stage of the patient’s condition or technology design that doesn’t enable patients to sufficiently adapt the application to their specific needs. For instance, Chen has found that in spite
of a similar set of self-management needs in newly diagnosed individuals, responses to these needs vary depending on the individual’s physiological, social, and personal circumstances. If the application that is being evaluated does not adequately match patients’ current self-management needs, patients will use the system irregularly or stop using it altogether. In such cases, trial results that report average effects for the whole sample would show lower efficacy than would be found in a subsample of patients whose self-management needs were well matched by the evaluated application. Given that the large majority of current mHealth tools for diabetes rely on a single self-management strategy, tracking, the possibility of a mismatch between patient needs and available support cannot be ignored.

While research in health sciences has focused on assessing efficacy of self-management tools for diabetes, work in human-computer interaction (HCI) is exploring new approaches for technological support for behavior change, such as personalization and sense-making. For example, Mamykina et al. have focused on the development of problem-solving skills for diabetes self-management. Drawing on the construct of sense-making, they developed a mobile-phone application, MAHI, which enables patients to collect contextual information related to their glucose measurements (e.g., what they ate, where they are, etc.). The information is uploaded to a secure website where patients can reflect on patterns in their information and discuss their data with a diabetes educator. Frost and colleagues took a similar approach: to facilitate reflection on patterns in glucose measures, the researchers used photographs to annotate glucose readings to enable patients and their providers to better understand each individual’s values.

The work in HCI and in health sciences has only begun to explore how patients’ needs for self-management technologies evolve over the course of the disease and how we can design technologies to account for the evolving nature of diabetes self-management. For example, Chen has suggested that seeking of health information is cyclical rather than linear. If the needs for self-management support substantially change over time, the benefits we are seeing from self-management tools might be less than they could be, in part due to the potential mismatch between the type of technology being tested and the specific needs of the patients participating in the study. To avoid such mismatches, we need to better comprehend individuals’ evolving self-management needs and the ways that technology can support them over time.

In this paper, we begin to close this gap in understanding how diabetes patients’ health-management needs change over the course of the disease and how they use various technologies and devices to support those changing needs, using a grounded theory approach. Our findings can inform the design of technologies that account for the shifts in self-management priorities brought about through the progression of the disease, changes in treatment, and the patients’ own evolving skills and understanding of diabetes self-care.

2. Methods

2.1. Data collection

After receiving approval from the Institutional Review Board, we recruited adults with T1D or T2D through flyers in Diabetes Clinic of the University of Washington, convenience sampling, and a diabetes support group from September 2011 to October 2012. We excluded individuals with gestational diabetes because of its limited duration, as well as those on dialysis, because they see their care-providers much more frequently than other individuals. Participants received $25 for participation. We collected participants’ socio-demographic characteristics, and information about their technology and healthcare use. We chose not to perform purposive sampling by disease duration, as the relationship between disease duration and disease stage is not clearly established.

We led in-depth, semi-structured, individual interviews with 11 participants. All sessions were audio-recorded and transcribed for subsequent analysis. The sessions ranged from 35-100 minutes. We asked individuals to describe their current diabetes management, their trajectory since they were diagnosed, and their use of technologies, such as their use of mobile devices and the Internet (e.g., forums, blogs, other websites). We also explored their perceived role in coordinating the care they receive. Finally, we asked them about their perceptions of barriers and motivators for diabetes self-management. We also conducted a two-hour focus group with four participants, three of whom had been interviewed individually: three individuals with T2D (diagnosed in the past two years) and one individual with T1D (diagnosed 20 years ago). During this session, participants discussed their disease, their evolving needs, barriers and motivations, and discussed their use and need for supportive technologies for diabetes.

2.2. Data analysis

Two coders each analyzed the transcripts of the individual interviews and the focus group in Atlas.ti 7 software, using open coding to establish prominent themes encountered in the data: the evolution over time of the disease and
its management; the tracked information; the comprehension, availability and usefulness of technologies such as glucose meters and their companion websites, insulin pumps, blood pressure monitors, smartphones and tablets, online forums and social networking. Codes were developed for the disease trajectory, modifications in symptoms, treatments, barriers and motivations for self-care. The two coders iteratively compared their coding schemes, revising or merging them as they discovered common and contrasting themes. We took into consideration duration and type of disease for this analysis. Reaching saturation allowed us to terminate the data collection.

3. Results

3.1 Participant characteristics

Across the interviews and focus group session, we enrolled 12 diabetes participants (six T1D and six T2D patients), who had been diagnosed for periods ranging from 6 months to over 20 years. There were five male participants, four of whom had T2D. One patient with T2D used insulin. The patient characteristics are presented in Table 1. The age range in our sample is representative of T1D and T2D demographic characteristics in the general population. Three T2D participants were Asian, one T2D participant was Black, all other participants were Caucasian.

3.2. Evolution in health management needs

A key finding from our work is that patients’ priorities and needs for self-management support change substantially over the course of the disease. In this section, we describe patients’ needs and priorities in the following phases: (1) the learning phase in the initial period after diagnosis, (2) the stabilization phase, when they gained gain confidence, (3) the relearning phase, when they need to learn how to respond to changes brought about by the disease progression and adjustments in treatment, and (4) the expertise phase revealed during long-term management.

3.2.1. Learning phase: Developing understanding after diagnosis

Our findings indicate that the initial period after diagnosis is characterized by acute psychological distress, a need to learn about the disease, and to adopt new routines and health behaviors to control glucose levels. During this period, patients make heavy use of tracking tools and of educational websites, but find the available information insufficient.

Participants find this initial stage difficult, both at a physical and psychological level. Two participants consulted mental health professionals to help cope with their new chronic disease. Diabetes has a negative reputation, with its ban on sweets, its amputations, the painful pricks and injections and medications. Such perceptions are often buttressed by friends or family members with diabetes who have presented these complications. For one participant (P1, T2D) the moment of diagnosis was “the branding, the shock” and her initial thought was “I’m a failure.” The DAWN study found that 85% of individuals reported a high level of stress (shock, guilt, anger, anxiety, depression, and helplessness) after receiving this diagnosis. The difficulty of finding practical information heightened the feeling of being overwhelmed by the disease in the early stages as they tried to understand the expectations for their new lifestyle: “I wanted something early on, I just want to know if I can eat five crackers, if that’s all I have to eat, I’ll eat crackers for 90 days. [...] Give me a recipe, I can follow it and not have to think about it so much.” – FG, P7 (T2D)

In addition, a need for intensive learning characterizes this initial period as participants search for answers about diabetes and discover how to incorporate management strategies to get better and prevent complications. Self-management at this stage focuses on understanding the basics of the disease, and changing daily activities, such as nutrition. Lifestyle changes are particularly important in type 2 diabetes, where portion control, healthy food choices, and physical activity are initial steps to decrease and stabilize glucose levels. As FG, P7 (T2D) noted,
“Going back, early on, it’s food. You know, you have to figure out what you can eat, and then it’s exercise and then it’s the combination of everything and then it’s working it all in the lifestyle stuff too.”

Although some information seemed difficult to find on the Internet, our subjects found comfort in its constant availability as a resource: “It’s not just ‘go to this class that’s taught in two weeks’ but ‘here’s where you could start online tonight when you’re freaking out at two o’clock in the morning’” – Intv, P5 (T1D). However, they also described how time-consuming and impractical websites were to use, particularly at early stages. This was particularly the case for a nutritional website which provides detailed breakdowns of nutrient data for an extensive selection of foods; participants described how it was difficult to utilize this data when combining several foods together. “There’s not a website that says ‘eat this - you can eat this, in this proportion’, none of that. And the same thing with exercise. You know, they say ‘exercise’ but then they don’t give you – they don’t just say ‘10 minutes per meal’.” – FG, P7 (T2D). The challenge of controlling glucose levels with food and exercise is compounded by the lack of concrete, actionable plans that new patients can adopt to get them started. Although many websites, handouts and textbooks about diabetes exist, patients expressed frustration with finding concrete information to guide daily choices. Participants found the available food plans bland, describing the need to adjust to, “taste, lifestyle, you know, even down to the city, because [most] is tailored to the Caucasian diet right now.” – FG, P9 (T2D)

At this early stage, patients describe strategies to help adopt new routines for disease management. They integrate new behaviors like tracking, glucose testing, and they limit their food choices to those that were successful in the past: “I was tracking down to individual ingredients I was putting into my recipes and just breaking it down to what I can. You know, we were measuring every two hours after a meal, doing exactly what they were telling us to do, wake up: check, after breakfast: check, two hours before lunch: check, two hours after lunch: check. So it was a whole routine for about the first month, two months.” – FG, P7 (T2D)

Detailed tracking helped participants learn how different foods and routines had an impact on their blood sugar levels. However, in this early phase, participants would also simplify their lifestyle and choices to activities that they already knew how they impacted their bodies. One participant described always going to the same fast food restaurant while on the road, “because I know exactly what that’s going to do to my blood sugar” – Intv, P6 (T1D). Restricting options is difficult, but it saves time and decreases anxiety about glucose management.

Individuals use intense tracking to learn how to interpret many numbers, including blood glucose results and carb counts and the effect of behaviors on their body. Patients might also start new medications and want to observe the effects of those drugs. Some participants used pen and paper or Excel spreadsheets, while others turned to their smartphones for tools to assist them, with options for averages and other analyses. They particularly appreciated the ease of data retrieval and seeing associations between trends in carbs and glucose levels: “The nice thing about having it on the phone is I can just give [my providers] my last 90 days, without having to scroll back through a bunch of spreadsheets and paperwork and calculate the number. I can just quickly at a glance say where I am” – FG, P7 (T2D)

Even though some of our participants developed tracking strategies on their own, they wished for more guidance from their care-providers for electronic resources (websites and smartphone apps). A number of websites and apps are available for diabetes, nutrition, physical activities and weight, yet providers do not seem familiar with these resources. Patients expect their providers to suggest and advise them about these resources to ensure that patients are accessing high quality information: “I feel like the good [providers] are also learning to go online or at least realize that there are conversations online [...] knowing good resources whether it’s diabetes.org or the TuDiabetes.com network. So giving patients a starting place and not making them go to Google.” – Intv, P5 (T1D).

Supplementing their interactions with providers, our participants also leveraged peer support from other individuals with diabetes, particularly at this early stage of disease. The experiences of peers can provide information not given or emphasized by care professionals: “My friend actually was the one who told me to take my insulin earlier to offset like spikes and stuff. [...] She was the only person who said that to me, I guess. She’s kind of clued me in, that’s helped a lot.” – Intv, P10 (T1D)

During this initial phase, then, patients face the challenge to understand how their bodies respond to food, medication, and exercise, and, based on that knowledge, to come up with daily routines that help stabilize their blood sugar levels. Tracking tools are a key support for this process, as are online resources such as blogs and forums where patients can get advice and tips from other patients.

3.2.2. Stabilization phase: Building confidence

As individuals make efforts to adjust to new lifestyle choices, they progressively build skills in and confidence about diabetes self-management. They realize that they can delay the onset of complications and that their actions can bear
positive results, reflected in their HbA1c numbers or feedback from their care-provider. Patients also master the diabetes lingo, as P8 (T1D) described: “Breakfast was one protein, two starches, one fat, one dairy, one fruit...” After they gain initial control, patients also begin to slowly integrate new behaviors into their daily routines:

*I think that initial first three months was just getting an understanding of “can we get these numbers down,” “what is it going to take” and then now that we got them down, it seems like it’s okay to go out and have a couple of drinks with your co-workers after work or happy hour, and do stuff. [That shift occurred] after the first A1c that went down.* – PG, P7 (T2D)

During this stabilization phase, individuals gradually lose interest in tracking their diet or other activities, because they have adopted routines that generate satisfactory results. They have discovered which foods to eat in what proportion, and have developed skills at interpreting glucose results and at estimating carbs in common foods.

[I made] a master list of all the items that I could possibly eat and the glycemic load and the calories [...] For the first 60 days, [our glucose results] were always low because we knew exactly what we ate. So then after a while it was like it was the same thing we’re eating every day, you know what it’s going to be. So after that I just stopped [tracking]. – FG, P7 (T2D)

*I can usually look at things and [...] probably 70 - 75 % of the time I get at least in the ballpark.* – Intv, P8 (T1D)

Individuals gain confidence in their skills to assess carbs, or predict their response to certain activities. They might even search for ways to fine-tune their glucose results through detection of complex interactions among emotions or physical activity. They recognize that mobile technologies can provide a lot of information, but do not use them as much at this point.

*Some apps will tell you like if say, you know, three strawberries, or whatever, they will tell you how many carbs that is. But I kind of just eyeball it and you know, from experience, just sort of trial and error with different things* – Intv, P4 (T1D)

*There have been a couple of times where I come out of the pool and been really low – it was at the beginning when I didn’t know exactly how it would affect me but I feel like, generally, at least now, I’m able to kind of predict what’s going to happen and I take glucose tablets with me when I run and bike and that kind of stuff.* – Intv, P10 (T1D)

The key feature of the stabilization stage, then, is that patients have managed to internalize knowledge that previously required them to use external tools. By better understanding their bodies and the ways in which factors that affect their sugar levels interact, they are able to “eyeball” different types of foods and predict the effects that eating something will have on them. Consequently, intensive tracking technology became less useful at this point.

### 3.2.3. Relearning phase: Responding to changes

Some participants described feelings of guilt when their glucose results were less satisfactory. Consideration about staying healthy for their loved ones only compounds this feeling: “I think I just start feeling guilty because [...] I was not managing my diabetes the way that I should. [...] And it’s unfair to my husband to be so nonchalant about it. So there’s that guilt that kicks you into action in a positive way.” – Intv, P6 (T1D)

Glucose levels can start reacting differently over time for various reasons. Even though individuals have learned how life choices affect glucose results, how various factors affect a person’s body can change over time. Our participants described a continuous need to re-evaluate their lifestyle in order to understand changes in glucose patterns.

Some changes in glycemic control are necessitated by the changes in the body itself, often as a result of the disease progression: “It’s [been] two years now that I’ve had diabetes; it’s changing pretty significantly now. And so I’m having to like re-learn things that I thought I kind of at least had a feel for the last couple of years. [...] But I’ve noticed that I need more insulin for any of the carbs that I do eat. I need to take them earlier, like 15 minutes before. [...] Generally speaking, I need more insulin, so any of the numbers I did learn for the foods that I typically eat, I’m kind of relearning now, how it affects me now” – Intv, P10 (T1D)

The need for relearn glucose control can also be brought about by changes in treatment such as new treatment regimens or a new device, such as a continuous glucose monitor (CGM) or insulin pump, which can drastically alter diabetes self-management. “Before I got my CGM, it was really a guessing game. It was very much like, you think that you know what’s going on and what’s happening. [With a CGM,] you have this meal every single morning and this is what your blood sugar did every single morning. What was the difference with this morning versus others,
you know, because everything else is the same?" – Intv, P4 (T1D). Finally, relearning can be necessitated by changes in the patients’ lives, such as travels or a new job: “To try to eat on a regular schedule, to try to eat foods that are appropriate on a regular schedule are not simple on the road” – Intv, P2 (T2D).

Whenever patients notice that their bodies are responding in unexpected ways, they must determine whether the change in glucose response is a one-time event or a pattern that would require an adjustment of diet or insulin regimen. Individuals adopt different strategies to answer that question: some will look at previous days, others rely on their memory, and yet others will again start tracking their food, glucose, insulin, and activities more closely: “I don’t really track much unless I am specifically looking for a pattern.” – Intv, P4 (T1D)

To monitor changes in glucose patterns, providers may ask individuals to track their diet and glucose in preparation for visits. This helps assess if there is any gradual change in trends, and provides concrete points for feedback if abnormal results are found. Although care-providers can provide insight into some abnormal results, they might not have the contextual and lifestyle information needed to interpret all results. Tracked results without context can lead to misunderstandings and frustration for the patients, while limiting the provider’s ability to provide feedback... As P4 noted, “The chart of all my blood sugars, it’s, like, each number has a story behind it. And it’s like, I remember that meal or I was sick or, you know, there’s so much more than just numbers that goes into it.” – Intv, P4 (T1D)

Learning to manage diabetes is not a one-time shot, but rather a continuous process. As the circumstances change, patients have to relearn how their bodies react to different factors that were once a known quantity. The need for external support often goes up in these situations. Patients will turn to their clinicians as well as technology to regain control of their glucose levels.

3.2.4. Expertise phase: Managing for the long-term

Long-term management of diabetes is important, because effective diabetes management can reduce complications. Yet, the disease does not remain patients’ main focus and instead they begin to prioritize quality of life. Over time, patients develop a nuanced and detailed understanding of their illness that leads to balancing glucose management with the desire to explore new foods and activities.

This quality of life: like I know that I can spend so much time and be so diligent and write everything down and do what you were doing in the beginning. But is that really worth it in the long run? [...] I test on average 10 times a day. [...] But that’s seven seconds out of my life, the tracking. So that’s definitely a goal of mine, [...] finding that balance a little bit better and maybe doing a little less work, but still getting the good results – FG, P4 (T1D)

I mean, you’re not going to live your whole life watching, counting calories, every grape that you eat. I mean I’m getting really close to that point now where [...] I’m not thinking about my meals every day. I’m content with like, if I miss a snack so, I’ll make it up at dinner – FG, P7 (T2D)

As individuals grow to live with diabetes, there is a point when they understand enough about what behaviors they should adhere to, but also realize that they are not enjoying life as much as they would like to.

Individuals discover over time that the metabolism of glucose can be intricate and sensitive to a range of factors: “I’ve had [diabetes for] almost 20 years now, it’s crazy. But, I’m still learning everyday just what I can and cannot eat and – because even if you go straight off carbs, fiber, glycemic index, like there’s other things that go into it. [...] And glycemic load is a little bit dependent on the meal. So like if you eat like grapes by themselves, they might have a certain glycemic load but if you eat them with cheese, it’ll change it.” – FG, P4 (T1D). In addition, Type 2 patients not on insulin therapy frequently taper their glucose monitoring to avoid the unpleasant finger prick required. Although this can be patient-initiated, providers also encourage this when results are satisfactory: “Since I’ve been a diabetic for over 20 years, I just do it in the morning. I don’t watch it other times of the day that usually ends up being a good reflection about how things are being handled.” – Intv, P1 (T2D)

As individuals loosen their dietary restrictions, they may wonder how this affects their glucose and initiate a short period of glucose tracking to see if they are still on track: “I check [my blood glucose] once in a while when I do try something different, when I eat something different or, you know, if I’m feeling awkward or something.” – Intv, P7 (T2D). While some individuals used electronic spreadsheets or handwritten notes, others used smartphone weight-tracking applications that provided detailed information about the breakdown of foods.

3.3. Social and emotional impacts across phases

Diabetes, like many chronic conditions, can lead to a variety of different emotions. The pressure of handling food choices, calculating carbs and insulin doses, and testing glucose on a daily basis can lead to anxiety in some
individuals: “I want to be able to eat food. Like I want to able to try food and not be really scared of everything I put in my mouth” – FG, P4 (T1D). These emotions also occur in T2D individuals, even without insulin therapy: “There’s really a mental pressure. You’re talking about the constant thing. It’s a constant mental pressure on me to always keep track of what I eat, how much I eat, when I eat, and on and on” – FG, P11 (T2D)

For many, the motivation to keep up with the many daily requirements of one’s regimen is to stay healthy and delay the onset of complications or need for new medications. Many individuals are influenced by a parent or relative who has experienced, or even succumbed to these complications. Fear of consequences can drive motivation for self-management: “The negative aspect would be knowing that eventually, [diabetes] will catch up. It’s a non-stopping disease and eventually it will catch up with me and I don’t know why, I don’t know what will happen to my bones or my eyes or skin or heart or something will eventually go. […] And that knowing is sometimes hard to handle, that knowing. So my own father passed away because of complications of diabetes.” – FG, P11 (T2D)

The balance between highly controlled self-management and spontaneous activities is a fine line. Individuals can push themselves by setting high standards with the risk of being too demanding, or they can feel pressure from their care-providers to improve numbers. Performance in disease management can be a sensitive topic, as P8 (T1D) describes: “While I’m willing – able and willing to talk about my diabetes, I’m not – I don’t want to have any perception of being judged.” This may be why some individuals feel a particular affinity with peers, particularly care-providers who also have diabetes. There is a shared understanding that behaviors cannot be perfect all the time and less than ideal results do not invite critical judgment.

This doctor, who is a type 1 diabetic that I met at diabetes camp, […] she was the only doctor I’ve ever met that like I felt like really understood and really just made it okay to eat ice cream if you knew what to do and… It’s okay if you have high blood sugar every once in a while, just keep on going, and keep figuring out. – FG, P4 (T1D)

To an outsider, diabetes appears to be a burdensome disease with many requirements for testing, medications, lifestyle changes and restrictions in diet. Yet our participants had a very positive approach and expressed an acceptance with having to live with this condition. Individuals with T1D tended to describe the disease as the way their body was, whereas T2D participants considered it as a wake-up call because they had become so unhealthy.

I still have diabetes, and I still have to do this every day. […] That’s the way I am as a person – Intv, P4 (T1D)

I always tell the doctor that being diagnosed with diabetes was the best thing that ever happened to me, because it stopped me in my tracks. I wish I did that I’d been diagnosed twenty years ago because I would not be in the same health situation as I am now. – Intv, P12 (T2D).

4. Discussion and design implications

Our finding that self-management needs change over time aligns well with the Corbin and Strauss’s Chronic Illness Trajectory and suggests that technology will play different roles at different stages of the disease. In particular, based on our studies, we identified four functions where technology could play a supportive role: understanding the new disease, responding to changes in times of stability, improving communication, and tailoring to individual motivations and needs.

4.1. Understanding the new disease

Supportive technologies can play a particularly useful role at the onset of disease, as patients create their mental model of the disease and its management. Mobile technologies can guide initial lifestyle choices of nutrition, physical activity, glucose monitoring or medication in three ways: (1) Tools can facilitate tracking by guiding patients to easily capture a full range of factors that affect glucose levels. By taking advantage of sensing and lightweight self-report, a new generation of tracking apps could enable patients to log, with little burden, not only glucose levels and food intake, but also sleep, stress, physical activity, and other potentially relevant influences on glucose variations. (2) Applications can support learning by enabling patients to understand the interactions among the factors they are tracking. This data interpretation could be achieved through the use of visualizations, coaching (e.g.,), games, and through the use of machine learning algorithms for automatic pattern detection. For instance, a tracking application could not only visualize patterns in historical data, but also use logged data to provide visualizations of likely glucose changes over the next couple of hours—visualizations that could help the user understand and make more informed choices about different foods, activities, or types of insulin. Such visualizations could help the user to get an intuitive understanding of, for example, why foods with the same amount of carbohydrates can affect their bodies so differently or on the duration and effect of the different types of insulin. (3)
Finally, mobile applications can support skill development through the use of video clips, for instance, to teach patients how to perform a foot exam.

4.2. Responding to changes in times of stability

Participants indicated that intense tracking and diet restriction occurred mainly in the early stages of disease. As individuals grasp how to make healthy choices and adopt healthier behaviors, the perceived benefits of intensive tracking are surpassed by the cost in time and effort. While ongoing glucose tracking is recommended for insulin use, it might not be necessary for those who do not need insulin. In addition, as patients learn to estimate content of different types of foods, regular carb tracking becomes less useful. At this stage, the burden of tracking could be decreased for insulin users by switching to a lower-intensity mode for routine tracking, where information is added to the patient’s log automatically (via the glucose meter and sensors), while maintaining enough data to enable the system to detect significant pattern changes that need to be brought to the patient’s attention.

As the disease stabilizes and the concerns about quality of life take front stage again, individuals begin to break out of strict routines and experiment with new foods and activities. One role supportive technology can play at this stage is to support such experimentation while helping individuals to maintain good glucose control. One way to do this is through the creation of a personal knowledge base that patients can use to track their glucose responses and insulin use when they try new foods or activities. Such a system could help improve future decisions through rapid retrieval of prior personal experiences and may help reduce the anxiety of decision-making under uncertainty (P4, T1D and P11, T2D). This is also an area where a large-scale, patient-reported repository could be particularly useful. If a system knew insulin sensitivity parameters for different users, it could automatically use one user’s data to recommend insulin dosages for the same food or activity to other users. Practical applications of this crowdsourcing framework include insulin recommendations for areas with inadequate standardized information available such as restaurant menus, athletic activities, travel, and other activities that affect patients’ glucose levels.

Finally, one challenge in the period of stability is how to detect and communicate abnormal test results. Not all abnormal results require changes in behavior. Machine learning could help detect repeated anomalous events over a short period of time and prompt the user to make an appropriate change, such as changing the basal insulin rate. In our study, we found that the way to communicate a need for change is important. Warning alerts in response to a missing or abnormal glucose measurement may aggravate an individual’s feelings of guilt or may be perceived as a judgment. Future research could explore the use of more subtle cues such as changing the color of the phone’s wallpaper to provide a gentle indication to examine potentially concerning changes in glucose values.

4.3. Improving communication

When individuals have a better understanding of diabetes and its management, they can select relevant information to report for in-depth discussions and useful feedback with their providers. P4 explains how there is a “story behind each [glucose] number”, a lens through which to interpret abnormal results. Self-management technologies should allow individuals to easily capture contextual information that might be relevant for interpreting their glucose results. Smith et al.’s work on photo annotation of glucose data is a step in the right direction. Easily connecting information about location, recent sleep history, workload, stress levels, etc. with specific glucose readings would further support learning and sense-making that can occur in discussions with healthcare providers.

Our findings showed a gap between patient expectations and provider guidance for websites and apps related to diabetes. Participants’ providers welcomed various formats (paper, email or apps) for patient-reported data and appreciated patients’ technological expertise, but they were not a good resource of technical information themselves. Creating a well-maintained database of diabetes-related resources and their reliability could improve patient care.

Sharing with and learning from peers is important. Individuals with a disease become experts in that disease. Our participants readily turned to peers for practical information, such as food recipes or management of insulin with a new type of sport. Peers bring in a different type of information than the providers, because they “get it”, and grasp the challenge of having to always be on top of the disease management. Future technologies could make peer exchange of actionable information and social support easier by integrating a social component with tracking tools and enabling patients to seek support (e.g., on understanding why their glucose responded in a certain way to a particular food or activity) in the context of the information that prompted the need for support. How such social functionality can be designed in a privacy-sensitive and unobtrusive way is an open research challenge.
4.4. Tailoring to individual motivations and needs

Motivations for diabetes self-management vary: for some people delaying the onset of complications is a motivator, whereas for others that same thought creates anxiety. Likewise, for some, the mental burden of disease is increased with tedious data entry and tracking, or bothersome alerts, whereas for others, technology simplifies data retrieval and reminders serve their purpose, allowing patients to concentrate on other activities. Such differences can lead one patient to abandon the same technology that another patient finds invaluable. For these reasons, technologies intended for long-term not only need to support simple customizations—enabling or disabling of reminders, for example—but may need personalization at a much more fundamental level. An application that had a robust user profile that included user’s goals, motivational orientation (e.g., whether the user is promotion- or prevention-focused), attitudes toward illness, and other similar factors, could adapt its behavior to the user’s need at a deep level—employing motivational strategies to which the user would be most receptive, framing glucose results in terms that would not be discouraging, and using personalized content (e.g., user’s professional goals) to support health behaviors. How to construct such rich profiles with minimal user burden is an important research question.

Just as patients’ motivations vary, so do the situations in which they have to perform health activities. Such situations—locations, people patients are with, etc.—can act both as facilitators of and barriers to effective health management. Technology can further support patients’ self-management by helping them create implementation intentions—plans when, where and how they will perform health-promoting activities or resist activities that hurt their health. Given enough data from sensors and the information that the patients themselves log, technologies could both help patients to discover situations that influence their health-related activities and incorporate those situations into effective implementation intentions that can strengthen their health practices.

By taking into account how self-care needs change over time and the individual differences that shape diabetes management, future technologies could help patients with diabetes to manage their disease effectively over the long-term, contributing both to their health and quality of life.

4.5 Limitations

Although our participants are representative of the two types of diabetes, a limitation of our study is the small size of our sample. Due to disease type-related and individual differences in approaches to diabetes self-management, the full range of needs for supportive technologies may not be entirely covered in our sample. Self-selection to participate in studies can be a bias, particularly as most of our participants had outstanding diabetes management.

5. Conclusion

With several short-term studies showing promising results for mobile technologies in chronic disease management and in particular diabetes, we need to explore how to establish long-term engagement with these technologies. Where self-management evolves over time alongside disease trajectories, engagement with technology also becomes a dynamic process. Our findings suggest that the design of tools for diabetes that support long-term engagement should allow periods where the individuals can suspend use of one or more features of the application. A tool that can accommodate intermittent use raises questions of how to reengage the user at timely moments when repeatedly abnormal results or new trends are detected. If designed properly and flexibly, such technologies could provide patients with the support that is most important to them at their own stage of illness, communicate with their providers more effectively, and maximize the technology’s effectiveness in helping patients improve their self-management and their health.

Evolving Patient Compliance Trends: Integrating Clinical, Insurance, and Extrapolated Socioeconomic Data

Joseph J. Klobusicky, PhD, Arun Aryasomayajula, Nicholas Marko, MD
Geisinger Health System, Danville, PA

Abstract

Efforts toward improving patient compliance in medication focus on either identifying trends in patient features or studying changes through an intervention. Our study seeks to provide an important link between these two approaches through defining trends of evolving compliance. In addition to using clinical covariates provided through insurance claims and health records, we also extracted census based data to provide socioeconomic covariates such as income and population density. Through creating quadrants based on periods of medicine intake, we derive several novel definitions of compliance. These definitions revealed additional compliance trends through considering refill histories later in a patient’s length of therapy. These results suggested that the link between patient features and compliance includes a temporal component, and should be considered in policymaking when identifying compliant subgroups.

Introduction

In the field of pharmaco economics, compliance (or adherence) to a medication is defined as the degree to which a patient follows instructions from a health care provider\(^1\). Compliance measures span over all fields of treatment, including preventative measures such as exercise and diet. However, the most intensely studied form of compliance is with prescription drug consumption, due to its major economic impact. Approximations for annual costs of noncompliance due to medication related hospital visits are as high as $100 billion\(^2,3,4,5\), while the consulting group Capgemeni Worldwide recently published the striking estimate of $564 billion of annual costs suffered globally by pharmaceutical companies, of which American companies lose $188 billion\(^6\). Along with staggering economic losses, patient compliance also presents a major hurdle to patient health. For instance, compliance rates below 90\% for HIV patients can cause viral replication and disease progression\(^7,8\), while for diabetics, proper compliance is essential in preventing hypertension and myocardial infarction\(^9\).

Given a specific prescription, compliance can be further classified with respect to the potential ways a patient can deviate from a provider’s instructions. Primary compliance is defined as a patient’s fidelity of filling and refilling prescriptions. Secondary compliance refers to whether a patient actually consumes their medication. While direct observation and blood tests can validate secondary compliance, these methods are mostly infeasible, and instead rely on methods such as surveys\(^1\). Our data focuses on an aspect of primary compliance which observes patterns of drug intake conditioned on the existence of a patient refill history. Our concern, therefore, is not the event that a patient has taken a medication, but rather the discrepancy between recommended and observed fill dates.

Studies based on claims data most commonly use \(\text{MPR}\), or medication possession ratio, as a means for quantifying patient compliance. This ratio is defined as the total number of medication supply days divided by the total length of therapy. To illustrate, a patient with a prescription history spanning 60 days receiving 2 prescription fills for 15 days is assigned an \(\text{MPR}\) of 30/60, or .50. Studies have linked high \(\text{MPR}\) with commonly used covariates such as age, race, and sex\(^10\), as well as insurance related quantities including out-of-pocket payments\(^11,12\). Our study diverges significantly from other investigations through a novel analysis of evolving patient trends. Rather than testing changes in compliance under some intervention (e.g. smart pill counters or medication reminders), we define notions of general, initial, eventual, and consistent compliance, and compare patient trends across these different features. These notions of compliance can address questions of policy, which seek not only to identify high risk patients, but also those patients most likely to respond to intervention.

Our main dataset is insurance claims data of prescription orders. While not accounting for secondary compliance, fill records provide an objective history of intake that is resistant to biased responses, which can arise in survey data. Insurance claim data is natural for questions concerning consistency of medication refills, as the dataset includes prescription fill dates, supply lengths, and refill numbers. This approach was taken by Soloman and colleagues\(^13\) and Gibson and colleagues\(^14\) for studying the relation of cost sharing and compliance. Our statistical approach is similar to Rolnick and colleagues\(^10\), who also use prescription fill data to examine trends, including census derived
covariates of education, income, and poverty. For our study, we use extrapolated data from the US Census and American Community Survey (ACS) to examine compliance with median family income and population density.

Figure 1: Data flow. A data broker combines GHP (insurance) and EHR (clinical) datasets, available from GHS database (lower left). Zip codes from the EHR dataset are used to obtain extrapolated census data (top left). The data broker (center) then deidentifies all data for statistical analyses (right).

Data Sources

All clinical and insurance claims data is aggregated through available databases of Geisinger Health System (GHS), a hospital located in central Pennsylvania which serves approximately 2.6 million people, mostly residing in surrounding rural areas. To collect clinical features such as body mass index (BMI), we restrict attention to patients who have both insurance and clinical data. The use of city-based geographic data, an instance of PHI (Protected Health Information), in addition to other deidentified data for this study was approved through an IRB.

Using zip code information from EHR data, we use census data to create an enhanced dataset containing socioeconomic factors, with coarseness at the city level. For the purposes of anonymization, we use the following scheme. A certified data broker deidentifies GHP and EHR data through random date shifting and random patient number identifier assignments. All PHI sensitive data is restricted to a work computer inaccessible to other investigators. From this computer, the data broker collects web-based data, and returns deidentified data, along with socioeconomic data, to an analyst for running statistical models. An illustration of the data flow between agents is given in Figure 1.

The chief dataset which contains information about prescription fills is collected through the Geisinger Health Plan (GHP), a subsidiary HMO of GHS. For each patient in the GHP database, there exists a collection of prescriptions taken, each with its separate history. For each of these drugs there are lists of dates corresponding to refill occurrences and supply length of medication. As the purpose of this study is to investigate changes in compliance over a series of refills, we will require at least three fills and a minimum of 180 day length of therapy. Each separate prescription for a person taking multiple prescriptions will be treated individually. Thus, in the sequel, to avoid confusion, we will use the term compliance of prescriptions, rather than compliance of patients, to denote scores for a single prescription. Through taking averages over all prescriptions, we can calculate patient compliance scores in a straightforward manner.

For a prescription with $N$ refill dates $d_1, \ldots, d_N$, with corresponding supply of prescription $s_1, \ldots, s_N$ given in days, we can define the medical possession ratio ($MPR$) as

$$MPR = \frac{\sum_{i=1}^{N-1} s_i}{|d_N - d_1|}.$$
where $|d_N - d_1|$ denotes the length in days between $d_N$ and $d_1$. Note that the final fill is not taken into account when calculating $MPR$, as we have no way of deducing a patient’s compliance if there is no subsequent refill. We will use the conventional definition of a compliant prescription as one with an $MPR$ of greater than .80, a commonly used threshold.

Electronic health records (EHR) were obtained from patients who were also members of GHP. The entirety of data available from EHR is massive in both magnitude and variety, containing millions of records of patient medications, events such as surgeries, complications such as occurrence of disease, and lengths of stay. While this rich dataset is certainly of future interest for more specific investigations, for this study we have selected a restricted set of covariates, consisting of age, sex, race, and BMI. Socioeconomic data was provided through the 2010 US Census and 2006-2010 ACS, which provide specific socioeconomic features. For our additional variables, we have chosen median income and population density.

Methods:

Definitions of Evolving Compliance. We now define different ways of describing compliance based on changes in behavior in time. To do so, we separate each prescription with a length of therapy of $L$ days into an initial period of day range $r$ to $\lfloor L/2 \rfloor$, and a final period of day range of $\lceil L/2 \rceil + 1$ through $L$, where $[x]$ denotes the floor value of $x$. For each period and prescription, we calculate the corresponding $MPR$ to give us initial and eventual compliance scores. This split defines each prescription as belonging to one of four quadrants Q1-Q4:

**Q1: Consistently Compliant.** A prescription is compliant in both initial and final periods.
**Q2: Compliant to Noncompliant.** A prescription is compliant in the initial period, and noncompliant in the final period.
**Q3: Consistently Noncompliant.** A prescription is noncompliant in both initial and final periods.
**Q4: Noncompliant to Compliant.** A prescription is noncompliant in the initial period, and compliant in the final period.

There are seven ways of dividing quadrants, either through comparing one quadrant against three quadrants, or two quadrants against another two quadrants. Our study focuses on three such divisions with conditions (see Figure 2):

1. A prescription is **consistently compliant** (Q1 vs. Q2, Q3, and Q4).
2. A prescription is **initially compliant** (Q1 and Q2 vs. Q3 and Q4).
3. A prescription is **eventually compliant** (Q1 and Q4 vs. Q2 and Q3).

We refer to a patient who is compliant over the entire length of therapy as **generally compliant**. Thus, each prescription was given four classifications based on which types of compliance are realized.

Statistical Design. For each variety of compliance, we ran chi-square tests of independence and logistic regression models through binarizing inputs. For EHR, we classified prescriptions as white, male, obese ($BMI >30$), or above median age (54 years old). For census data we classified by median household income ($\$43,837$ per year) and population density (245 residents per square mile). We repeat the fact that individual prescriptions were taken as separate data points, meaning that a patient with $N$ prescriptions provided $N$ separate data points with repeated inputs and varied outputs of $MPR$. The full dataset consists of 75940 prescriptions for 8889 patients. The median $MPR$ is 65.5%. This number is smaller than other studies which take $MPR$ as a compliance measure for specific chronic conditions. However, our study was over the space of all prescriptions, including those which were non-chronic or with more irregular drug intake patterns.
Figure 2: Variations of compliance. (a) A prescription record over a length of therapy consists of an initial first period and subsequent second period. Tiles denote individual days, and prescription symbols define fills. (b) Considering $MPR$ only over the entire length of therapy, patients can be partitioned as compliant or noncompliant based on a threshold score of .80. (c) Left: Considering $MPR$ over both first and second periods, patients can fall into one of four types of compliance behaviors. Right: Separating quadrants creates several definitions of compliance, including compliance over first period (initial), second period (eventual), and both periods (consistent).

Results

Summaries of chi-square tests for independence and multivariate logistic regression models are presented for the four compliance types in Tables 1-4 of the Appendix. The $p$ values for logistic regression are based on a Wald test with the null hypothesis that odds ratios are equal to 1. Age and race are the strongest predictors of compliance, as white and older patients have higher scores across all definitions of compliance. While race has a greater difference of compliance scores than age, $p$ values are consistently lower, as the sample population was largely homogenous (about 90% white). Males and obese patients are also more likely to have higher compliance scores, although differences in compliance are less pronounced than those for age and race. Census related data, income and density, produce the smallest differences in compliance, suggesting that high income and low population density related to higher compliance. However, while compliance scores are slightly higher for those living in more rural areas, we are not able to reject the null hypothesis that population density is independent of compliance.

Consistent and eventual compliance produce the most statistically significant variables for $p<.05$, whereas initial compliance produce the least. In particular, a small, but statistically significant, difference in scores was reported with respect to income data when observing consistent and eventual compliance, while there no such evidence of a difference with initial and general compliance. Also, race produces statistically significant differences in all definitions of compliance except for initial compliance.
Discussion

Changing Compliance Measures Imply Changing Significant Populations

While we observed certain covariates as statistically significant in terms of general compliance, the focus of this study was to develop alternative metrics which can capture information not available from traditional measures of compliance. In this analysis, we create variations in scores by considering compliance as a function dependent upon time. When considering compliance over the entire length of therapy for a patient, the more random nature of initial compliance can hide trends that more clearly occur after a patient has received several refills. A direct method of removing initial noise would consider either consistent or eventual compliance. While consistent compliance does, in fact, capture new socioeconomic trends, requirements are more stringent, leading to a smaller set of testable patients. Thus, it is reasonable to condition medication compliance scores after several refills have taken place, especially in the case of studying chronic conditions spanning over several years. The question of how many refills we should exclude before testing would be specific to the type of condition of question, both in the inherent compliance statistics, as well as the relative important for early compliance to medication.

New perspectives of analyzing quadrants can also shed light on different topics of interest. One particularly interesting approach is to investigate behavior in quadrants Q2 and Q4, which describe patients who experience a change in compliance. In terms of policy, a practical option when considering target audiences might focus on those who are susceptible to changes. While our current set of covariates was too generic to provide a definitive profile of such patients, we have provided a metric that can measure such subgroups for new studies with more specific datasets.

New Directions for Compliance Metrics

Our extensions to medication compliance can be used for providing a notion of “persistence” for claims related studies, which is considered as a distinct measure. Medication persistence is defined as the act of continuing a treatment for a prescribed duration. While claims data only offers information on prescriptions which have been filled, notions such as consistent compliance may be seen as a type of persistence with respect to the lag between drug consumption and refill dates. Notions of initial and eventual compliance should also be taken into account when conducting studies which focus on temporal changes, as the population may have tendencies toward compliance change. We also note that this type of analysis is an initial step for targeted intervention of patients who are likely to experience changes in compliance.

A natural extension of our study would consider MPR as a continuous function of time. One such approach for comparing MPR can be understood through comparing cumulative functions of total missed medication days. Through an appropriate normalization, we can then compare cumulative distributions for different prescription histories. While the common method for comparing such functions would be through calculating a Kolmogorov-Smirnov distance, the promising field of quantile regression, popular in econometrics, offers more relevant information on quantiles conditioned on certain feature sets. While studies have used methods from quantile regression, they use general compliance rates as the object of study, without considering variations in time. Another point of research would examine the differences between adherence and a patient’s medication portfolio, including focusing on frequency of intake effects on coupling certain drugs.

Another future direction of study involves the almost limitless source of data available from text scraping or data aggregation services. Strategies of utilizing social media tend toward intervention, where findings are currently mixed. A comprehensive study from Scheurer and colleagues of over 5000 articles reached the conclusion that online social support networks, including social media, can increase compliance. However, the same study showed that “practical social support”, such as offering transportation to pharmacies, offered the greatest increase. A less studied aspect uses alternative data sources for compliance prediction. Examples of success stories are from social feeds such as Twitter and Yelp restaurant reviews, which have been used to track the progression of influenza and post-partum depression. For socioeconomic issues, data aggregators can provide more specific public information which may relate to compliance, such as housing and criminal justice records. This additional inclusion of data may allow for a more advanced analysis of compliance scores through machine learning techniques.
Conclusion

Estimates of patient compliance are sensitive to temporal considerations. Trends toward eventual compliance are similar to those of overall compliance, while compliance near the beginning of a prescription tends to be more uniformly random over all features. This suggests that studies should consider conditioning compliance studies after a patient receives several refills. Future work will focus on more extrinsic data collection and partitioning methods that more accurately capture compliance trends.

ABSTRACT

We study machine learning techniques to automatically identify limb abnormalities (including fractures, dislocations and foreign bodies) from radiology reports. For patients presenting to the Emergency Room (ER) with suspected limb abnormalities (e.g., fractures) there is often a multi-day delay before the radiology report is available to ER staff, by which time the patient may have been discharged home with the possibility of undiagnosed fractures. ER staff, currently, have to manually review and reconcile radiology reports with the ER discharge diagnosis; this is a laborious and error-prone manual process. Using radiology reports from three different hospitals, we show that extracting detailed features from the reports to train Support Vector Machines can effectively automate the identification of limb fractures, dislocations and foreign bodies. These can be automatically reconciled with a patient’s discharge diagnosis from the ER to identify a number of cases where limb abnormalities went undiagnosed.

Introduction

The misdiagnosis of a patient’s true clinical condition due to misinterpretation of radiological evidence by the treating clinician is an occasional problem in hospital emergency departments. There is always a time delay between reporting of the radiologist and clinical treatment by the Emergency Room (ER) clinician. The large amount of manual processing of unstructured text is one of the main issues that can be resolved by technology enabled solutions.

A good example of a misdiagnosis issue is the identification of subtle limb abnormalities (fractures, dislocation or foreign bodies). Radiological evidence of limb abnormalities, when subtle, can be missed by clinicians working in the ER. The reporting of a abnormalities by a radiologist may not occur in real time and therefore may not be available to the clinician treating a patient. Consequently, patients may be sent home without appropriate treatment and follow up. A study by Cameron1 reported that 2.1% of all fractures were not identified on their initial presentation to the ER. Furthermore, Sprivulis and Frazer9 reported that 1.5% of all x-rays have abnormalities not identified in the ER records. Similarly, Mounts et al.5 reported that 5% and 2% of the x-rays of the hand/fingers and ankle/foot from a paediatric ER had fractures missed by the treating clinician. Although small, these percentages are not insignificant.

The need to reduce errors is well recognised4,7,8. To ensure a diagnosis is not missed, radiology reports are commonly checked and patient records are reviewed, but this may not happen until days after the initial presentation. The current clinical practice of identifying limb abnormalities from radiology reports is highly labour intensive and is subject to human error or omissions. There is a need to streamline the process of identifying missed abnormalities for better patient outcomes. Technology enabled solutions that can streamline the diagnosis identification would certainly improve efficiency in the existing process.

Previous work has focused on automatically detecting fractures from free-text radiology reports. De Bruijn et al.3 considered acute fractures of the wrist and reported that a Support Vector Machine algorithm (SVM) was able to identify fractures in free-text radiology notes, achieving an overall F-measure of 91.3%. While, Thomas et al.10 developed a text search algorithm that accurately classified radiology reports into the categories "fracture", "normal" and “neither normal nor fracture”. Zuccon et al.15 have studied Naive Bayes and Support Vector Machines based classifiers for the identification of limb abnormalities. They have shown that machine learning techniques coupled with both word and semantic features are very effective for this task, achieving an overall F-measure of 92.3%. Their evaluation however was limited to a sample of 99 radiology reports from a single hospital radiology service.
Table 1: Three different datasets of radiology reports, along with the number of normal and abnormal cases as identified through our annotation process. The average document length for free-text reports in each dataset is also recorded: the large difference in average length between GCH and RBWH/RCH may be due to differences in reporting language and style conventions.

In this paper, we build upon the work of Zuccon et al.\textsuperscript{15} and we experiment with the automatic classification of free-text radiology reports for identifying abnormalities of limb structures using machine learning algorithms and features such as bigrams formed by stemmed tokens, negations, and SNOMED-CT concepts extracted from the free-text. While previous work has shown promise, it does not address a number of important areas for the practical use of such techniques in a clinical setting. We outline these below and highlight the contribution this study makes in addressing each.

1. Where the majority of the existing methods only used term-based features we extract medical concepts from the SNOMED-CT ontology and exploit these for training the classification model.

2. Previous studies used datasets that were small and homogenous\textsuperscript{10,3,15}. Instead, in this study, we use a larger set of reports taken from different hospitals and different ages (adults vs. children). An important requirement for the general applicability of these methods is the robustness of the models across different hospital datasets; i.e., how well would one method, developed using one hospital’s set of reports work when deployed at another hospital, where particular institutional conventions may result in different language and authoring styles in radiology reports. In addition, radiology reports for children and adults may also differ. To address this issue, we evaluate our method on three different sets of radiology reports from three different hospitals (adults and children). These types of heterogeneous data sources were not considered in previous studies. In this study, we empirically show, via different training/test combinations, that the method developed on one hospital’s reports (with differing conventions and patient cohorts) can be applied to another with marginal loss in effectiveness.

3. Finally, and perhaps most importantly, we investigate how the classification of radiology reports can be used in a real clinical setting to reconcile the radiology diagnosis with that of the patient’s discharge diagnosis from the ER, thereby identifying a number of cases where limb abnormalities may have been undiagnosed. Thus we study an end-to-end application of natural language processing and machine learning to aid clinicians in the identification of undiagnosed limb abnormalities.

Materials and Methods

Data

A set of 2,378 free-text radiology reports of limb structures was acquired from the Emergency Department of three large Australian public hospitals (adult, children and mixed adult/children). Ethics approval was granted by the Human Research Ethics Committee at Queensland Health to use the non-identifying data. Free-text reports were short in length, containing on average 47 words, and an (unstemmed) vocabulary comprising 4846 unique words. Details of the three datasets are outlined in Table 1. Free-text reports in the GCH dataset were found to be on average consistently shorter than those in the other two datasets: this may indicate differences in reporting style and conventions between the hospital sites.

Free-text reports were manually annotated by an Emergency Medicine Registrar and a Medical Officer as being either: “normal” — the radiography does not exhibit a fracture, dislocation or presence of a foreign body; or
“abnormal” — some fracture, dislocation or foreign body was found.

A software tool was developed to assist clinicians in the recording of their interpretation and to highlight the portion of text in the report that lead to their interpretation.

Initially, assessors agreed on the annotations of 2,215 out of the 2,378 reports. A senior Staff Specialist in Emergency Medicine was then asked to act as third assessor and resolve disagreements. The distribution of normal and abnormal cases across the three datasets is reported in Table 1. The Fleiss’ kappa ($\kappa$) calculated on the initial set of annotations provided by the two first assessors was 0.85, thus exhibiting strong inter-rater reliability.

### Automatic Feature Extraction and Weighting

Machine learning algorithms require documents to be described by features. The text analysis capabilities of the Medtex tool were developed to automatically extract features from the free-text radiology reports. Medtex is a text analysis system that has been previously used for classify cancer-notifiable pathology reports and produce a minimum set of synoptic factors. A wide range of features were initially extracted, including:

- token, i.e., a word found in a report;
- punctuation;
- token stem, i.e., the stemmed version of a word contained in a report;
- token negation, i.e., if a token or phrase was explicitly negated (e.g., “no fracture”); the Medtex implementation of the ConText algorithm was used to identify negations in free-text;
- token stem bi-gram, i.e., a pair of adjacent stemmed words as found in a report;
- token stem tri-gram, i.e., a 3-tuple of adjacent stemmed words contained in a report;
- SNOMED-CT concepts extracted from the text of the report;
  - the fully specified terms of extracted SNOMED-CT concepts restricted to morphologic abnormalities and disorders;
  - SNOMED-CT concept bi-gram, i.e., a pair of adjacent SNOMED-CT concepts as found in a report.

While a number of these features are commonly used for the classification of free-text documents, the use of SNOMED-CT features have not been widely evaluated by previous works on classification of radiology reports. To our knowledge, only Zuccon et al. investigated these features but their evaluation was limited to a small sample of 99 radiology reports. In this work, SNOMED-CT concepts were extracted by annotating the radiology reports with the MetaMap: a natural language processing tool that identifies medical concepts mentions in free-text. The actual feature used in training the classifier was the SNOMED-CT concept ids found my MetaMap. Previous empirical results have shown that SNOMED-CT concepts, in particular those referring to abnormalities (e.g., fracture, dislocation, etc.) and disorders (e.g., fracture of bone, traumatic injury, etc.), provide valuable evidence for representing free-text radiology report data. Table 2 provides an example of feature sets extracted from the free-text of the radiology reports.

Automatic Classification and Evaluation Methodology

To classify radiology reports we used the Weka toolkit API and the corresponding implementation of the Sequential Minimization Optimization (SMO) classifier. The SMO classifier is a support vector machine (SVM) algorithm where training is performed according to the sequential minimal optimisation algorithm and a polynomial kernel is used. The parameters of all classifiers were set to the default values (see Witten et al. for details).

To explore the effectiveness of the machine learning classifier for identifying limb abnormalities we conducted three sets of experiments.

Experiment 1. We combine all three datasets of Table 1 and use the 10-fold cross validation methodology to evaluate the classification algorithms. In this methodology, the dataset is randomly divided into 10 stratified folds of equal dimension (in our case nine folds will contain 238 reports, while the remaining fold will contain only 236 reports). The model for each classifier was then learnt on nine of these folds, leaving one fold out for testing the model. The process was repeated by selecting a new fold for testing, while a new model was learnt from the remaining folds. Classification performances were then averaged across the folds left out in each iteration. The aim of this experiment was to evaluate the effectiveness of a classifier learnt on the whole combination of datasets.

Experiment 2. We consider the reports from each hospital dataset separately. For each dataset, we use the 10-fold cross validation methodology to evaluate the classification algorithms specific to that dataset. Thus, experiments on the larger RBWH dataset are characterised by larger folds than those on the remaining two smaller datasets. The aim of this experiment was to evaluate the effectiveness of classifiers specifically learnt on individual datasets and thus individuate whether a dataset is more challenging than others for automatic classification (and what the possible causes for this are).

Experiment 3. We performed a split train/test evaluation: train on one hospital’s reports and test on another hospital’s reports. This procedure was repeated for all combinations of hospitals and included training on reports from two hospitals and testing on those from another. The aim of this last experiment was to evaluate the robustness of our method across reports from different hospitals.

As a baseline for comparison against our machine learning method, we included a keyword spotting system, which resembled the method by Thomas et al. and Wagholkar et al. A set of regular expressions were defined based on common phrases or terms that identify an abnormality; these were based on discussion with a senior Staff Specialist in Emergency Medicine. (Details of the regular expressions are provided in Appendix.)

Two evaluation measures were considered: precision and recall (also called positive predictive value and sensitivity, respectively). Precision is the fraction of positively classified reports that contain abnormalities, while recall is the fraction of actual abnormalities that were positively classified. In addition, to provide a single, overall evaluation measure, precision and recall are combined into a third evaluation measure, F-measure.

Reconciliation of Radiology Reports with Emergency Room Discharge Diagnosis

Using the methods described here we are able to automatically identify abnormalities from a patient’s radiology report. The benefit of such a method is the ability to reconcile the abnormality classification with the discharge diagnosis from the ER to ensure that an abnormality did not go unrecognised and the patient discharged without proper treatment. To demonstrate the utility of this, we reconciled all the radiology reports used in the classification task with the ER discharge diagnosis ICD-10 code. If the ER discharge diagnosis ICD-10 code matched a predefined set of “abnormal” codes then the patient was marked as abnormal; else they were marked “normal”.* (The full list of ICD-10 codes considered as abnormal was provided by an ER clinician (KC) and is provided in Appendix.) Patients that had a abnormal radiology classification using our automated method but did not have any abnormality related ICD-10 code recorded in the ER discharge diagnosis were flagged as possible misdiagnosis for immediate followup.

*Note that in Australian Emergency Departments ICD-10 codes are used as a diagnostic classification and are not used for billing purposes.

Classification Results and Discussion

The overall classification results (Experiments 1 and 2) are shown in Table 3. F-measure was used as the overall effectiveness measure and the percentage change in F-measure shows the improvement of the machine learning method over the keyword baseline. For all hospital datasets, the SVM method outperformed the keyword baseline in all evaluation settings. This is consistent with previous results. In addition, the keyword baseline had more variance across datasets (lower on RBWH, higher on RCH), whereas the SVM method was more stable across datasets. For the SVM method, both precision and recall were of similar value, indicating that the errors that did occur were a mixture of false positive and false negatives.

Split Dataset Training and Testing

The split training/testing F-measure results (Experiment 3) are shown in Table 4. The first column in the table corresponds to the dataset used in training; the first row corresponds to the dataset the model was tested on; grey shaded cells are the previous cross validation results repeated from Table 3. Comparison with the grey cell cross validation results shows that there was some loss in effectiveness when applying models across datasets (e.g., F-measure of RBWH was 0.89 for cross validation and 0.80–0.81 when trained on other datasets). However, even with some loss in effectiveness, the results indicate that the models were still robust when applied across datasets (certainly compared to the results of the keyword baseline).

Combining datasets for training (e.g., train on GCH+RBWH, test on RCH) showed no significant benefit over using a single dataset to train (e.g., train on RBWH, test on RCH). This result reveals that simply adding more training data
Figure 1: Comparison of similarity between datasets (or itself) and F-measure effectiveness of the classifier. Points with two datasets represents a different train/test combinations RCH/GCH = train on RCH test on GCH), while points with a single dataset (e.g., RCH) are the cross validation results for a single dataset.

does not lead to immediate improvement in effectiveness. Instead, effectiveness was more influenced by the particular dataset used for training. For example, when testing on GCH, it was better to train on RCH than RBWH, even though RBWH was a larger dataset. Based on this finding we set out to understand how similar each of the three datasets were to each other in order to explain the differences in effectiveness in training/testing combinations.

Dataset Similarity and its Effect on Performance

A pairwise similarity calculation was made between the three datasets. This was done by comparing the similarity of every document in one dataset to every other document in another dataset and recording the overall mean similarity. The similarity measure between two individual documents can be calculated by taking the cosine angle between the two documents’ term vectors\[†\] — a standard approach applied in information retrieval when comparing text\[11\]. Note that the average similarity of a dataset to itself (e.g., GCH vs. GCH) can actually be interpreted as a cohesiveness measure: how similar reports in the dataset are to each other. To understand the similarity results in light of the classifier effectiveness we provide a plot of similarity vs. F-measure in Figure 1 and discuss this in further detail below.

We first consider the cohesiveness of each dataset with itself (i.e., single dataset points). The child-only reports of RCH were the most cohesive, while the mixed adult/child reports of GCH were understandably the least cohesive; adult reports from RBWH were in between. The cross validation training on these datasets obtained the best F-measure — obviously it is best to train and test on same dataset. For these three cross-validated datasets, similarity did not correlate with F-measure (e.g., GCH still had a high F-measure but the lowest similarity score).

Comparing across datasets, any combination containing both RCH (children) and GCH (mixed) had the lowest similarity yet produced the best F-measure (and effectiveness was similar for both RCH/GCH and GCH/RCH). In contrast, for the other four dataset combinations that contained RBWH, the F-measure was lower. In addition, there was a large difference in F-measure for swapping the training/test combination, i.e., RBWH/RCH was lower than RCH/RBWH. For all four combinations that involved RBWH, training on RBWH was better than testing on RBWH. An immediate

\[†\]A term vector \(\vec{d}\) for document \(d\) is an \(n\) dimensional vector, where \(n\) is the size of the (stemmed) vocabulary. Each element in \(\vec{d}\) is the TF-IDF weight of a stemmed term from the vocabulary in the document \(d\).
Reconciliation Results and Discussion

The reconciliation process involved checking the classification of a patient’s radiology report with their ICD-10 discharge diagnosis from the ER. Four different ER / Radiology combinations were possible: 1) Emergency Abnormal & Radiology Normal; 2) Emergency Normal & Radiology Abnormal; 3) Both Abnormal; 4) Both Normal. For case 2) (where the patient had a “abnormal” classification from radiology and a “normal” diagnosis from ER) the patient was flagged as a possible missed diagnosis case. The breakdown of these four combinations for each hospital dataset is shown in Figure 2. The majority of patients had no abnormality recorded in both radiology and ER (light green, Both Normal), followed by patients with abnormalities recorded in both radiology and ER (green, Both Abnormal). A small number of cases were found with no abnormality in radiology but an abnormality in ER (orange, ER Abnormal – Radiology Normal); this occurred when the ER clinician suspected a condition but this turned out to be negative from the radiological assessment (and was, therefore, not an area of major concern). Finally, the number of patients flagged (red), out of the total number of patients, were: GCH 16 / 400 (4%), RCH 26 / 498 (5%) and RBWH 232 / 1480 (16%). The number of flagged cases was considerably higher than previous studies on quantifying missed fracture rates\(^1\) (especially for the RBWH dataset). To understand the reason behind this, we performed a manual analysis of all ER Normal – Radiology Abnormal (red) cases, reviewing both the radiology report, discharge diagnosis ICD-10 code and any associated ER notes. (The judgements were primary provided by the clinical author, KC.)

Our manual analysis showed that the ER discharge diagnosis ICD-10 code was often ambiguous — it may have
Table 5: Categories used in the manual review of all flagged cases (i.e., Emergency Normal & Radiology Abnormal).

</tbody>
</table>

covered a fracture diagnosis (and thus an abnormality) but this was not explicit. For example, a patient with a fracture noted in their radiology report was discharged with S57 (Crushing injury of forearm). For this case, the clinician’s judgement was that it was not certain whether the crush injury actually indicated a fracture and therefore whether the ER clinician actually knew a fracture was present. S57 could not be added to the abnormal list as crush injury does not imply a fracture or other limb abnormality as defined here; indeed, there were many patients diagnosed with this code who did not have a fracture finding. Another common case was a discharge diagnoses of “strain or sprain” where an uncertain or very minor fracture was indicated in the radiology reports. For such cases, the ER clinician may have treated the patient (and therefore recorded the diagnosis) as having only a sprain/strain because the fracture was too minor or uncertain. Other flagged cases had a discharge diagnosis completely unrelated to limb injuries; e.g., an ICD-10 code representing self harm or congestive heart failure. To better understand the different flagged cases, all 274 were manually reviewed and assigned one of four categories described in Table 5. Note that all of the categories represent the situation where a limb abnormality (as defined in this work) may have been undiagnosed in ER; however, only the Missed Diagnosis category represents the situation where a limb abnormality was certainly missed.

The distribution of these different flagged categories, for each dataset, is shown in Figure 3. The most common category was a Related Diagnosis (e.g., the crush injury example). (All of the GCH and most of the RCH patients fell into this category.) The RBWH dataset contained a larger portion of both Unrelated Diagnosis and More General Diagnosis. This highlights the differences in the way the ICD-10 codes are assigned at different hospitals and how this might affect the use of these codes (our study being but one example of this). A total of 9 genuine Missed Diagnosis cases were identified in the RBWH dataset; these were either No injury found or Patient did not wait.

Clearly the way ICD-10 codes are assigned affects the reconciliation process, with many flagged cases being the situation where the ER clinician was aware of the abnormality but this fact was not conveyed in the ICD-10 code. However, even given this issue, if the clinician only had to review the 274 flagged cases, this would represent only 11% of the 2,378 reports they previously had to be reviewed — still representing a significant time saving.

Conclusions

We described a set of techniques to identify limb abnormalities from free-text radiology reports. The empirical evaluation showed that these methods are highly effective and that, importantly, they are robust across hospital datasets that are different in both size and similarity. We further show that the automatic classification can be used to reconcile the radiologist’s finding with the ICD-10 discharge diagnosis from the Emergency Room. Using this method, a number of potentially undiagnosed limb abnormalities were identified. A thorough manual analysis of these cases showed that some may be cases where the ICD-10 discharge diagnosis was ambiguous (highlighting the need for accurate ICD-10 coding in ERs); however, some genuine missed diagnoses were uncovered by the automated reconciliation process. Overall, the savings for a clinician were significant with only 11% of the entire dataset now requiring manual review.
Figure 3: Breakdown of different “flagged” cases (radiology abnormal but ER discharge diagnosis normal) according to the four different categories outline in Table 5. (Left plot show the absolute number of cases; the right plot shows the normalised portion of flagged cases.)

As such, the system is part of a pilot study in the Emergency Room of the Royal Brisbane and Women’s Hospital. While the final discharge diagnosis is recorded as an ICD-10 code, the ER clinician may also provide a short description. Although the ICD-10 code may be ambiguous (e.g., crush injury), the clinician’s description can contain an explicit mention of an abnormality. This additional source of information, in combination with the ICD-10 code, could be exploited to provide a better classification of the discharge diagnosis. In fact, similar machine learning techniques to those we have described for classifying free-text radiology reports could be adapted to classifying ER notes\textsuperscript{12}. The development and evaluation of such a method is an immediate area of future work.

Finally, this study has focused specifically on limb abnormalities described in radiology reports; however, the methods are not specific to this situation. Other types of abnormalities (e.g., presence of cancers) are currently being investigated and the methods are also being applied to the detection and reconciliation of different conditions mentioned in pathology reports (e.g., reconciling the antibiotic given to a patient against the antibiotic sensitivities identified in a microbiology report).

Abstract
We propose Latent Class Allocation (LCA) and Discriminative Labeled Latent Dirichlet Allocation (DL-LDA), two novel interpretable probabilistic latent variable models for automatic annotation of clinical text. Both models separate the terms that are highly characteristic of textual fragments annotated with a given set of labels from other non-discriminative terms, but rely on generative processes with different structure of latent variables. LCA directly learns class-specific multinomials, while DL-LDA breaks them down into topics (clusters of semantically related words). Extensive experimental evaluation indicates that the proposed models outperform Naïve Bayes, a standard probabilistic classifier, and Labeled LDA, a state-of-the-art topic model for labeled corpora, on the task of automatic annotation of transcripts of motivational interviews, while the output of the proposed models can be easily interpreted by clinical practitioners.

1. Introduction
Annotation or assignment of codes (labels) from a predefined codebook to fragments (entire documents or their parts) of clinical text is an integral part of medical practice and qualitative research. Such codes can be viewed as semantic labels, or high-level summaries (abstractions) of the raw textual data. Besides cataloging, such abstractions can facilitate the analysis of clinical text in general and clinical interview transcripts in particular. In this work, we focus on the transcripts of motivational interviews with obese adolescents conducted at a Pediatric Prevention Research Center (PPRC).

Childhood and adolescent obesity is a serious public health problem. Recent national data1 indicate that one in four children aged 2-5 years are overweight or obese. The trend of childhood obesity continues into adolescence – as of 2012, 18% of all adolescents and 23.7% of African American adolescents are obese1. Adolescents who are obese are likely to be obese as adults and have a greater risk of heart disease, type 2 diabetes, stroke, cancer, and osteoarthritis2. Therefore, childhood and adolescence are critical periods for healthy eating and physical activity interventions to establish healthy weight gain trajectories. To design such interventions, PPRC clinicians conduct interviews with children and their caregivers grounded in the principles of Motivational Interviewing (MI)3, an evidence-based communication technique to increase intrinsic motivation and self-efficacy for behavior change. Detailed analysis of those interviews aims at identifying clinicians' communication strategies that are effective in triggering patient's motivational statements for the behavioral changes that will ultimately lead to weight loss. Recent literature reviews of mechanisms of effect in MI4 have concluded that clients' motivational statements about their own desire, ability, reasons and need for or commitment to change (or “change talk”) consistently predict actual behavior change5, as long as 34 months later6. Strategies to elicit motivational statements are typically identified via retrospective analysis of past interview transcripts. Part of this analysis involves assignment of codes to patient replies during the interviews. Analyzing sequences of assigned codes allows clinicians to better understand the patient’s thought process during the course of the interviews, without having to wade through entire transcripts over and over again. Such understanding, in turn, leads to further specification of the mechanisms of effect for intervention models, which can then be used to refine theory and guide clinical practice7.

Annotation of interview transcripts has traditionally been performed manually by trained coders, which is a tedious and resource intensive process. Therefore, methods that can efficiently and accurately distinguish the nuances of patient-provider communication can have a tremendous positive impact on many areas of clinical practice and research. Inferring psychological state of the patients during clinical interviews using only lexical content of their transcriptions is a challenging task for several reasons. First, many important indicators of emotions such as gestures, facial expressions and intonations are lost during the transcription process. Second, some utterances from patients during the interview may be too short and lack sufficient context for accurate classification. Furthermore, patients come from a variety of social, cultural, and educational backgrounds and their language is therefore quite
different. This problem is exacerbated when the interviews are conducted with children and adolescents, since children, in general, tend to often use incomplete sentences and frequently change subjects.

Automating the annotation of clinical documents is one of the fundamental problems in medical informatics, which can have tremendous implications for clinical practice. It falls under a general class of classification problems, which are typically addressed using supervised machine learning methods (or classifiers). Given a set of pre-classified data samples (called the training set) represented as a feature vector, in which each feature is the value of a feature function calculated based on a data sample, these methods learn the mapping from feature vectors to their classifications. Once learned, such mapping can be applied to classify new, unlabeled data samples (called the testing set). Classification problems arise in many different domains, from analysis of scientific literature and online reviews to digital forensics and medical informatics. Performance of different classifiers (including Naïve Bayes) on most common text classification tasks has been examined in detail in previous work. However, biomedical context places additional restriction of interpretability on machine learning models, as they are not only required to make correct classification decisions, but to also allow humans to easily understand how they arrived at these decisions. Interpretability of classification models is particularly important for psychological studies, such as Motivational Interviewing, since each class needs to have distinct interpretation (i.e. clearly correspond to a certain communication or behavior type). Furthermore, annotation models for these studies often need to be manually corrected. While the effectiveness of non-interpretable classifiers leveraging external resources, such as concepts from the Unified Medical Language System (UMLS) or clusters derived from a large external corpus, has been previously studied, there is still a need for designing interpretable models for annotating clinical interviews for behavioral studies, which typically contain very limited, domain-specific terminology and thus render general purpose medical lexicons ineffective for this task.

In this work, we focus on the problem of designing an interpretable model for automatic annotation of utterances in clinical interview transcripts with fine-grained semantic class (such as behavior type) and propose two new latent variable probabilistic models, Latent Class Allocation and Discriminative Labeled Latent Dirichlet Allocation as effective solutions to this problem. Both methods model how human annotators approach classification using probabilistic generative process. In particular, during training, they learn to distinguish the vocabularies that are highly indicative of the given classes from the general and non-discriminative terms via probabilistic assignment of latent variables to each term in the training corpus. The learned vocabularies in the form of multinomial distributions (or language models) are used to probabilistically classify new textual fragments and are easily interpretable by clinical practitioners. Although all experiments in this paper were conducted using clinical conversation data, the proposed methods can be applied to annotate any other type of clinical text.

2. Methods

2.1 Classes

As a golden standard for all experiments in this work, we used a sample of obesity Motivational Interview transcripts, in which patient utterances were manually annotated by human coders according to the "Minority Youth Sequential Code for Observing Process Exchanges" (MY-SCOPE) coding manual. Each utterance in the golden standard is labeled with one class. Among others, MY-SCOPE defines the following five classes of patient utterances, which correspond to major target patient behaviors clinicians were focused on when conducting obesity Motivational Interviews:

- **CL-**: negative commitment language;
- **CL+**: positive commitment language;
- **CT-**: negative change talk;
- **CT+**: positive change talk;
- **AMB**: ambivalence.

Commitment language (CL) is statements about patients’ intentions or plans for enacting weight related changes, which are positive, when supportive of behavior change, and negative, when against behavior change. Change talk (CT) corresponds to utterances that describe patients’ own desires, abilities, reasons, and need for adhering to weight loss recommendations and are also positive, when supportive of behavior change, and negative, when against behavior change. Ambivalent utterances (AMB) are change talk or commitment language statements that contain a
combination of positive and negative sentiments about changing one's behavior. Examples of utterances for each class are presented in Table 1.

Table 1. Examples of utterances representing the language and behavior types considered in this work.

<tr>
<td>CL+</td>
<td>Well, I've been trying to lose weight, but it really never goes anywhere.</td>
</tr>
<tr>
<td>CT-</td>
<td>It can be anytime; I just don't feel like I want to eat (before) I'm just not hungry at all.</td>
</tr>
<tr>
<td>CT+</td>
<td>Hmm. I guess I need to lose some weight, but you know, it's not easy.</td>
</tr>
<tr>
<td>AMB</td>
<td>Fried foods are good. But it's not good for your health.</td>
</tr>
</tbody>
</table>

In the following sections, we present the classifiers used for the task of differentiating the above classes and report their performance in terms of standard evaluation metrics.

2.2 Features and baselines

We use standard bag-of-words feature generation framework, in which a predefined set of lexical features (or vocabulary), \( V = \{w_1, ..., w_N\} \), can appear in a given textual fragment. For example, one such feature could be the number of times a word (unigram) "exercise" appears in a given textual fragment. This way each textual fragment \( f \) is represented as a feature vector \( (n_{w_1,f}, ..., n_{w_N,f}) \), where \( n_{w,f} \) is the number of times feature (word) \( w \) occurs in \( f \).

To determine the best classification model for this task, in the following sections, we experimentally compare standard supervised machine learning methods, such as Naive Bayes\(^{13}\) and Labeled Latent Dirichlet Allocation\(^{18}\), with our proposed probabilistic classification models.

2.2.1 Naive Bayes

Naive Bayes (NB) is a standard probabilistic classifier, which annotates a given textual fragment \( f = \{w_1, ..., w_{N_f}\} \), consisting of \( N_f \) words, with a class \( c^* \), such that \( c^* = \arg \max c p(c|f) \), where \( p(c|f) \) is estimated by applying the Bayes' rule as follows:

\[
p(c|f) = \frac{p(f|c)p(c)}{p(f)} \propto p(f|c)p(c)
\]

In order to estimate \( p(f|c) \), Naive Bayes classifier makes an assumption about conditional independence of features given \( c \), the class of fragment \( f \):

\[
p(f|c) = \prod_{i=1}^{N_f} p(w_i|c)^{n_{w_i,f}}
\]

Despite its relative simplicity, NB has been experimentally demonstrated to be one of the most effective text classification algorithms ever created. In this work, we used a standard implementation of Multinomial NB algorithm from the Weka text mining toolkit.

2.3 Probabilistic models

We propose Latent Class Allocation (LCA) and Discriminative Labeled Latent Dirichlet Allocation (DL-LDA), two novel probabilistic generative latent variable models for the task of automatic coding of clinical interview transcripts, and compare their performance with Naive Bayes and Labeled Latent Dirichlet Allocation (L-LDA), a state-of-the-art probabilistic model for labeled data, on the task of annotating utterances in clinical text. LCA associates only one latent variable \( m \) with each word, which determines its type (whether a word is general or characteristic of a certain class). DL-LDA is an extension of L-LDA that makes a different set of assumptions about the structure of latent variables. Rather than directly associating each word with a latent variable determining its topic for a certain class, DL-LDA, similar to LCA, first associates with each word a latent variable, which determines whether a word is general or characteristic of a certain class and, only in the second case, associates it with another latent variable \( z \), determining its class-specific topic. Thus, DL-LDA can be viewed as a more structured version of Labeled LDA.
2.3.1 LCA

LCA models each textual fragment \( f \) labeled with class \( c_f \) as a set of alternating draws from a background multinomial \( \phi^{bg} \) that is drawn from a symmetric Dirichlet prior \( \beta^{bg} \) and a multinomial \( \phi^{cls} \) specific to \( c_f \) that is drawn from a symmetric Dirichlet prior \( \beta^{cls} \). The proportion of words drawn from \( \phi^{bg} \) and \( \phi^{cls} \) is controlled by a binomial distribution \( \lambda_f \). LCA generates annotated textual fragments according to the following probabilistic process:

1. draw \( \lambda_f \sim \text{Beta}(\gamma) \), a binomial distribution controlling the mixture of words in \( f \) drawn from the background and class-specific multinomials
2. for each word position \( i \) of \( N_f \) in \( f \):
   a) draw Bernoulli switching variable \( m_{ki} \sim \lambda_f 
   b) if \( m_{ki} = bg \):
      - draw a word \( w_{ki} \sim \phi^{bg} 
   c) if \( m_{ki} = cls \):
      - draw a word \( w_{ki} \sim \phi^{cls,c_f} 

The generative process of LCA in plate notation is presented in Figure 1a.

![LCA Diagram](image)

**Figure 1. Generative processes of the proposed and baseline latent variable models in plate notation.**

Annotation of textual fragments in the testing set with LCA is done using class-specific multinomials \( \phi^{cls} \) (or \( p(w|c) \)) determined as a result of posterior inference on the training set to derive \( p(c|w) \), distributions showing how indicative each word \( w \) is for each class \( c \):

\[
p(c|w) = \frac{p(w|c)p(c)}{p(w)}
\]

where \( p(c) = \frac{n_{fc}}{M} \) (\( n_{fc} \) is the number of interview fragments labeled with class \( c \) and \( M \) is the total number of fragments) and \( p(w) \) is a probability of word \( w \) in a collection language model estimated using maximum likelihood.

\( p(c|w) \) are then used to classify \( f \) according to the following formula:

\[
c^* = \arg \max_c p(c|f) = \prod_{i=1}^{N_f} p(c|w_i)^{n_{wi,f}}
\]

2.3.3 L-LDA

L-LDA directly associates a latent variable \( z \) with each word that determines its assignment to a topic specific to \( c_f \). It is state-of-the-art topic model for labeled textual collections that has been shown to outperform standard classifiers, such as SVM, for the task of multi-class classification\(^{18}\). The generative process of L-LDA in plate notation is presented in Figure 1b. L-LDA along with NB is used as a baseline in our experimental evaluation.
2.3.2 DL-LDA

DL-LDA models each textual fragment \( f \) labeled with class \( c_f \) as a mixture of the background topic \( \phi^{bg} \) drawn from a symmetric Dirichlet prior \( \beta^{bg} \) and \( K^{cls} \) topics drawn from a uniform Dirichlet prior \( \beta^{cls} \). DL-LDA generates the textual fragments in clinical interviews according to the following probabilistic process:

1. draw \( \lambda_f \sim \text{Beta}(\gamma) \), a binomial distribution controlling the mixture of background and class-specific topics for \( f \)
2. draw \( \Theta_f^{cls} \sim \text{Dir}(\alpha^{cls}) \), a distribution of class-specific topics for \( f \)
3. for each word position \( i \) of \( N_f \) in \( f \):
   (a) draw Bernoulli switching variable \( m_{ki} \sim \lambda_f 
   (b) if \( m_{ki} = \text{bg} \):
      - draw a word \( w_{ki} \sim \phi^{bg} 
   (c) if \( m_{ki} = \text{cls} \):
      - draw a topic \( z_{ki} \sim \Theta_f^{cls} 
      - draw a word \( w_{ki} \sim \phi^{cls, cf} 

The generative process of DL-LDA in plate notation is presented in Figure 1c. Classification using DL-LDA is performed by first deriving a class-specific multinomial \( p(w|c) \) per each class \( c \) from class-specific topics \( \phi^{cls, cf} \) (or \( p(w|c, z) \)) by marginalizing over \( z \):

\[
p(w|c) = \sum_{z=1}^{K^{cls}} p(w|c_i, z)
\]

and then using class-specific multinomials to directly classify \( f \), similar to LCA.

We would like to note that the inference algorithm for LCA, L-LDA and DL-LDA is adaptable to distributed environment and therefore the proposed methods can be scaled up to very large datasets\(^{19,20}\).

3. Results

The dataset used for experiments in this work consists of 2966 manually annotated fragments of interview transcripts. The distribution of the number of samples per each class is shown in Table 2.

The dataset was first pre-processed by removing very frequently occurring terms (that occur in more than 25% of textual fragments). We also used the following pre-processing methods to study their effect on classification performance:

- **RAW**: no preprocessing, original dataset is used;
- **STEM**: Porter stemmer is applied to each term in the dataset to eliminate morphological variation;
- **STOP**: stopwords are removed, but stemming is not applied;
- **STOP-STEM**: Porter stemmer is applied to each term in the dataset and stopwords are removed.

For all experiments we used randomized 5-fold cross-validation. The Gibbs sampler for posterior inference of parameters of LCA, L-LDA and DL-LDA was run for 1000 iterations. Classification performance of NB, L-LDA, LCA and DL-LDA on the task of differentiating 5 language categories when experimental dataset is pre-processed with different methods is summarized in Tables 3, 4, 5 and 6, respectively.

Since classification accuracy of DL-LDA is dependent on the number of per-class topics, which is a parameter that needs to be specified a priori, we first optimized it with respect to F1 score. Figure 2 indicates that the optimal classification results for DL-LDA in combination with different pre-processing methods are achieved when the number of topics is small (2 or 3 in most cases).

![Figure 2. F1 score of DL-LDA by varying the number of topics and in combination with different pre-processing methods on the task of classification of all language categories.](image)

The best results for each proposed model and the baselines are summarized and compared in Table 7, while the per-class breakdown of the best results for all models is provided in Table 8.

In the second set of experiments, we aggregated the interview fragments labeled as positive and negative commitment language (CL+ and CL-) and change talk (CT+ and CT-) into one combined class for commitment language (CL) and one combined class for change talk (CT), respectively, and evaluated the accuracy of our classifiers in distinguishing the interview fragments labeled with the resulting three broader classes.

Distribution of samples across these three classes is shown in Table 9. For this task we used raw data for each classifier (no preprocessing). We optimized the number of topics for DL-LDA with respect to the F1 score (Figure 3) and found out that again the optimal number of topics is 3. Performance of different classifiers on the task of differentiating the interview fragments labeled with CL, CT and AMB is summarized in Table 10. In the third set of experiments, we aggregated the interview fragments labeled as positive sub-classes of commitment language (CL+) and change talk (CT+) into one combined positive class (+) and negative sub-classes of commitment language (CL-) and change talk (CT-) into one combined negative class (-) and evaluated the accuracy of our classifiers in distinguishing the interview fragments labeled with the resulting sentiment modality-based broader classes.

</table>

Distribution of samples across these three classes in shown in Table 11. Similarly to the task of differentiating CT, CL and AMB, we tuned DL-LDA with respect to F1 score (Figure 5) and found out that this time the optimal number of per-class topics is 5.

Figure 5. F1 score of DL-LDA by varying the number of topics on the task of classification of aggregated positive and negative sub-classes across CL and CT.

Performance of different classifiers on the task of differentiating the utterances labeled with +, - and AMB is summarized in Table 12.

4. Discussion

Several important observations can be made from Tables 3, 4, 5 and 6. First, stemming and stopwords removal
degrade classification performance of DL-LDA, which performs best without any pre-processing, while Naïve Bayes, LCA and L-LDA achieve the best classification performance when stemming is applied.

</tbody>
</table>

However, for all 4 classifiers used in this work stopwords removal by itself and in combination with stemming decreases the accuracy of classification, which suggests that common stopwords might be important indicators for some of the language categories. Second, as follows from Table 7, LCA and DL-LDA outperform both baselines (NB and L-LDA) in terms of all three performance measures (Recall, Precision and F1 score). Across all models, DL-LDA achieves the best performance in terms of Recall, while LCA achieves the best performance in terms of both Precision and F1 score. As follows from Table 8, LCA and DL-LDA also achieve the best per-class performance for 4 out of 5 classes. These results lead to two important conclusions. First, explicitly accounting for discriminativity of terms (general or class-specific) in an utterance with a latent variable allows to improve annotation performance using probabilistic methods. Second, additional division of class-specific multinomials into class-specific topics by DL-LDA allows to improve recall, but not precision and F1 score.

Results of classifying language types without taking into account modality (Table 10) indicate that LCA is particularly suited for this task and again support our assumption about the utility of differentiating the terms by their discriminativity. LCA and DL-LDA use the strength of statistical associations of terms with the class labels as a measure of their discriminativity. Since non-discriminative words are the ones that occur in many fragments labeled with different classes, statistical associations of these terms with class labels are relatively weak, which is effectively captured by LCA and DL-LDA.

Table 13. Most characteristic words for each utterance label according to LCA.

<table>
<thead>
<tr>
<th>Class</th>
<th>Words</th>
</tr>
</thead>
<tbody>
<tr>
<td>CL-</td>
<td>drink sugar gatorade lot hungry splenda beef tired watch tv steroids sleep home nervous confused starving appetite asleep craving pop fries computer</td>

<td>stop run love tackle vegetables efforts juice swim play walk salad fruit</td>
</tr>
<tr>
<td>CT-</td>
<td>got laughs sleep wait answer never tired splenda fault phone joke weird hard don’t</td>
</tr>
<tr>
<td>CT+</td>
<td>time go mom brother want happy clock boy can move library need adopted reduce sorry solve overcoming lose</td>
</tr>
<tr>
<td>AMB</td>
<td>what taco mmm know say plus snow pain weather</td>
</tr>
</tbody>
</table>

Results of classifying modality (Table 12) indicate that DL-LDA is the best in detecting the attitude of the speaker. This can be explained by the fact that only a portion of vocabularies indicative of specific classes reflect the sentiment modality of an utterance, therefore splitting class-specific multinomials into class-specific topics by DL-LDA allows to isolate the sentiment-specific vocabularies and leverage them during classification.
Examples of the most characteristic terms for each utterance label determined by LCA are provided in Table 13. As follows from Table 13, negative commitment language is strongly associated with the words reflecting poor diet ("sugar", "pop", "fries") and sedentary lifestyle ("watch", "tv", "computer"), while positive commitment language is strongly associated with the terms related to exercise ("walk", "play", "run") and healthy food options ("salad", "vegetables", "fruit"). The words characteristic of CT- and CT+ generally reflect negative ("don’t", "never", "tired") and positive ("can", "need", "lose", "happy") attitudes towards weight loss, respectively.

5. Conclusion

In this paper, we proposed Latent Class Allocation, a novel interpretable probabilistic model for supervised text classification, and Discriminative Labeled LDA, an extension of Labeled LDA, that differentiates between class-specific and general terms. Through extensive experimental evaluation, we demonstrated that the proposed models have consistently better performance for the task of single class annotation of fragments of Motivational Interviewing transcripts than state-of-the-art methods, such as Naive Bayes and Labeled LDA.

Representation of Functional Status Concepts from Clinical Documents and Social Media Sources by Standard Terminologies

Abstract

Patient-reported functional status is widely recognized as an important patient-centered outcome that adds value to medical care, research, and quality improvement. Functional status outcomes are, however, not routinely or uniformly collected in the medical record, except in certain small patient populations (e.g., geriatrics, nursing home residents). To utilize patient reported functional status for clinical research and practice, we manually collected 2,763 terms from clinical records and social media sites and modeled them on the widely used Short Form-36 Health Survey. We then examined the coverage of the Unified Medical Language System (UMLS) for these functional status terms through automated mapping. Most terms (85.9%) did not have exact matches in the UMLS. The partial matches were prevalent, however, they typically did not capture the terms’ exact semantics. Our study suggests that there is a need to extend existing standard terminologies to incorporate functional status terms used by patients and clinicians.

Introduction

Patient reported functional status is widely recognized as an important patient-centered outcome that adds value to medical care, research, and quality improvement. For instance, during the late 1980s researchers observed that patients’ functional status was correlated to their compliance with antihypertensive treatment, even when treatment led to successful blood pressure control. Reduction in functional status is frequently the first sign of declining health for patients with chronic conditions and is related to the severity of acute illness and intensity of resource use. Functional status is a prognostic predictor of future risk of hospitalization readmission, morbidity and mortality. Functional status information is central to many healthcare decisions, including end-of-life care, living arrangements, and patient-tailored treatment. Some experts assert that functional status should be included as the “sixth vital sign”.

In the context of atrial fibrillation and heart failure, alteration to functional status is one of the most commonly reported symptoms, including reductions in exercise tolerance of 15-20% among patients diagnosed with atrial fibrillation. Measurement of functional status can help to inform diagnosis, prognosis, and can guide care/treatment strategies related to these conditions, in addition to facilitating examinations of treatment response.

While instruments such as the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36) have been developed to capture patient reported functional status, functional status is not routinely or uniformly collected in the medical record. At the same time, clinical records as well as social media data do contain a large number of descriptions of patient functional status.

There has been much interest in and effort toward development of methods to extract functional status terms, using existing frameworks, such as the International Classification of Functioning, Disability and Health (ICF), especially for healthcare delivery for nursing home and rehabilitation patients. The ICF was introduced 2001 by the World Health Organization as “a unified and standard language and framework for the description of health and health-related states”. This standard terminology is currently included in the Unified Medical Language System (UMLS), a compendium of over 100 national and international vocabularies and classifications.

As these and other standard terminologies have been developed, it is important to update findings related to their coverage of functional status concepts. Also, since prior work on functional status concepts has been limited to the rheumatology care setting, there is a need to extend these findings to other settings including other medical care settings and consumer health.
In this study, we specifically examined functional status documented in the electronic medical record (EMR) and social media for patients with cardiovascular diagnoses such as atrial fibrillation. The terms were categorized and mapped to standard clinical terminologies. We also analyzed the causes of non-matches and partial matches.

Methods

Data Collection

We defined functional status terms as a span of text that expresses an idea or description corresponding to functional status. To collect functional status terms, we used clinical records and social media, both of which have been increasingly utilized by biomedical researchers. In social media, patients voluntarily describe functional status in their own terms. In the EMR, patient reports are often paraphrased and sometimes clinicians document functional status using a variety of instruments.

EMR data were obtained from the Veterans Administration Informatics and Computing Infrastructure (VINCI) database\(^1\). The Institutional Review Board approved the use of electronic medical data from VINCI and no human subjects were contacted for this study. We randomly selected a set of 800 clinical documents of patients who were diagnosed with atrial fibrillation or atrial flutter for review. Clinical documents were free text documents or progress notes such as cardiology visit notes, primary care nursing/physician notes, telephone encounter notes, palliative/geriatric medicine notes, and discharge summaries. Generally, these clinical documents do not use standardized terminologies to convey information regarding functional status.

Social media data were obtained from three different online discussion forums for cardiovascular diseases and atrial fibrillation. These sources were: (1) Atrial Fibrillation Support Group on dailystrength.org, (2) Heart & Cardiovascular Disease forum on healingwell.com, and (3) Cardiovascular Disease Prevention Expert Forum on medhelp.org. Questions, replies and comments posted by patients were extracted from the discussion forums using Web Scraper, a Chrome browser extension used for extraction of data from web pages. From the extracted content, 150 latest posts from source 1 and 100 latest posts each from source 2 and source 3 were chosen.

For both datasets, one investigator then manually reviewed clinical documents or posts containing word/phrases that indicated functional status of the patient according to the SF-36 Health Survey, with the intent to identify all potential candidate terms. Then a second investigator reviewed all the extracted terms. When a consensus could not be reached, a third adjudicator was included in the extraction of functional status terms.

We excluded duplicate words/phrases and lists of unique functional status terms from VINCI and social media data sources were created. For the VINCI data, we collected 1,050 functional status terms and removed duplicate terms. A total of 974 unique terms were mapped to UMLS. For the social media data, a total of 1,623 functional status terms were extracted out of which 980 terms were unique.

Classification of Functional Status Terms Based on SF-36 Health Survey Scales

To understand the types functional status terms being used in medical records and social media, we categorized them according to the SF-36 Health Survey scales. The SF-36 Health Survey includes eight scales: Physical Functioning, Role-Physical, Bodily Pain, General Health, Vitality, Social Functioning, Role-Emotional and Mental Health (http://www.sf-35.org/tools/SF36.shtml). Scores for each of these scales are determined by all but one (self-reported health transition) of the 36 items of the SF-36 Measurement Model. There are two summary measures of the SF-36 Health Survey that the eight scales aggregate to. The Physical Health summary measure includes Physical Functioning, Role-Physical, Bodily Pain, and General Health. The Mental Health summary measure includes Vitality, Social Functioning, Role-Emotional, and Mental Health.

Using the 35 items listed for the eight scales as a reference, three investigators jointly reviewed a subset of VINCI and social media terms to develop a classification guideline for assigning each term to one of the eight SF-36 Health Survey scales. The three investigators divided the remaining terms (two investigators reviewed the VINCI terms and one reviewed the social media terms) to independently review and assign them to one of the eight SF-36 Health Survey scales and based on the classification guideline.
Classification of Type of Match by Standard Terminologies

For the purpose of mapping functional status terms to the UMLS Metathesaurus, we used the MetaMap system developed by the National Library of Medicine (NLM)\(^\text{18}\). Unique functional status terms from VINC1 and social media were parsed using MetaMap to determine the corresponding concepts in UMLS. The parsed terms, mapped concepts (along with concept unique identifiers [CUI]) and respective UMLS source vocabularies were recorded. Three investigators divided the functional status terms to independently review and categorize them as one of three types of matches: a 'complete match', a 'partial match', or a 'no match'. Terms where the entire word/phrase mapped to a single concept in UMLS were categorized as 'complete match'. Compound terms consisting of two or more words where only a few words mapped to UMLS concepts were categorized as 'partial match'. For example a ‘partial match’ could include “jogging (6 mph)”, where “jogging” mapped to the UMLS but the qualifier “(6 mph)” did not map. Terms that did not map to any UMLS concepts were categorized as 'no match', an example of a term that did not map to any UMLS concepts was “debilitated”. We further assessed whether complete matches were correct or incorrect. We defined complete incorrect matches as terms where the entire word/phrase mapped to a single concept in UMLS and did not capture the correct semantic meaning. An example of a complete incorrect match would be the term “fine”, where the incorrect semantic meaning would be a financial fine versus feeling fine.

Review of Classifications

Once all of the functional status terms were manually assigned to one of the eight SF-36 Health Survey scales and were categorized as a complete-, partial-, or no-match, the three investigators exchanged lists of classified terms to reach a consensus on the final SF-36 Health Survey scale assignment and type of match for each term. Where there was a disagreement between two investigators, the final assignment was reached by including a third adjudicator.

Data Analysis

We examined the overlap of functional status terms and matched concepts across the two sources (i.e. VINC1 or social media). For each source of functional status terms we examined the frequency distributions of functional status terms across SF-36 Health Survey scales. Percentages of partially matched terms, completely matched terms and terms that yielded no match under each of the SF-36 Health Survey scale were determined. We also calculated the percent coverage of functional status concepts by various vocabulary sources of the UMLS Metathesaurus.

Results

Description of Functional Status Concepts in VHA and Social Media Sources

Overall, there was an overlap of 14 terms (exact term match) across both functional status term sources (i.e. VINC1 and social media data). The overlap between mapped UMLS concepts from VINC1 and social media data was much larger - 44.7% (or \(n = 378\) concepts) of the mapped concepts from social media data were also found in VINC1 data.

The most common SF-36 Health Survey scales that the extracted 974 VHA terms were classified to were Physical Functioning (37.9%), Role-Physical (23.9%), and Mental Health (16.3%), Figure 1a. The top three SF-36 Health Survey scales for the social media terms were Physical Functioning (31.9%), Mental Health (23.5%), and Role-Physical (13.5%), Figure 1b. Fewer than 2.0% of terms were classified to Role-Emotional or Social Functioning scales, regardless of source of functional status term.

Abbreviations: VINCI, Veterans Affairs Informatics and Computing Infrastructure; BP, Bodily Pain; GH, General Health; MH, Mental Health; PF, Physical Functioning; RE, Role-Emotional; SF, Social Functioning; VT, Vitality

Coverage of Functional Status Concepts by Standard Terminologies

The comparison of the number of functional status terms that fell into ‘complete match’, ‘no match’ and ‘partial match’ categories in VINCI and social media data is shown in Figure 1 and Table 1. Overall, 14.1% of functional status terms were completely matched and 83.2% were partially matched to UMLS. Social media data contained a larger number of ‘complete match’ and ‘no match’ terms when compared to VINCI data. Most complete matches were in the Mental Health scale SF-36 Health Survey regardless of source of functional status term (Figure 1). Most match failures (‘partial-‘ and ‘no-match’ combined) corresponded to the Physical Functioning SF-36 Health Survey scale, regardless of data source.

The UMLS Metathesaurus is made up of more than 100 national and international source vocabularies and classifications. A concept can be found in one or multiple vocabularies. Mapped concepts from VINCI and social media data were spread across 43 different source vocabularies in UMLS. Table 2 lists the top 10 source vocabularies with the most mapped concepts. The top four vocabularies that had the most coverage were MTH, SNOMEDCT_US, National Cancer Institute (NCI) and Consumer Health Vocabulary (CHV) for both VINCI and social media data. Combination of these four vocabularies covered 96.2% of the mapped concepts from VINCI data and 97.3% of the mapped concepts from social media data.

Some functional status terms from VINCI and social media data yielded complete matches, most of which were correctly matched. There were 123 complete matched terms from VINCI out of which 120 were correctly mapped and were found in 26 UMLS source vocabularies. Social media data had 153 complete matches out of which 141 mapped to correct concepts. These concepts were found in 24 different vocabulary sources of the UMLS Metathesaurus. Percentages of coverage of completely matched correct concepts by 10 source vocabularies that had maximum coverage for VINCI data and social media data are reported in Table 2b. SNOMEDCT_US, MTH, CHV and MSH were the top 4 source vocabularies with respect to coverage of completely matched terms that were mapped to correct concepts for both VINCI data and social media data. Combination of these top 4 source vocabularies contained 96.7% and 93.61% of the correctly mapped concepts from VINCI data and social media data, respectively.

</table>
Most of the partial matches did not capture the exact semantics of the terms. We did not attempt to assess the correctness of the partial matches because frequently, a part that matched could be considered to be correct while another part could not. For instance, for the term “back to normal” the term “back” mapped to a number of concepts none of which were correct and the term “normal” mapped to the concept “Normal” which was correct. Together, they also failed to represent the complete semantic meaning.

We explored reasons for failures for a subset of non-matches and partial matches, these examples are presented in Table 4.

Discussion

With the goal of utilizing patient-reported functional status in research and clinical practice, we collected and analyzed 1,954 unique functional status terms extracted from VINCI EMR data among patients diagnosed with atrial fibrillation or atrial flutter and from social media posts of three cardiovascular disease-related online discussion forums. Overlap of the exact term across the two sources of functional status terms (i.e. EMR clinical documents containing free text data or social media posts) was small although, further examination of the overlap of mapped
UMLS functional status concepts across sources was much larger. The most common types of terms according the eight scales of the SF-36 Health Survey were Physical Functioning (34.9% of all terms) and Mental Health (20% of all terms). The least common types of terms were Role-Emotional (<0.1% of all terms) and Social Functioning (1.0% of all terms).

Overall, the coverage of functional status terms by current standard clinical terminologies was low: only 12.6% of terms extracted from VHA and 15.6% of terms extracted from social media were completely mapped to UMLS concept names. Some complete matches were not correct. Examples include the term “work out” (as in exercise) was mapped to “Unemployment” and the term “cardio” (again, as in exercise) was mapped to “Heart”. Partial matches can be found for most of the remaining terms. They, however, do not reflect the complete semantic meaning of the terms. In many cases, they do not capture the core semantic meaning either. Natural Language Processing (NLP) frequently uses standards for automated data retrieval and there is a need for mapping functional status descriptions to standard terminologies. Although standard terminologies may contain many of the important and useful concepts related to functional status, our study suggests that the use of NLP for functional status data extraction requires mapping ontologies to more descriptive terms and concepts such as the ones we identified.

While the percent coverage of functional status terms by standard clinical terminologies was similar comparing VINCI EMR to social media sources, there was a lack of overlap in the terms used across sources. This lack of exact overlap of terms between the VINCI EMR and social media online discussion forums reflects the differences in the context and purpose of the writing as well as their authors. Aside from paraphrasing patients’ reported functional status (e.g. “ambulate with assistance”) about their activities, EMRs tend to use medical language as well as templates for functional assessment instruments (e.g. Activities of Daily Living (ADLs), Functional Independence Measure (FIM)). Patients who describe their functional status on a social media website may tend to use their own language which can be more informal, erratic, expressive or ambiguous. It is worth noting that the mapping rates of the two sources are fairly similar. In other words, in this domain, the standard vocabularies represent neither the clinician nor the patient terminology well. In addition, no single vocabulary stood out as a particularly good source for functional status terms. The mapped terms were spread across a number of different terminologies.

We found several reasons for failures for the subset of non-matches and partial matches that we investigated (Table 4). While some concepts did not exist in the UMLS, many more failed to match completely due to use of a colloquial term, no match for a qualifier/modifier or too many descriptive terms. In the VINCI data some terms failed to match due to use of templates. For the social media data some terms were not completely matched due to use of metaphors.

Increasingly, researchers are examining standard terminologies in terms of their support of interoperability and coverage of concepts existing in the biomedical domain. For instance, Bodenreider et al. evaluated coverage by the UMLS for bioinformatics concepts from LocusLink and the Gene Ontology database. Others, including Frost et al. are developing sophisticated methods such as the Markov Chain Ontology Analysis to improve analytical applications for biomedical ontologies such as enrichment analysis, which quantifies the importance of ontology classes relative to a dataset.

However, to the best of our knowledge, we are aware of only one other study by Ruggieri et al. that examined the representation by standard terminologies of functional status concepts. The authors of this study found that the UMLS was superior to SNOMED-RT in matching functional status concepts from the Clinical Health Assessment Questionnaire (CLINHAQ) and the Modified Health Assessment Questionnaire (MHAQ). The CLINHAQ and MHAQ questionnaires are used to evaluate functional status of patients diagnosed with rheumatoid arthritis. Consistent with our study Ruggieri et al. reported that neither terminology had complete coverage of functional status terms and SNOMED-RT coverage was especially poor for concepts in the “activities” semantic class (terms found in the Physical Function and Role-Physical scales in our study).

There are a number of ongoing efforts to standardize functional status terminologies in industry. For example, standard representation of functional status has been actively studied in health information exchange and quality measures. Various groups including the Office of National Coordinator of Health Information Technology (ONC), Centers for Medicare and Medicaid Services (CMS) and Integrating the Healthcare Enterprise (IHE) are proposing functional status standards. The Consolidated-Clinical Document Architecture (C-CDA) specification defined the functional status section and specified vocabulary constraints for different types of functional status.
There has been increasing interest in automated extraction of functional status based on patient notes, including the use of the ICF standard terminology. One preliminary study, for example, used the ICF to extend an existing NLP system to encode functional status information noted in patient rehabilitation summaries. In our study ICF was among the UMLS terminologies that were examined. The coverage of functional status terms by ICF was low, 1.9% for the VINCI data and 4.1% for social media data. We note that terms in the ICF are generally noun phrases, however as Ruggieri et al. observed with functional-status language in questionnaires, we found that functional status information was mainly expressed with verbal phrases or sentences and included fewer medical terms. This may partly account for the low coverage.

One limitation of our study is that we focused on data from patients with atrial fibrillation or other cardiovascular diseases. Focusing on these patients may have limited the number of terms assigned to the Role-Emotional and Social Functioning SF-36 Health Survey scales. Future studies are needed to extend the research of functional status representation for other clinical domains. A second limitation is that we reviewed documents for a limited number of patients.

To address the gap in vocabulary coverage, we plan to update the Consumer Health Vocabulary (CHV), which is a UMLS source vocabulary developed by our research group, with terms identified in this study. Other possibilities include creating an ontology to represent the variety of functional status concepts and exploring the use of post-coordination. In anticipation of these efforts, one of the challenges we will face is to correctly map or link the terms, which are subjective by nature, to existing medical concepts. For example, it is not clear whether terms like “can’t get out of bed” or “feels like I’m going to die” refer to a physical or mental issue. At the same time they do indicate that the patients are not functioning well.

Conclusions

Individuals describe their physical status in a much more diverse way than current standard vocabularies capture. We collected a large number (2,763) of patient-reported functional status terms from both clinician and consumer sources of data, including terms from social media. With the increasing emphasis on patient-reported outcomes and the application of automated data retrieval methods, it is important to capture both patients’ own reports as well as those rephrased by clinicians. We further examined the coverage by current standard terminologies of functional status terms extracted from the VINCI EMR and social media data sources, sources that to our knowledge have not been previously examined. Overall, we found that standard terminologies do not sufficiently provide coverage of patient-reported functional status, and could be enhanced by studying these existing textual sources from clinicians and patients.

Reproducing a Prospective Clinical Study as a Computational Retrospective Study in MIMIC-II

Fabício S. P. Kury, MD, Vojtech Huser, MD, PhD, James J. Cimino, MD
National Library of Medicine, Bethesda, MD, United States

Abstract
In this paper we sought to reproduce, as a computational retrospective study in an EHR database (MIMIC-II), a recent large prospective clinical study: the 2013 publication, by the Japanese Association for Acute Medicine (JAAM), about disseminated intravascular coagulation, in the journal Critical Care (PMID: 23787004). We designed in SQL and Java a set of electronic phenotypes that reproduced the study’s data sampling, and used R to perform the same statistical inference procedures. All produced source code is available online at https://github.com/fablury/paamia2015. Our program identified 2,257 eligible patients in MIMIC-II, and the results remarkably agreed with the prospective study. A minority of the needed data elements was not found in MIMIC-II, and statistically significant inferences were possible in the majority of the cases.

Introduction and objectives
The presently widening scale of production and sharing of electronic health records (EHRs) [2] increases the interest on possible secondary uses for them. In this paper, we approached one publicly available dataset of electronic health records – the MIMIC-II database [3], version 2.6 – and applied one possible study design, namely, a computational retrospective study [4].

The central objective of our retrospective study was to demonstrate how MIMIC-II could be used to reproduce, and thereby validate, a contemporary prospective clinical study. The chosen prospective clinical study was by Gando et al., for the Japanese Association for Acute Medicine (JAAM) Sepsis Registry Study Group, published in 2013 in the journal Critical Care Medicine [1], hereafter referred to as the reference study. The objective of the reference study was to validate the prognostic value of the JAAM scoring system for diagnosis of disseminated intravascular coagulation (DIC). It was performed in Japan, from June 1, 2010 to May 31, 2011, and largely succeeded in demonstrating, among other things, that the higher the JAAM DIC score of the patient on day 1 of diagnosis of severe sepsis, the higher the mortality and morbidity. Therefore, our central objective was to reproduce the reference study in the MIMIC-II data, as an inexpensive computational, retrospective, observational study.

Scoring systems for disseminated intravascular coagulation
Disseminated intravascular coagulation (DIC) is a health condition characterized by the intravascular activation of the coagulation cascade [5] that is secondary to a range of disparate causes such as sepsis, pancreatitis, malignancy, heat stroke, and others. Prospective clinical studies have demonstrated that the development of DIC in patients with sepsis or severe trauma roughly doubles the risk of death, and is an independent predictor or mortality [7]. While its treatment hallmark remains to treat the provoking cause, there is interest in improving the identification of poor prognosis in DIC patients so that a more intensive or specialized therapy can be started earlier [8] or later [16] in the progression of the disease. The definition of DIC itself is not free from debate, and four scoring systems for the diagnosis of this condition have been published in the clinical literature by four institutions [5]. In this paper, we, intentionally replicating the reference study, applied and compared the one created and revised by the Japanese Association for Acute Medicine, and the one by the International Society of Thrombosis and Hemostasis (ISTH) (Table 1). Of note, our source code, available online [9], presently allows the computation of these two scoring systems as well as the other two (KSTH and JMHLW), which are outside the scope of the present study.

Reproducible research
To increase transparency and to allow re-execution of our analysis on other datasets, we voluntarily sought to adhere to the criteria for reproducible research as accepted by the journal Biostatistics [10]. Therefore, we offer the complete source code produced for this paper free online [9], while remarking that all data we used – MIMIC-II v. 2.6 – is publicly available for research, for free, via its own regulations. [3] We welcome critical review, correspondence and contributions to our work.

Methods
The reference study specified a list of data elements that were collected from patients in days 1 and 4 of diagnosis of severe sepsis, including the calculated JAAM and ISTH scores for DIC, and then used that data for statistical analysis. Our retrospective study had to therefore emulate these procedures in MIMIC-II as closely as possible. We used the Java and R languages because of our expertise with them and their free availability. The process is described below.

A. Data retrieval
We analyzed the reference study for its data sampling procedures and definitions, which Gando et al. dutifully report in the Data Sampling section of their paper, and manually listed all conceptual data elements it produced from each eligible patient (Table 2). Each item in that list would become the header of a column in a table called Clinical Data Table.

For knowing or calculating the value of those conceptual data elements, we knew, from their definitions, that we needed a much larger list of raw data elements. For example, for calculating the JAAM DIC score (a conceptual data element) it is necessary to know raw data elements from the patient such as platelet count, fibrinogen level, prothrombin time, and others. We manually produced a list of all those raw data elements needed, and then searched for the MIMIC-II-specific code(s) (ITEMIDs) for each. We did those searches inside MIMIC-II itself using SQL queries, and on the documentation of the database [11]. Table 3 brings examples of those raw data elements.

B. Electronic phenotyping
We used Java to reproduce the reference study’s inclusion criteria and data sampling procedures. Our program screened all hospital admissions of non-neonates in the database, and read the results of the laboratory tests and charted data in chronological order. For each case where the patient met the eligibility criteria, the program created one row in the Clinical Data Table, as defined in section A, and populated it with the required study data elements. In cases where MIMIC-II did not contain the required input data at the required point in time, which are common in retrospective studies [4], the Java program generated “Not Available” (NA) as output. The program eventually produced a CSV file that was imported into R for subsequent statistical analysis.

C. Statistical analysis
The reference study provided clear descriptions of the statistical analyses, which were reproduced using R. Groups were compared using Welch’s t-tests for data with unequal variances and Mann–Whitney U tests for data with equal variances. Effect of independent variables predicting mortality was calculated by stepwise logistic regression. For comparing patient survival, we simply counted how many patients were alive at the end of the follow-up period.

Results

A. Data retrieval

We identified 15 data elements produced by the Data Sampling methodology of the reference study, listed in Table 2. A few of them could potentially be derived from others, but were kept separate for simplicity. In order to produce all of them for each patient, we identified 49 raw data elements from MIMIC-II. Most of the raw data elements were MIMIC-II-specific ITEMIDs of charted data such as laboratory test results, but others were demographic or related to workflow such as patient age, gender, hospital admission date and date of death if it happened. Table 3 shows examples of raw data elements; the complete list can be found online together with this paper’s accompanying source code.

B. Electronic phenotyping

The eligibility criteria of our reference study consisted of the presence of diagnosis of severe sepsis [1]. Although not specified in the paper, we assumed as an additional, implied eligibility criterion that the patient be not a neonate. We based this assumption on the expectation that neonatal patients would have been mentioned in the reference study if they were included, since the usual setting in hospitals is to have separate ICUs for neonates and for non-
neonates. In MIMIC-II, a specialized variable — ICUSTAY_AGE_GROUP — informs you whether the patient is an “adult”, “neonate”, or “middle”. The eligibility criteria of our retrospective study consisted thus of the patient not being labeled “neonate”, and a diagnosis of severe sepsis be established.

Table 4 shows the definitions we used for identifying Systemic Inflammatory Response Syndrome (SIRS), sepsis, severe sepsis and organ failure from raw clinical data elements such as white blood cell count, partial pressure of carbon dioxide in arterial blood, urinary output in the last 24 hours, and others. They derive from the original definitions used in the reference study [13][14]. We translated our definitions into algorithms in Java that read each data element and compared it to its threshold(s) (e.g. Temperature < 36 C or >38.3C = one SIRS criteria).

**Sepsis**: SIRS + known or documented infection.

- Hospital admission must contain ICD-9 code for sepsis or septicemia.

**Severe sepsis**: Sepsis + organ dysfunction.

- Overall SOFA score ≥ 3.

Due to unavailability of ready means to know, from the data available in MIMIC-II, the moment when a patient first had a known or documented infection, which is a requirement for establishing a diagnosis of sepsis [13], in our electronic phenotype we adopted an alternate criterion for diagnosing severe sepsis. We accepted that, given the satisfaction of the remaining criteria of severe sepsis (Table 4), the requirement of known or documented presence of infection was satisfied by the presence of an ICD-9 code for either sepsis (ICD-9 = 995.91 or 995.92 [severe sepsis]) or septicemia (ICD-9 = 038.X) on the hospital admission. Our electronic phenotyping algorithm for severe sepsis thereby consisted as follows. First, SQL queries retrieved patients from MIMIC-II by their ICD-9 code for sepsis, severe sepsis or septicemia. For each of those patients individually, the Java program ingested and processed all pertinent EHR data. If the program found together two or more SIRS criteria, with at least one Overall SOFA score ≥ 3 in the same day, the patient was deemed eligible for our retrospective study, starting from the chart time of the data element with the latest chart time.

*: All non-neonates in MIMIC-II v. 2.6. Please note that this number differs from earlier versions of MIMIC-II.

**: For one patient that information was not available (NA).

For identifying groups of data elements together (e.g. the presence of two SIRS criteria together with a SOFA score above 2), we had to implement the concept of time windows, because each data element is charted at a potentially
different time. In a prospective study there is no necessity for such windows, because patient data (e.g. laboratory tests, vital sign measurements) is collected on-demand, according to the study protocol, virtually all at the same planned time. In our retrospective study, the essential question to be answered was: how far from each other, in time, can patient data elements be (e.g. a platelet count, a fibrinogen level measurement, and prothrombin time measurement) and still be considered effectively simultaneous?

The definitions of the DIC scoring systems also assume that all needed tests are performed on-demand, virtually at the same time, thus they also do not provide such specifications of time windows. Therefore, to adapt the prospective study’s design to a retrospective study design, we arbitrated two separate time windows.

- **Time window one:** for answering whether one data element, such as one record of overall SOFA score, was present at a point in time T, the algorithm returned the record closest to that time T, in the future or in the past, within 24 hours of distance of T, that is, within the interval T ± 24 hours.

- **Time window two:** for the calculation of scores of DIC or SIRS, which are aggregations of raw data elements, at a given point in time T, we considered only the EHR data charted until that time T and within the 48 hours immediately before T. That is, we considered only data charted within the interval from “T − 48 hours” until T.

Inside any time window, and for any data element, the record of that data element that was closest to time T was always the one used.

Table 6 exposes the characteristics of the patients after the screening for eligibility and calculation of DIC scores, reproducing the composition of Table 3 of the reference study. The difference is the column “Missing data”, which informs the percentage of patients that, on day 1, did not have that data element available.

* The count of patients add up not to the number of total eligible patients in the study, but only to the number of patients whose DIC status was known on day 1, that is, 13.16% less than all eligible patients.
† From a t-test comparing the proportion of male/female between the two groups.
†† This cell differs from the others in the column because here the denominator is the number of eligible patients, rather than the number of eligible patients with known DIC status.
Figure 1, below, illustrates how the JAAM DIC diagnosis on days 1 and 4 correlate with mortality and Multiple Organ Dysfunction Syndrome (MODS). It is possible to identify a relative drop in the numbers in the case where the patients did not have JAAM DIC on day 1, then acquired it by day 4, which differs from this same graph in the reference study.

Figure 1. Mortality and Multiple Organ Dysfunction Syndrome (MODS) in JAAM DIC patients

The charting time of calculated scores – SIRS and DIC

The specific points in time of any score assessment or diagnosis (and suspension of thereof) naturally coincided with the chart times of the data in MIMIC-II. We considered the chart time to be the moment when, ideally, each new piece of data about the patient data became known in the original clinical setting that originated MIMIC-II, such as a new platelet count, or a new measurement of body temperature. All patient data was read and processed in chronological order according to the chart time.

C. Statistical analysis

Our results agreed with those of the reference study. As the JAAM DIC score at day 1 increased, so did the mortality at day 1, as well as the SAPS I and organ dysfunction scores, as can be seen in Table 7. One intriguing exception was the score of 7, which did not follow the trend.

Table 8 shows that a diagnosis of DIC by the JAAM scoring system increased the odds of mortality by 18.2% to 43.2% (95% confidence interval), and that a decrease in the JAAM score within 4 days was associated with a 13.3% reduction in the odds of mortality (Table 8).

Discussion

Our endeavor in this paper builds upon a central concept that is as follows. Given structured data from the electronic health record, and cautious design of the data processing pipeline, a computer algorithm is able to calculate some popular scoring systems used in clinical practice. The criteria for the Systemic Inflammatory Response Syndrome is one example of such a scoring system, as well as essentially all four criteria for diagnosis of disseminated intravascular coagulation published in the literature [5]. Supported by this concept, we have accepted our electronic phenotype for severe sepsis without formal validation against a gold standard. Otherwise, one could interpret the high agreement of our results with those of the reference prospective study as evidence that the electronic phenotype, and the calculations of the used disease scores, had altogether acceptable performance.

Foremost, this paper shows the value of retrospective studies for clinical research, and that MIMIC-II can be used for them. Despite not a new resource [3], and the many studies with MIMIC-II [3], to our knowledge this is the first validation of a clinical study done in this valuable database. Our results (especially Tables 8 and 9) demonstrated resilience towards the limitations of a retrospective study, and remarkably followed the direction of the results of the reference study, which was done at a different country, and across 15 hospitals instead of one (which is the case of MIMIC-II).

Table 9. Comparison of final conclusions between the reference study and this study

<td></td>
</tr>
</tbody>
</table>
The JAAM DIC patients were more seriously ill and exhibited more severe systemic inflammation, a higher prevalence of multiple organ dysfunction syndrome (MODS) and worse outcomes than the non-DIC patients. Disease severity, systemic inflammation, MODS and the mortality rate worsened in accordance with an increased JAAM DIC score on day 1. Dynamic changes in the JAAM DIC score from days 1 to 4 also affected prognoses. The JAAM DIC score on day 1 (odds ratio = 1.282, P < 0.001) and the Delta JAAM DIC score (odds ratio = 0.770, P < 0.001) were independent predictors of 28-day death. Dynamic changes in the JAAM DIC score from days 1 to 4 also affected prognoses. The JAAM DIC scoring system included all patients who met the International Society on Thrombosis and Haemostasis (ISTH) overt DIC criteria on day 1. The International Society on Thrombosis and Haemostasis scoring system missed a large number of nonsurvivors recognized by the JAAM scoring system.

Limitations

**Missing data:** A problem inherent to a retrospective study, the extent of missing data in our study ranged from zero to 83.21% (Fibrin/Fibrinogen Deg. Prod. [FDP] level) or 100% (“known source of infection”). We did not perform statistical artifacts on the data to fill in missing values. As can be seen in Table 6, it was of utmost importance to this study the fact that the clinical data required by the reference study is commonly collected as part of routine care. The appraisal of data availability can easily be the foremost concern to a researcher considering a retrospective study. For the “known source of infection”, which we deemed completely unavailable and translated into the presence of an ICD-9 code for sepsis or septicemia in the patient’s hospitalization data, this workaround can be expected to be imparting selection bias according to imperfections in the ICD-9 coding. For the FDP level, as well as other charted patient information, our program understood as Not Available (NA) any needed data element that was not available within the requested time window. This approach brought the design
caveat that for aggregations of raw data elements such as SIRS and DIC scores, it was not clear how to differentiate a known zero from a NA. This is because any pertinent data element can cause each score to be nonzero. However, in a retrospective study, it can easily be too restrictive to require that all possible data elements must be available before you can accept a known zero. This is because, unlike in a prospective study, you cannot collect patient data on-demand to satisfy your data needs. Our approach to this issue was a simplifying one – we chose to ignore any score below 1, and treat them as Not Available. Our understanding was that, because the diagnostic threshold is much higher than 1 (Table 1), this would be of minimal to no impact to our study. The absence of score zero can be readily noticed in Table 7.

**Diagnosis of severe sepsis/DIC near death:** From manual inspection of the data, we noticed that in a considerable (approx. 10%) of the cases a diagnosis of severe sepsis and/or DIC was only ever made in the last hours before the moment of patient death – and not rarely a bit after the time of death. We rationalized that, near the moment of passing, a clear laboratorial diagnosis of severe sepsis or disseminated intravascular coagulation is clouded by a greater disruption of body homeostasis, and the computation is clouded by possible imperfections in data collection such as tests collected or charted after the moment of death. Therefore, we ruled to completely ignore any patient data charted within 12 hours of the time of patient death. Patients could be electronically phenotyped only before that point in time.

**Issues with data representation:** Three data elements from MIMIC-II – namely: D-Dimer level, Fibrin/Fibrinogen Degradation Products level, and Fibrinogen level – were found to be available as notations rather than only numbers, for example: `<10`, `10-40`, `160-320`, `>10000`. We decided that our Java program would thereby perform conversion of those values.

- The sign `<` was interpreted as `95%`, thus `<10` became 9.5;
- ranges were averaged, thus `160-320` became 240;
- The sign `>` was interpreted as `105%`, thus `>10000` became 10500.

Furthermore in this issue, some scoring systems requested data in a level of granularity that was not available in MIMIC-II. That was the case of Fibrin/Fibrinogen Degradation Products (FDP) level for the JAAM DIC scoring system. The JAAM DIC scoring system defines three ranges – 0-10, 10-25 and >25 – with different values, however, that data element is available in mimic as the following ranges: 0-10, 10-40, 40-80, and so on. Our referred averaging method turned `10-40` into 25 (3 points in the JAAM DIC) and `0-10` into 5 (0 points), effectively impeding any patient to receive just 1 point for that criteria inside the JAAM DIC.

**Conclusion**

We reproduced a contemporary prospective clinical study as a computational retrospective study in an EHR database – MIMIC-II – which found considerably more eligible patients than the prospective study, and was executed at a fraction of the cost and time. Despite the limitations of the retrospective study design, the results demonstrated resilience and agreed with those of the prospective study in a large majority of the findings.

Our results speak in favor of the usefulness of computational retrospective studies [4] as eventual proxies to costlier clinical studies, and suggest an altogether good performance, in MIMIC-II, of our developed electronic phenotypes for SIRS, severe sepsis and two scoring systems for disseminated intravascular coagulation available in the clinical literature.

We strived to maximize the dissemination and reuse of the work by making all source code we produced available online free [9], in addition to the fact that MIMIC-II is also available free to the research community.

From the clinical perspective, we offer our results as one contribution to the body of evidence on the validity and use of scoring systems for diagnosis of disseminated intravascular coagulation. In particular, we highlight the value of our study as a positive third-party validation of the work by Gando et al.

Abstract

Although performance feedback has the potential to improve the quality and safety of care, healthcare organizations generally lack knowledge about how this guidance is best provided. In low-resource settings, tools for theory-informed feedback tailoring may enhance limited clinical supervision resources. Our objectives were to establish proof-of-concept for computer-supported feedback message tailoring in Malawi, Africa. We conducted this research in five stages: clinical performance measurement, modeling the influence of feedback on antiretroviral therapy (ART) performance, creating a rule-based message tailoring process, generating tailored messages for recipients, and finally analysis of performance and message tailoring data. We retrospectively generated tailored messages for 7,448 monthly performance reports from 11 ART clinics. We found that tailored feedback could be routinely generated for four guideline-based performance indicators, with 35% of reports having messages prioritized to optimize the effect of feedback. This research establishes proof-of-concept for a novel approach to improving the use of clinical performance feedback in low-resource settings and suggests possible directions for prospective evaluations comparing alternative designs of feedback messages.

Introduction

Globally there are significant gaps between best practices drawn from medical evidence and decisions made by healthcare professionals⁶. Closing these gaps is increasingly difficult because of accelerating rates of the production of biomedical knowledge and the increasing complexity of healthcare systems⁷. The urgency of overcoming these challenges has motivated the development of a Learning Health System (LHS), a cyber-social infrastructure that enables both learning from data and the creation of feedback loops to improve the delivery of patient-centered care⁸.

Audit and feedback (AF), defined as the provision of clinical performance summaries to healthcare providers, teams, and organizations, is widely used to support learning and behavior change for healthcare quality improvement⁹. A recent Cochrane review including 140 clinical trials shows that AF can significantly improve compliance with desired practice, but that it is unclear how and when it is effective⁰. Seeking to improve the utility of AF evidence, researchers have called for a shift from overall effectiveness studies towards comparative effectiveness studies, evaluating how and when AF intervention components will workⁱ. To better understand AF components, researchers have argued for the explicit use of psychological theory that explains how AF operates to change behavior and support clinical learning⁵. Frameworks that enable the use of theory in behavior change interventions include the Theoretical Domains Framework (TDF) and the Capability, Opportunity, Motivation and Behavior (COM-B) system¹¹. A mapping between the TDF and COM-B enables researchers to model determinants of behavior within COM-B, and to relate these determinants to a broader set of causal mechanisms within theoretical constructs in the TDF that may hold implications for the effective delivery of performance feedback in organizations.

We have proposed that a theory-informed feedback tailoring tool used by clinical supervisors could improve AF for individual healthcare provider recipients¹². Computer-supported feedback tailoring requires clinical supervisors to use their familiarity with the recipient and situation to select an optimal feedback message from a menu of potentially relevant messages. This approach may be especially useful in low-resource settings where factors such as staff turnover, disruptions to care, and minimal dataset collection create a need to handle high uncertainty and missing information in the analysis of clinical data¹³. Understanding the design space for individually-tailored feedback messages is a key step toward designing and implementing such a system. Our objectives for this research were to analyze clinical performance data to understand the requirements and potential impact of computer-supported feedback message tailoring in a low-resource setting.
Methods

To establish proof-of-concept for using computer-supported feedback message tailoring in low-resource settings, we used a five-stage process (Figure 1). First, we measured clinical performance using four guideline-based indicators. Second, we developed a preliminary model of the effect of feedback on performance for a range of barriers to performance improvement in antiretroviral therapy (ART) clinics. Third, we created a rule-based message tailoring process that used the model of the effect of feedback in our specific context. Fourth, we used the message tailoring process to retrospectively generate menus of tailored messages about each individual healthcare provider within the performance dataset. Finally, we analyzed the performance dataset and the resulting tailored message data to understand the potential impact for computer-supported feedback message tailoring in this context.

Figure 1. Study design to establish proof-of-concept for a computer-supported feedback message tailoring system

Setting and data collection

We evaluated our approach in Malawi, where healthcare providers use a national electronic medical record system (EMR) in the provision of ART in public hospitals\(^\text{4}\). Malawi is a landlocked country in Sub-Saharan Africa with a population of close to 17 million people. The country has a largely agricultural economy, a highly rural population, and high rates of poverty, with approximately 74% of the population earning less than $1.25 per day. Like most low-income countries, Malawi has a significant shortage of healthcare providers. With a ratio of approximately one physician for every 50,000 inhabitants, Malawi and neighboring Tanzania have the lowest doctor-to-patient ratio in the world\(^\text{4}\). For this reason, care in ART clinics is primarily provided by clinical officers (non-physician clinicians with 3 to 4 years of post-secondary medical training) and nurses. We collected de-identified EMR data from ART clinics in public hospitals in Malawi. This research was approved by the University of Pittsburgh Institutional Review Board (IRB), protocol #PRO12100159 and the Malawi National Health Sciences Research Committee (NHSRC), protocol #1019.

Performance measurement

Performance indicators are commonly used to identify potential problems that may represent data quality problems or valid exceptions to recommended clinical practice\(^\text{5}\). In prior research we developed a method for identifying guideline-based performance measures that could be routinely evaluated within EMR data for ART in Malawi\(^\text{6}\). Using this approach, we identified four performance measures based on statements from Malawi’s national guideline for the clinical management of HIV, 2011 edition\(^\text{7}\) which have also been used for quality improvement purposes in multiple Sub-Saharan African countries\(^\text{8}\) (Table 1). We measured individual-level rather than clinic-level performance because each task is commonly performed independently and because performance may be influenced by individual differences in knowledge, skills and motivation.

The performance measures in Table 1 use ratios that accommodate both individual and team-based care. The denominator reflects the total number of opportunities a provider had to provide recommended care to each patient. For example, if a provider used the EMR to document an ART visit with a patient who was eligible to receive cotrimoxazole preventative therapy (CPT), this patient was counted towards the total number of patients in the provider's denominator for the month of that visit. The numerator reflects the documented care received by the patients who were counted in the individual provider’s denominator, regardless of who provided the care to the patient. For example, in a scenario where a provider does not prescribe CPT to an eligible patient at the time of an ART visit, but the patient receives a prescription for CPT on another day during the review period from any other provider, the patient would still be counted in the provider’s numerator. One exception is for patients whose care happens to be provided adequately but over a time frame spanning review periods. We used the Ruby programming language, the MySQL database system, and R statistical analysis software to measure and graph performance for each of the four performance indicators. To validate the results we reviewed the scripts, queries, and graphs of the
performance data with EMR developers. We conducted the review by discussing the approach for performance measurement, the structure of each SQL query, and the definitions of clinical concepts used by each query.

Modeling the effect of feedback on clinical behavior

We created a preliminary model of the influence of feedback on ART performance, adapted from an earlier model of the effect of feedback on clinical behavior20 (Table 2). The use of this model requires several key assumptions to be met. First, we assume that performance is measured routinely at individual and clinic levels so that a recipient's performance can be interpreted in relation to group performance. Second, we assume that a supervising clinician is charged with giving feedback and has a) some awareness of the events that have occurred in the clinic during the performance measurement interval and b) some awareness of or willingness to make estimations about the individual recipients' determinants of behavior such as knowledge, skills, and motivation18. We demonstrate how the tailoring approaches in the rightmost column of Table 2 could be applied in a prototype feedback planning menu that a clinical supervisor to could use to select tailored messages for a healthcare provider (Table 3).

Message tailoring process

Using the performance features from Table 2, we developed a rule-based message tailoring process (Table 4) to identify and make inferences about observable features of clinical performance data. The purpose of the tailoring process is to infer when individualized feedback might be useful, in various formats, and to prioritize a set of tailored feedback messages within a menu (Table 3) for a clinical supervisor to use.

1. Identify performance features: The first step of the message tailoring process is to classify each known feature as present or absent for an individual's performance. Performance features are the individual and situational characteristics associated with an individual provider, and his or her behavior that is targeted by an AF intervention. Our objective was to demonstrate the feasibility of using a range of performance features that could support inferences about barriers to behavior change and their associated theoretical constructs. We selected a preliminary set of 11 performance features such as “consistently low performance” and “consistently high performance” based on our understanding of the clinical setting gained from a qualitative study of performance feedback in ART clinics in Malawi18. We anticipate that this feature set is a small sample of the meaningful features that could be used.

2. Infer construct salience: Once performance features are identified, these can be used to make inferences about an individual's potential barriers to behavior change and associated theoretical constructs. For example, when individuals demonstrate consistently high performance for a behavior, we may infer that barriers to behavior change are not likely to be present. Conversely, consistently low performance may indicate that barriers associated with capability constructs such as a lack of knowledge or skills are in effect, especially when accompanied by concurrent high performance of peers.

</table>

| Opportunity       | Social influences | Social pressure | Material resources | Social influences and resources based on availability of material resources | None (no direct influence on social norms) | Low | Low group performance | Withhold feedback: Withhold or deprioritize individual feedback |
| Social pressure   | Social norms     | Peer pressure and social norms | | | | |

| Motivation        | Beliefs about capabilities | Self-efficacy | Beliefs about specific capabilities | Feedback can influence perceptions of ability that lead to behavior change | Conditions on situation | Low individual performance, improvement trend | Self-comparison: Prioritize individual feedback using a truncated scale graph when improvement trend is present |

3. **Infer message component relevance:** Some components of potential messages will be more relevant to an individual and situation that others. For example, showing a graph of performance data that emphasizes a trend by using a truncated scale will only be relevant when the improvement trend is above some threshold of meaningful improvement. We propose that performance features can also be used to determine which elements of feedback messages are most relevant for a recipient. For example, performance features could be used to estimate the relevance of the following feedback message components from the tailored messages in Table 3:

- Scale truncation: The use of a truncated vertical axis to emphasize change in performance
- Self comparison: Comparing an individual’s past performance with current performance
- Peer comparison: Comparing an individual’s current performance with current peer performance.

4. **Prioritize messages:** Finally, we prioritized messages appearing in the menu to place messages that were most likely to address barriers to behavior change at the top of the menu. To prioritize the messages, we evaluated both the message component relevance scores and estimated construct salience scores for the provider’s current month of performance. We created preliminary rules based on hypothetical causal mechanisms from Table 2 to prioritize each of the tailoring approaches in Tables 2 and 3 (Current score, peer comparison, withhold feedback, and self-comparison). We created two additional prioritization categories: no prioritization for the cases where no messages could be prioritized, and prioritized combination, in the event that two or more messages were equally of highest priority.

</tbody>
</table>
| Recipient may be unaware of how he or she is performing relative to peers. | **Peer comparison:** Prioritize individual feedback, include peer comparison | Your performance: 22%
Top peers: 85%
In the last month, your performance was more than 60% below your top-performing peers in the ART clinic. |
| Recipient may not know how to use the EMR to record a patient's weight. | **Current score:** Prioritize individual feedback, recommend or provide EMR training | In the last month, 22% of patients who you provided care for in the ART clinic had their weight recorded. To record a patient's weight using the EMR, select “Record vitals” from the ART visit menu... |
| Recipient does not have access to a functioning scale to record patient weight. | **Withhold feedback:** Withhold or deprioritize individual feedback | [None] |
| A common practice in the clinic is to deprioritize the recording of patient's weight relative to other tasks, especially during times of high workload. | **Withhold feedback:** Withhold or deprioritize individual feedback | [None] |
| Recipient is aware of his or her past performance. Recipient may believe he or she is not capable of improving performance. Increased effort is likely to lead to improvement. | **Self-comparison:** Prioritize individual feedback using recent performance history and a truncated scale graph when improvement trend is present | In the last 2 months, your weight recording performance has improved by 7% |

*Analysis of performance data and prioritized messages*

We conducted two simple analyses to understand the potential impact of message tailoring in ART clinics in Malawi: identification of performance gaps, and analysis of variability in message prioritization. We first calculated the average number of performance gaps occurring each month to estimate how frequently peer comparison feedback could be provided. We defined a performance gap as a 10% or greater difference in performance between an individual healthcare provider and the average performance of two higher-performing peers working in the same clinic in the same month. We excluded providers who had seen 10 or fewer patients in a month.
Table 4. Feedback message tailoring process

<table>

<td>Integer score</td>
</tr>
<tr>
<td><strong>Example</strong></td>
<td><strong>Feature:</strong> consistently_low_performance</td>
<td><strong>Construct:</strong> self-efficacy Rule: If consistently_low_performance is present, increase the salience score for self-efficacy as a barrier to improvement</td>
<td><strong>Message component:</strong> peer_comparation Rule: If a 10% performance gap exists between the recipient and top-performing peers, increase the relevance score for messages containing peer_comparation</td>
</tr>
<tr>
<td><strong>Rule:</strong> If performance has remained below 50% during the performance interval then consistently_low_performance is present</td>
<td></td>
<td></td>
<td><strong>Rule:</strong> If self_efficacy is salient as a barrier, decrease the priority score for messages using peer_comparation</td>
</tr>
</tbody>
</table>

Our second analysis concerned the variability of prioritized messages within a tailoring menu. The purpose of this analysis was to understand how often a standardized message format could be used for all providers as compared to the routine tailoring of messages. We anticipate that increased variability of message priorities indicates a greater potential impact of message tailoring because it reflects individual and situational differences among healthcare providers that standardized feedback formats are less likely to accommodate. If messages of the same format have the same priority for more than 95% of providers, it would suggest that message tailoring is not necessary. However, if the priority of messages is more evenly stratified across message type groups, and if the size of these groups changes over time, it would suggest a greater potential impact for message tailoring. We created a prioritized list of message types for each performance measure across all individuals and months. To assess the variability of message formats, we identified the top-priority message format only and did not consider the rank of lower-priority message formats. We calculated the percentage of individual performances that had each of the four types of message as the highest priority, plus the two additional prioritization categories.

**Results**

*Data collection*

Data collection for this study occurred in November, 2013. We collected de-identified EMR data from 11 ART clinics in Malawi that were using the National ART EMR (Software version BART 1), and which was recorded between October, 2011 and September, 2013.

*Performance measurement*

We retrospectively measured clinical performance from 372 healthcare providers in 11 hospital-based ART clinics over a two-year period. We measured individual performance for all four measures at a monthly frequency by individual provider for a total of 7,448 individual monthly performance reports having a denominator of five or more patients. Across all clinics, an average of seven automated monthly performance reports could be generated per month for each performance indicator.

Summary statistics for each of the four guideline-based performance measures for all healthcare providers grouped by ART clinic are shown in Table 5. The average monthly performance for weight recording and WHO clinical staging were consistently high (> 94%) for all but one clinic. The average monthly performance for pediatric height recording ranged from 2.3% to 98.4%, while the average monthly performance for CPT prescribing ranged from 48.9% to 87.6%. For CPT prescribing performance, there was a generalized decrease in performance in 2012 across clinics, with providers at most clinics having a wide range of performance during the period. The generalized decrease in performance is associated with a national shortage of CPT drugs that occurred in 2012.
Performance gaps of 10% or greater

Performance gaps that could be used for peer-comparison feedback occurred slightly more frequently than 1 gap per month on average across all clinics and measures. The mean monthly total of performance gaps for each indicator across sites between October, 2011 and September, 2013 is shown in Figure 2. The average number of performance gaps that could be used to give peer comparison feedback to a single provider for all 11 sites ranged from 0.32 to 2.45 gaps per month.

![Graph showing performance gaps](image)

Figure 2. Average monthly performance gap totals between October, 2011 and September, 2013

Message prioritization variability

Based on the preliminary rule set, the tailoring process resulted in 35% (2,624 / 7,448) of individual monthly reports being prioritized to optimize the effect of feedback on performance. We calculated the percentage of all messages that had each message type as the highest priority on an individual’s monthly report (Figure 3). No reports had peer comparison messages as the highest priority. Across all performance indicators, increased stratification of tailored message types appears to be associated with lower performance. For example, the indicators having higher performance, which are weight recording and WHO clinical staging, had a higher average percentage of messages that were not prioritized, at 75% for weight and 83% for WHO clinical staging. In contrast, pediatric height recording and CPT prescribing, which have lower overall performance, had increased stratification of highest priority percentages across message types.
Discussion

We found that computer-supported feedback message tailoring could be routinely used in ART clinics in Malawi. The results of this study answer several important questions about using EMR data to generate tailored performance feedback messages in a low-resource setting. Most significantly, we identified an opportunity to use existing EMR data to routinely monitor individual clinical performance and provide tailored feedback across a range of guideline-based performance indicators in a low-resource setting. This approach could be expected to yield individualized monthly reports for ART providers working at each site, with approximately 35% of reports being tailored to optimize the effect of feedback on performance. Although performance appears to allow limited room for improvement in some ART clinics, we found regular opportunities to provide individualized feedback to address performance gaps and potential performance or data quality problems. These findings are significant because the existing National EMR infrastructure in Malawi would allow these reports to be generated in every ART clinic using the EMR, totaling 66 clinics at the end of June, 2015. Moreover, such a system may enable feedback to be generated more rapidly than the current quarterly reporting schedule of the National ART monitoring and evaluation program.

We sought to understand if feedback message tailoring could potentially impact clinical performance by exploring differences in features of performance data. We found differences in performance features that appear to hold meaningful implications for the design of feedback messages. On average, based on a preliminary set of hypothetical causal mechanisms offered by behavioral and cognitive theories, more than 50% of feedback messages for pediatric height recording could be tailored for individual or situational differences in performance. Similarly, close 50% of feedback messages could be tailored for differences in performance with regard to CPT prescribing in this setting. Where performance is higher, there appear to be fewer opportunities to tailor feedback messages. However, even the indicators having higher performance allowed for routine tailoring for approximately 25% of messages for weight recording on average, and for an average of 16.3% of messages for WHO clinical staging.

These findings are significant because they represent the first evaluation, to our knowledge, that uses a model of clinical behavior and psychological theory for the purpose of feedback message tailoring. To our knowledge, this approach represents a novel contribution that holds implications for related research in biomedical informatics, implementation science, and global health. In the field of biomedical informatics, this work introduces a novel class of knowledge-based system to support evidence-based care and quality improvement. In implementation science, this work is the first demonstration of theory-informed tailoring of feedback messages for individual healthcare providers based on standardized measures of clinical performance. In the domain of global health, this work represents the first supervision tool of its kind for a setting where supervision resources are limited. The significance of these findings increases with the increasing availability of eHealth data that can be used to generate performance feedback.

This research has several limitations. A key limitation of this analysis is that the application of theory within tailoring rules was not rigorously validated. In a prior model formation study we applied theory using knowledge gained from a review of the literature. Furthermore, the model we developed for the effect of feedback on ART performance was a general model that did not accommodate potential differences in barriers to behavior change.
between the four clinical behaviors. Developing behavior-specific models, which is an important next step, may yield different message tailoring approaches.

A potential limitation of this approach is the ability of a clinical supervisor to accurately perceive barriers to behavior change that inform the selection of feedback messages. We anticipate that supervisors who use a feedback message tailoring system could overcome this limitation by observing the effects of their selected feedback messages on clinical performance. These observations could enable a supervisor to learn how to improve the use of feedback for individual recipients.

Our assessment did not account for data quality problems, however we anticipate that performance feedback could also be used to target the improvement of clinical data quality where such problems exist. The message tailoring process may also provide a systematic approach for integrating routine data quality assessment into AF, to inform clinical supervisors when clinical data is not “fit for use” as performance feedback.

The classification thresholds that we used for this analysis were chosen based on our understanding of the clinical context rather than empirical research. For example, we classified low group performance as an average performance below 50%, but it is likely that the actual thresholds for low group performance may vary across ART clinics, and across performance indicators. In the case of WHO clinical staging, a threshold for low group performance might be set much higher for most clinics because there are no valid exceptions for this guideline recommendation. In the case of CPT prescribing there are exceptions for patients with CPT contraindications, therefore a lower threshold would be expected. To address this limitation, we chose classification thresholds that err on the side of a lower bound, meaning that thresholds that we validate are likely to lead to greater variability of tailored messages.

Finally, a limitation of this proof-of-concept approach is that the manual development and maintenance of a message tailoring process for each clinical context is not likely to be sustainable. We aim to address this and other limitations in future research by developing a publicly-maintained feedback message tailoring knowledge-base that builds on established frameworks for applying psychological theory to behavior change interventions\textsuperscript{20,21}, and which uses an argumentation model to represent dynamic and contextualized evidence\textsuperscript{22}.

Conclusion

Computer-supported feedback message tailoring is a promising approach for improving the use of AF within LHSs. In this research we explored the design space for individually tailored feedback messages, to establish proof-of-concept for computer-supported feedback tailoring in Malawi. We found that individually-tailored performance feedback can be generated using routinely collected EMR data in ART clinics in Malawi. This finding suggests that clinical supervisors could use feedback tailoring tools to improve the effect of feedback on clinical performance in low-resource settings. Future research should study the use of a feedback tailoring system and its impact on clinical performance.

Abstract

Phenome-Wide Association Studies (PheWAS) comprehensively investigate the association between genetic variation and a wide array of outcome traits. Electronic health record (EHR) based PheWAS uses various abstractions of International Classification of Diseases, Ninth Revision (ICD-9) codes to identify case/control status for diagnoses that are used as the phenotypic variables. However, there have not been comparisons within a PheWAS between results from high quality derived phenotypes and high-throughput but potentially inaccurate use of ICD-9 codes for case/control definition. For this study we first developed a group of high quality algorithms for five phenotypes. Next we evaluated the association of these and 4,636,178 genetic variants with minor allele frequency > 0.01 and compared the results from high-throughput associations at the 3 digit, 5 digit, and PheWAS codes for defining case/control status. We found that certain diseases contained similar patient populations across phenotyping methods but had differences in PheWAS.

Introduction

Phenome-Wide Association Studies (PheWAS) are used to investigate the association between a collection of genetic variants and a wide and diverse range of phenotypes, diagnoses, traits, and/or outcomes. PheWAS highlight novel connections between multiple phenotypes and can elucidate more of the phenotype-genotype landscape as well as generate new hypotheses for further exploration. The complex results of PheWAS also have the potential for uncovering new mechanistic insights. Electronic health record (EHR) data coupled with genetic data have been used repeatedly for PheWAS. For example, through the Electronic Medical Records and Genomics (eMERGE) network, EHR based International Classification of Diseases, Ninth Revision (ICD-9) codes have been used to establish case/control status for identifying significant associations between medical record diagnoses and genetic data, including using datasets from the Geisinger Health System (GHS) MyCode™ biorepository. Each PheWAS has shown the ability to replicate previously reported associations, clearly showing that the high-throughput PheWAS approach is valid as well as identifying hypothesis-generating novel associations.

EHR based PheWAS have used various methods of grouping and counting ICD-9 codes to define case/control status for analyses. For example, there are three digit ICD-9 codes that specify disease categories (e.g. code 405 for “secondary hypertension”) that can be further subdivided using multiple four or five digit sub ICD-9 codes (e.g. 405.1 for “benign secondary hypertension”, 405.11 “benign renovascular hypertension”), that are more specific. The most common methods of defining case/control status using EHR data include grouping ICD-9 codes by three digits (e.g. 250.02 rolls up to 250), five digits (e.g. 250.02 stays 250.02), and “PheWAS Codes”. The choice of which patients to consider a case or control based on their number of instances of a given code and who should be excluded (not classified as case or control) for a code has varied depending on the study. For example, one approach defines case status by requiring three or more instances of a given code per individual (rule of three), considering those with no instances of the code a control, and one or two instances of a code are excluded from further analysis. PheWAS Codes go a step further by collapsing and grouping ICD-9 codes that are highly related and expanding the exclusion of individuals based on ICD-9 codes with revisions based on code frequency and human review.

Case and control status based on the presence of an ICD-9 code has been one of the most accessible forms of EHR-based high-throughput phenotypes allowing researchers to look for known and novel associations across a very
broad range of phenotypes. This can be attributed to the fact that the phenotype definitions can be easily applied across the spectrum of ICD-9 codes and results are more easily compared to other EHR based PheWAS. These methods have limitations, however; the positive and negative predictive values (PPV/NPV) vary greatly from phenotype to phenotype. For example, a single diagnosis of myocardial infarction is highly predictive whereas a single diagnosis of stroke is not highly predictive.

While existing studies have demonstrated that PheWAS is a viable method to identifying genome/phenome associations which replicate well known associations, the measurement of EHR based PheWAS success have been focused on known associations and not a comparison of the phenotype definitions themselves. Thus, for this study, using the Geisinger Health System MyCode Biorepository, we identified ICD-9 code based case/control status using multiple methods. We then compared the results of the existing phenotype algorithms case/control status to high-quality algorithmically defined EHR phenotypes ("gold standard") case/control status for type 2 diabetes (T2DM), acute coronary syndrome (ACS), non-obstructive coronary artery disease (CAD), obstructive CAD, and obesity. Finally, we performed a genome-wide association study for each phenotype and contrasted highly significant results of these GWAS with association results from performing PheWAS using different ICD-9 code based case/control definitions.

Methods

Study Participants

The MyCode dataset had a total of 3,022 individuals available with both phenotypic and genotypic data for this study. Because the majority of subjects were of European ancestry (EA), only EA subjects were selected for these analyses.

Gold Standard Algorithmically Defined Phenotypes

Five phenotype algorithms developed within Geisinger Health System with a high PPV/NPV (≥ 95%) were selected to compare to the phenotype definitions from various approaches for identifying case/control status based only on ICD-9 codes. These phenotype algorithms are considered to be “gold-standard” because of their high PPV. The algorithms for these gold standard phenotypes incorporate EHR data (labs, meds, procedures, etc.) and temporality in addition to ICD-9 codes used in traditional PheWAS phenotyping. Table 1 illustrates the different types of data used in the gold standard phenotypes and shows the gold-standard phenotype overlaps with ICD-9 codes for different ICD-9 code levels/abstractions. The asterisks (*) in the table refer to a wildcard operator which would indicate any digit (0-9) included in the range.

At Geisinger Health System, data for creating phenotype algorithms are extracted from Geisinger’s Clinical Decision Intelligence System (CDIS), an enterprise data warehouse, additionally supplemented data from the Department of Cardiology. CDIS is updated every 24 hours with feeds from multiple source systems, including the EHR, tumor registry, financial decision support, claims, patient satisfaction and high-use third-party reference.
datasets. The source data are transformed through a complex “Extract-Transform-Load” (ETL) process. Laboratory results, medications, procedures, past medical history, and encounter setting are often key components of validated phenotypes and help to improve PPV/NPV.

Phenotype algorithm development is a very iterative process that incorporates input from researchers, clinicians, clinical support staff, and Information Technology (IT) teams to understand how and why data was captured at the point of care in order to inform algorithm development. Programmer/Analysts in the Phenomic-Analytics and Clinical Data Core (P-ACDC) use existing methods of phenotyping and expand the process to allow for increased iteration and validation. First, analysts receive input from the members of the research team to determine if all data needed for the phenotype exists in the data warehouse and if not, the analyst will work with IT staff to incorporate that data into CDIS. Once complete data is obtained to define a phenotype, the algorithm is developed. Using the algorithm, one hundred positive (cases) and 100 negative patients (controls) for that phenotype are identified, and an analyst reviews the clinical records to validate the algorithm and calculate the PPV/NPV. If the predictive values are below desired levels (ie, < 85%), the analyst will identify areas of improvement, modify the algorithm, and repeat the validation process until desired results are achieved.

All attributes of the validated phenotypes are saved as value sets (terminology) and business rules (setting, timing, etc.). The collection of value sets and business rules is based on existing processes and repositories so that phenotypes can be consumed and shared across organizations. The National Library of Medicine (NLM) Value Set Authority Center (VSAC) (https://vsac.nlm.nih.gov/), the Center for Disease Control and Prevention (CDC) Public Health Information Network Vocabulary Access Distribution System (PHIN VADS) (http://www.cdc.gov/phin/tools/PHINvads/index.html), Phenotype Knowledge Base (PheKB) (https://phekb.org/), and PhenotypePortal (http://phenotypeportal.org/) are well known national standards for consuming and authoring value sets and business rules.

Matching ICD-9 Based Phenotypes to Gold Standard Phenotypes

ICD-9 codes from the MyCode participants EHR that also had genotypic data were used for this study. For our 3 digit and 5 digit PheWAS analyses, case status was defined as having ≥ 3 visits per individual, zero instances of an ICD-9 code to be considered a control. Individuals between 0 and 3 instances of a code (i.e., 1-2 visits) were omitted from the analyses for that code. At least ten case subjects per ICD-9 code to retain that ICD-9 code in association testing was required.

Genotypic Data and Quality Control

GHS MyCode subjects were genotyped using the Illumina HumanOmniExpress-12 v1.0 array a total of 729,078 SNPs. Imputation was used to improve genomic coverage of the datasets. The imputation was performed using the IMPUTE2 algorithm after phasing with SHAPEIT211 using the 1,000 Genomes cosmopolitan reference panel, resulting in a total of 38,054,243 SNPs in 3,111 samples for MyCode12. Genotype Quality Control (QC) procedures were performed prior to association testing using the R programming statistical package13 and PLINK software14. The first step was to filter out the SNPs with poor imputation quality; SNPs with imputation quality scores > 0.9 were used for further analyses. Data were filtered further for 99% genotype and sample call rates and minor allele frequency (MAF) threshold of 1%. Also, related samples were removed using Identity by Descent (IBD) kinship coefficient estimates. After QC, the genotypic data consisted of 4,636,178 SNPs and 3,022 samples with both phenotypic and genotypic data from MyCode.

Association Testing

Logistic regression with an additive encoding for the SNPs was used to evaluate the association between SNPs and the gold standard phenotypes. For each association, models were adjusted for decade of birth and sex. Association results were filtered for p-values < 1x10^-5, to focus further analyses on highly significant results associated with the gold standard variables. Results were annotated using Biofilter15, to add information about any genes that the SNPs were in or near, as well as to annotate the SNPs with any known results from the NHGRI GWAS catalog16. The NHGRI GWAS catalog contains results from published GWAS in the literature reaching genome-wide significance.
Next, a PheWAS was performed using all SNPs identified through the previous step with \( p < 1 \times 10^{-4} \). As described above, logistic regression with an additive encoding of the SNPs was used while controlling for decade of birth and sex. This was performed at the 3 digit and 5 digit ICD-9 code diagnosis level, and with PheWAS codes. Results for the association testing were plotted using GGPLOT2\(^1\) and PheWAS-View\(^1\) software.

**Results**

**Comparing Case and Control Status: Gold Standard Phenotypes and ICD-9 Methods**

After patients were classified as either a case or control using the various methods a comparison was conducted to demonstrate the overlap existing between the defined case/controls sets according to each method (Table 2). Not surprisingly, it was found that the methods agree in some areas and not in others. For example, T2DM was very closely matched across all of the methods (Figure 1) and obesity showed a large overlap (Figure 2) using diagnosis codes but incorporating vital measurements in the gold standard picked up additional patients that were otherwise missed. The cardiovascular phenotypes did not show agreement between the 3-digit and 5-digit code methods with the gold standard because of the inherent lack of information in the ICD-9 codes themselves. Using results from the cardiac catheterization laboratory and elevated biomarkers helps to appropriately classify the disease state. Overall, evaluating the absolute value of the difference in the number of cases according to the gold standard definition with that of PheWAS Codes, 3 digit codes, and 5 digit codes, it is observed that 3 digit and 5 digit codes have the closest case counts to the gold standard in all phenotypes except for obesity. To better understand the various case classifications, Venn diagrams were used to show the differences in actual patient overlap, not just absolute count.

Comparing Association Results between Gold Standard Phenotypes and ICD-9 Code Based PheWAS

A total of 2,585 SNPs passed the p-value cutoff for the gold-standard phenotypes. Eight of these SNPs were present in the NHGRI GWAS Catalog. Those SNPs significantly associated with gold-standard phenotype at p-value > 1x10^{-4} were evaluated by performing a PheWAS with the ICD-9 codes at 3 digit, 5 digit diagnosis level, and PheWAS code level. Table 3 shows the average p-value of the gold standard associations passing our p-value cutoff, and what the maximum p-value was. Table 3 also shows for each gold standard phenotype the number of associations with p < 1x10^{-4} matching the same SNP-phenotype gold association. Note, more than one ICD-9 code corresponds to some of the gold standard phenotypes (Table 1), thus matches were only counted once when they occurred. The results of the PheWAS using different ways to define case control status recapitulate what was observed in the case/control definition comparisons of Table 2. For phenotypes where the ICD-9 codes offer more specific or appropriate terminology about a diagnosis, such as with T2DM, there is a better match in associations identified through PheWAS. For phenotypes poorly represented in ICD-9 code terminology compared to high-quality algorithmic development using multiple inclusion and exclusion criteria, the number of associations repeated in PheWAS compared to gold standard results is reduced, particularly in ACS.

Also, of note, while PheWAS Codes had higher case numbers than the algorithms for CAD, this did not result in more overlap in associations with the gold standard associations when compared to the 5-digit and 3-digit approaches. Ranges of p-values for associations where there was the same SNP from the gold standard phenotype and a matching ICD-9 code from Table 1 were evaluated and shown in Table 4. Depending on the gold standard phenotype, one case/control approach (PheWAS codes, 5 digit, and 3 digit) performs better than another method, however the differences are mostly minimal across the definitions of case/control status. While the case numbers can be lower for ICD-9 codes compared to gold standard algorithms, which can affect power to detect associations, there will also be more individuals incorrectly defined as cases and controls when using ICD-9 based case/control definitions alone. As a result, this will impact the ability to detect significant associations, as well as the degree of the significance of the association. Supplementary materials have containing all the individual association results used for Table 3 and 4 are located online: https://ritchielab.psu.edu/publications-supplementary-data/amia-phewas.

Figure 4. Manhattan-plots of all results. These are the results for the 5-digit ICD-9 code defined case/control diagnoses. Supplementary figures show the results for the 3-digit and PheWAS Code defined case/control status and are available online. The points in gold show the significance of the association result for the ICD-9 based diagnoses most similar to the gold-standard defined phenotype, for example the ICD-9 code 250.00 is the ICD-9 code for T2DM.

Variability in the identification and significance of associations was observed across the various methods of defining case/control status definitions when compared to the results using gold standard phenotypes. Some of this variability may be due to shifting case identification; different ICD-9 approaches resulted in identifying different individuals. Interestingly, the study did not observe the 3 digit or PheWAS code approach as having the most significant results of the three approaches from SNP to SNP, even though there could have been increased power through increased case numbers. Three examples are shown (Figure 5-7) of single SNPs. and the results across three different methods for the phenotypes of obesity, non-obstructive and obstructive CAD, and T2DM. Larger versions of figures are available in the online supplementary materials. For all three of these SNPs the ICD-9 diagnoses most similar to these gold-standard phenotypes have a similar direction of effect of the association. Figures 5-7 illustrate the significance of association through ordering by most significant at the top of the figure with decreasing significance plotted clockwise. The length of the each line corresponds to the −log(p-value) of each result.
**Figure 5.** Sun Plot of association results for SNP rs7127254, coded allele T, present across the three methods of identifying case/control status used for these analyses. This SNP was associated with the gold standard phenotype of obesity in our study with p-value $6.19 \times 10^{-7}$, and the array of metabolic syndrome comorbidities also associated with SNP notable. The most significant association for this SNP was with the 5 digit ICD-9 of T2DM.

![Sun Plot for SNP rs7127254](image)

**Figure 6.** Sun Plot of results for SNP rs2277251, coded allele T. This SNP was associated with the gold standard phenotype of T2DM with p-value $7.08 \times 10^{-7}$. SNP-phenotype associations ($p < 0.01$) that were also present for this SNP across the 3 methods of identifying case/control status. The spectrum of other comorbidities related to T2DM also associated with this SNP is notable.

![Sun Plot for SNP rs2277251](image)

**Figure 7.** Sun Plot of results for SNP rs10009355, coded allele T. This SNP was associated with the gold standard phenotype of obstructive CAD with p-value $8.24 \times 10^{-7}$. SNP-phenotype associations ($p < 0.01$) that were also present for this SNP across the 3 methods of identifying case/control status. Additional comorbidities related to CAD are associated with this SNP.

![Sun Plot for SNP rs10009355](image)
Discussion

Studies have shown that PheWAS can be a viable method for identifying known and/or novel associations in phenotypes and genotypes for hypothesis generation. The current methods used to define phenotypes allow for simple application of business rules to define a wide range of diseases. Defining gold standard methods for phenotypes is a laborious task that cannot be reasonably applied to all diseases. Comparing these methods of defining phenotypes shows that there are certain diseases where using code based case methods agree with more complex phenotype algorithms ("gold standard") while other diseases cannot use codes alone and require additional data from the EHR. For example, good agreement across the various methods was observed for T2DM, whereas ACS exhibited poor agreement due to the lack of specificity PheWAS codes.

For the gold-standard phenotypes, some associations were identified from previously published replicated results (annotated in the supplementary results of associations). The sample size was relatively small and thus the analysis had low power to identify new associations or replicate known associations. Therefore, for these exploratory analyses, a less stringent p-value cutoff of $1 \times 10^{-4}$ was used and p-values for multiple testing were not corrected for. Future directions include exploring these analyses within a larger genetic dataset linked to EHR based phenotypic data as well as repeating these analyses with a "rule of one" applied, where the presence of an ICD-9 code will indicate an individual is a control, instead of the "rule of three" applied here. Requiring less instances of an ICD-9 code for case/status will increase the number of controls. For some ICD-9 codes this may increase the number of false-controls; however it may increase the power of associations for ICD-9 codes that are rare and unlikely to have been assigned to a patient incorrectly.

Additional research needs to be done to compare the positive and negative predictive value of the ICD-9 code based method phenotypes and compare the patient populations that do not agree to potentially identify additional methods that are generalizable and can be added broadly to phenotype definitions. In addition, comparing more gold standard phenotypes to code based approaches would help to identify disease areas that have a high degree of agreement between the simple and complex approaches. Collaborating with existing efforts such as eMERGE, VSAC, and PHIN VADS would allow comparison to be completed at a much larger scale and across multiple institutions. Machine learning approaches are also a next step in developing phenotypes that perhaps can be semi-automated.

Building Structured Personal Health Records from Photographs of Printed Medical Records

Xiang Li, PhD¹, Gang Hu, MS¹, Xiaofei Teng, PhD¹, Guotong Xie, MS¹
¹IBM Research, Beijing, China

Abstract
Personal health records (PHRs) provide patient-centric healthcare by making health records accessible to patients. In China, it is very difficult for individuals to access electronic health records. Instead, individuals can easily obtain the printed copies of their own medical records, such as prescriptions and lab test reports, from hospitals. In this paper, we propose a practical approach to extract structured data from printed medical records photographed by mobile phones. An optical character recognition (OCR) pipeline is performed to recognize text in a document photo, which addresses the problems of low image quality and content complexity by image pre-processing and multiple OCR engine synthesis. A series of annotation algorithms that support flexible layouts are then used to identify the document type, entities of interest, and entity correlations, from which a structured PHR document is built. The proposed approach was applied to real world medical records to demonstrate the effectiveness and applicability.

Introduction
Personal health record (PHR) is an electronic application through which individuals can access, manage and share their health information¹, which can help individuals take a more active role in their own health, and provide decision support to assist patients in managing chronic diseases². Data collection is a base functionality of a PHR system, and it is time-consuming and error-prone for individuals to manually enter their PHR data¹. Hence, a more practical manner for collecting PHR data is to give individuals access to their own electronic health records (EHRs), which has been or is being implemented in some developed countries. For example, in the United States, many individuals can access and download their own EHR data using Blue Button⁴. And in England, all patients will have online access to the EHR data that their general practitioners hold by 2015⁵.

In China, even though PHR has been given much attention by health authorities and researchers⁶, at the present stage it is still difficult for Chinese individuals to access their EHR data, especially in underdeveloped areas. So far, China has not released a privacy standard like HIPAA⁷ (which mandates that patients can access their health records), and many Chinese individuals are regarded as lack of security and privacy concerns. Therefore, China health institutions tend to be conservative in giving patients access to their EHR data. Moreover, there are dozens of EHR vendors in China, and the EHR systems from different vendors widely vary due to the lack of implementation guidelines. So it is also difficult to develop unified interfaces for individuals to access their data in EHRs. Instead, individuals can easily obtain from hospitals the printed copies of their medical records, such as prescriptions, lab test reports, etc. This situation is not unique to China, but is widespread in many regions, especially in the developing countries.

Smartphones are very popular nowadays. China now has more than 500 million smartphone users, most of whom are accustomed to use phone cameras to take pictures of paper-based documents, including printed medical records, for the purpose of storage. Figure 1 shows some printed Chinese medical records, which were photographed using mobile phones. Because the data in photographed medical records are not structured, they cannot be directly used to build PHRs. A potential solution is to identify structured data in them using optical character recognition (OCR) techniques.

However, it is a challenging problem to build structured PHR from the photographs of printed medical records. First of all, the images are shot by ordinary mobile phones rather than high-quality scanners. Compared with the scanned images, they tend to have uneven light and shade, lower clarity, more noise, as well as paper skewing. Secondly, different types of medical records are involved to create PHRs. Even for a specific type, as shown in Figure 1, the layouts of printed medical records are not standardized in China, which may obviously vary in different time and different hospitals. Furthermore, various categories of entities, such as diagnoses, medications, test items names and values, are supposed to be extracted from medical records, where different types of characters can be observed, including Chinese characters, English characters, digits and punctuation. Existing OCR systems in clinical settings⁸,⁹,¹⁰ focus on the identification of structured clinical or privacy information from scanned documents, and do not consider photographed images. Moreover, these systems were designed for standardized documents, where the entities of interest are written in English and Arabic numerals. None of these systems can support unstandardized documents that may have very flexible layouts or have complex character sets as Chinese medical records do.
In this paper, we address these issues by proposing an approach to extract structured data from the photographs of printed medical records. Before OCR, several image processing algorithms, including denoising, binarization and deskewing, are performed to reduce the influence of low image quality of photographs shot by mobile phones. Multiple OCR engines are then applied to recognize text, and the results of the engines are synthesized to achieve a higher performance in recognizing characters of a complex character set. Furthermore, a series of flexible annotation algorithms that support diverse document layouts are designed to identify document types, entities of interest and entity correlations, using machine learning, pattern matching, and slot-based techniques. Based on these algorithms, we developed a system pipeline to automatically build structured PHR documents from printed medical records. The proposed approach has been applied to build PHRs from real world prescriptions and lab test reports, with high precision and sensitivity.

**Methods**

The goal of the proposed approach is to accurately extract entities of interest and entity correlations from photographs of printed medical records as many as possible. Therefore, both precision and recall (sensitivity) of the approach should be taken into account when designing the system and algorithms. The system pipeline and sample data flow are shown in Figure 2. A user first shoots a printed medical record using an ordinary mobile phone camera, and sends it to the system. Then the system performs image pre-processing on the photo. The processed image is sent to multiple OCR engines to build documents with recognized text, which are then resegmented and synthesized in the post-processing step. After that, the document type, entities of interest and entity correlations of the document are automatically annotated. The credible entities are adopted to create a structured PHR document, which is finally sent back to the user for further editing. In this study, two types of documents, prescriptions and lab test reports, were involved. And four categories of entities were focused on, including diagnosis names, medication names, test item names and test item values, which are critical to collect for building PHRs.

**Corpus**

The corpus of this study consists of 100 printed medical record documents (including 54 prescriptions and 46 lab test reports, see Figure 1) from 19 different hospitals in China, which were voluntarily provided by individuals. These documents were respectively photographed by several volunteer users using their own mobile phones, including Apple iPhone 4S, iPhone5C, iPhone 5S, LG Nexus 5, Samsung SCH-I779, Xiaomi HM Note, etc. All records were mainly written in Chinese, with many numerical values and a small amount of English words. The corpus includes 1476 entities to recognize, including 84 diagnosis names, 111 medication names, 650 test item names and 631 test item values. For evaluation purpose, these entities were manually annotated by three human readers.
Figure 2. The system pipeline and sample data flow
Image Pre-processing

Document photographs that are shot by mobile phone cameras tend to have lower quality than scanned images due to uneven light and shade, photo noise and skewing. For obtaining reliable OCR results, image pre-processing of the photographs needs to be first performed to enhance image quality.

To reduce the negative impacts of light and shade on OCR, image binarization, which converts an image into a black-and-white image, was performed. Since a photo shot by phone usually has different lighting conditions in different areas, the binarization algorithms that use a global value as threshold cannot generate a reasonable binary image. Thus, we applied the adaptive thresholding algorithm that calculates the local threshold for a small region of the image. For a pixel, its local threshold is the weighted sum of neighborhood grayscale values of the pixel, where the weights are computed in a Gaussian window. The pixel whose grayscale value is greater than the local threshold is assigned white, otherwise it is assigned black. Figure 3(c) shows a binarized image derived from the photo in Figure 3(a).

As shown in Figure 3(c), the binarized result of a photo shot by phone can have much salt-and-pepper noise, which may lead to additional OCR errors in some cases. Notice that most of the salt-and-pepper noise in the binarized image is derived from the Gaussian noise in the original photos. So we used the non-local means denoising algorithm, which replaces a pixel with the average color of the most resembling pixels in a search window, to remove the Gaussian noise in an original image before it is binarized (see Figure 3(b)). And as shown in Figure 3(d), a majority of the salt-and-pepper noise in the binarized image were removed accordingly. In this study, we utilized the implementation of the binarization algorithm and the denoising algorithm provided in the OpenCV 2.4.9 library.

Since it is difficult for users to exactly align their phone screens with paper-based documents during photographing, documents in photos often become skewed, which also reduces OCR accuracy. Therefore, we performed a deskewing algorithm that rotates an image to make text run as horizontally across the document as possible (Figure 3(e)). In this study, we utilized the deskewing algorithm in the image process toolkit provided by IBM Datacap Taskmaster Capture 8.1. We also tried some image cleanup algorithms such as line removal and dot shading removal offered by Datacap. However, in our experiments, these cleanup algorithms did not significantly improve the OCR performance because they also removed useful strokes in text. So these algorithms were not integrated in our current system pipeline.

Optical Character Recognition

For building PHRs, multiple types of characters were supposed to be recognized in medical records, such as Chinese characters, English characters, digits and punctuation. In general, a single OCR engine cannot achieve a satisfactory accuracy in recognizing characters of this complex character set. For example, the accuracy of a Chinese OCR engine in recognizing English characters and digits is usually relatively low, while an English OCR engine normally identifies Chinese characters as garbled text. To address this problem, we applied multiple OCR engines and synthesized the results of the engines in the following post-processing phase. In this study, the OCR was performed using IBM Datacap Taskmaster Capture 8.1, which embeds the Nuance OmniPage OCR engines and supports OCR in multiple languages. We applied the embedded Chinese OCR engine and the English OCR engine, and Figure 4(b) and 4(c) show the results of these two engines respectively for the processed image shown in Figure 4(a). The OCR errors of the examples are highlighted, including the character recognition errors (red circle) and the word segmentation errors (red blank). Note that here we show the results of the OCR engines in plain text for simplicity. Actually, the output of each OCR engine was formatted as a XML document with a line-word-character structure, where each line, word or character has its minimum bounding box B and a confidence value v ∈ [0, 1].
As mentioned above, the results of the multiple OCR engines were synthesized in the post-processing phase. Before doing that, the word segmentation errors from the OCR engines should be corrected, because both the synthesis and annotation approaches work on word-level, and incorrectly segmented words can cause extraction errors.

OCR engines normally segment characters into words based on inter-character intervals, and rarely consider the syntax information such as punctuation. For example, non-numeric characters separated by a full point “.” should be segmented, while two integers separated by a point “.” (e.g., “5.50”) usually represent a decimal number that should not be split. As these criteria are not captured by the OCR engines, we performed two rules sequentially to resegment the words more accurately: 1) Punctuation segmentation, which splits words using a set of pre-defined punctuation, including English punctuation such as “.” and “,” as well as Chinese punctuation such as “。” and “，”; 2) Decimal recombination, which concatenates two integers (e.g., “5”, “50”) that appear in the same line and have none but a point “.” or “，” between them. Figure 4(d) and 4(e) show the resegmented results of Figure 4(b) and 4(c) respectively, where the decimal numbers were correctly recombined (except for a misrecognized QXPEHU in Figure 4(e)).

After the resegmentation, we synthesized the results of the Chinese OCR engine and the English OCR engine to achieve an optimal recognition result. We first initiated a synthesis document by simply copying the result recognized by the Chinese engine. For each word $w_{cn}$ with a bounding box $B_{cn}$ in the document, we found the word $w_{en}$ recognized by the English engine whose bounding box $B_{en}$ has the largest overlap with $B_{cn}$. Then we replaced $w_{cn}$ with $w_{en}$ in the document if $w_{en}$ and $w_{cn}$ fulfill the following three criteria: 1) $w_{cn}$ has at least one digit character; 2) the confidence value of $w_{en}$ is not less than that of $w_{cn}$; and 3) the string length of $w_{en}$ is not shorter than that of $w_{cn}$. Using this rule, we adopted the correct numerical values recognized by the English engine while avoiding its garbled Chinese text. Figure 4(f) shows a synthesized result of 4(d) and 4(e), where the wrong numbers of the two engines were corrected.

From the recognized text, we then annotated relevant medical data. Multiple types of medical records were involved, and in general different categories of data entities can be identified in different types of documents. For example, medication names can only be detected in prescriptions and lab test items can only be identified in lab test reports. Therefore, a document classifier was first built to determine the document type. Besides, since the layouts of Chinese medical records are not standardized and can be very flexible, the location-based methods cannot be used to annotate entities of interest and build entity correlations. Thus, we applied flexible entity annotation algorithms such as fuzzy term matching and regular expression matching to locate and identify the entities of interest, and used a slot-based correlation annotation algorithm to locate the related entities (e.g., pairs of test item names and test item values).

1) Document type annotation: keyword-based approach and machine learning approach

Document type annotation is a general problem in the document classification/categorization area. In this study, we focused on two document types, prescription and lab test report. And in each type of documents, there indeed exist some typical keywords which are able to differentiate each other, therefore a keyword-based document classification approach was used. Having explored hundreds of prescriptions and lab test reports, we collected typical keywords for them. For example, the keywords for prescription include {处方(prescription), 药房(pharmacy), 资费(medical fee), 发药(drug dispensing), …}; and those for lab test report include {检验(test), 标本(sampl specimen), …}. Each keyword set was then written as one regex (regular expression) pattern to facilitate the matching process. Once a medical records is matched against a regex pattern, the document type is determined accordingly.
However, since medical records are multifarious and OCR is error-prone, for some documents, neither of the keywords can be matched. In these cases, we also applied the Naïve Bayes model, which is a machine learning model commonly used for document classification, to annotate the documents. The Naïve Bayes approach constructs a classifier by calculating the probability distribution of selected features from training dataset, and then assigns document labels to problem instances. In this study, the training dataset came from an EHR system in China, which contains 2319 prescriptions and 2803 lab test reports. We used bag-of-words as features, and took “tf-idf” (term frequency and inverse document frequency) instead of “tf” (term frequency) to minimize the noise of common words.

2) Entity annotation: dictionary-based approach and regex-based approach

Named entity recognition (NER) is a subtask in information retrieval, which seeks to locate and classify elements in text into pre-defined categories, such as medical terms (e.g., diagnosis names, medication names and test item names) and numerical values, using linguistic-based approaches and statistical models. Differing from general-purposed NER approaches, there is little context information in medical records; instead, hint information like entity inner structures and closed sets of medical terminologies can be used to develop specific annotation algorithms.

For medical term entities, a dictionary-based approach was used to detect the matches of dictionary terms in text, which required a dictionary with high coverage and good quality. By collecting the standard medical terminologies like ICD-10 and the local medical terminology systems in China, we developed a dictionary-based engine to annotate medical terms. Considering the non-standard terminology usage and inevitable OCR errors, a fuzzy matching algorithm was used by calculating the similarity between a recognized word and a dictionary term:

\[
similarity = w_1 \times \text{unigram similarity} + w_2 \times \text{bigram similarity},
\]

where \( w_1, w_2 \in [0, 1] \), and \( w_1 + w_2 = 1 \). Unigram similarity is the ratio of intersected single words to the total number of single words, and bigram similarity is the ratio of intersected two consecutive words to the total number of two consecutive words. If the similarity is above a pre-defined threshold, the term is taken as an entity candidate. Multiple entity candidates for one word are allowed, which can be finally determined during correlation annotation.

Besides, a regex-based approach was used to annotate the entities with obvious structural patterns, such as numerical value, date and identifier. For example, a numerical value can be identified using the regex pattern “[0-9]+(\.[0-9]+)?”.

3) Correlation annotation: slot-based approach

Correlation annotation aims at locating the relationship among entities (e.g., the correspondence between test item names and test item values). Correlation annotation is usually solved using syntax parser or semantic parser within a given context. Since little syntax information is available in printed medical records, we adopted the semantic approach and leveraged layout and entity type information, where the correlations were represented in pre-defined slot-and-filler formats. A pivot entity (e.g., test item name) must be first identified from the entity annotation results (i.e., entity candidates), then the correlated entity (e.g., test item value) of the pivot can be located according to the entity type. Since there are usually multiple correlations of a same type, to avoid incorrect correlation annotation, two entity-span constraints were applied: 1) the correlated entities must occur in a same line or in two consecutive lines; 2) the correlated entities cannot be interrupted by another pivot entity with the same type.

PHR Construction

Before the annotated entities were adopted to construct PHR documents, we checked whether each entity is credible and rejected the entities with low confidence. Both the confidence value \( v \) that represents the OCR engine’s certainty and the similarity value \( s \) were considered. For a medical term entity, \( s \) is the similarity between the word recognized by the Chinese OCR engine and the annotated dictionary term. And for a numerical value, \( s \) is the similarity between the words recognized by the two OCR engines. If the product \( v \times s \) is not less than a pre-defined confidence threshold \( \theta \), then this entity is accepted. Otherwise, it is rejected and not be adopted in building PHR documents.

Finally, we built structured PHR documents from the accepted entities. For each document type such as prescription and lab test report, a template PHR document was defined, as well as mappings from correlated entities to elements in the template document. The template documents are based on the interface XML format used in our EHR system, which can be easily transformed into the standard CDA (HL7 Clinical Document Architecture) format. Given the annotation results of a document, a template PHR document is first determined according to the annotated document type. Then the accepted entities are mapped to the elements in the PHR document. As shown in the example in Figure 2, three pairs of correlated entities (“Name” and “Value” in the “Lab Test” correlations) were transformed to three elements (“TestResultObservation”) in a PHR document of lab test report.
Results

To evaluate the performance of our methods, we validated the PHR documents automatically built by our approach against the gold standard created by human readers using the corpus described above which has 100 testing documents. The exact match evaluation was performed, where an automatically extracted entity is correct if its text exactly matches that of the gold standard entity (i.e., “5.5” and “5.50” are not regarded as equal). For each experiment configuration, precision (positive predictive value), recall (sensitivity) and F-measure (harmonic mean of precision and recall) were computed.

In our study, we first configured our system pipeline as described in the above section, and performed the evaluation for the confidence threshold value $\theta = 0.0$ (i.e., all the recognized and annotated entities are adopted to generate PHR documents). Table 1 demonstrates the results for every entity category and for all entities. Here the category of “Term” means the union set of the categories of diagnosis name, medication name and test item name. As shown in Table 1, without constraining the confidence value, our system could identify over 80% (recall) entities that were annotated by human readers, and over 90% (precision) of our extracted entities were precise. The performance for the term entities, with a recall of 0.88, outweighed that for the value entities (i.e., test item values), with a recall of about 0.75.

To demonstrate the influence of the confidence threshold, we kept the same configuration as above but gradually changed the threshold $\theta$ from 0.0 to 1.0. As shown in Figure 5, with the increasing of the threshold, the precisions of the system slowly rose and could achieve over 0.98 for the term entities and 0.94 for the value entities, whereas the recalls and the F-measures dramatically descended accordingly.

![Figure 5. Precision, recall and F-measure of the system with respect to the confidence threshold](image)

Besides, we also performed the evaluation on different pre-processing and post-processing algorithms for our system. Table 2 shows the results of the PHR document evaluation on image pre-processing approaches, where the configurations of the other modules except pre-processing were set in the same manner as the experiment shown in Table 1. Compared with the results of directly using original images, the image processing algorithms we used did not significantly improve the precision of the system. However, all the three algorithms promoted the recall to some extent, and the combination of these algorithms achieved the best performance.

Table 3 shows the results of the PHR document evaluation on different configurations of post-processing approaches. Both the word resegmentation algorithm and the multi-engine synthesis algorithm obviously improved the precision and recall of the system, and their combination obtained the best results.

To evaluate the performance of the document type annotation algorithms, we directly compared the types classified by the algorithms with the type tags given by the human readers for the 100 testing documents, and computed the classification accuracy. As shown in Table 4, both the keyword-based and Naïve Bayes algorithms led to a few classification errors, and the combination of these algorithms achieved an absolutely correct result on our testing set.

To evaluate the performance of the term matching approaches, we performed the PHR document evaluation on the exact matching algorithm as well as the fuzzy matching algorithms using unigram similarity and using the combination of unigram and bigram as Equation (1) \((w_1 = 0.4, w_2 = 0.6)\). As shown in Table 5, though the precision of the exact matching algorithm was the highest, its recall was relatively low. The recalls of the two fuzzy matching metrics had no significant difference, but the precision of the combined metric was obviously higher than that of unigram.

To evaluate the applicability of the proposed system, we also performed an experiment on same medical record documents photographed by different users using different mobile phones. 20 printed documents were randomly selected from the corpus and 5 volunteer users respectively shot the 20 documents using their own mobile phones. Figure 6 shows examples of a same document photographed by different users, where the clarity and illumination distribution of the images are obviously different. The quality of the photos shot by user #5 is on the low side in comparison to others. We performed our pipeline on these 20 documents for the 5 users respectively, using the same configuration as the experiment shown in Table 1, and the evaluation results are shown in Table 6. For the images from each user, our system achieved a precision of over 0.85. And the recalls for the images from all the users except #5 were also close (from 0.75 – 0.79).

To analyze the extraction errors of our system based on the results of the experiment shown in Table 1. We detected total 284 errors including 169 missing entities that were annotated by the human readers but not identified by the system, 23 superfluous entities that were not manually annotated but extracted by the system, and 92 incorrect entities of which the results recognized by the system were different with the gold standard. The reasons of the errors were also classified by the human readers, which are shown in Table 7. More than a half of the errors were caused by the OCR engines, and the annotation algorithms also contributed to a large proportion of errors.
Admittedly, the image quality of photographed medical records significantly affects the performance of OCR and annotation. There are two primary image problems that may cause extraction errors: 1) printing and typesetting defects in original printed documents; 2) problems caused by camera or careless photographing. As shown in the experimental results, a majority of the image problems could be solved by the image pre-processing approach and the fuzzy term matching algorithm. The overall system had good tolerance to uneven light and shade, Gaussian noise, and skewing in images, and was adaptable to photos shot by different users using different phones. However, as shown in Table 7, there were still some extraction errors caused by image defects that were not eliminated. Figure 7(a) gives some examples of printing defects where some strokes were not completely printed, and Figure 7(b) shows a typesetting problem where two entities (test item name and value) are concatenated with each other. Besides, more errors tended to occur when the system handled images with low clarity (e.g., some images shot by user #5).

As shown in Table 2, the image pre-processing approach significantly improved the sensitivity of our system, because the uneven illumination distribution, Gaussian noise and skewing problems could be relieved. However, as shown in Figure 7(c), these image processing algorithms also made a few additional errors, where some extremely thin strokes disappeared in the binarized images. Even so, we still applied these algorithms in the current system because the overall performance could be promoted. And a detail-preserving image processing approach can be used to solve this problem in the future.

The limitation of the OCR engines caused more than a half of the extraction errors. Although we did not attempt to modify the algorithms of the OCR engines, we observed that reasonable post-processing algorithms, such as word resegmentation, could greatly improve the overall performance (see Table 3). More importantly, we observed that with well-defined synthesis criteria, the results of multiple OCR engines could be combined to correct some errors from each OCR engine alone. In this study, we only synthesized the results of one Chinese OCR engine and one English OCR engine. It can be predicted that if more OCR engines are integrated in a reasonable manner, OCR errors can be further reduced. As shown in Table 7, the post-processing algorithms produced very few additional errors (one of which has been shown in Figure 4(f)), and the benefits significantly outweigh the drawbacks.

Another key factor that contributed to the extraction errors is the annotation algorithms. We observed two main types of annotation errors. The first type was the superfluous term entities caused by the fuzzy term matching algorithm. Compared with the exact matching algorithm, the fuzzy similarity metric greatly improved the recall of term identification, but indeed incorrectly matched some entities that were not regarded by human readers as terms of interest, and therefore reduced the precision as shown in Table 5. Since the performance goal of the system was not only precision but also recall, we finally used the fuzzy matching algorithm in the system. Another type of errors was the item values that were exactly recognized by the OCR engines and correctly annotated as numerical value entities, but were not correctly linked to their corresponding item names by the correlation annotation algorithm. That is primarily because the location information of the entities is not adequately used by the slot-base algorithm. For the value entities that were correctly identified, the current slot-based algorithm could achieve an approximately 86% recall of correlation annotation, which can probably be further improved by combining statistical learning models such as conditional random field. Besides, though we achieved a 100% accuracy of document classification on our testing set by combining the keyword-based and Naive Bayes approaches, more testing data in the document type level is still needed to further prove the effectiveness of the classification algorithm.

Although the confidence threshold of the system can be configured, we did not finally use it in the current system configuration (i.e.,  $\theta = 0.0$). That is because the performance goal was to achieve both high precision and high recall, and we observed that with the increasing of the threshold, the recall descended more dramatically than the precision increased (see Figure 5). However, if a case requires a higher precision, we can accordingly raise the threshold (and can also use the exact term matching algorithm instead of the fuzzy matching algorithm as discussed above).
Conclusion

Data collection, which is the basis of building PHRs, is very difficult in a developing country like China due to the policy and technical obstruction to giving patients access to EHR data. Considering the easy availability of printed medical records and the high popularity of smartphones, we proposed a practical approach to build structured PHRs from printed medical records photographed by mobile phones. By combining a series of image processing, OCR, pattern matching and machine learning techniques in a reasonable system pipeline, we addressed the problems of low image quality, layout diversity and content complexity of photographed medical records. The proposed approach was applied to build PHRs from real world prescriptions and lab test reports, and the results showed that our approach can automatically extract structured medical data with relatively high precision and recall, and has wide applicability.

As discussed above, the limitations of the current approach caused some errors that could be eliminated by improving the architecture and algorithms in the future, including detail-preserving image processing, synthesis of more OCR engines, as well as layout-aware and statistic-based annotation. This paper focused on the extraction of medical information, such as diagnosis, medication and test item, from medical records. Actually, the privacy information specified by HIPAA, such as patient information and dates, can also be located using our methodology for entity and correlation annotation, which can then be de-identified for data transfer and distribution purpose. Besides, though the current system was designed for printed Chinese medical records, our methodology can also be adapted to those of other languages or hand-written medical records by extending the OCR and annotation modules.

Abstract
When coupled with a common information model, a common terminology for clinical decision support (CDS) and electronic clinical quality measurement (eCQM) could greatly facilitate the distributed development and sharing of CDS and eCQM knowledge resources. To enable such scalable knowledge authoring and sharing, we systematically developed an extensible and standards-based terminology for CDS and eCQM in the context of the HL7 Virtual Medical Record (vMR) information model. The development of this terminology entailed three steps: (1) systematic, physician-curated concept identification from sources such as the Health Information Technology Standards Panel (HITSP) and the SNOMED-CT CORE problem list; (2) concept de-duplication leveraging the Unified Medical Language System (UMLS) MetaMap and Metathesaurus; and (3) systematic concept naming using standard terminologies and heuristic algorithms. This process generated 3,046 concepts spanning 68 domains. Evaluation against representative CDS and eCQM resources revealed approximately 50-70% concept coverage, indicating the need for continued expansion of the terminology.

Introduction
Need for data standardization
Despite the demonstrated potential for clinical decision support (CDS) to improve care quality and promote patient safety (1-4), CDS availability continues to be limited in most clinical settings (5-7). An important reason for this limited CDS availability is the difficulty of scaling CDS across institutions (8-10), with the lack of data standardization being a predominant barrier to sharing (11). Electronic clinical quality measurement (eCQM), which shares many requirements with CDS and can be implemented using a common underlying system (12), has a similar need for standardized data. Indeed, the U.S. Office of the National Coordinator for Health IT and the Centers for Medicare & Medicaid Services are sponsoring an initiative known as the Clinical Quality Framework to develop a harmonized set of standards to fulfill the needs of both CDS and eCQM (13).

Figure 1 provides an overview of aspects of data standardization for CDS and eCQM. One aspect of standardization is the information model, which identifies data classes (e.g., Problem), attributes (e.g., problem code), and the relationship of classes to one another (e.g., the relationship of Problems to Encounters; not shown). Coded attributes
describe concepts such as “diabetes mellitus,” which in turn may be defined by a value set of instance codes that are indicative of the concept (e.g., SNOMED-CT 314902007, type II diabetes mellitus with peripheral angiopathy).

**Need for a concept terminology for CDS and eCQM**

Data standardization efforts in CDS and eCQM have generally focused on standardization of (i) the information model, (ii) the superset of instance codes that may be used within coded attributes, and, in some cases, (iii) individual value sets (14, 15) However, to our knowledge, there has been no systematic effort to define a common concept terminology for CDS and eCQM to facilitate knowledge sharing and semantic interoperability.

Many standard terminologies, such as SNOMED-CT, RxNorm and LOINC, are available for use in CDS and eCQM with relatively adequate breadth, depth, and granularity (16). However, the sheer volume of concepts in these terminologies can make it challenging to ensure that different CDS and eCQM implementers choose the same concepts in their respective implementations. For example, the number of coded concepts in the UMLS Metathesaurus (>1,400,000), SNOMED-CT (> 310,000), RxNorm (> 93,000), LOINC (> 46,000), and ICD-10 (> 12,000) makes consistent concept selection challenging (17). Meanwhile, many terminologies remain semantically incompatible (18). The diversity in different terminological systems hampers the possibility of sharing and reasoning with data within different systems (11). Therefore, the challenge lies less with the lack of relevant standards, but more with the fact that multiple terminologies are in concurrent use (18), and with the sheer volume of concepts. Furthermore, the lack of hierarchical structures in some terminologies makes it difficult to find useful terms that are less specific, as is often needed for CDS and eCQM. Consequently, it is imperative to identify and maintain a much smaller subset of broader concepts with utility for computerized CDS and eCQM. Here, we describe an effort to meet this need within the context of OpenCDS, which is a multi-institutional collaborative initiative to develop open-source, standards-based tools and resources to enable CDS and eCQM at scale (12, 19).

**Methods**

**Project context and operational use of terminology**

The concept terminology was developed in the context of the OpenCDS effort to support CDS and eCQM. OpenCDS has been implemented in a number of electronic health record (EHR) systems and provides a reference implementation of the HL7 vMR data model standard (12, 19-22). The vMR was designed originally for CDS but has been subsequently applied to eCQM as well (12). The vMR contains 68 coded attributes, such as Adverse Event, Encounter Type, Goal Focus, Observation Focus, Problem, Procedure, Medication, and Supply (Table 1).

![Figure 2. Use of concept terminology in OpenCDS knowledge authoring.](image)

In OpenCDS, CDS or eCQM modules are authored as a series of human-readable rules and then translated into machine-executable knowledge. Concepts are accessed via drop-down lists specific to the type of concept involved (e.g., gender) (Fig. 2). These concepts, in turn, are mapped to value sets containing applicable local or standard codes. The use of concepts enables a clear separation of concerns between terminology mapping and logic authoring.

**Objectives and requirements**

The objectives of this project were to (i) define a standard and extensible approach for curating a concept terminology for CDS and eCQM that can be leveraged by the OpenCDS community and to (ii) populate the terminology with an initial set of common, high-level concepts useful for CDS and eCQM knowledge authoring. Requirements included (i) adherence to the 80-20 rule, with a goal of initial inclusion of high coverage of concepts likely to be needed for
typical CDS or eCQM use cases; (ii) the leveraging of standard terminologies; (iii) internal consistency; and (iv) avoidance of duplicate concepts.

**Overview of approach**

The terminology was developed using three steps. First, relevant concepts were identified in a systematic, physician-curated manner. Second, concepts were de-duplicated using UMLS MetaMap and Metathesaurus. Finally, concepts were named using standard terminologies and heuristic algorithms. These steps are outlined in greater detail below.

**Step 1a: Candidate concept identification**

To identify relevant concepts, we first reviewed the Healthcare Information Technology Standards Panel (HITSP)’s Clinical Document and Message Terminology specification (HITSP C80, Version 2.0.1) (23). This document defines the vocabularies used by HITSP specifications for clinical documents and messages to support the interoperable transmission of information. If this specification defined a finite value set for a targeted coded attribute type, that value set was used as the set of candidate concepts for physician review and curation in the next phase of this step.

If HITSP C80 did not define a value set for a coded attribute type, we next searched the Public Health Information Network Vocabulary Access and Distribution System (PHIN VADS) and Value Set Authority Center (VSAC). If an appropriate value set was identified here, then that value set was identified as the candidate concept set.

If the above resources did not identify a relevant value set, or if the value set identified was extremely large in scope, the potential concepts for physician review were restricted using various methods. For example, HITSP C80 recommends concepts using the Veteran Administration and Kaiser Permanente (VA/KP) problem list subset of SNOMED-CT for describing problems (23). However, the VA/KP problem list subset contains over 15,000 concepts, making it a challenge to review. Therefore, we instead used the Clinical Observations Recording and Encoding (CORE) subset of SNOMED-CT (24). CORE was based on datasets submitted by 8 institutions, and it is a frequency-based approach to problem list development. Compared to VA/KP, CORE is smaller, and 94.8% of coded problem entries from Brigham and Women's Hospital are in the CORE subset (4), indicating high coverage of used concepts. For our purposes, we started with the 266 CORE problem list entries that were reported by most (8 or 7) of the institutions as the candidate set of problem concepts for potential inclusion in the initial CDS/eCQM terminology.

Similar methods were used for enriching the candidate set of concepts designated for physician review. For example, laboratory test concepts were restricted to the LOINC Universal Laboratory Order Codes, whose approximately 300 codes cover more than 95% of the lab test orders in the United States (25).

**Step 1b: Physician curation**

After candidate concepts were identified in the step above, a physician informaticist (VK) who is a practicing hospitalist reviewed each concept in the candidate set and identified those that have a reasonable likelihood of being useful for CDS purposes based on personal experience. The physician informaticist classified these concepts into 4 categories: 1 - high priority, 2 - moderate priority, 3 - low priority, and 4 - not appropriate. Concepts with priority 1 and 2 were uploaded into the Apelon Distributed Terminology System (DTS) terminology server for management.

**Step 2: De-duplication**

Duplicate entries are a common problem in terminologies (6, 26), even in the UMLS Metathesaurus (27). To identify and deprecate duplicate concepts, we implemented a systematic methodology for identifying potential duplicates, which were verified through physician review (Fig. 3).

Before starting, we identified candidate concepts for de-duplication by excluding concepts that had previously been deprecated or were being used for administrative purposes (e.g., to name a specific quality measure, such as HEDIS Breast Cancer Screening). We then searched for exact string matches to SNOMED-CT terms (including synonyms) in the UMLS Metathesaurus, capturing the corresponding UMLS concept unique identifier (CUI) through the process. This subset of the terminology (T1) represented a large portion of the original set, indicating that SNOMED-CT was a reasonable source for concept names. The remaining OpenCDS concepts (R1) were then screened for perfect string matches to the terms in any other standard terminologies in UMLS, and the results were processed similarly (T2).

For the remaining concepts with no perfect string matches available (R2), the UMLS MetaMap tool (28) was used to identify potential matching UMLS CUIs. Concepts that could not be matched to any UMLS terms in this manner
(R3) were generally unique concepts used as intermediate conclusions (e.g., “age $\geq 50$ and $< 75$ years”) and were not processed further for de-duplication.

Next, we combined all the concepts and the corresponding UMLS CUIs from T1, T2 and T3 and identified potential duplicate concepts sharing the same CUIs. These potential duplicates were reviewed by a physician. If two or more concepts shared the same CUI but were deemed to be distinct, we updated the CUI for one of the concepts using the UMLS Metathesaurus. If two or more concepts were deemed to be duplicative, one was kept and the rest were deprecated.

![Strategy to identify duplicate concepts](image)

**Figure 3.** Strategy to identify duplicate concepts.

**Step 3: Concept naming**

For concepts matched to more than one CUI, the preferred term for each CUI was obtained from the UMLS Metathesaurus and reviewed to identify the most appropriate CUI for the concept. Next, using the CUI associated with each concept, preferred terms from appropriate standard terminologies were obtained by leveraging the UMLS as shown in Fig. 4. Finally, concept names were post-processed for consistency using heuristic algorithms. For example, capitalization schemes were standardized. Also, concepts were named as the first major category followed by any modifiers to facilitate finding all variations on a root concept in a drop-down list. For example, “Bilateral Mastectomy” was renamed “Mastectomy, Bilateral” and “Lower Extremity Amputation” was renamed “Amputation, Lower Extremity.”
Evaluation of concept coverage
We evaluated the degree of coverage of the concept terminology for sample CDS and eCQM knowledge resources. For CDS, we reviewed the data sections of example Arden Syntax Medical Logical Modules provided in the appendix of version 2.8 of the standard (29). For eCQM, we reviewed the first 50 value sets in the National Quality Forum’s eCQMs from 2011 (30).

Results
Concept identification, de-duplication, and naming
3886 concepts spanning the 68 vMR coded attributes were identified for potential inclusion in the terminology. Following physician informaticist review, approximately 2,200 clinical concepts were selected for inclusion.

![Figure 4](image)

Figure 4. Strategy to identify standard terms for local terminology.

Our systematic de-duplication method identified 110 potential duplicates. After review by a physician, 72 concepts were confirmed to be duplicates and deprecated. For example, “Urinary retention” and “Retention of urine” were found to be duplicates, leading to one of the concepts being deprecated. Finally, 1,928 concepts with UMLS CUIs were named using SNOMED-CT, RxNorm, and other standard terminologies included in the UMLS.

Concept upload to Apelon DTS terminology server
Concepts were then uploaded into the Apelon DTS terminology server and mapped to corresponding coded attribute types. Each of these concepts from the external terminologies then became a unique Apelon DTS concept, and a code was assigned automatically to the concept. All concept names were capitalized (proper case). This import also updated the hierarchical relationships so that concepts are the descendants of corresponding vMR coded attribute types. In some cases, a single concept can be associated with two or more coded attribute types, but concepts were defined only once. For example, “Pregnancy Test” can be either an Observation Focus with a possible result value or simply a Procedure that was performed. Accessing “Pregnancy Test” from Observation Focus or Procedure in OpenCDS will bring the user the same concept and code (C1693).

Concept coverage
The terminology created was evaluated against a previously unseen set of Arden Syntax Medical Logic Modules and National Quality Forum eCQMs. This analysis showed that the terminology developed covered approximately 70% of the concepts referenced in the Medical Logic Modules and approximately 50% of the concepts referenced in the
eCQMs. Many of the concepts that were not covered by the terminology consisted of concepts for specific medications.

Discussion
Implementing CDS capabilities usually requires several terminologies due to their different domain(s) of coverage and granularity (20, 31). As a result, concurrent use of different terminologies is a significant challenge, and a CDS resource designed for use in one setting may not be readily usable in another setting that uses a different set of terminologies, even when similar concepts are being captured (18). Furthermore, when different institutions use different subsets with non-overlapping terms, significant interoperability challenges occur (4). To address these issues, we built a terminology for CDS and eCQM based on the HL7 vMR information model as a part of the OpenCDS initiative. A central part of this terminology development effort was the definition and application of systematic approaches to de-duplication and naming standardization.

Achieving semantic interoperability for CDS and eCQM depends on the use of common information models and common associated concepts (32). In our study, we sought to define a “starter set” of concepts that have a reasonable likelihood of being useful for CDS or eCQM purposes. However, identifying what terminology is “best” or which term is “common” is challenging. For example, some concepts that are common to ambulatory care may not be relevant in an inpatient scenario. Thus, besides the domain-specific expertise from our group, our strategy was to leverage established sources of common concepts such as the SNOMED-CT CORE problem list and HITSP recommendations.

Implementing effective vocabulary control in medical informatics includes facilitating the selection of the most appropriate concept for a given clinical scenario (33). Wright et al. used human immunodeficiency virus (HIV) as an example to demonstrate the importance of screening the concepts for a specific data attribute. In this example, they note that SNOMED-CT has 138 concepts related to HIV and that, without appropriate filtering, a clinician may easily select an incorrect code by mistake (4). We believe our terminology consisting of common and relevant concepts will lead to less chances for inadvertent selections of inappropriate concepts during knowledge authoring.

We included concepts from standard terminologies, such as SNOMED-CT, LOINC, and HL7. In addition, we have added concepts without correspondence to standard terms, primarily administrative concepts such as intermediate conclusions (e.g., “Denominator Inclusion Criteria Met”) or quality measure specifications (e.g., “HEDIS Frequency of Prenatal Care Measure”). Thus, the OpenCDS terminology brings concepts together from disparate controlled terminologies and non-standard terminologies into a single conceptual dictionary of medical concepts. This approach is supported by the vMR information model, which can make use of both standard and local codes. Although OpenCDS can make use of data expressed in many different medical terminologies, it does so through the use of OpenCDS concepts, which map one or more specific and concrete codes from standard or proprietary medical terminologies to a single OpenCDS concept code. An OpenCDS concept is the interface between the clinical ideas and the data details that represent instantiations of the clinical concepts. The clinical rules use OpenCDS concepts in preference to references to the raw data, and terminology mappings provide implementations of those concepts as value sets of codes from one or more code systems. This separates the logic of the rules from the details of the data that the rules work on, thereby facilitating knowledge authoring, maintenance, and sharing.

We learned some lessons when building and maintaining the foundational terminology. When adding concepts in the future, a careful analysis is needed to determine if a concept closely relates to an existing concept. Care should also be taken to ensure consistent naming schemes (34). To avoid ambiguity and to offer an easy way to identify duplicates during maintenance, full names should be provided, either directly or as a concept property.

Building this terminology is an ongoing task. As identified in the evaluation, while the terminology had substantial coverage of relevant concepts, there were still significant gaps in the content. To address this need for continual enhancement and maintenance, we are developing standard operating procedures for adding new content in a systematic, consistent, and non-duplicative manner. In particular, we are seeking to make it easier for OpenCDS users who are not a part of the core development team to request the addition of new concepts.

While the focus of this study was on CDS and eCQM, there are potentially many other contexts in which a standards-based, domain-optimized terminology could provide value. For example, clinical specialties may wish to define common concepts used in their domains, and information systems may benefit from the definition of common concepts.
used in specific sub-systems (e.g., order entry). While we have not yet applied our methodology to the development of any additional terminologies, we speculate that the methods used in this study—entailing systematic concept identification, deduplication, and naming—could be helpful in developing and maintaining such domain-optimized terminologies.

Conclusions
In this paper, we shared our experiences in building and maintaining a terminology for CDS and eCQM, which is in active use within the OpenCDS community. To the best of our knowledge, this is the first terminology developed specifically to meet CDS and eCQM needs. These concepts and tools are freely available to the open-source community to use and adapt. Because this terminology was built in reference to a standard HL7 clinical information model, our methods and results are likely to be applicable for implementations in other institutions and settings. We believe our experiences described herein will also be informative for others who seek to maintain controlled terminologies in pursuit of semantic interoperability.

Analysis of empty responses from electronic resources in infobutton managers

Abstract

Infobuttons provide context-aware educational materials to both providers and patients and are becoming an important element in modern electronic health records (EHR) and patient health records (PHR). However, the content from different electronic resources (e-resource) as responses from infobutton manager has not been fully analyzed and evaluated. In this paper, we propose a method for automatically analyzing responses from infobutton manager. A tool is implemented to retrieve and analyze responses from infobutton manager. To test the tool, we extracted and sampled common and uncommon concepts from EHR usage data in Intermountain Healthcare’s enterprise data warehouse. From the output of the tool, we evaluate infobutton performance by multiple categories, including against the most and less common used concepts, grouped by different modules in patient portal, by different e-resources, and by type of access (standardized Health Level Seven (HL7) vs not). Based on the results of our evaluation, we provide suggestions for further enhancements of infobuttons to the current implementation, including suggesting accessing priorities of e-resources and encouraging the use of the HL7 standard.

Introduction

Infobuttons have been becoming an increasingly important element in modern EHRs and PHRs and serve as a notable solution for addressing clinical information needs at the point-of-care. Currently infobuttons are an important part in the HL7 standard and well as in the meaningful use. Infobuttons can be used to deliver educational materials to both physicians and patients. Infobuttons provide services to deliver context-aware information, which has proved to be an effective way for retrieving more accurate information to the end users. The context of an infobutton request includes basic information from the user, the patient, the system, and the requested concept. As a result, besides the requested concepts that a user would normally type into the search box, the infobutton manager is intelligent enough to retrieve information from different e-resources and find the best match of an input concept given the provided context. In that way, content from the infobutton response is tailored to be more accurate to reflect the needs of the end users.

It is very important that infobuttons perform well to satisfy users’ information needs, especially in PHRs where the ends users have less professional knowledge than physicians in seeking out good clinical information. However, the content brought up by infobutton manager has not been fully analyzed and its performance is not well-documented in the medical informatics literature. The lack of a full systematic analysis of the content might put designer’s bias into the infobutton manager and result in less than optimal responses. These can result in a frustrating end-user experience, one that could lessen their likelihood of using the tool in the future.

One of the interesting limitations of most current infobutton implementations is that the infobutton manager is typically not aware of the content it will receive before it generates a link that directs users to it. This occurs because the first version of the HL7 standard (the one that is most widely adopted) is a unidirectional standard that does not allow for metadata to flow back to the infobutton manager. As such, there is an implicit trust between the infobutton manager (on the EHR side) and the content provider that there will be relevant content returned. Clearly, content providers have a finite set of available content, and it may not be indexed in such a way that all of it is readily accessible from the infobutton manager. This creates the potential for ‘empty responses’ from e-resources linked to from the infobutton manager, or scenarios in which a user clicks on a link from the infobutton and arrives at a page with zero results. This scenario is to be anticipated at least some of the time when linking from very uncommon concepts, but it becomes notably worse if the infobutton manager returns empty responses in commonly used concepts or highly-trafficked modules.

However, systematically analyzing content brought up by infobuttons is a new challenge. In the current implementation of infobutton managers, the rank of e-resources is predefined based on the designer’s interest. There is nowhere in the current design to collect user’s feedbacks on the content of e-resources from infobutton manager.
In this research, we propose a method to automatically detect empty responses from e-resources and provide statistics on the empty responses. The content from infobuttons is retrieved from Intermountain Healthcare’s patient portal MyHealth (12). The content coverage presented in this manuscript includes three modules in MyHealth and seven different e-resources in these modules. We implemented a tool to automatically detect empty responses for sampled concepts. Each concept sends an infobutton request. These concepts are sampled from the three most trafficked ‘infobutton-supported’ modules in our personal health record, including health concerns (problem list), medications, and tests and procedures (lab values). We implemented a tool that is capable of firing a series infobutton requests (from a list of input parameters), automatically detecting empty responses, and recording data for further analysis. The number of empty responses is then classified by module and by e-resources.

**Hypothesis**

In approaching this evaluation, we anticipate that (1) websites with HL7 standardized API will return fewer empty responses; (2) infobuttons will return fewer empty responses in more commonly used concepts; (3) the most used infobutton module will return the fewest empty responses (4) websites will exhibit variance in supporting different modules and in supporting common and uncommon concepts. We expect that the conclusions help researchers to better understand the vacancy rate in content brought by infobutton and therefore improve the current performance of infobutton. From the distribution of the empty responses, the conclusion also help designers to better assign accessing priorities for different websites so the end user will see less empty responses which sometimes are frustrating.

**Background**

Intermountain Healthcare is a not-for-profit integrated healthcare delivery system based in Salt Lake City, Utah. It provides healthcare for the entire state of Utah and parts of southeastern Idaho. Intermountain maintains 22 inpatient hospitals (including a children’s hospital, an obstetrical facility and a dedicated orthopedic hospital), more than 185 outpatient clinics, and 18 community clinics serving uninsured and low-income patients. Intermountain provides primary and specialty care for approximately half of the residents of the state of Utah. Intermountain Healthcare has been recognized in the literature for supporting best care practice with clinical decision support interventions (13). Intermountain’s infobutton manager (a key component of this effort) is used regularly and its development and uptake have been detailed previously (14).

Infobuttons have been in use at Intermountain Healthcare for over 15 years (15,16). They have been integrated in two separate clinical systems, including usage from 4 major modules within these systems. Usage has steadily increased over the years, with over 1,700 unique monthly users, accounting for over 18,000 infobutton sessions per month.

Infobuttons have been made available for patient use from Intermountain’s patient portal MyHealth since early 2014. MyHealth is actively used by many patients, with tens of thousands of logins per month. This implementation based on the general OpenInfobutton (15) has been augmented with local services, supporting internal logging, integration with terminology services, and enhancements to satisfy local security requirements. This is the first exposure of infobuttons to the public network in Intermountain Healthcare. Infobuttons are available from the health concerns, medications, and lab value modules in myHealth. Currently, infobuttons link to seven different e-resources from MyHealth, including Krames StayWell, MedLine Plus, HealthFinder.gov, FamilyDoctor.org, Mayo Clinic, Drugs.com, and LabTestsOnline.

This research analyzes infobutton responses in MyHealth from three modules including Medications, Tests and procedures, and Health concerns. The analysis is based on 400 sampled concepts from each module. Specifically, we focus on automatically detecting empty responses for these concepts in infobutton responses and report the related statistics in pursue of enhancing the current implementation of infobuttons.

The targeted concepts are sampled from the Enterprise Data Warehouse (EDW) where patients’ health records are saved. In each module, we select the two sets of concepts, which are the top 200 and the bottom 200 ranked by the usage of all the concepts. The selection of these two sets enables us to differentiate infobutton performance between the most common conditions and the least common conditions. We expect that infobutton supports the common conditions better than the uncommon conditions.

The empty responses will be recorded and sorted out by module and by e-resource respectively. By Module, since Medication has over 75% of infobutton usage from the previous research, we expect that infobuttons will perform...
well in Medication with less empty responses than the other two modules. Also, by classifying empty responses in each e-resource, we could evaluate the performance of e-resources and expect variances in performances of e-resources.

In addition, the research compares empty responses in e-resources which supports HL7 standard with these without HL7 standard. We expect that the HL7 standard API results in more accurate search items as well as less empty responses because HL7 standard is context-aware with the patient information as well as the matching criteria are based on the standard coding systems, instead of free text.

Methods

This section describes the complete process of retrieving infobutton links and detecting empty responses from all the infobutton supported e-resources in three modules of patient portal MyHealth. The process includes building a tool, sampling concepts, and collecting empty responses from each e-resource. The tool automatically sends an infobutton request for each sampled concept and record empty responses if detected. The concepts are sampled from Intermountain’s enterprise data warehouse, which stores longitudinal patient data. The empty responses are collected by running the tool against the sampled concepts.

Automatically detect empty responses

We designed a program to analyze the content of e-resources derived from infobutton requests in MyHealth. In Figure 1, we demonstrate the workflow of the automatic process. First, a series of concepts is fed into the program for analysis. For each input concept, an infobutton request is composed, using the context information from a test patient and a test provider (which were both predefined and fixed for all the infobutton requests). The infobutton manager processes the request and generates a corresponding response with supported e-resources. For each URL listed from the supported e-resources, the program runs the URL and retrieves and parses the remote content. By parsing the header of the content we record the status code from web pages while the number of returned items from each URL is recorded by parsing the body of the content. A set of rules leads the process of parsing the remote content. In a rule, we define the path in HTML/XML to extract interested information from a specific e-resource. Each e-resource has its own set of rules that allow us to find and pinpoint key information in the page for analysis. By these predefined rules, our program is intelligent enough to identify empty responses and record URLs and other metadata for further analysis.
We extracted a large data set for analysis from each of the three infobutton domains. We created two sets of concepts for each infobutton supported modules including medications, health concerns, and tests and procedure. In a module, these two sets represent the most common conditions and the most uncommon conditions based on usage of concepts. In this research, we selected the top 200 to represent to most common conditions while the bottom 200 to represent the uncommon conditions. For each sampled concept, we compose an infobutton request. In Table 1, we display the count of hits for the concepts in the top and bottom set respectively in each module in year 2014. In Table 2, we demonstrate the representations of concepts from the top 5 and the bottom 5 in each module separately, where by (T) it refers to the top 200 concepts and by (B) it refers to the last 200 concepts ranked by the count of concepts’ hits in EHR system.

Result from auto-detection of empty responses

We ran this tool for auto-detecting empty responses against the top and bottom 200 concepts in the module of Health concerns, medications, and Tests and procedures. Each concept sends an infobutton request. The process resulted in a report of empty responses for all the e-resources. As shown in Figure 1, the last step involves the capture of relevant output from the auto-detection of empty responses. These records includes information such as calling module, concept, the name of website, number of returned items from the website, status code of http response from the website, and the URL if the link does not return any items for the query. In our research, we processed and stored all 'empty responses' from the e-resources linked to from infobuttons in MyHealth, including Family Doctor, MedlinePlus, Krames, Health Finder, Mayo Clinic, Drugs.com, Lab Tests Online.

The number of empty responses was classified per e-resource and per module separately. In Table 3, we report the number of empty responses from each module as display in rows and from seven e-resources as shown in columns. In each row, a module contains the two sets of concepts represented by (T) for the top 200 concepts and (B) for the last 200 concepts ranked by the count of concepts’ hits in EHR system, as described in the Section of Dataset. The modules include health concerns, medications, and tests and procedures. The symbol ‘-’ in the table means that the e-resource in the column does not support the according module in the row from the initial design. In Figure 2, we visualize the result from Table 2, displaying the number of empty responses (vertical) for each e-resource in the top and bottom 200 concepts in three modules (horizontal). Health concerns has five e-resources, medications has four e-resources, and tests and procedures has 3 e-resources.

By module, the health concerns (B) has the most number of empty responses while the medication (T) has the least number. By e-resource, Drugs.com has 0 empty responses for all the infobutton requests while Health finder has the most of empty responses. We will further analyze the result in the next section.

Table 3. Total number of empty responses from each e-resource in three modules
(T): top 200 concepts; (B) bottom 200 concepts.
We also record the number of returned items from each e-resource. Table 4 shows the total number of returned search items from e-resources given the top and bottom 200 concepts in three modules. The result will be further analyzed in the next section.

Table 4. Total number of returned items from each e-resource in three modules (T): top 200 concepts; (B) bottom 200 concepts.

Analysis of empty responses

The empty responses from websites were categorized by module and by e-resource. From the result, we evaluated the performance of infobutton by module, by e-resource, and by support for the HL7 standard (or the lack thereof).

An e-resource can be configured to support only one or multiple modules. For example, Krames supports all the three modules while Lab Tests Online only supports tests and procedures. In our results, per concept calculation accounts for only the supported concepts in supported modules for an e-resource in order to normalize for comparing performance of different e-resources that have different coverage.

In Table 5, we demonstrate the rate of empty responses and the average number of returned items from each e-resource. Each column refers to an e-resource where the last column reports the average over all the e-resources. In the row for rate of empty responses, for each e-resource, the rate is computed from all the infobutton requests in the process by:

\[
\text{rate of empty responses per eResource} = \frac{\text{total number of empty responses per eResource}}{\text{total number of infobutton visits to the eResource's website}}
\]

The average of the return items per concept for an e-resource is computed by:

\[
\text{average of returned items per request} = \frac{\text{total number of returned items per eResource}}{\text{total number of infobutton visits to the eResource's website}}
\]

The average rate of empty responses for all the e-resources is 30.60%. HealthFinder.gov had the highest rate, which almost doubles the average rate for all the e-resources. Drugs.com and Krames have the lowest overall ‘empty
response’ rate. Drugs.com has a zero empty responses because of its large database as well as possibly broader matching criteria, which can be inferred from its average number of the returned items, at 37,450 per requested concept. That average number is much bigger than the rest of the e-resources. By taking out Drugs.com from the average returned items, the average number of returned items for all the e-resources changes from 5,407 to 57 per requested concept. Krames has low rate at 1.00% of empty responses and a moderate number 54 for the average number of search items, which is close to the average number by counting out Drugs.com. Health Finder returned few search items but it has a high rate of empty responses, which indicates that the website might have less coverage of concepts. Mayo Clinic has a lower than average of the empty responses but has a bigger number of returned items, which means that it has a good coverage of content and therefore is more likely to return results.

Table 5: Rate of empty responses and average returned items per e-resource

In Table 6, we report the percentage of empty responses for each e-resource by sets of concepts. The concepts are sampled from the top 200 and bottom 200 and grouped from all the supported modules. For example, Krames supports three modules so its top concepts cover the top 200 from all the three modules. For an e-resource, the percentage in the table is computed by the sum of empty responses over the total number of concepts in the top and bottom concepts separately. Noticeably, the top concepts, with an average rate of empty responses at 14.69%, always have lower percentage of empty responses comparing to the bottom concepts, with an average rate of empty responses at 46.51%. That means, all the e-resources support the most commonly used concepts better than the least used ones. Drugs.com has 0 empty responses while Krames and MedlinePlus have the lowest rate of empty responses. But MedlinePlus has a significant number of empty responses for the bottom concepts, comparing the Krames. Health Finder and Family Doctor have both the highest rate of empty responses in the bottom concepts, where the rate is 85.50% and 86.00% respectively. With that high rate of empty responses, we could suggest removing the Health Finder and Family Doctor from the list for these bottom concepts and have users focus on these which return non-empty items.

</tr>
</tbody>
</table>

Table 6: Empty responses from e-resources in the top and bottom 200 concepts

In Table 7, we present the rate of empty responses for each e-resource by module. The symbol ‘-’ means that the e-resource in the column is not supported in the module in the row. For an e-resource, the rate of empty responses is computed by the number of concepts with empty responses over the total number of concepts in a module. The medication has the lowest rate of empty responses at an average of 10.42%, comparing to the highest of 35.20% in Health concerns. Medication has the most usage from previous research of infobutton usage. That suggests that the e-resources provide better coverage in modules with higher infobutton usage. Krames is supported in all the three modules and performs well, where Krames has the lowest rate of empty responses in all of the modules. Health Finder and Family Doctor both support a single module of Health concerns but have a high rate of empty responses, where is at 60.50% and 51.75% respectively. We would suggest lower the accessing priority of these two e-resources in Health concerns so people will have less chance to be frustrated with empty responses. Medline Plus and Mayo Clinic perform similarly in Health concerns and Medications, which are both close to the average of all the e-resource in each module. Lab Tests online has a high rate of empty responses, so we would suggest to lower the accessing priority for Lab Tests online while the vender could try to broaden the search criteria as well as improving content coverage in the backend.
The difference in rate of empty responses between e-resources with and without a HL7 standardized API is sharp, as shown in Table 8. The rate of the empty responses is computed by the number of empty responses grouped by the e-resource’s API over the total number of infobutton requests fired from that group. In Table 8, we compare the rate of empty responses between e-resources with HL7 standard API and non-HL7 standard API, in each module with the top and bottom concepts. All the e-resources have a very low rate of empty responses for the top concepts in both HL7 standard and non-HL7 standard column. However, the e-resource supporting HL7 standard API has a noticeably different performance in Health concerns and Tests and procedures. In Medication module, the performance of infobutton requests is generally the best for both the HL7 standard API and the non-HL7 standard API, where the rate of vacancy is similarly low. The non-HL7 standard API, especially Drugs.com which has zero empty responses, is mostly based on free text search and has adjustable broader matching criteria, which results in a lower rate of empty responses. Overall, the bottom 200 concepts using the non-HL7 standard API in the Health concern have the highest rate of empty responses. Interestingly the top 200 concepts also using the non-HL7 standard have the lowest rate of empty responses, mostly because of Drugs.com’s zero contributions to the empty responses in this module. Despite the contribution of the non-HL7 standard API from Drugs.com, the HL7 standard API performs similarly to the rate of empty responses in Medication.

Table 8: Rate of empty responses in e-resources supporting HL7 API and non-HL7 API

**Discussion**

This paper analyzes the empty responses from infobutton manager by module, by e-resources, and by supporting HL7 standard or not.

The common concepts always have less empty responses than the uncommon concepts. All the e-resources perform better at returning content for the common concepts than the rare ones. We conclude that the overall content coverage for common concepts is good. In the meantime, more effort should be sent to improving the content coverage of the less commonly used concepts.

By module, medications has the best performance in terms of returning less empty responses and more number of returned items for a requested concept. That matches the fact that medications has the highest usage of infobuttons. As a module with higher demand, we conclude that infobuttons do well support the usage.

By e-resource, Krames is notably the best e-resource among the seven e-resources we analyze in this paper. Krames has the lowest rate of empty responses and returns a moderate number of items. HealthFinder and Family doctor will need to improve significantly upon the number of empty responses in order to be viable e-resources on the infobutton. Drugs.com never brings users to a blank page, but leaves some questions about users’ perceptions with the content returned. Further analysis will be needed to assess the quality of the returned items.
E-resources supporting HL7 standard consistently perform better than the non-HL7 standard e-resource by a significant margin. As such, we would encourage implementers toward the usage of the HL7 standard for e-resource providers as possible.

Conclusion and Future work

We present a method to analyze the content from infobutton requests. The empty responses are automatically detected from e-resources. The result of the empty responses is analyzed by module and by e-resource. We suggest that more effort will be needed to cover content from the less common conditions, such as less used concepts and less used modules. We also encourage e-resource providers to implement the HL7 standard therefore the performance of infobuttons can be improved.

In future, we will need to analyze the quality of the content from different e-resources. Also we will need to read through the empty responses and categorize the reasons for the failures. Furthermore, we can build a tool to analyze the content offline and dynamically create the list of e-resources promoting these with better content and therefore avoid the empty responses at real time.

Abstract

Multiple choice questions play an important role in training and evaluating biomedical science students. However, the resource intensive nature of question generation limits their open availability, reducing their contribution to evaluation purposes mainly. Although applied-knowledge questions require a complex formulation process, the creation of concrete-knowledge questions (i.e., definitions, associations) could be assisted by the use of informatics methods. We envisioned a novel and simple algorithm that exploits validated knowledge repositories and generates concrete-knowledge questions by leveraging concepts’ relationships. In this manuscript we present the development and validation of a prototype which successfully produced meaningful concrete-knowledge questions, opening new applications for existing knowledge repositories, potentially benefiting students of all biomedical sciences disciplines.

Introduction

Multiple choice questions (MCQ) have been widely used as an assessment tool in biomedical sciences education, currently being a major component of recognized tests such as the Graduate Record Examinations (GRE)1, the United States Medical Licensing Examination (USMLE)2, and the American Board of Medical Specialties3. Appropriately constructed, MCQ can be used to objectively assess all levels of learning of the Bloom’s taxonomy of cognitive learning4, from concrete-knowledge up to application5.

A MCQ usually consists of a question or a statement to solved (usually referred to as “stem”), followed by a list of possible answers to choose from. There is only one correct answer, while the incorrect answers are distractors. Formulating MCQ, specially finding meaningful distractors, is resource intensive and time consuming. This, prevents educators from openly sharing question-banks with students, usually restricting access to local cohorts6. This behavior limits the contribution of MCQ to evaluation purposes mainly, while it is recognized that they can contribute to the student training process by improving knowledge retention and learning.7 Furthermore, it has been reported that exposing students to questions before receiving learning material can have beneficial effects on students’ learning8.

Thus, in an attempt to facilitate MCQ generation and expand their use beyond evaluation purposes, automatic MCQ generation approaches has been attempted.9 Although applied-knowledge questions require a complex formulation process10 (e.g., “what is the best antibiotic for a patient with infection X and allergic to Y?”), automatic MCQ formulation strategies have been able to successfully generate concrete-knowledge questions. Distinct approaches range from entirely automatic generation of true and false statements by leveraging classes and relationships from domain ontologies, and presenting those statements as possible answers for the stem “choose the correct sentence”9, up to complex computer-aided natural language processing (NLP) based methods11.

Expanding the previous efforts in automatic MCQ generation from domain ontologies, we envisioned a novel approach that automatically leverages existing knowledge repositories, aiming at providing open MCQ banks for students to train and learn. We hypothesize that a simple generation strategy based on concepts’ definition and their hierarchical relationships can be leveraged to generate MCQ with meaningful distractors. In the current manuscript, we describe the development and validation of our novel approach based in a controlled vocabulary thesauri, and present a working prototype: a new resource for students in biomedical sciences to learn and review concepts.
Methods

Central paradigm. We attempted to create concrete-knowledge questions, specifically definitions, relying on the premise that hierarchical relationships of concepts could be leveraged to retrieve meaningful distractors. Based on a hierarchical tree structure of concepts and definitions (i.e., a taxonomy), we can select a concept, and expose its definition as the “question”. Then, the concept name becomes the correct answer. Since concepts that share a parent concept are similar but at the same time mutually exclusive, they can be considered appropriate distractors. Thus, we then search for siblings in the hierarchy to retrieve distractors and complete the question (see Figure 1).

Data source. Ontologies, particularly in the biomedical domain, are well maintained repositories of concepts and relationships, suitable for our aim. We began our search for an appropriate source for questions’ generation in the Unified Medical Language System (UMLS) definitions table (MRDEF.RRF), which encompasses over one million definitions contributed by the National Cancer Institute metathesaurus (50.1%), the Gene Ontology (27.4%), the National Library of Medicine’s Medical Subject Headings (21.2%), the Foundational Model of Anatomy ontology (0.9%), and the Systematized Nomenclature of Medicine - Clinical Terms (0.5%). Out of the three major contributors, we selected the National Library of Medicine’s controlled vocabulary thesaurus (MeSH) due to its broad scope within the biomedical sciences, its rich definitions, the general good acceptance and recognition among the scientific community, and because of its interesting category-based hierarchical tree schema, which would allow us to easily navigate distinct disciplines.

Data representation. After accepting a memorandum of understanding, MeSH provides universal free access to the descriptors (or subject headings, hence the name) in both XML and ASCII format, and to the tree structure in ASCII format. The MeSH 2014 tree has 55,611 nodes, representing 27,983 unique descriptors from 16 categories (any given descriptor may be represented more than once in the hierarchical tree). For example, the descriptor “Respiratory Tract Fistula” is represented twice in the hierarchy: in location C08.702 and location C23.300.575.687. “C” stands for “Diseases”, “C08” for “Respiratory Tract Diseases” and “C08.702” for “Respiratory Tract Fistula”. Same wise, “C23.300” stands for “Anatomical Pathological Conditions”, “C23.300.575” for “Fistula” and “C23.300.575.687” also for “Respiratory Tract Fistula”. Most of MeSH descriptors contain a short free-text narrative, the scope note, giving the scope and meaning of the concept written by the MeSH team, sometimes referencing specific sources.

We transformed the path enumeration format of the MeSH tree and created an adjacency list model and a nodes table. Then, from the concepts table, we extracted each MeSH Heading (the descriptor name), the associated MeSH Scope note and the MeSH tree numbers (the location or locations within the hierarchy), and loaded everything onto a relational database (MySQL).

Algorithm. Out of the 27,983 concepts contained in MeSH, only 26,144(93.4%) had a definition (the “scope note”), reducing the number of useful initial nodes to 54,148. We did not delete concepts without definitions since even if they are not suitable for question generation, they can be used as distractors. We designed the algorithm following the simple approach stated above (Figure 1): it selects a random node from the tree and
exposes the definition of the node as the question. One of the choices is the name of the node being displayed (correct answer), while the other alternatives (distractors) are retrieved by looking for siblings within the sub tree.

Education-related research has shown that 3 options MCQ (2 distractors) provide a similar quality of a test as compared to those with 4 or 5 options\(^{12,13}\) which could improve efficiency in question generation. For our prototype, time was not a concern, but the available number of siblings was important. Table 1 shows the number of nodes with x number of siblings. For example, 36,321 nodes (67.1% of the tree) have at least 3 siblings, and thus could produce a question with 4 alternatives. Since the recommendations of using 3 alternatives MCQ comes from human generated questions, we thought to increase it to 4 to reduce the chance of selecting the correct answer by guessing while still being able to use 67.1% of the tree.

When more than 3 siblings are available, distractors retrieval occurs at random and the order of the choices (distractors + correct node name) are alphabetically sorted before being presented to the user.

### Application development.
In our preceding study concerning medical education (MoCK Test, manuscript under preparation), we parsed an existing open question bank, only available as a flat web page, and developed a native mobile application providing mobile-optimized access for students to test their knowledge on the go. We described the wide adoption and usage patterns, evidencing the benefits of mobile-optimized content: it allowed users to study whenever they had a short opening in their busy and interrupted life.

Based on those results, and our belief that learning tools should be available for all students regardless of their device preference or operating system, we named the new tool “MoCKTest 2.0” and developed it as a web based application, following the mobile first paradigm. We used free web technologies, including the Foundation (ZURB)\(^{14}\) framework on the client side, and PHP and MySQL on the server side. The responsive web design we used made our concept available to any internet capable device, while ensuring a mobile optimized presentation of the content.

### Evaluation and user acceptance.
Because biomedical science students were thought as the group that would most likely benefit from the content of MoCKTest 2.0, we invited medical, nursing and pharmacy students to try the application and participate in the evaluation section of our study. We contacted Ohio State University students from those disciplines via their institutional weekly newsletter and/or via personal referral, while access to the app was open to anyone willing to participate in the study (previous acceptance of the informed consent). A likert-scale based usability survey was created to evaluate user acceptance, consisting of 15 questions measuring concepts including ease of use, usefulness, satisfaction, and intention to use. The survey was triggered after users completed 15 questions, and participation was voluntary. In addition, we conducted semi-structured interviews with subject matter experts (SME) in biomedical education to examine and comment on the quality and meaningfulness of questions generated by MoCKTest 2.0, the potential benefits that this tool could provide to students as well as suggested improvements. The Office of Responsible Research Practices (ORRP) at The Ohio State University determined that this research protocol was exempt from IRB review, as it corresponds to a review exemption category established by federal regulations. This protocol was approved as such by the ORRP.

### Results

#### Prototype.
Our algorithm successfully generated questions using the proposed approach. The adjacency list model used to represent the tree resulted in good performance for question generation. We designed an appealing and intuitive user interface, and ensured mobile-optimized content with the responsive design provided by Foundation. The final prototype, MoCKTest 2.0, was successfully deployed in our production environment at the OSU Wexner Medical Center IT servers, and can be accessed at [http://www.mocktest2.com](http://www.mocktest2.com).
In an effort to minimize barriers to adoption, we implemented social login capabilities using OpenAuth standards[15]. This approach eliminates the requirement to create a user and remember a new password. It relies on permissions granted by the users to get their email address from their preferred social account, which is then used for authentication purposes. Users can choose to login with Facebook, Google or Microsoft accounts.

On application launch, users can select one of the MeSH categories and subcategories and start answering questions concerning the selected topic (see Figure 2). Due to the considerable size of the question bank (36,000+ concepts) and the randomness of question generation, we provide a favorite feature, allowing users to tag questions to practice later. By default, the app also permits students to answer questions they have gotten wrong in previous attempts. After each answer, the user receives immediate feedback, informing them which choice was the correct one, in case they selected a wrong answer (Figure 3). New question requests happen on the background via an AJAX call without page refresh, improving user experience and decreasing traffic to/from the server. Users can also assess their performance and get an overview of the number of questions answered per sub-category and the percentage of success on each of them. Stats can be reset by students to begin a new study cycle at any point.

**Users’ perception of the tool.** Invitations to participate in our study were sent to the students of The Ohio State University through their college specific newsletter of the second week of February 2014. In three weeks, 325 unique visitors (not exclusively Ohio State University students) viewed the landing page, while only 120 accepted the informed consent and created an account.
(conversion rate of 36.9%). Of those who used the tool, 50 answered the survey (41.7% response rate). Seventy eight percent found it useful for biomedical knowledge self-assessment, while 75% agreed that using the app could improve their biomedical knowledge and be useful for their medical, nursing or pharmacy education. Sixty seven percent believed that using the system could improve their performance in school. Ninety seven percent of respondents believed that learning to navigate the app was easy. A complete report of the survey results can be found in Appendix 1.

Feedback from educators. We interviewed four subject matter experts (SME) in biomedical education: a Vice Dean for Education and Associate Vice President for Health Sciences Education of a College of Medicine, an Assistant Dean for Prelicensure Programs and Professor of Clinical Nursing of a College of Nursing, and an instructor of licensure review courses including the National Council Licensure Examination for Registered Nurses (NCLEX-RN) and the National Council Licensure Examination for Practical Nurses (NCLEX-PN). During 15 minutes of detailed assessment of random questions, SME evaluated the question generation process and the quality and meaningfulness of the questions presented, based on standard MCQ item-writing guidelines16. Despite an overall satisfaction with the quality of distractors generated, two scenarios raised concerns with the stems. The first scenario corresponded to high-level nodes (close to the root), which seemed to produce vain and basic questions (i.e. “Tumors or cancer of the uvea.”. Answer: “Uveal neoplasms”). The second scenario corresponded to questions where, despite an appropriate level of complexity, the user was able to “guess” the correct answer. This seemed to happen when a variation of the node name was present in the definition itself (i.e. synonyms). The application received a consensual very good feedback on ease of use, and most importantly, they all agreed on the benefit of providing such a question bank to students for training purposes.

Discussion

Although adding complex post-processing for better articulation of the questions might improve the prototype, the novelty of our proposal relies on the simplicity of the algorithm presented. By relying only on a hierarchical structure and definitions, our approach is discipline agnostic and allows the use of any knowledge representations meeting these requirements.

Due to the nature of the datasets involved and the scope of the questions, our tool might not be used by teachers to generate questions for tests. However, the easy implementation of our approach and the open nature of the content, provides an unprecedented platform for students to train, learn and self-assess their knowledge. Despite the two conflicting scenarios identified, the tool as is, presents itself as a contribution to education for all biomedical students.

Overcoming conflictive scenarios. Regarding the first scenario where “high level nodes” might be too general and produce vain questions, a potential solution corresponds to limiting questions retrieval to certain levels of the tree. However, each MeSH category has different number of branches (sub categories), and each “branch” has different levels of depth [Figure 4]. For example, the subcategories of “Publication Characteristics” have only five levels of depth, while one of the subcategories of “Organisms” reaches twelve levels of depth. For that reason we believe that level 4 of “Publication Characteristics” might not be comparable in complexity to a level 4 question from Organisms. We hypothesize that a meaningful way of overcoming this issue might be to retrieve nodes from up to a certain level away from the leaves (bottom up). For example, a level 8 question from the geography category (deepest level) is as granular as that category can go, and thus might be equivalent in complexity to a level 11 question of Chemical and Drugs category (deepest level). A complementary approach would be to trim out categories that are expected to produce futile questions, such as “publication characteristics”. Future work will focus on validating these hypotheses.

Although the second scenario - where the user could guess the correct answer- might be regarded as a limitation of the tool for evaluation purposes, we believe that this event could also be seen as a learning opportunity. The end goal of our tool is to empower the user to learn, not to serve as an evaluation tool. Thus, even if the student is able to guess the answer to a question he would have missed, he is actually learning the concept by reading the definition and associating it to the correct answer. Moreover, many times the definitions
contained in MeSH provide more detailed information than what would be strictly necessary to answer the question, thus providing more content to this learning opportunity.

**Ongoing efforts.** Based on feedback received during the interviews, we envisioned possible improvements for the prototype. First, we will provide the ability to read the definition of distractors when receiving feedback on any given question, thus increasing the learning opportunities for unknown domains. Second, we will provide the user with module for navigating down the tree and discovering definitions of unknown concepts, akin to the MeSH browser\(^\text{11}\). Another interesting idea proposed by the nursing experts corresponds to an alternate question generation process, also based on the hierarchical structure available. The model proposes to create “except” questions by selecting a random parent node, presenting the name of the node as the group name, and listing the siblings plus a random node retrieved from a distant relative. Thus, the user will be asked to identify the term that doesn’t belong to the group. For example: All of the following correspond to Peroxisomal Disorders EXCEPT: Adrenoleukodystrophy, Mevalonate Kinase Deficiency, Refsum Disease, Fanconi Syndrome and Zellweger Syndrome. Although the idea seems interesting, it requires further testing and tuning, since the meaningfulness of these approach might be highly related and affected by the depth of the nodes.

**Limitations.** Although we successfully validated the question generation strategy, the use-case as an educational tool for biomedical students might be limited due to the data source selected: MeSH might not be the best source of comprehensive medical knowledge, and may have several biases in the concepts included/excluded in this hierarchy. Our evaluation of the prototype seems to suggest that the strategy might be useful for medical education, although a more large-scale evaluation effort is probably needed. Future efforts will focus on expand the tool to a larger population to gain feedback. The persistent data storage implemented in our prototype is not

---

**Figure 4:** Composition of MeSH. The central pie chart represents the relative contribution of each category to the tree. The orbital graphs represent each category composition (distinct number of subcategories, and distinct levels of depth). For example, “Geographical” has only one subcategory, with 5 levels of depth, while “Organisms” has 5 subcategories, varying from 4 levels down to 11 levels of depth). The size of a node represents the relative number of concepts in that level.
the most efficient in this context. A graph database would improve the queries to lookup distractors. The approach used might become limited if the project scales to large populations.

**Conclusion**

We introduce MoCKTest 2.0: a new asset for students in biomedical sciences to learn and review concepts. Our simple tool leverages existing resources such as controlled vocabulary thesauri, creating concrete-knowledge questions and opening a new educational use for knowledge repositories. Students and educators recognized the contribution of such a question bank to the learning process, extending multiple choice questions contribution beyond evaluation purposes. Despite minor limitations, our idea has the potential to contribute to the training and education of scientists and researchers of all the biomedical sciences.

Veterans Health Administration Experience with Data Quality Surveillance of Continuity of Care Documents: Interoperability Challenges for eHealth Exchange Participants

Jay Lyle, PhD, Omar Bouhaddou, PhD, Nathan Botts, PhD, Marie Swall, Eric Pan, MD, Terry Cullen, MD, Margaret Donahue, MD, Nelson Hsing, ScD*

US Department of Veterans Affairs, Washington, DC

Abstract

As part of ongoing data quality efforts authors monitored health information retrieved through the United States Department of Veterans Affairs’ (VA) Virtual Lifetime Electronic Record (VLER) Health operation. Health data exchanged through the eHealth Exchange (managed by Healtheway, Inc.) between VA and external care providers was evaluated in order to test methods of data quality surveillance and to identify key quality concerns. Testing evaluated transition of care data from 20 VLER Health partners. Findings indicated operational monitoring discovers issues not addressed during onboarding testing, that many issues result from specification ambiguity, and that many issues require human review. We make recommendations to address these issues, specifically to embed automated testing tools within information exchange transactions and to continuously monitor and improve data quality, which will facilitate adoption and use.

Introduction

The United States Veterans Health Administration (VHA) provides healthcare for almost nine million veterans. Increasingly, this care is provided in coordination with private sector providers. When care responsibilities are distributed among different providers, it is critical that all participants stay informed of each other’s activities and decisions so that care continuity can be maintained for the patient. Reliable quality data is needed for referrals and transitions of care: this is a key driver development of the VLER Health program. The Healtheway initiative, a public-private collaborative that promotes standardized and trusted exchange of health data among participating member organizations, provides the means through which the VA could effectively test this type of national-level health information exchange.

In 2012, the VHA participated in a pilot program to test the use of Healtheway’s eHealth Exchange (at the time known as the Nationwide Health Information Exchange, or NwHIN). This pilot program included VA, Department of Defense, and 12 extant Health Information Exchanges (HIEs) as part of the VA’s VLER program. Subsequently, in 2013 the project became operational, and now includes upwards of 45 exchange partners with whom over 80,000 Continuity of Care Documents (CCDs) have been shared. VA is currently exchanging CCDs based on the HITSP C322 and C62 formats, and has initiated the process of enhancing the infrastructure to incrementally migrate partners to the Consolidated CDA document specification (C-CDA).

Research previously conducted by the VLER team, based on the VLER Health pilot period, identified several important data quality findings, including issues with C32 conformance to the specifications, optionality in the specification that adds to interoperability problems, and evidence that current testing tools cannot effectively validate clinical data during clinical operation. D’Amore, et al. showed that data quality issues persist even after migration to the newer C-CDA standard and after EHR systems have been certified based on the Meaningful Use criteria. At the same time, we showed that even pilot phase data monitoring provided critical enhancements to the data quality. These findings suggested that ongoing data quality monitoring and quality surveillance would continue to enhance adoption, decision-making and the quality of care for veterans using multiple providers by continuing to identify potential areas of miscommunication and interoperability challenges.
Comparison of VA data quality evaluation results to those gathered by other researchers in this domain has identified similar classes of issues independent of the specific study settings (3). In this paper, with over a year of experience in production, we report specific data quality issues presented by C32 documents provided to the VA. These have informed a data quality surveillance framework that includes the use of automated tools and systematic scoring of received documents.

**Objectives**

We posit that there are two key goals for improvement of the current quality of exchanged data: 1) reliable automated data integration that supports semantic interoperability and 2) increased clarity and usability of the data when accessed by care staff. In the long term, health systems should support automated semantic interoperability, including rule-based alerts and automated integration of received data into the health record. It is widely recognized that interoperability and decision support standards are not yet mature enough to support large-scale implementation of this sort of functionality (incremental improvement to support such a goal being a motivator for this research). However, while we are not yet able to completely rely on automated interfaces for the management of clinical data, current health information exchange standards increasingly support consistent representation of health record data to human reviewers. Although the current operation does not automatically incorporate received data in the patient health record, it does present externally sourced documents to clinicians on demand. The near-term requirement, then, is that the data be comprehensible to the viewing clinicians. It is important to note that clinicians may review the data not only one source document at a time, but more naturally, as combined data aggregated from multiple source documents. The first option can be satisfied by the narrative block of the CCD, but the second option requires parsing of the structured entries, and thus requires that these structured entries share design assumptions to a degree approaching that required for automated integration.

Whether a document meets one of these two requirements for a given element does not imply that it meets the other: a document may be structured correctly but provide information that is confusing to read, or it may provide clearly comprehensible information in a file that fails to conform to the rules defined by the standard specification. The focus of this research is to identify cases where information may be confusing or incomplete to a human viewer so that the specification may be refined—ideally to the point where it may support even more automated functionality—and to identify opportunities to leverage automated standards conformance tools to assist in that effort.

**Methods**

We have identified several cases where incoming documents do not conform to the published specification. We provide these cases to the institutions from which they were received as feedback to support their document generation improvement efforts. We score these documents according to their richness (how many of the sections supported by C32 are sent for a given sample of patient cases), quality (percentage of present fields filled in correctly), and semantic interoperability (percentage of fields of coded data type that are provided in the specified standard terminology). We are in the process of automating this process, as it is extremely time-consuming to perform manually. The automation will also allow us to process a larger sample of documents, perhaps even every document received, and achieve more accurate scores that account for data quality variability from one patient record to another.

Of equal interest are documents where a field instance may conform to a specification but fail to provide unambiguous information. We also find that assessing these issues with an eye to automation facilitates unambiguous definition of quality criteria even for manual review.

We designed a two-stage process to address both questions. In the first stage, a document is tested for conformance to specification by automated tooling; in the second, the document is inspected for clarity in a human interface. This process identifies a majority of technical errors, and it also identifies clarity issues not detected by automated tools. Further, by conducting the automated tests first, we would pre-populate the manual scoring template, reducing the effort required and allowing the analyst to focus on otherwise undetectable semantic issues.

Figure 1 shows the process at a high level.
Referring to the numbering in Figure 1, incoming documents (1) are automatically scored by existing tools, such as Model Driven Health Tools (MDHT) (2), or by other products, such as the SMART CCDA evaluation tool (3). The results of these automated activities are output in a common format (4) and stored in a database (5). The database supports an analyst screen (6) for the document, in which an analyst can identify problems found while inspecting the document in the clinician’s VistaWeb interface (i.e., VA clinician user interface) (7); this input is also stored in the database (5). The resulting detailed database can then support any number of reports, scoring algorithms, or other analytical processes (8). These processes can even employ different standards of conformance; e.g., whether and when a particular conditional field should be considered required.

We encountered a number of issues in this effort, including most notably a shortfall in tooling functionality and difficulty in distinguishing the causes of clarity issues.

XML parsers can provide validation to the CDA schema. For example, the National Institute of Standards and Technology (NIST) CDA validation tools perform much of the validation to the template constraints; however, it
provides only limited support for assessing conformance to terminology constraints. And, while the validation that it provides is useful guidance for developers, it is not designed for monitoring quality in a production environment by detecting or counting issues over time, across multiple patient cases. We have defined requirements for the enhancement of the MDHT utility, but their implementation has not been completed.

Our process for assessing clarity relies on the transformation of the CDA xml document into a legible web page. This is performed by a transform—an XSLT template—that renders the xml as html for a web browser to display. The selection of this transform is significant. The CDA Release2 specification includes a simple transform, based on rendering the narrative blocks of the CDA-based document. The VA has built another type of style sheet that renders the information by parsing the structured entries. This more functional approach addresses several issues of optionality and alternate permissible patterns, as observed among VA exchange partners. Furthermore, as mentioned above, this method allows for aggregated views of data domains across multiple sources of data: e.g., one allergy list that consolidates data from the VA EHR and from external sources. These solutions are locally useful, but the CDA specification stipulates that a document cannot rely on a particular transform for faithful presentation. All enhancements built into the transform will have to be fed back to the standards development process (i.e., at HL7) to ensure a common understanding of these ambiguous points.

**Sampling**

We sampled documents retrieved by the VA from Exchange partners via the eHealth Exchange program in response to queries made by VA clinicians for the purpose of treatment. We tested from one to three documents from each partner, intending to support ongoing, operational monitoring of the quality of data in the eHealth Exchange. We selected documents that had already been requested and received: we were assessing actual operations, as experienced by clinician users, not requesting de novo data to test functionality. All analysis was conducted by trained analysts on systems behind the VA firewall to protect patient confidentiality.

Because we were interested in how participants populated their documents, we did not select files at random, but rather selected those document instances with the most data. As a result, the assessments do not represent an absolute proportion of well-formed data instances provided by a partner, but the proportion of defined elements for which the partner demonstrates the ability to form properly. If a partner had many documents with few sections populated and a few documents with many sections populated, we assessed the latter.

A similar interest guided our scoring within documents. We did not want a preponderance of data in a field with many instances to drown out the quality measure of a field with few instances.

**Error Classification**

Data quality errors were detected in three ways. First, required fields are counted as errors if missing; optional and conditional fields are not. Second, some errors can be detected by conformance tools, e.g., terminology conformance. And third, human review will identify cases where the document may conform to the technical specification but still fails to provide clear meaning to a reader.

We also endeavored to categorize errors by cause. The general assumption is that an error is the responsibility of the sender, and this is true for all conformance errors. However, there are three possible sources of clarity issues: 1) the author or sender, 2) the stylesheet used to present the data to the reviewer, and 3) in some cases the specification is not sufficiently detailed to be unambiguous, and consequently partners may make different assumptions, each of which conforms to the specification. For any clarity issue, we had to inspect the underlying xml code to determine which of these the case was.

If the issue seemed to be ambiguity in the specification, we identify the ambiguity so that stakeholders can propose new rules—whether to refine the standard specification or to share among eHealth Exchange participants who can then implement them in their own data quality monitoring.

Source errors are reported to the document sender. Transform errors are reported to the VA EHR GUI (VistAWeb) development team so that the assumption can be corrected. Ambiguities in the specification (and recommendations
for their resolution, if appropriate) are reported to the HL7 Structured Documents working group and to the Healtheway Specifications Factory workgroup.

**Scoring**

The partner richness score is a percentage defined as the average number of sections provided in the sample set of selected documents divided by the total number of sections defined by the specification.

The document quality score is the average of quality scores for all of the elements in the document. In a given document instance, each data element gets a score ($S_e$) consisting of the total error-free instances divided by the total expected instances.

$$S_e = \frac{\text{count of present & correct instances}}{\text{count of expected instances}}$$

For singular elements, this value is either one or zero, but for repeatable elements it is calculated. A document listing three allergies, but only two with reaction types (a required field for a C32 allergy), would receive a score of 0.67 for the reaction type data element. This way, we can capture effects of intermittent errors without ignoring evidence of appropriate integration.

The document quality score ($S_d$) is the average of these data element scores.

$$S_d = \text{Average} (S_e)$$

This average weights all elements equally, so that a heavily populated section does not have undue influence on our understanding of the sender’s capabilities.

The construction of the score in this compositional manner allows scores to be calculated not only for individual documents, but for any slice of information—partners, partner classifications (by size, geography, onboarding stage, etc.), data elements, sections, time periods, etc. It can be used not only for static scores, but also for trends, outliers, fraud detection, or any other perspective that might assist with the continuous improvement process.

The semantic interoperability score is the proportion of coded elements correctly formed, by element, not instance. This distinction is important because a document may contain a code that is incidentally correct. One document, for instance, uses “mg” for milligram, which appears to be the correct Unified Code of Unit of Measure (UCUM) code, but it also uses “K” for thousand, whereas the UCUM meaning of “K” is degrees Kelvin. This document is using local unit codes, some of which happen to be identical to the standard codes. If any errors are detected, all codes for the field must be considered suspect.

Because the tooling for evaluation is still under development, we only have preliminary quantitative assessment of the semantic interoperability score, based on manual counts. All counts are noted in a specially created Excel spreadsheet.

**Results**

![Data Quality and Interoperability Levels](image)
Figure 2: Example CDA Document Assessment Scores

Figure 2 shows an example partner assessment. The assessed partner’s documents included slightly under half the number of sections specified by the C32 (data richness = 45%). While overall quality scored 70%, coded elements as a group fared significantly worse (26%). Parenthetical figures indicate change from the partner’s previous scores.

Overall VLER partners richness scores ranged from 12% to 82%, with an average of 55% and median of 59%. When richness is low, it is unclear whether the sender is incapable of sending the missing sections or the data is simply not applicable to the patient in question. Automated operational inspection of greater volumes of documents should provide benchmarks for this judgment.

Figure 3: Histogram of CDA documents richness score across VA Exchange partners

The manual quality assessment process requires appreciable amounts of time. Due to the small sample size, we are able to provide only qualitative assessments of document quality. In addition, we have been unable to demonstrate a clear trend of quality improvement in incoming documents, given the short time range. We do know that individual sending institutions have responded to our feedback by addressing issues, but this knowledge has not been generalized to the community at large, so any new partner assessed is likely to have quality scores similar to the population average.

We identified several common conformance issues. The existence of these issues suggests that the onboarding process is not sufficient to ensure ongoing operational data quality, and that operational monitoring should be a critical part of the national interoperability infrastructure.

The issues most commonly identified include the following:

1. **Missing required element** (blank field), as required by the C32 specification. Common areas include laboratory result interpretations & reference ranges, encounter comments, allergy reactions and confirmation dates, and medication prescription numbers, dates, and sigs.

2. **Wrong terminology** (populated but with a code not from the specified terminology). Common errors concern units of measure and status values following record status (e.g., “complete”) rather than clinical status (e.g., “resolved”). Local codes and labels for encounters and procedures are often too vague or too organization-specific to be useful, though standard values are not required by the C32.

3. **Misplaced information**. Common errors include stipulation of dose magnitude in medication quantity (which should contain dispensed quantities) and inclusion of immunizations in the medication section. Less
clear are inclusion of radiology results in a results section, and laboratory qualifiers such as patient challenges or blood bank product identifiers.

These errors—clearly stipulated in the specification, yet commonly mis-implemented in incoming documents—confirm that the onboarding process is not sufficient to ensure operational conformance. There is overlap between this list and that provided by D’Amore et al. Our “misplaced data” is very similar to their “inappropriate organization,” and our “wrong terminology” is a large subset of their “terminology misuse.” We do not adopt the category “incorrect data,” as we feel the nature of the error can usually be specified. The “Heterogeneity” classifications from that paper are only represented here where an issue creates an error or a clarity issue—e.g., where, in their example, the sporadic reference to narrative text causes a required element to be missing.

Other errors common enough to require their own classification, include

4. **Terminology codes too general to be useful**; e.g., ICD-9 799.9 “Other unknown and unspecified cause of morbidity and mortality.” Usually, this indicates a free-text entry.

5. **Formatting errors**, including the concatenation of type codes (“home,” “work”) or other unidentified text with displayed text.

6. **Duplicated data** - elements that are either duplicated or are valid but so similar to other valid elements that they appear to be duplicates. This occurs more readily when elements are classified at a higher level in a terminology, where a more detailed classification might allow discrimination (see # 4).

We identified a smaller number of issues with the stylesheet used to present documents to clinicians. These findings are fundamentally internal to the VA; we share them in case others have similar issues.

1. Patient names may be repeated or concatenated with aliases.
2. Blood pressure readings are concatenated for a conventional “Systolic/Diastolic” display, but units are omitted.
3. The transform presents scientific notation in an unconventional and potentially ambiguous fashion. Most of the numbers in figure 4 are presented without symbols to orient the reader to the fact that this is scientific notation: “0.4 10” could easily be read as “0.410.” (This presentation issue is in addition to the sender error of not sending the UCUM unit—in the case of monocytes, “%”—making it difficult to compare, e.g., monocyte and granulocyte measurements, as well as the sender error of pairing “count” test names with percentage result values.)

| #BASO | -- | 0.4% | Normal | 0.3 - 1.0 |
| #LYMPH | -- | 1.10 | Low | 1.5 - 2.9 |
| #MONO | -- | 0.410 | Normal | 0.3 - 0.8 |
| #GRAN | -- | 4.010 | Normal | 2.8 - 4.8 |
| #EOSIN | -- | 0.110 | Normal | 0.00 - 0.20 |
| #BAFO | -- | 0.010 | Normal | 0.00 - 0.10 |
| Erythrocytes[/volume] in Blood by Automated count | -- | 4.56 x 10 | Normal | 4.00 - 6.00 |

**Figure 4**: Examples of ambiguous scientific notation in the lab section of a CDA document

The most important findings are those related to specification ambiguity. These issues cannot be solved by testing and feedback loops internal to any organization; they must be solved by consensus within the interoperability community. Given the timeframe necessary to modify a standard, interim measures could be taken within interoperability communities (e.g., Healtheway) by codifying rules that we expect or recommend be adopted by HL7 Structured Documents Workgroup (SD) or C-CDA. This approach has informed the adoption of the “Bridge c32”—a specification used by Healtheway to reduce optionality and ambiguity within its community of participants while
at the same time increasing the richness of the data—as well as the development of the C-CDA. It should be extended to leverage the collective experience of all participants.

These issues include questions about the validity of included data, how to format information consistently, and several questions regarding heterogeneity in the results section.

Questions about the validity of data:
1. What is the temporal scope of a summary document? How far into the past should it reach, and how does this rule vary per clinical topic (e.g., medications, presumably limited, vs. allergies, presumably without limit).
2. May a summary document include data from other sources? From the requestor?
3. If data has been corrected, how is this indicated?
4. For Health Information Exchanges, should the custodian be the HIE or the originating facility or the system that captured the information (e.g., ADT)? A clinician may be more interested in the facility. Documenting data provenance is an area where further specification is needed.
5. How specific should textual information be? Can providers be listed as "historical provider"; or can sourced institutions be listed as abbreviations?
6. Must medications include specific information (e.g., dose), or is the clinical drug alone sufficient?
7. How should fields that are not applicable be represented? For example, in a record of "no known allergies," how should the allergy reaction be consistently represented? As blanks? As "not applicable"?

Questions about the C32 results section:
1. How should result sections support different kinds of results—hematology and chemistry tests, microbiology tests, radiology reports, etc.?
2. How should ambiguous kinds of acts be listed? Is an x-ray a procedure or a result? What guidelines should be given to implementers regarding what goes into the Results section vs. the Procedures section?
3. How should sparsely populated result qualifiers be represented? E.g., patient challenges, blood bank products, method used, etc.
4. Should reports and clinical notes (e.g., radiology and surgery reports, progress notes, consult notes, discharge summaries, H&Ps) be included in a health summary?
5. If a result itself is an interpretation (e.g., “present”), should there be a redundant value in the interpretation field? An explicit null (e.g., “Not applicable”)? A blank?

Questions about the display text of data:
1. Should a coded element display the preferred term from the code system or a local or manually typed term? Should a code always be represented by the same term in a document? In a facility?
2. When a data element is described with more than one representation (a standard code, a translation code, and an original text), which text should be displayed to a clinician?
3. How should LOINC names be presented? The formal names are often too detailed for clinical use and the short names too abbreviated to be easily understood. Abbreviations affect all sections (e.g., ‘DMII WO CMP NT ST UNCNTR’ for a problem name, ‘O’ for an Encounter type).
4. Is there a problem with appending a code to a coded concept display term (e.g., appending the ICD9 code after the diagnosis name)? Should it be encouraged?
5. Should empty sections be allowed or prohibited? Does an empty section constitute useful information?
6. How can problem or lab lists be kept to a manageable length? In general, how can the relevant data be made more clear to the receiver?
7. Should the community enforce that the information in the narrative blocks and structured entries be equivalent? If a sender expects the narrative text, as the “attested” data, to be understood, whereas the receiver constructs the human display from the structured data, how can we know that they are semantically
equivalent? Should there be more prescriptive recommendation that the clinician display always be derived from the narrative blocks?

As we consider these questions, we observe that some of them can, once answered by the consensus of stakeholders, be implemented as verifiable rules in the evolving standard. Classification of laboratory information, for instance, should be done once, codified, and implemented. Other questions, however, will require a more nuanced response. Determination of the appropriate temporal or clinical scope of a summary, for instance, will likely be the result of an ongoing discussion among practicing clinicians. The solution to such a question is unlikely to be encoded in a conformance rule, at least in the near future. Instead, practicing clinicians will need a feedback channel to provide insight to document senders. Whether such a loop leverages the expertise of the clinician requesting the document in the first place or that of a dedicated review team remains to be seen, but either way, it should minimize the risk of imposing a burden on clinicians by supporting feedback as terse or detailed as the clinician feels is warranted.

Conclusion

In this paper, we share the VA experience with data quality surveillance of eHealth Exchange participants C32 documents. This surveillance is conducted with real patient data and produces several scores, including data richness, data ‘correctness’, and semantic level.

We offer five recommendations from this experience.

First, we have identified common issues that seem to result from ambiguity in the C32 specification. When the community has moved largely to the C-CDA format, we expect these issues will continue to cause problems, to a lesser degree, but we hope that our experience provides some of the data needed to ameliorate those issues.

Second, we show the importance of continuous surveillance of data quality in a production environment after the certification and onboarding phases are completed. It may be appropriate that certification be a necessary condition for participation in Healtheway, but it is not sufficient to guarantee quality. Each participating organization should consider a C-CDA quality monitor running within their firewall.

Third, we demonstrate that automation can enhance the understanding of data quality, and we support continued investment in tooling for this purpose. While we have seen enough documents to have confidence in our qualitative judgments, we look forward to having the ability to monitor these issues over larger samples, to do so in near-real time, and to use this data in operational feedback to improve the quality of care. These automated tools would come with a set shared public rules that each organization can implement in their environment to continuously assess and alert about the data quality index of the information exchanged. Interoperability is enhanced only when all exchange participants cooperate in monitoring and improvement. One organization cannot do it alone.

Fourth, we have identified several items that may not be amenable to automated testing. Processes for monitoring these issues will require human intervention. Initially, these processes can be conducted based on sampling, but methods should be assessed for capturing operational feedback.

Finally, we recommend that the efforts to identify ambiguities be centralized to support continuous improvement across the Healtheway eHealth Exchange community. As the questions we raise are answered and built into the specification, it will become incrementally more useful, but the list will continue to grow for some time to come, and a governance mechanism will be needed to manage their resolution in ways that continue to support interoperability. This mechanism should support reporting of issues, consensus on solutions, methods for sharing examples, and channels for advocating solutions to standards development groups.

Abstract

Building a medical registry upon an existing infrastructure and rooted practices is not an easy task. It is the case for the BNDMR project, the French rare disease registry, that aims to collect administrative and medical data of rare disease patients seen in different hospitals. To avoid duplicating data entry for health professionals, the project plans to deploy connectors with the existing systems to automatically retrieve data. Given the data heterogeneity and the large number of source systems, the automation of connectors creation is required. In this context, we propose a methodology that optimizes the use of existing alignment approaches in the data integration processes. The generated mappings are formalized in exploitable mapping expressions. Following this methodology, a process has been experimented on specific data types of a source system: Boolean and predefined lists. As a result, effectiveness of the used alignment approach has been enhanced and more good mappings have been detected. Nonetheless, further improvements could be done to deal with the semantic issue and process other data types.

Introduction

Data analysis is important for health care systems optimization. Studying medical administrative data helps institutions to take right decisions toward health policy so as to lower costs and improve healthcare quality and access. In this context, the French health ministry is funding the BNDMR project (Banque Nationale de Données Maladies Rares) in order to build a medical data warehouse for rare diseases.

Currently, the French rare diseases (RD) care network is based on 131 rare disease centers of excellence. Each center is composed of one or more healthcare RD units, called sites, located in hospital structures that are known for their expertise and specific skills in managing and treating particular rare diseases.

In their daily activity, professionals from those sites use different systems to enter patients’ data such as administrative data, biological/imagery results and reports in the hospital information system; disease specific data in national or international registries; genetic or biological data in specific applications; customized data in local data bases, etc.

In order to avoid duplicating data entry for health professionals, the BNDMR will propose the deployment of connectors to retrieve data from the different source systems and allow interoperability at a national level.

The first step to ensure interoperability was to define a minimum data set built on common information to all rare diseases. This minimum data set was built and standardized following a methodology. The next step to collect data from all the different systems used by health professionals is to align the data schemas of source systems with the target data schema, the BNDMR minimum data set, in order to detect the mappings linking data elements. To manually align the data schemas is a tedious task. Even though we are familiar with the target data schema and its sixty data elements, there is a huge number of potential source systems, about 500 systems, with heterogeneous datasets that are more or less voluminous. The automation of this task becomes necessary.

The literature describes many automated alignment tools based on different approaches. Those tools have been used in different contexts to discover mappings between heterogeneous data sources e.g. BiobankConnect. Obtained results are promising and reliable but they are not sufficient to proceed directly to data exchange. An important consideration is missing: the values of data elements. If the value element level is not taken into account, first we can miss some mappings that exist at that level, and second, we cannot define a concrete mapping between data elements that can be directly implemented in the data integration process.

In this context, we previously proposed a mapping formalization in order to take into account the value element level that can be used to generate some parts of the program in charge of data import or export. In this paper we describe how this formalization contributes in a whole data integration process. Then, we present a concrete application by aligning a sub dataset of a data source schema, CEMARA, an academic rare disease data base, with the target data schema, the minimum data set of the BNDMR.
Background and proposal

Authors of different comparative studies on alignment or matching approaches agree to say that the efficiency of those approaches depends on data types and the application context. Furthermore, the aim of those tools is to align two sets of concepts (concepts of a thesaurus or an ontology). Using a certain measure, they detect pairs of concepts and assign them a similarity level. The obtained results are mappings in this format: \([C_1, C_2, s(C_1, C_2)]\), e.g. \([\text{Cystinosis}, \text{Cystin}, 0.8]\).

These results are not sufficient to define a complete data integration process. In fact, value elements are only considered when the alignment tools use instance-based approaches, but they are not integrated in the mappings definitions, they are only used to detect mappings between data elements. Data elements from the different schemas are often not coded the same way. Data transformation will be needed in order to complete the harmonization and proceed to data import. Data transformation includes: aligning lists of data values (thesaurus, specific lists...) and other operations like arithmetic operations to harmonize units or simple concatenation.

Rahm and Bernstein quickly mentioned some important issues, they pointed out the importance of “mapping expressions” to specify how the elements of two schemas are related. They also underlined the fact that, in practice, the criteria matching the elements are based on heuristics and are not mathematically precise to be used when implementing the match. On the basis of those considerations, it is necessary to: (i) optimize the use of the different alignment approaches in the data integration process while taking into account data types; (ii) generate well-defined mappings, integrating a value element level that can be directly exploitable.

(i) Integrate schema alignment approaches in a whole process

The alignment algorithms intervenes in the second step of a four phased data integration process:

- **First phase: data selection**
  
  As depicted in most studies, some alignment approaches can be considered as appropriate or inappropriate depending on data types. This phase will allow data selection according to the data types that will be addressed: numeric types, string and text types, Boolean type, lists and enumerations, etc. Data selection can be carried further by considering some constraints on data like strings length, bounds and units of numeric types, or source terminologies of some enumerations. It is also important to specify the context and domain of study in order to adapt the external resources that will be used: dictionaries and terminologies.

- **Second phase: mappings detection**
  
  In this phase, automatic alignment tools will be used to detect mappings in the way that have been designed for the selected data. This can be done by applying directly one alignment approach or by defining a complex path that will be taken by the data. External resources can be used to semantically enrich the data schemas and, for example, be able to map synonyms.

- **Third phase: mappings validation**

  Validation is generally a human validation involving persons familiar with the source and target data schemas.

- **Fourth phase: code generation**

  Once the mappings validated, they are integrated in the program in charge of data transformation and exchange. This implies that mapping expressions have to be readable by programming languages.

(ii) Mapping formalization

As proposed in our previous publication, a mapping from a source schema \(S\) to a target schema \(T\) can be characterized by the triplet \([E^S_i - E^T_j ; e^S_{ik} - e^T_{jl} ; r]\):

- A binary relation \(E^S_i - E^T_j\) between a source data element and a target data element. A data element is a unit of data identified by a name having a definition and that can be permissive to only some values.
- A binary relation \(e^S_{ik} - e^T_{jl}\) between a source value element of \(E^S_i\) and a target value element of \(E^T_j\). A value element is a value out of a set of permissible values pertaining to a data element.
- A rule \(r\) expressed in the “ if … then …” format defining the exact relation linking the different data and value elements.

This formalization is not a bijection; it links the source elements to the target elements and the reverse path is not always true.

Example: \(\{\text{“Coming CPC”} \rightarrow \text{“Patient addressed by”}; \text{“Y”} \rightarrow \text{“CPC”}; \text{if “Coming CPC” = “Y” than “Patient addressed by” = “CPC”}\}\)
Experimentation

We experimented our methodology by aligning a sub dataset of our first data source schema, CEMARA, with the target data schema, the minimum data set of the BNDMR.

- Data selection

The process we defined is able to detect simple mappings between source and target elements from Boolean and predefined lists data. Among the 72 data elements from CEMARA schema, 39 are Boolean data and 15 are predefined lists. As of the BNDMR schema, it contains 15 Boolean and 16 predefined lists among its 62 data elements.

Since the Boolean value elements (“true” and “false”) are not enough informative to infer mappings, we settled for considering only the data element level. For instance, we will try to map the data element’s label “the patient is deceased” and we will not do so for the value elements “true” or “false”. However the value elements will be integrated in the formalization of mappings into the rules during the final phase.

On the other side, considering the value element level becomes more important than considering the data element level when we are dealing with predefined lists. Furthermore, value elements from two lists can be mapped even though their respective data elements are not semantically similar.

E. g. the source data element “act type” and the target data element “participant profession” are two different concepts however their respective value elements, “nurse intervention” and “nurse” are closely linked.

The number of elements to map moves from 15 data elements to 86 value elements for the source CEMARA and from 16 data elements to 106 value elements for the target BNDMR.

- Mappings detection

A linguistic approach is used to operate a cross alignment between the different types of elements. This linguistic approach is based first on a semantic enhancement of both source and target data schemas and second on a lexical matching between the elements using the Levenshtein algorithm (also called the Levenshtein distance used to measure the differences between two sequences using the number of characters’ deletions, insertions and substitutions)(8). For the semantic enhancement, synonyms and English translations have been assigned to the elements.

OnAGUI⁸, a tool for aligning ontologies integrating different algorithms, has been used to apply the Levenshtein algorithm on the source and target schemas that have been translated in OWL format.

The same information can be structured differently from one schema to another. Cross alignment between different typed data is necessary. Four alignments have been done, operating either at the same level (data element or value element level) or at different levels (both data element and value element levels) depending on the type of data that we are aligning, as explained in the data selection phase (Figure 1).

![Figure 1. Alignment process: Cross alignment for Boolean data and predefined lists](image)

- Mappings validation

For our experimentation validation, a person familiar with both source and target databases has done a manual alignment between the different elements to establish a gold standard. Two experts of both databases validated this alignment. This liable set of mappings allowed the validation of mappings that have been detected by the defined process.
In routine use, a simple selection of the valid mappings would have been sufficient for this phase.

- Code generation

The table below (Table 1) shows that four simple types of rules will be generated by this process, linking Boolean value elements (true and false) and lists value elements.

**Table 1. Generated mappings expressions**

* DE: data element, VE: value element

Below some examples of the generated mapping expressions:

- If PropLink=propositus [source] then Propositus=true [target]
- If ConfCyto=true [source] then ConfirmationMode=cytogenetic [target]

**Results**

The similarity threshold for the Levenshtein distance has been set to 0.9 to contain the number of false positive mappings. Counting is relative to the target elements: How many target data elements and value elements have been mapped? How many have been correctly mapped or not mapped?

In Matching 1 and Matching 2, the algorithm is used to search mappings with source elements for the 16 Boolean target data elements. In Matching 3 and Matching 4, the algorithm is used to search mappings with source elements for the 106 target value elements building the predefined lists of some data elements (Table 2).

</tr>
</tbody>
</table>

* TP: true positives, FP: false positives, FN: false negatives, TN: true negatives

For a comparative evaluation, we ran the Levenshtein algorithm on the complete source and target data schemas as a reference test. We kept the same threshold of 0.9 of similarity. Fifteen mappings have been detected linking 14 CEMARA data elements to 14 BNDMR data elements. Among the 15 mappings, 5 were false mappings, e.g. Diagnostic status – Patient status. Operating on a data element level can be misleading especially when dealing with predefined lists. The 10 good mappings are distributed as shown below (Table 3).
Table 3. Comparative evaluation: number of good mappings for the reference test and the experimentation

<table>
<thead>
<tr>
<th></th>
<th>Reference Test</th>
<th>Experimentation</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Matching 1</td>
<td>3</td>
<td>3</td>
<td></td>
</tr>
<tr>
<td>Matching 2</td>
<td>0</td>
<td>1</td>
<td>Not the same total number of elements. In the reference test, only data elements are considered</td>
</tr>
<tr>
<td>Matching 3</td>
<td>1 (2 missed)</td>
<td>22</td>
<td></td>
</tr>
<tr>
<td>Matching 4</td>
<td>6 (2 missed)</td>
<td>35</td>
<td></td>
</tr>
</tbody>
</table>

Besides the missed mappings, mappings that have been detected by the reference test are linking data elements and not value elements. Thus, seven of the ten “good” mappings are not precise enough to be considered as good mappings.

Discussion

To summarize, the proposed method is based on a new way to formalize mappings with rules specifying the exact relationship between source and target data elements and their values. The alignment process is designed to suit the data types chosen as inputs in order to generate well-defined type of rules as output. In our experimentation we studied two data types: Boolean and predefined lists, we operate a cross-alignment at both data element and value element levels and detected four types of rules defining the mappings.

The comparative evaluation shows that using the same data schemas (CEMARA and BNDMR) and the same alignment tool (OnAGUI) as the reference test, more mappings could have been detected when using the proposed methodology. Further, value elements form integral part of the mapping expressions. Moreover, results show that globally we obtained good recall and precision. Wrong mappings (false positives) that move away the precision from 1 can be explained by the generic nature of some value elements, e.g. “other”. Their occurrence in different list data elements explains their wrong mapping to similar elements several times. Such cases can be processed differently in the alignment process by linking them to their data element or siblings value elements. However, precision remains acceptable, greater than 0.8. The recall is more related to semantic issues. Some mappings have not been detected (false negatives) this is mainly due to the chosen alignment approach that is based on a simple string similarity metric. Moreover, and despite the efforts made to build and enrich the schemas, the algorithm does not use at the moment an external semantic resource to search more synonyms or vocabulary variants, like the difference between “medically assisted procreation” and “medical assistance to procreation” and thus improve on the recall.

If the data integration process were totally automated with no human intervention to validate or reject the proposed mappings, the registry data quality will be negatively affected. A bad recall would mean a non-efficient alignment with missing mappings and therefore missing data. A bad precision would mean wrong mappings and therefore importing false information in the target data base. The priority in our work is to maintain the precision as high as possible while trying to improve the recall making the task easier for the user which validation remains essential to not affect the data base quality and maintain the reliability of the ensuing studies. Thus, among the next evolutions of our work, an automatic semantic enrichment will be integrated to the process. The first step would be to request the MeSH terminology to retrieve data elements and value elements synonyms to catch some undetected mappings. It would also be interesting to consider other data types and define the suitable alignment process to detect their mappings. E.g. in order to integrate some measures like the patient weight and height, numeric data alignment may be addressed with taking into account the unit conversion. And finally, a global validation will be conducted using other source systems.

Conclusion

The proposed methodology aims to optimize the use of existing alignment approaches and to limit human intervention in the data integration process. Our work takes part of a global effort for the healthcare systems interoperability. Data schemas alignment can be an alternative to address the lack of standardization in the existing systems or as a complement if different standards are implemented.

Diagnostic Characteristics of Patient Self-Assessment of Preoperative Cardiac Risk for Non-Cardiac Surgery - Foundations for Patient Driven Decision Support

Sharad Manaktala MD, PhD 1; Todd Rockwood PhD 4; Terrence J. Adam RPh MD, PhD1,2,3

1 Institute for Health Informatics; 2 Minneapolis VA Healthcare System; 3 College of Pharmacy; 4 Health Services Research and Policy, School of Public Health, University of Minnesota

Introduction
Surgery is a frequent health care intervention with an estimated 6 million non-cardiac surgical procedures performed every year in the United States, with progressive growth in the number of procedures noted each subsequent year(1). Preoperative medical evaluations have been a cornerstone of pre-surgical care planning and patient management. The clinical providers who carry out these pre-operative evaluations are guided by their medical knowledge, institutional policies and clinical practice guidelines. To address the challenge of standardizing the evaluation and management of perioperative cardiovascular complications of non-cardiac surgery, the American College of Cardiology/American Heart Association (ACC/AHA) issued perioperative guidelines for non-cardiac surgery in 2007 with a focused update on preoperative beta blockade in 2009(2), followed by the latest update in 2014 (3). These guidelines modified recommendations on the Revised Cardiac Risk Index (RCRI) (4,5) to highlight a set of conditions associated with higher post-operative morbidity and mortality for patients undergoing non-cardiac surgery.

As surgical interventions continue to evolve with increasingly complex and costly procedures, there is a critical need to improve the preoperative assessment to effectively identify clinical risk factors and manage existing co-morbidities. In the typical perioperative window, from one month before to one month after the surgical intervention, targeted risk mitigation can be implemented to reduce surgical complication risk. In the context of growing surgical work volumes, there is a paucity of well-trained primary providers and preoperative assessment clinics to address patient needs with ongoing growth in the number of preoperative assessments (6-8).

An important partner for the surgical team is the patient, who ultimately has the most at stake from the surgical benefits and potential complications (9). Unfortunately, few tools are available for patients to self-identify surgical risk and empower them to work in tandem with multi-disciplinary surgical teams. Such tools could help patients become better informed of their surgical risk and address an important knowledge gap since most patients have limited recall of the risks and benefits of surgical interventions after completing the pre-operative clinical workup (10,11). In addition to the potential educational and clinical benefits to patients, patient driven decision support tools could also be a cost-effective adjunct tool for surgical quality efforts including Accountable Care Organizations (ACO), medical homes, and other efforts to enhance clinical quality. Having effective patient driven clinical assessments can provide surgical providers a greater appreciation of risks prior to their planned procedures and facilitate optimized multi-specialty care delivery.

Decision support tools that offer patient self-assessment can potentially help mitigate time pressures in the typical 30-day preoperative window by adding important triage data to better identify the at-risk populations. To use patient-driven clinical information to its optimal capacity, it is important to establish its validity and reliability. The ability of patients to self-identify clinical risk factors has been previously established in many studies of chronic disease (12-17). There are several strategic advantages to having patients identify their own clinical risk factors, both to have patients better understand their own clinical conditions and risk of surgical complications, as well as potential cost savings with obtaining valid clinical information without the cost of provider mediation (11,18,19). However, tools for patient self-identification of clinical risk factors have not always crossed directly from large research studies into use in clinical care (9,17). Technologies like clinical decision support systems (CDSS) hold immense potential to enable patients to access higher tiers of the knowledge pyramid, thereby gaining from the collective wisdom of scientific literature.

This study aims to create and validate prediction rules to form the basis for a future patient generated risk prediction tools. These validated tools integrated into electronic and patient interfacing formats like personal health records, mobile and internet-based applications can be instrumental in promoting patient-centric health care and timely risk stratification of preoperative risk.
Methods

Experimental Design - A prospective, single center, hospital based observational study was performed to evaluate the diagnostic characteristics of patient self-reported health information, after approvals were received from the Institutional Review Board (IRB).

Site Description - The Minneapolis Veterans Administration Hospital is a major referral site within the VA system with care provision by multiple surgical specialties in the VISN 23 region. The VISN 23 clinical health care network serves more than 400,000 enrolled Veterans residing in the states of Iowa, Minnesota, Nebraska, North Dakota, South Dakota and portions of Illinois, Kansas, Missouri, Wisconsin and Wyoming. The preoperative medical clinic operated from the Minneapolis clinical site is a large preoperative medical site with 10 clinicians providing preoperative medical assessments.

Survey Design - To accurately assess and capture patient medical and surgical history, exercise tolerance, and cardiovascular risk perceptions; a survey instrument was iteratively developed in the form of a 25-point assessment tool. This instrument was developed by mapping the recommendations of American Heart Association (AHA) Guidelines for Pre-operative risk assessment of Cardiac complications of Non-Cardiac Surgery (2) The AHA recommends using the Revised Cardiac Risk Index (RCRI) (5) which stratifies cardiovascular complication risk based upon 6 key risk factors: history of coronary artery disease (CAD) or unstable angina, history of cerebrovascular accident, history of Congestive Heart Failure (CHF), diabetes mellitus requiring insulin for control, serum creatinine greater than 2mg/dL, and high risk surgical procedure. A questionnaire survey instrument was developed by modifying existing patient self-report instruments including: Modified Rose Questionnaire for IHD (20,21); Questionnaire to Verify Stroke Free Status (QVSFS) (22) for Stroke and Cerebrovascular accident (CVA); and Compendium of physical activity (23) to assess patient exercise capacity. Symptomatic questions were developed based on expert consensus when a suitable validated instrument was not available for risk factor assessment. After identifying each of the six revised cardiac risk index factors, a patient reported RCRI score was generated along with other patient reported health information such as cardiovascular and procedure history. In addition to objective cardiac risk factor assessment, questions were developed to identify patient cardiac risk perceptions on a graded scale. These results were scored with a mapping algorithm to identify the relative levels of risk perceived by patients while reflecting current clinical guidelines. The survey content was tailored for patient use with an estimated reading level of grade 7 by Flesch-Kincaid readability analysis to facilitate patient use. Questions on important surgical contraindications including certain high risk surgical preclusion criteria, pre-existing conditions, cardiovascular risk perception, exercise tolerance, and the elements of the 6 revised cardiac risk index risk factors were adapted for patient use and incorporated into the instrument.
**Survey Validity** - An intended referential was established along with the connotative meaning of each question to ensure that the respondents interpreted the questions as intended. The survey was developed while making broad consideration for the educational level of a wide range of participants but focused on those in the VA Medical Center, Minneapolis. The survey content was tailored for patient use with an estimated readability level < grade 8 on the Flesch-Kincaid Readability Scale (24,25), consistent with readability level of a high school graduate. The questionnaire was designed and assessed to avoid biased wording, double negatives and leading questions to check for response bias. Closed ended questions were framed around almost all questions with ordered and partially ordered responses for most questions, to allow a continuum of responses and to facilitate ease and accuracy of responses (26). Survey length was kept at less than 25 questions that were spread over 3 letter-sized pages. Survey completion times were recorded during pre-testing in a sub-set of participants to ensure that the respondents are able to complete the questionnaire within a reasonable time frame. Pre-testing on a small sub-set of participants revealed that all participants were able to complete the survey within 3 to 4 minutes. Concordance between patient and provider reported RCRI scoring was evaluated in a separate study (27).

**Data Collection** – Patients checking in at the preoperative medicine clinic were asked to complete the survey questionnaires while they waited to be seen by their clinicians. Patients at the preoperative medicine clinic completed a total of 500 surveys during the study period. Since the survey development process was iterative, only 401 patients, who completed the finalized survey version, were included in the study. Patients visiting the preoperative medicine clinic in the Department of General Medicine VAMC Minneapolis during the study period were included in the study. Provider data was retrospectively collected from chart review of provider visit notes, problem list, drug list and surgical records of corresponding patients from the VistA electronic medical record system. We excluded eighty-seven more patients that had missing or incomplete survey responses and for some cases incomplete or cancelled preoperative clinician evaluations. Thus, only the remaining 314 surveys and their corresponding clinician evaluations were used for comparison of RCRI scores, risk perception and validity analyses.

**Data Analysis** - Descriptive statistics were used to tabulate patient demographics, cardiac risk self-perceptions, and cardiovascular risk profiles using SAS version 9.3 (SAS Institute Cary, NC). We evaluated the association between provider perceptions of patient risk, provider generated RCRI score with patient subjective perception of risk and RCRI scores generated by patient provided survey information. We calculated Cronbach’s alpha to estimate the internal consistency of this survey.

**Results**

At the end of the study period we included study participants with ages ranging from 25 to 91, with an average age of 66 (+12.4) years for the study population. Typical for veteran populations (28) who constituted the majority of study participants, 9 out of 10 participants were males. Other details for patient demographic data is presented in table 2. The calculated standardized Cronbach’s alpha (0.93) indicated that the survey had excellent internal consistency.

Table 2 – Prevalence of provider diagnosed risk factors in study population

We also calculated frequencies and prevalence of cardiovascular risk factors outlines in the RCRI using descriptive statistics. We noted that coronary heart disease was the most common risk factor with a prevalence of 21% (n = 85),
followed by Diabetes requiring insulin 9% (n = 38), with renal insufficiency observed as least prevalent at 4% (n = 17) (Table 2).

To evaluate concordance between RCRI scores generated by patient provided information and comprehensive chart review and provider assessment, we created a comparison matrix (Table 3).

Table 3 - Comparison Matrix of Patient Generated RCRI scores with Expert Provider Assessment {Absolute difference between provider generated and patient RCRI score: Green - Zero, Yellow - One, Red - More than one}

This RCRI comparison demonstrated complete agreement between the patient and provider scores in 261 out the total 314 surveyed patients, with some level of disagreement in the remainder. This observation illustrates the fact that patient identified risk factors and the generated RCRI scores were in 83% agreement. There were only a limited number of subjects (n = 8) for whom the absolute difference between patient driven and provider RCRI scores were greater than 1.

**Patient Self-Perceptions of Cardiovascular Risk**

To explore potential drivers of patient self-perception of cardiovascular risk, we evaluated the strength of association between patient self-perceived risk and gold standard physician diagnosed risk factors (Table 4). We noted that patients who had physician diagnosed CAD were 5 times more likely to perceive themselves as high risk for cardiovascular complications peri-operatively compared to patients who had a negative history for physician diagnosed CAD, despite the nearly same risk of other factors such as renal insufficiency. Similarly, patients with physician reported history of CABG were 8 times more likely to consider themselves as high risk for cardiovascular complications peri-operatively compared to those who had not had a CABG. The perceived risk association for stroke, heart failure, diabetes requiring insulin and renal insufficiency, were however, statistically insignificant.

**Validity of Patient Self-reported Health Information**

We also performed an analysis of the operating characteristics for validity of patient self-diagnosis versus gold standard clinician diagnosis for peri-operative risk factors. As seen in Table 5, all patient self-reported risk factors had a statistically significant overall accuracy of at least 0.93 compared to gold standard clinician evaluation. We also noted that all patient reported risk factors including coronary heart disease (CAD), cerebrovascular accident (CVA), diabetes, and exercise tolerance had acceptable sensitivity values of 0.77, 0.83, 0.87, and 0.86 respectively. However, all five patient reported risk factors had high specificities, Negative Predictive Values (NPV) and positive Likelihood Ratios (LR +).

**Clinician perception of patient risk for complications**

The validation study by Goldman et al concluded that all risk factors (CAD, CVA, diabetes requiring insulin, CHF, renal insufficiency and high risk type surgery) had an equivalent contribution to the risk of post-operative cardiovascular complications after non-cardiac surgery (4). However, we observed that certain patient risk factors influenced clinician perceived risk more than the others. For example, we used logistic regression to calculate odds ratios for evaluating the association between patient risk factors and provider perceptions of post-operative adverse
cardiac events. We observed that after adjusting for age, providers perceived patients who self-reported a history of CAD to be 9 times (95% C.I. 4.98-16.45) higher risk of having an adverse cardiac event after surgery as compared to patients who had no history of heart disease. History of chest pain, history of CHF, presence of cardiac pacemaker or defibrillator, high-risk type planned procedure were among the other significant driver of clinician risk perception for their patients. Discussion
The results of this study provide key insights on the association between patient self-reported health information and expert clinician diagnosis of preoperative cardiovascular risk for patients undergoing non-cardiac surgery.

We investigated the concordance between RCR scores generated by gold standard provider assessment and patient self-identified risk factors, and generated RCRI scores were in near perfect (83%) agreement. We also concluded that patient reported coronary heart disease, congestive heart failure, presence of pacemaker or defibrillator, were perceived by provider to have higher risk for cardiovascular complications.

Upon examining the validity of patient reported health information, we concluded that patient self-reported RCRI risk factors (Ischemic heart disease, congestive heart failure, cerebrovascular accident, diabetes requiring insulin, and renal insufficiency) had a good and statistically significant overall accuracy, high specificity and negative predictive values compared to gold standard clinician evaluation. This underscores the fact that detailed pre-operative testing, evaluation and resources can be reserved for patients who report to have these risk factors, potentially saving on hospital costs and clinician time and avoiding risk of unnecessary testing and assessment which may create iatrogenic risk of otherwise low risk patients.

The results from our study agree with a large body of scientific literature suggests that patient self-reported health information is a valid resource of information and holds immense potential for improving the provision of healthcare (12,13,17,18,20,29,30). We acknowledge that there are number of limitations of this study. The study sample size is

relatively modest, which makes it difficult to ensure that the patient self-report of cardiac risk factors and self-perception data is a true representation of Veterans Administration preoperative patients. The data collected in the study focused on a regional Veterans Administration pre-operative patient population and the data was generated from a single clinical practice site. It is unclear if these results could be extended to non-VA clinical sites given the predominant male distribution of the sample, which mandates further study. In addition, since this was a self-administered survey, the authors could not assess behavioral factors like patient denial or over-report for subjective patient health perceptions, but the availability of provider assessment data on the patient risk factors allowed for within patient comparisons. The authors also limited their scope to the assessment for perioperative cardiovascular complications to minimize bias. Thus, patient and provider perceptions of post-operative risk that may also be driven by other risk factors and pathologies like gender, age, race, and other co-morbidities.

In conclusion, we developed a patient self-report survey instrument that had excellent internal consistency. We also concluded that patient self-report is a valid resource for obtaining health information for preoperative cardiovascular evaluation. Our future goals include validating our findings through a study extending to a larger, non-veteran population; develop and evaluate other risk factors (like respiratory, neurological and medication management components) from patient driven data acquisition and management of perioperative risk, empowering patients in playing the pivotal role in their health care decisions.

Abstract

The increasing prevalence of multimorbidity is a challenge for physicians who have to manage a constantly growing number of patients with simultaneous diseases. Adding to this challenge is the need to incorporate patient preferences as key components of the care process, thanks in part to the emergence of personalized and participatory medicine. In our previous work we proposed a framework employing first order logic to represent clinical practice guidelines (CPGs) and to mitigate possible adverse interactions when concurrently applying multiple CPGs to a multimorbid patient. In this paper, we describe extensions to our methodological framework that (1) broaden our definition of revision operators to support required and desired types of revisions defined in secondary knowledge sources, and (2) expand the mitigation algorithm to apply revisions based on their type. We illustrate the capabilities of the expanded framework using a clinical case study of a multimorbid patient with stable cardiac artery disease who suffers a sudden onset of deep vein thrombosis.

Introduction

Mitigating clinical practice guidelines (CPGs) for a multimorbid patient is identified as a crucial step in the adoption of CPGs at the point of care\(^3\). The key problem lies in identifying and mitigating adverse interactions between guidelines given a specific multimorbid patient encounter. In addition to the CPGs, secondary knowledge applicable to both the multimorbidities and the patient state, and patient preferences must be used to propose a consistent therapy for the particular patient encounter. In previous work we proposed a logic-based approach to the mitigation problem that uses first-order logic (FOL) as the formalism for representing CPGs, patient information, and secondary medical knowledge in the form of revision operators\(^3,4\). With the emergence of personalized and participatory medicine\(^5\), patient preferences have become important components of the care process\(^6,7\).

Representations for CPGs, secondary medical knowledge, and patient information have been studied and formalized\(^8,9\), including in our own previous research\(^3,4,10,11\). Yet up to this point preferences were applied to decisions made together by the physician and patient (shared decision making) or by the patient (informed decision making). Furthermore these preference were represented at a very high level and not considered alongside revisions made to CPGs, making it difficult to identify and mitigate adverse interactions introduced by these preferences. Therefore, a multimorbid patient’s preferences must be represented formally so they can be part of the reasoning needed to mitigate concurrently applied CPGs.

In this paper we show how our FOL-based mitigation framework is flexible enough to support patient preferences and we describe how these preferences are represented in a format that is compatible with our FOL-based CPG formalism. Specifically, we broaden our previous definition of an operator and define revisions described in secondary medical knowledge and in preferences as two classes of operators. We also introduce a slight modification to our mitigation algorithm to apply as many preferences as possible while maintaining the consistency of the proposed therapy. Finally, we use a clinical scenario with a multimorbid patient who suffers from deep vein thrombosis (DVT) and a pulmonary embolism (PE) while being treated for stable cardiac artery disease (SCAD) and who has stated preferences for novel oral anticoagulants versus low molecular weight heparin and warfarin.

Supporting Preferences in a First-Order Logic Mitigation Framework

In this section, we describe the extensions to our first-order logic-based mitigation framework to support patient preferences. Our most recent published work covered our mitigation framework’s transition to FOL\(^1\), including a case study of a patient managed for type 2 diabetes and an onset of severe rheumatoid arthritis\(^4\), and our extension of the framework to support a broader set of CPGs (such as those that include parallel paths) and more complex secondary medical knowledge\(^12\). The extensions presented in this work serve two purposes: (1) to represent patient preferences and (2) to apply preferences during the mitigation process rather than as a post-processing step. These
extensions demonstrate the flexibility of our mitigation framework in supporting an additional form of secondary knowledge (patient preferences). To ground the extensions described below, we briefly reintroduce those framework components that are affected by or extended to support patient preferences. These include the combined mitigation theory $\mathcal{D}_{\text{comb}}$, revision operators, and the mitigation algorithm.

FOL is a widely used formal system for representing and reasoning about knowledge\textsuperscript{13}. This knowledge is represented as a logical theory $\mathcal{D}$, which is a collection of sentences in a first-order language $L$ defined over vocabulary $V$. $L$ consists of logical symbols (quantifiers, connectives, variables, and logical constants) and a finite number of non-logical symbols (predicates and functions) from $V$. The former have a fixed meaning in any FOL language, the latter are domain-dependent. The meaning of the non-logical symbols in $L$ is given by an interpretation $I$. If $I$ satisfies all sentences in $\mathcal{D}$, then it is called a model for $\mathcal{D}$. Theory $\mathcal{D}$ is consistent, iff there exists at least one model of this theory, and consistency is checked using theorem proving techniques. If $\mathcal{D}$ is consistent, it is possible to find models for this theory using model finding techniques, and to check for implications (logical consequences) of this theory through entailment\textsuperscript{3}.

In our work we assume a specific patient encounter is represented as the combined theory $\mathcal{D}_{\text{comb}}$. $\mathcal{D}_{\text{comb}}$ uses our defined vocabulary (see\textsuperscript{3} for its description) and is defined formally as the triple:

$$\mathcal{D}_{\text{comb}} = (\mathcal{D}_{\text{common}}, \mathcal{D}_{\text{cpg}}, \mathcal{D}_{\text{pi}}),$$

where $\mathcal{D}_{\text{common}}$ is a theory that axiomatizes the universal characteristics of CPGs as part of a FOL representation. It is the common (shared and reusable) component of all mitigation theories. $\mathcal{D}_{\text{cpg}}$ is a union of theories, each theory representing a single CPG that is being applied to a multimorbid patient. And $\mathcal{D}_{\text{pi}}$ is the theory that describes available patient information. It contains FOL sentences representing patient data, including results of tests and examinations, or indicates already prescribed therapies and procedures.

In our mitigation framework, all secondary knowledge is captured in revision operators. In our recent work\textsuperscript{12} we expanded the definition of a revision operator to allow for a more detailed description of the context and type of modifications they perform. This flexibility allows us to use these operators to represent patient preferences without any changes to their definition.

Formally, a revision operator $RO^k$ is defined as:

$$RO^k = (\alpha^k, Op^k)$$

where $\alpha^k$ is a logical sentence that describes the interaction applicability of the operator to the theory $\mathcal{D}_{\text{cpg}}$, and $Op^k$ describes the revisions introduced by $RO^k$. In particular, $Op^k$ is a set of $n$ pairs of formulas $(\varphi^k_i, \phi^k_i)$ $(i = 1 \ldots n)$ that define a single operation within the operator. These operations are applied only to $\mathcal{D}_{\text{cpg}}$, so other components of $\mathcal{D}_{\text{comb}}$ are protected from unwanted revisions. For example, $\mathcal{D}_{\text{pi}}$ is never modified thus patient information is never inadvertently changed. The formulas are interpreted as follows (where $\emptyset$ indicates an empty formula):

- $(\varphi^k_i, \emptyset)$ means that $\varphi^k_i$ is removed from any sentence in $\mathcal{D}_{\text{cpg}}$ where it appears,
- $(\emptyset, \phi^k_i)$ means that $\phi^k_i$ is added as a new sentence to $\mathcal{D}_{\text{cpg}}$,
- $(\varphi^k_i, \phi^k_i)$ means that $\varphi^k_i$ is replaced by $\phi^k_i$ in any sentence in $\mathcal{D}_{\text{cpg}}$ where it appears.

Checking the applicability of $RO^k$ to $\mathcal{D}_{\text{comb}}$ translates into the entailment problem $D_{\text{comb}} \models \alpha^k$. We demonstrate in the Applying Preferences section how we leverage this property in our mitigation algorithm.
Figure 1 shows the general architecture of our mitigation framework. It involves two levels of operation -- FOL and regular expressions (RE), i.e. string patterns, often used in find and replace-type operations on text in document retrieval, data analytics and database queries. The core component is the mitigation algorithm, presented later in detail, that operates at the FOL level. The algorithm takes as input a combined theory \( D_{\text{comb}} \), uses revision operators \( RO_k \) to mitigate (identify and address) adverse interactions, and finally constructs a therapeutic scenario \( D_{\text{th}} \) -- a theory that represents a “safe” (free of adverse interactions) course of action. \( D_{\text{th}} \) highlights the clinical actions to be taken (along with the order in which they should be carried out), and includes assumptions made about the patient's state.

**Previous work on Applying Patient Preferences**

Patient preferences and values are considered the third important component of evidence-based medicine\(^1\), the other two being research evidence and clinical experience. Incorporation of patient preferences is especially relevant when dealing with “gray zone” decisions associated with a high level of uncertainty\(^2\). This uncertainty is associated with insufficient evidence\(^3\), evidence indicating the same attractiveness of multiple options or significant differences in preferences across target population. As such these decisions are often referred to as “preference-sensitive”\(^3\). Patient preferences are also relevant when deciding on long-term treatments (for example in case of diabetes, hypertension or osteoporosis)\(^4\). Given the importance of patient preferences, it is now advocated that patients should not only be involved in making decisions when a CPG is being followed, but they should also participate in the development of CPGs\(^5\).

There has been significant research on decision aids that help patients express their preferences (see the next section for more details)\(^1\). Depending on the applied approach to treatment decision making (shared or informed), preferences are considered by the physician and patient or by the patient alone when manually making a specific treatment decision\(^1\). A trial of decision aid tools (implemented as paper charts) for patients considering total knee arthroplasty was described in \(^1\). According to the results of the trial, patients exposed to decision aids demonstrated significantly higher quality decisions (informed choice -- surgery vs. non-surgery -- that matched their values for outcomes of options) than patients that did not use decision aids.

There is also ongoing work on embedding patient preferences in clinical decision support systems. This line of work is exemplified by the MobiGuide system\(^2\). MobiGuide supports remote and CPG-based patient management. The system first learns patient preferences (given in the form of utilities) and applies them when making preference-sensitive decisions in order to establish support for specific options. The system currently contains CPGs for atrial fibrillation\(^3\) and gestational diabetes\(^2\).

**Eliciting Preferences**

Patient preferences represent “the desirability of a health-related outcome, process or treatment choice.” Patients might prefer less invasive tests or procedures over those that cause discomfort, tests that are carried out by nurse practitioners versus those performed by physicians, or specific drugs over others within the same drug class. Such preferences are often represented using “health utilities”\(^6\) that are elicited using various decision aids integrated with
CPGs. These aids typically take the form of charts where patients assign weights or utilities to available options. However, there is no consensus whether this is the best approach that should be adopted in practice.

In our research we use a different approach to elicit patient preferences -- instead of asking patients for direct specification of utilities associated with individual options, we ask them to compare pairs of selected options (for example those for which they have pronounced preferences). These comparisons are then used to derive a preference model in the form of an additive value function that is a sum of marginal value functions associated with specific features of considered options (e.g. their cost, complexity, or side effects). For this purpose we employ the Generalized Regression with Intensities of Preference (GRIP) method that not only constructs value functions, but also allows for detailed analysis of pairwise comparisons and for indicating conflicting or inconsistent answers. This makes GRIP very well suited for interactive use and an example of using GRIP to elicit patient preferences related to pain management therapies is presented in 22.

Value functions constructed by GRIP can be used to evaluate options, also those not included in pairwise comparisons. In our framework we use these evaluations to define desired revisions to CPGs. Specifically, we consider pairs of options for a given action, i.e. a default option and its alternative. If an alternative option receives a better evaluation than the default one, we introduce a revision that replaces the default option with the alternative (see Representing Preferences section below for more information).

Representing Preferences

Up to this point, our mitigation framework only used revision operators to represent secondary medical knowledge (such as drug-drug or drug-disease adverse interactions) that, when relevant to the patient encounter, must be applied to the combined theory used to construct the therapeutic scenario for the patient. Support for preferences introduces the notion of modifications to the combined theory that are desired but not required. Therefore, the mitigation framework must distinguish between these two classes of revisions and apply all applicable interaction-related revisions, while it can skip any of the triggered preference-related revisions that medically invalidate the combined theory.

In this work, we describe revisions as one of two types: those related to preferences and those related to adverse interactions. As such we broaden the definition of an operator to cover all secondary knowledge to be considered when mitigating concurrently applied CPGs. Using this broader definition of a revision operator, we introduce two classes of operators: preference-related revision operators and interaction-related revision operators. The class distinctions are used to define what secondary knowledge must be contained in the combined theory and what secondary knowledge is desired by not required in the combined theory. We note however that the framework uses the same formalism to represent both classes. Therefore, preference-related as well as interaction-related operators can replace, remove, or add clinical actions.

Specific examples of both classes of revision operator are given in the Case Study section. While the preference-related revision operator example and its representation is quite simple, our mitigation framework supports more complex revisions. Preferences for drugs can include dosage adjustment, ordering changes (taking some drug before/after another) and other supported revisions as further described in 7.

Applying Preferences

Providing a formal representation for preferences enables our mitigation framework to apply them while constructing a therapeutic scenario. As integral components, preferences must be vetted medically to ensure no adverse interactions are introduced as a result of their application. Furthermore, formally representing preferences means they can be expressed across a broad range of therapy characteristics. Not only can they refer to higher level concepts such as drugs or medical tests, but preferences can be defined for the type of drug administration (oral, injection, etc.), the number of times the drug is taken per day, if a drug is covered/not covered by insurance, and other similar characteristics. The power of FOL allows our mitigation framework to expand the vocabulary as needed to increase the richness of preferences. In this section we describe how preferences are applied by an extended mitigation algorithm while maintaining medical validity of the proposed therapy.

Our existing mitigation algorithm is a core component of the mitigation framework and it is described in pseudocode in Figure 2. The algorithm takes as input a combined theory $\mathcal{D}_{comb}$, uses interaction-related revision operators $RO^k$ to mitigate (identify and address) adverse interactions, and finally constructs a therapeutic scenario $\mathcal{D}_{th}$. The algorithm iterates over available interaction-related revision operators (line 3). It checks through entailment whether the current operator $RO^k$ is applicable to $\mathcal{D}_{comb}$ (line 5) using a theorem prover. If $RO^k$ is applicable, then the
The mitigation algorithm in Figure 2 employs interaction-related revision operators. When applicable, they must be used so that the therapeutic scenario $D_{th}$ can be constructed. With the introduction of preference-related revision operators, whose application is desired but not strictly required to produce the therapeutic scenario, we extend the mitigation algorithm to treat each type of revision operator differently. The key innovation lies in an extended procedure that acts as a wrapper around the existing mitigate procedure.

Our extended algorithm is more formally shown in Figure 3 as procedure customize_and_mitigate. As input it takes the combined theory $D_{comb}$ and outputs the therapeutic scenario $D_{th}$ that includes changes introduced by all applicable interaction-related revision operators and those preference-related revision operators that do not conflict with the CPGs and with interaction-related revisions. The extended algorithm first orders preference-related revision operators $RO^k$ in decreasing priorities (line 2), as identified by the patient. It then iterates over the ordered operators (line 3), considering more important ones first. For each preference-related $RO^k$, the algorithm checks its applicability through entailment (line 5). If $RO^k$ is applicable, then the algorithm creates a temporary combined theory $D_{comb}'$ by revising $D_{comb}$ (line 7). If $D_{comb}'$ is consistent (i.e. the preferences represented by $RO^k$ do not conflict with the CPGs), then it is passed to the mitigate procedure defined in Figure 2 to apply relevant interaction-related revision operators and to ensure the existence of a therapeutic scenario $D_{th}$. If $D_{th}$ exists, the preference-related revisions are preserved (lines 13-14), otherwise they are discarded due to their conflict with interaction-related revisions. The extended algorithm also invokes the mitigate procedure if no preference-related revision operators were successfully applied, due to no applicable preference operators or applied operators only resulted in conflicts (line 19-20). This case is equivalent to the operations carried out by our existing mitigate algorithm.

Here we note that because the extended mitigation algorithm sequentially applies preference-related revision operators in order of decreasing priority, it is possible that preference-related revisions introduced earlier could “block” preference-related revision operators with lower priorities. Still, the algorithm attempts to consider as many
preference-related revision operators as possible given it does not terminate when a specific operator introduces conflicts, but instead skips over this operator. The framework also assumes that it is better to select the therapeutic scenario $D_{th}$ that contains paths through the CPGs that do not require a preference-related revision to be made. Intuitively, this means the framework elects to return the scenario with as many actions as possible to which the patient has no applicable preference-related revision operators. Our expanded mitigation approach, with respect to preferences, assumes when a patient does not express preference-related revisions for a given clinical action, she fully accepts what is suggested by the CPG.

```
procedure customize_and_mitigate(inout D_comb, out D_th) begin
    preferences_applied := false;
    order preference-related RO's according to their decreasing priorities;
    foreach preference-related RO do
        begin
            if $D_{comb} = a^k$ then
                begin
                    $D_{comb}' :=$ revise $D_{comb}$ using $Qp^k$;
                    if $D_{comb}'$ is consistent then
                        begin
                            mitigate($D_{comb}'$, $D_{th}$);
                            if $D_{th} <>$ null then
                                begin
                                    preferences_applied := true;
                                    $D_{comb} := D_{comb}'$
                                end
                            end
                        end
                    end
                end
            end
        end
    if not preferences_applied then
        mitigate($D_{comb}$, $D_{th}$);
end
```

**Figure 3.** Extended mitigation algorithm.

**Case Study: Management of a Patient with Stable Cardiac Artery Disease Who Suffers a Sudden Onset of Deep Vein Thrombosis**

Stable coronary artery disease (SCAD) encompasses several patient populations at different stages and with different types of coronary disease, excluding acute coronary syndromes. SCAD has a number of manifestations, including some form of chest discomfort (the most common one) that is induced by exercise, emotion, or stress. People with hypertension, hypercholesterolemia, diabetes, obesity, and those who smoke are at a higher risk of developing SCAD\(^23\). Treatment of a typical SCAD patient begins with short acting nitrates combined with beta blockers or calcium channel blockers as well as lifestyle management to control for cardiovascular risk factors. If SCAD symptoms persist, a second line of treatment is initiated that includes long lasting nitrates combined with potassium channel activators (e.g. nicorandil), statins, and aspirin.

In the clinical scenarios described below we assume a SCAD patient presenting with symptoms of deep vein thrombosis (DVT) related to either DVT itself or a pulmonary embolism (PE) -- we refer to this presentation as DVT/PE. A patient diagnosed with DVT/PE is managed according to the standard CPG\(^24\) and a simplified version of this guideline is presented in Figure 4 as an actionable graph\(^10\) (we omit the figure showing the SCAD CPG due to space limitations but it is available from the authors upon request). The management of DVT/PE involves aggressive in-patient therapy especially for those patients who exhibit haemodynamic instability or are diagnosed with renal failure. Such a therapy is followed by out-patient management. The development of novel oral anticoagulants (NOACs) opened up new treatment options beyond management with low molecular weight heparin (LMWH) and warfarin. It is in the context of NOACs that patient preferences start playing an important role in selecting the most suitable and clinically sound treatment. In the case of DVT/PE out-patient management, a patient can consider one of the following therapeutic options:
LMWH and warfarin; this is the default treatment (and presented in Figure 4) that requires regular blood work in order to assess the effect of oral anticoagulation with warfarin. This assessment is done using the international normalized ratio (INR).

LMWH for 5 days followed by NOAC (dabigatran) twice daily; some patients may prefer to start with a parenteral agent (e.g., LMWH injection) as it is perceived as a more effective immediate treatment. No blood work is required for this option.

NOAC alone; possibilities include either rivaroxaban that is taken once a day or apixaban that is taken twice a day and has a slightly lower risk of bleeding than rivaroxaban. Treatment with NOACs does not require blood work.

Figure 4. DVT/PE CPG represented as an actionable graph (DVT = deep vein thrombosis, PE = pulmonary embolism, UFH = unfractioned heparin, LMWH = low molecular weight heparin, IVCF = inferior vena cava filter)

Patient preferences governing the selection of a given treatment option may include such factors as perceived effectiveness (injection vs. oral administration), ease of use (injection vs. oral vs. number of daily administrations), convenience (no need to monitor effects of anticoagulation, no need to buy and store syringes), or insurance coverage of medication (government, private, or out of pocket expense). In the subsequent sections we illustrate how patient preferences are modeled as part of our mitigation framework and how they impact the development of a therapeutic scenario. We start with a simple illustration of mitigation that does not include patient preferences and finish with one that does.

Clinical Scenario 1: Mitigating Adverse Interactions

In the first scenario we assume an elderly male patient is treated for recurring SCAD and has not expressed any preferences for their DVT/PE treatment. According to the SCAD CPG, he is placed on long lasting nitrates, potassium channel activators, statins, and aspirin. This patient arrives at the Emergency Department (ED) complaining of swelling and tenderness in his left leg. An ultrasound and D-dimer test confirm DVT. Further
investigations rule out haemodynamic instability and renal failure. The patient is immediately started on anticoagulation therapy (unfractioned heparin (UFH) and warfarin).

However, a patient should not be put on two different anticoagulation treatments (in this case aspirin or clopidogrel for SCAD and any type of anticoagulation for DVT/PE). Supporting this scenario requires the codification of secondary knowledge preventing the use of two anticoagulation therapies. As stated in medical literature for patients treated for DVT/PE, the administration of aspirin and clopidogrel must be stopped when the patient is put on another anticoagulation therapy. The interaction-related revision operator $RO^1$ represents the secondary knowledge that can be used to mitigate this drug-drug interaction. Note we use a simplified representation that does not use variable names but only presents their labels:

$$RO^1 = \langle \alpha^1, Op^1 \rangle,$$

$$\alpha^1 = \text{diagnosed(DVT\_PE)} \land \text{execute(anticoag)} \land \text{execute(aspirin)},$$

$$Op^1 = \langle\text{execute(aspirin)} \land \text{execute(clopidogrel)}, \emptyset \rangle.$$  

For this scenario we have the following subset of sentences describing the patient’s state $D_{pi}$.

$$D_{pi} = \text{diagnosed(DVT\_PE)}, \text{diagnosed(SCAD)}, \text{execute(aspirin)}.$$  

The following sentences are part of the theories for SCAD and DVT/PE, including a sentence describing the applied anticoagulation therapy that uses warfarin and unfractioned heparin (UFH).  

$$D_{SCAD}^{DVT\_PE} \ni \text{execute(clopidogrel)}$$

$$D_{cplg}^{DVT\_PE} \ni \text{execute(anticoag)} \implies \text{execute(warfarin)} \land \text{execute(UFH)}$$  

To check for the applicability of $RO^1$ we formulate the entailment problem $D_{comb} \models \alpha^1$. Because $\alpha^1$ is entailed by $D_{comb}$, we immediately establish that $RO^1$ is applicable to $D_{comb}$ and we consequently apply $Op^1$ to remove aspirin and clopidogrel from $D_{cplg}^{SCAD}$. This resolves the drug-drug interaction and the returned therapeutic scenario $D_{Th}$ includes the administration of long lasting nitrates, potassium channel activators, statins, but not aspirin or clopidogrel for the subset of the model for $D_{Th}$ related to treating the patient’s SCAD. Had the entailment problem $D_{comb} \models \alpha^1$ failed, we would be unable to revise $D_{comb}$ and find a model for it. Similarly, because no preferences were expressed by the patient, only interaction-related revision operators are checked and applied. We omit the full theory describing this patient encounter due to space limitations and refer the reader to previous work for more detailed scenarios \cite{3,4,12}.

**Clinical Scenario 2: Applying Patient Preferences**

Considering the same patient as in the first scenario, now the patient has expressed a preference for a simple treatment of DVT/PE, defined as the fewest drug administrations in a day as possible, oral route preferred over injection, and the administration of drugs covered by insurance (the patient has supplementary private health insurance). Due to the blood work required before administering warfarin, the patient prefers to take rivaroxaban. Taking this drug allows the patient to start with pills only (no parenteral agent), does not require blood work, the pill is taken only once a day, and is covered by the government (e.g., for seniors) and private insurance. This is a common patient preference as indicated by the medical expert (Dr. Carrier) on our team. The preference-related revision operator $RO^2$ represents, in a structured form, the above expressed patient preference that was elicited prior to prescribing a treatment. Note again we use a simplified representation to improve readability:

$$RO^2 = \langle \alpha^2, Op^2 \rangle,$$

$$\alpha^2 = \text{diagnosed(DVT\_PE)} \land \text{execute(anticoag)},$$

$$Op^2 = \langle\text{execute(warfarin)} \land \text{execute(UFH)}, \text{execute(rivaroxaban)} \rangle.$$  

To check for the applicability of the preference-related revision operator $RO^2$ we first formulate the entailment problem $D_{comb} \models \alpha^2$. Because $\alpha^2$ is entailed by $D_{comb}$, we immediately establish that $RO^2$ is applicable to $D_{comb}$ and we consequently apply $Op^2$ to replace the anticoagulation therapy that uses warfarin and UFH with one that uses rivaroxaban in $D_{cplg}^{DVT\_PE}$. Note that this results in the sentence $\text{execute(anticoag)} \implies \text{execute(rivaroxaban)}$ as part of $D_{comb}'$. Applying the $\text{mitigate}$ procedure to $D_{comb}'$ results in a revision made according to $RO^1$ since $\alpha^1$ is still entailed by $D_{comb}'$. As such, the returned therapeutic scenario $D_{Th}$ both resolves the drug-drug interaction
described in RO1 and applies the patient’s preference for a simpler treatment of his DVT/PE condition as represented by RO2. We again omit the full theory describing this patient encounter due to space limitations.

Discussion

In this paper we describe extensions to our FOL-based mitigation framework to add support for patient preferences when mitigating multiple concurrently applied CPGs to a multimorbid patient. The flexibility provided by FOL allowed us to easily expand the definition of an operator to include two subclasses that use the same representation formalism as before. We leverage these classes of operators in an extended mitigation algorithm to either apply all revisions represented by the set of interaction-related revision operators or as many as possible from the set of preference-related revision operators. We also describe how preferences are formally elicited, further demonstrating our incorporation of preferences as first-class citizens in the mitigation process.

In supporting preferences, we demonstrate our mitigation framework’s ability to represent different types of secondary knowledge. The current version of the framework supports preferences that replace a medical action(s) with one or more different ones. As future work we will support the full range of operations for preference-related revision operators. Additionally we are further working on the mitigation framework’s theoretical foundations that will make it possible to expand the notion of mitigation to include preferences, with the goal of developing an interactive clinical decision support system (CDSS) to be used at the point of care.

Abstract

Community-engaged health informatics (CEHI) applies information technology and participatory approaches to improve the health of communities. Our objective was to translate the concept of CEHI into a usable and replicable informatics platform that will facilitate community-engaged practice and research. The setting is a diverse urban neighborhood in New York City. The methods included community asset mapping, stakeholder interviews, logic modeling, analysis of affordances in open-source tools, elicitation of use cases and requirements, and a survey of early adopters. Based on synthesis of data collected, GetHealthyHeights.org (GHH) was developed using open-source LAMP stack and Drupal content management software. Drupal’s organic groups module was used for novel participatory functionality, along with detailed user roles and permissions. Future work includes evaluation of GHH and its impact on agency and service networks. We plan to expand GHH with additional functionality to further support CEHI by combining informatics solutions with community engagement to improve health.

Introduction

In biomedical informatics, the level of community remains a fairly unexplored application domain. While public health informatics generally addresses population health, community-level engagement is rarely investigated from an informatics perspective. Community-based participatory approaches have rarely been applied in public health informatics. Meanwhile, there is increasing recognition that how people live in their communities is a major determinant of health. Recent healthcare policies in the U.S., such as patient-centered medical homes and population-based accountable care initiatives, are consistent with the idea of situating patients and health resources in communities. Academic medical centers, such as the Columbia University Medical Center in New York City where the present study is located, are moving towards the population health model required by the Affordable Care Act by recognizing the value of partnering with community stakeholders and leveraging a broad spectrum of community assets.

Goodman and colleagues provide a useful definition of community health as “a multi-sector and multi-disciplinary collaborative enterprise that uses public health science, evidence-based strategies, and other approaches to engage and work with communities, in a culturally appropriate manner, to optimize the health and quality of life of all persons who live, work, or are otherwise active in a defined community or communities.” The potential power of community-level health interventions is increasingly recognized. The characteristics of the ecological systems paradigm for community interventions encompass a focus on community capacity and issues identified through community engagement; ecological and systemic perspectives; empowerment of the community; and the permeating role of culture.

Community-engaged health informatics (CEHI) applies information technology and participatory approaches to improve the health of communities. CEHI facilitates community participation in research and dissemination of evidence. The emerging agenda of CEHI incorporates concepts and methodologies from biomedical informatics, community-based public health approaches, and other fields such as community informatics. Community informatics is the application of information and communication technology to enable and empower community processes. CEHI applies tenets of community informatics in the domain of health. Community-based participatory research (CBPR) is a public health research approach defined as a partnership approach to research that equitably involves community members, organizational representatives, and researchers in all aspects of the research process and in which all partners contribute expertise and share decision making and ownership. Interestingly, CBPR shares many aspects with participatory approaches to information technology design that actively involve end-users in the design process.
Community health interventions can be more effective and sustainable if they build on existing community capacity. CBPR emphasizes community asset mapping. Community-based organizations (CBOs) and service providers are essential assets for building community health interventions. They are important stakeholders in health systems because they provide a wide spectrum of programs and services to members of their community, link with other health and social services to help provide care, and advocate for broader system-level supports. Emerging literature in the area of knowledge translation is also beginning to highlight the potential of CBOs in translating evidence into the community. Many barriers hinder evidence use and evidence-based practices of CBOs. Research has consistently identified that CBOs struggle with: access to evidence; time to process evidence; skills to review, summarize, and synthesize evidence; research terminology; and local applicability and acceptability of evidence. Strategies are needed to address these barriers in order to realize the potential of CBOs as important agents of improving population health.

CEHI takes an ecological systems approach to community health. It extends the notion of Learning Health System to the community-level, and investigates the ecology of community health information in a “cyber-social ecosystem.” The present community intervention seeks to integrate a participatory online environment in the setting of a real geographic community environment. The rationale of the intervention is supported by evidence that online participation and public/civic participation are found to mutually reinforce each other. While many online health communities have broken down geographic barriers by connecting people with similar health interests, it will also be important to build online health communities that have great potential to support health promotion in real geographically defined communities.

The objective of our research was to translate the concept of CEHI into a usable and replicable model informatics platform that will facilitate community-engaged practice and research. The goal of the research is to generate generalizable knowledge and tools that apply to communities outside of Washington Heights/Inwood (WAHI). GHH in WAHI is used as a “laboratory” environment to develop the concept of the CEHI platform. Plans are currently underway to bring CEHI platforms to other communities. This paper describes the methods and results of the GHH CEHI platform design process.

Methods

Setting

The setting of this study, the Washington Heights/Inwood (WAHI) neighborhood, is located in upper Manhattan within New York City (NYC), north of Harlem and directly south and west of the Bronx. It is a densely populated urban area with approximately 280,000 residents. A large proportion of the community residents are Hispanic (71%) and nearly 90% belong to a racial/ethnic minority group. African Americans represent 14% of the population. Most residents are foreign-born, mainly from Latin America, with the vast majority from the Dominican Republic (71%), followed by Ecuador (4%). Less than 50% are proficient in English. The median household income in 2007 was $35,456, and 27% lived below the 200% federal poverty level in 2007. A large percentage (44%) of community residents (persons over the age of 25) did not graduate from high school, and the unemployment rate is over 12%. The most common sources of employment are services and sales industries. Health concerns in the community are significant compared to NYC as a whole. One third (32%) of WAHI residents rate their health as fair or poor, compared to 21% citywide. Residents are less likely to have a regular doctor, more likely to seek care from the emergency department, and more likely to be uninsured. The community rates poorly regarding risk factors for heart disease, with higher rates of high blood pressure, high cholesterol, obesity and diabetes than the overall NYC population, combined with less recreational exercise.

Design Process

Design process is iterative, unique in each case, and may incorporate a variety of practices from different fields. The GHH design process involved a core team at the Department of Biomedical Informatics at Columbia University, including all authors of this paper, and ongoing consultation with community-based organizations and other stakeholders. The idea for GHH originally emerged from lessons learned from another community health portal, GetHealthyHarlem.org, which was previously developed under Dr. Kukafka’s leadership. Whereas GetHealthyHarlem.org was designed primarily for dissemination of local health information to community members, GHH was designed for multiple levels of the community--from community residents to CBOs and other
community stakeholders—to share health related content and connect with each other. The GHH team sought to develop a platform that would facilitate community engagement in health practice and research. CBOs with a health-related mission were recruited as initial primary users. A full range of other stakeholders and related community sectors may also participate in GHH, including, for example, schools, law enforcement, urban planning, and religious organizations.

Following is a list of key steps in the CEHI platform design process for GHH. It is important to note that the steps often deviated from the numeric order shown here, with iterative loops repeating prior steps and with overlapping steps conducted simultaneously.

1. Preliminary community asset mapping
   The design of GHH is supported by Columbia University’s Irving Institute for Clinical and Translational Research, which is the Clinical and Translational Science Award (CTSA) at Columbia University. The Community Engagement Core Resource (CECR) of the Irving Institute conducts extensive outreach and community asset mapping in WAHI, which is the neighborhood where Columbia University Medical Center (CUMC) and the Irving Institute are located. The relationships CECR has established with community-based organizations and other stakeholders are the foundation for the community-based participatory approach of our design process. CECR is also responsible for ongoing site management and promotion, and engagement of organizational users, including coordination of the GHH Steering Committee.

2. Logic modeling
   As is common practice in public health program planning, the team constructed a logic model to represent inputs, activities, outputs, and outcomes envisioned for GHH.

3. Guiding principles for CEHI platform
   The team reached consensus on several guiding principles that helped align the work with a common understanding of CEHI and architecture of participation.

4. Key informant interviews
   Six semi-structured interviews were conducted with key stakeholders, including community leaders, executives of community-based organizations, and leaders of CUMC groups that engage in community-based participatory research. The interviews covered a broad range of questions relevant to GHH planning, but in this paper we present key themes related to functional needs expressed by the interview participants. Several team members engaged in the collaborative qualitative coding process to derive these themes.

5. Identification of open-source tools
   One of the guiding principles (see Step 3) was to use open-source tools when possible. The team identified suitable tools for the GHH CEHI platform and decided to use Drupal as the primary development environment.

6. Exploration of affordances in Drupal
   The team reviewed Drupal documentation, engaged a Drupal developer consultant, and explored design features in publicly available health and non-health websites designed using Drupal.

7. Use cases and requirements
   Step 7 occurred simultaneously with Step 6. The team analyzed use cases, partly informed by the key informant interviews, and articulated most important requirements for a CEHI platform, given affordances available in Drupal.

8. Iterative development process
   Wireframes and prototypes were developed iteratively, working closely with a Drupal expert consultant.

9. Definitions of roles and permissions
   Once the team decided to use Drupal Organic Groups module for the essential participatory functionality, a thorough process was undertaken to configure user roles and permissions.

10. Quality testing
    Student interns and other team members conducted a systematic quality assurance process of all features of GHH over several months.

11. Soft launch with early adopters
    An initial group of 10 organizations were invited to participate in the soft launch of GHH.
12. Survey of early adopters
   During a session that introduces GHH and reviews key functionality, early adopters (n=18) completed a structured survey asking about user needs and reactions to GHH functionality.

13. Plan for full launch
   A detailed plan was developed for full community-wide launch of GHH, including several strategies of outreach and marketing.

Results
The mission of the GHH CEHI platform was collectively defined by the GHH team and early adopters as “an online community that engages people in Washington Heights-Inwood to connect, discover, and share resources to get healthy”. Figure 1 shows one part of the GHH logic model, representing the sequence of outcomes leading from use of GHH to intermediate outcomes and then to improved community health as the long-term outcome. A degree of shared understanding about the mission, intermediate outcomes, and long-term outcomes was achieved early on in the design process.

![Figure 1. Logic of GHH outcomes.](image)

The team had extensive discussions to clarify basic principles to guide the design of a CEHI platform. One of them was to use a CBPR approach and to incorporate community stakeholder input and engagement throughout the process to a maximum extent possible. Another principle was to utilize open-source technologies when possible, given their multiple advantages over proprietary tools, such as customizability, flexibility, interoperability, and support options. An essential principle underlying all functional requirements was to strive for opportunities and strategies to increase active user participation. To that end, the team reviewed dozens of publicly available websites, with a special emphasis on health-themed sites, and listed ideas for functions that facilitate contributions from and engagement by users.

Semi-structured key-informant interviews were used to further elicit input from important stakeholders. The six key informants included community leaders, executives of community-based organizations, and leaders of community-engaged research and service providers from the medical center. Table 1 shows key themes that reflect functional needs the informants expressed for accomplishing their work with the WAHI community. Six themes are listed, with sub-themes under each. There was a high degree of agreement across the different types of key informants. For example, both community-based and medical center-based informants emphasized the first five main themes listed in Table 1. Although medical center stakeholders expressed more needs around research production and use, research related needs were also discussed by community-based participants. The interview data provided the team an understanding of higher-level functional needs among potential users.
Table 1. Qualitative interview coding themes for functional needs among key informants.

The next step in the process described in the method section (Step 5) involved identification of suitable open-source technologies. Based on discussions with experts and examination of functionality, Drupal open-source content management system was selected as the primary tool for building the GHH CEHI platform due to its rich functionalities, support for multilingual sites, support for multiple content types, advanced user management that allows for multiple site stakeholders, stability, and scalability. Open source LAMP stack (Linux operating system, Apache HTTP server, MySQL relational database management system, and PHP programming language) was used as software components of the underlying platform. An iterative process (Steps 6-8) was undertaken with a Drupal developer consultant to explore Drupal features, refine use cases and requirements, and design several iterations of wireframes.

In response to the findings from use cases and key-informant interviews, the team selected an essential-set of functions to engender community engagement. Selected functions included a community calendar, a local service directory, posting of multiple types of content (e.g., articles, videos, and links), the ability to comment and rate content, integration of social media for content sharing, use of Google Translate (especially for Spanish translation of content), and the creation of social networking groups. For example, the local service directory functionality relates to the interview theme “Information on community resources and services” (Table 1), and the interview theme of “Information on health” motivated the functionality for posting content. The social network group functionality was deemed an essential design point of GHH. It entailed forming subgroups within the general community based on a localized interests or purposes. Groups could be public or private in nature, with the ability to determine their own membership, host relevant content and provide feedback or communicate with its members. A core role of GHH as a CEHI platform revolved around providing this group functionality to the WAHI community. This functionality meets requirements derived from two particular themes listed in Table 1: “Connections with organizations and people” and “Communication with constituents”.

To enable this function, GHH chose to deploy Drupal 7.1 Organic Groups module. The ability to dynamically form groups is core to the social network group functionality of GHH. Groups within GHH are defined by users and have access to communication forums, email, blogging and notification services, content-sharing services, event calendars and links to social media sites. Ownership and management of the group is kept at the community-level through the pre-defined role of a group owner. Specific group features were defined at both the content creation and the content consumption level. By design, Organic Groups also links to Drupal administrative and reporting services, thus allowing GHH to monitor and provide access and security to groups from an overall site perspective. The full vision of GHH is to support local groups within the WAHI community. These groups must be able to dynamically form, grow, shrink and even disappear according to community preferences. Through Drupal Organic Groups, GHH provides this ability online and fulfills a crucial tenet of community-based participatory research.

Given the required type of participatory architecture of GHH, definition of user roles and permissions also became a complex and important design task for the team. Over several weeks, the team constructed a set of user role and permission settings for the GHH site as a whole (Table 2), and sets of permission settings for public and private groups by type of group member status. The public group settings are shown in Table 3.
Numerous issues were discovered during the quality-testing phase. The user roles and permissions in particular required extensive testing and re-testing to ensure functioning of the exact specifications listed in Tables 2 and 3. Other issues involved appropriate requirements for file sizes and formats of content that users can post. Issues of security, including CAPTCHA verification, also required attention. Overall, our experience demonstrated the value of extensive testing and gradual launch process.

To provide a feel for the final design product at this stage, Figure 2 shows a screen-shot with some of the participatory functions. (The full website is accessible at http://www.gethealthyheights.org.) On the top left of Figure 2 is the list of content categories used during the soft launch. This list is currently undergoing revision, based on feedback from early adopters. On the bottom left is community event calendar, which has received extremely positive early user feedback. The right hand side shows the area where users can post different types of content (articles, videos, services, links, and events). We will continue an iterative process of gathering further user feedback and refining the functionality. For example, focus groups are planned to obtain feedback from the community member perspective.

![Figure 2. Screen-shot from GHH, illustrating participatory functionality.](image)

Early adopters (n=18) were asked to participate in a brief survey during GHH orientation sessions. One of the survey questions asked users to indicate how likely they think they are to use specific features of the site. The data are shown in Figure 3. The team is currently using this information to further refine functionality. For example, early adopters indicated an interest in linking GHH with social media with 90% responding that they are very likely or somewhat likely to promote GHH on social media (Twitter, Facebook, etc.). As a result, the team is designing more robust features for social media integration. On the other hand, fewer people indicated likelihood to become regular content contributors or post articles, prompting the GHH team to design a strategy for systematically inviting contributions. During the early use period, we discovered that CBO users preferred to create user names on behalf of their organizations, rather than as individuals. This is an example of users appropriating technologies their own ways, sometimes contrary to the designer’s intentions. We decided to allow organizational user names on GHH.
The CEHI platform configurations are presented here as the primary outcome of the research. GHH was launched to an initial set of users from CBOs in April 2015. As of early July 2015, there has been robust use by the CBOs as well as others who have discovered the site. In the first three months, there were 57 registered users, 26 partner organizations, and 5 interest groups on GHH. Table 4 shows further early use statistics of GHH, obtained through Google Analytics. We plan to present updated use data at the AMIA meeting in November 2015, including use patterns of specific functionalities. During the initial months, a steering committee was established as the governing body of GHH. Twelve CBOs are actively participating as part of the steering committee.

Discussion

We have described the methods and results of a design process for the GHH CEHI platform with an architecture of participation. Public health methods, such as logic modeling and community asset mapping, were integrated with information technology design methods, including analysis of functional requirements and iterative development of features to meet user needs. Both qualitative interview data and quantitative survey data were utilized as part of the design process. Throughout the process we show how user needs and requirements are translated into platform configurations and features, resulting in a design product that follows the principles of CEHI and is tailored for the local community. In the GHH CEHI platform, configurations for user roles and permissions became central to achieving the desired participatory functionality with the Drupal Organic Groups module. The general model presented here can be applied as a CEHI intervention in any community but needs to be customized for local needs.

CEHI combines the potential of community-engaged public health interventions with the potential of informatics tools. There is little prior work in this intersection of fields, but an increasing demand for innovative community-level interventions has recently emerged in the context of the Affordable Care Act and healthcare reform. The present study addresses the need for community-level interventions and leverages the power of online tools to facilitate community health in the context of geographically defined high-need communities. Other pioneering community health websites have started emerging in the U.S. and other countries. Examples include websites for Sonoma County, CA [http://www.healthysonoma.org], and London, UK [https://www.myhealth.london.nhs.uk], but GHH is distinguished by its degree of participatory architecture and community stakeholder engagement.

While our aim is to develop a platform that can be adapted for a variety of community settings, one limitation of our work is that the characteristics of the GHH CEHI platform may not be suitable for all communities. For example, it is possible that urban settings with relative density of CBOs and health services may benefit from the functionalities in this type of CEHI platform more than rural communities. On the other hand, rural communities may utilize the CEHI platform in a way that is different, requiring modification to the platform’s functionalities. Generalizability of GHH as a CEHI platform will need to be verified in a variety of communities. Another limitation of our work is that we do not have design, programming, and technology infrastructure resources comparable to commercially supported websites.

Future work includes evaluation of GHH use patterns and the impact of GHH on health-related agency and service networks in the WAHI community. We plan to measure community network connectivity outcomes using system-level network analysis techniques. We are currently collecting baseline survey data on the social network connections among agencies in WAHI. The evaluation plan involves measurement of the network connectivity over time and correlating use of GHH with network connectivity outcomes. In order to demonstrate impact on specific community health outcomes, we plan to identify health conditions and specific projects that utilize the GHH platform. Some of the projects under discussion include focus on obesity, breast cancer, and healthy aging. We also plan to develop informatics approaches to further community asset mapping, with the goal of building a robust and updatable community service directory as part of GHH. GHH is intended to be a CEHI platform that allows further exploration of novel functionalities that promote community engagement and community health. Additional desired functionalities include centralized access to data on WAHI and exploration of opportunities to exchange data among community agencies. We will identify best practices for managing and evolving a CEHI platform of this size and scope. A well-structured development and release methodology will be documented based on the GHH team’s experience. After a number of release cycles, the information will be disseminated to the CEHI community to assist in the development of other CEHI sites.

Conclusion

GHH was developed as a model platform for CEHI. This work begins to expand biomedical informatics into the community-level, which is where many important determinants of human health occur. CEHI approaches, such as GHH, are needed to facilitate engagement of community-based assets and resources to promote community health. A CEHI perspective expands the vision of the Learning Health System beyond medical care settings, to fully include community stakeholders in the health data ecosystem.

Knowledge Extraction from MEDLINE by Combining Clustering with Natural Language Processing

Jose A. Miñarro-Giménez, PhD, Markus Kreuzthaler, MSc, Stefan Schulz, MD
Institute of Medical Informatics, Statistics, and Documentation,
Medical University of Graz, Austria

Abstract

The identification of relevant predicates between co-occurring concepts in scientific literature databases like MEDLINE is crucial for using these sources for knowledge extraction, in order to obtain meaningful biomedical predications as subject-predicate-object triples. We consider the manually assigned MeSH indexing terms (main headings and subheadings) in MEDLINE records as a rich resource for extracting a broad range of domain knowledge. In this paper, we explore the combination of a clustering method for co-occurring concepts based on their related MeSH subheadings in MEDLINE with the use of SemRep, a natural language processing engine, which extracts predications from free text documents. As a result, we generated sets of clusters of co-occurring concepts and identified the most significant predicates for each cluster. The association of such predicates with the co-occurrences of the resulting clusters produces the list of predications, which were checked for relevance.

Introduction

The state of the art of a scientific discipline and the progress of investigations about a particular topic are described by their set of scientific publications. The identification of new knowledge, which in the past exclusively relied on human effort, has become increasingly difficult due to the accelerating growth in academic literature. Consequently, scholars rely more and more on machine filtering and preprocessing of scientific articles.

The MEDLINE database, with currently about 22 million bibliographic records, is the most important source of biomedical literature. Each record has been semantically annotated by experts of the U.S. National Library of Medicine using the MeSH thesaurus. These metadata are not only useful for document retrieval, but also constitute valuable assets for information and knowledge extraction. They include sets of MeSH terms, which can be further qualified by one or more MeSH subheadings (Table 1), which specify the semantic context of the MeSH term, e.g. Anti-Inflammatory Agents / Therapeutic use, or Nephrotic Syndrome / Drug therapy. As much as this is useful for targeted document retrieval, it falls short of typical knowledge representation use cases, which demand predications like \(<\text{Anti-Inflammatory Agents} \square \text{Treats} \square \text{Nephrotic Syndrome}>\).

The file MRCOC within the UMLS Metathesaurus contains all annotations of co-occurring MeSH terms and subheading qualifiers for each MEDLINE record (aka citation). In the past, the content of MRCOC was used for diverse objectives, such as knowledge extraction, the identification of associative relations, semantic relation discovery, mining of symbolic and statistical gene-disease relationships, and text mining in general.

Another UMLS component is the Semantic Network (UMLS SN), an informal upper-level ontology, which provides 133 generic categories, so-called semantic types, linked by 54 directional relationships. All Metathesaurus concepts are assigned to one or more SN semantic types. Table 2 shows how the semantic types Disease or Syndrome, Organism Function and Pharmacologic Substance are linked in UMLS SN, which, in addition, defines directional relationships such as \(<\text{Disease or Syndrome} \rightarrow \text{Manifestation_of} \rightarrow \text{Organism Function}>\) or \(<\text{Pharmacologic Substance} \rightarrow \text{Disrupts} \rightarrow \text{Organism Function}>\). They are pattern for typical predications, with their subject and object positions to be refined by UMLS Metathesaurus concepts.

The identification of relevant semantic relations is crucial for the generation of predications. Natural language processing (NLP) is the method of choice for extracting such predications from textual sources. One example is SemRep, a system that recovers predications from biomedical text using syntactic analysis and structured domain knowledge from UMLS. However, ambiguity and complexity of biomedical language hinder the accurate extraction of biomedical facts. Capitalizing on the availability of semantic explicit MeSH annotations, we will investigate how this resource can be used to extract factual statements from MEDLINE, despite the lack of relational predications in its metadata annotations.

This will be addressed by analyzing, in parallel, (i) patterns of MeSH term / subheading co-occurrence as extracted from MEDLINE metadata, and (ii) the text of the paper abstracts, using SemRep. In both cases, the target representations are triplet-based predications, using UMLS SN relations. Based on the frequency of natural language predicates in the abstracts, we attempt to infer relations that interpret the statistical associations regarding the distribution of 83 subheading types in MeSH annotations.
Rather than formal-ontological relations, we expect, primarily, to extract associative relations between the subject and the object concept, which express what is typical or probabilistic. We are not interested in statements like \(<\text{Nephrotic Syndrome} \mid \text{Is}_a \mid \text{Kidney Disease}>\) which are already extensively covered by ontologies like SNOMED CT or OBO (“all nephrotic syndromes are kidney diseases”). Instead, we focus on triples like \(<\text{Corticosteroids} \mid \text{Treats} \mid \text{Nephrotic Syndrome}>\), which represent contingent or probabilistic (“non-ontological”) knowledge, which cannot be translated into first order logics\(^{17}\) and is not expected to be found in domain ontologies. However, this is exactly the kind of content we consider more “interesting” from a biomedical knowledge representation point of view\(^{18}\).

We limited the scope of our experiment dataset to the MEDLINE records published in the last 5 years (2009-2013). Besides, we focused on the most relevant MeSH terms that (i) co-occur in the MEDLINE records and (ii) are linked to the UMLS SN types Disease/Syndrome and Pharmacologic Substance. Despite of such limitations, the amount of data involved is still huge and therefore requires efficient and scalable methods typical for big data analytics\(^{19}\), including a distributed framework that supports multithreaded, massively parallelized computing tasks.

**Material and Methods**

**Resources:** The main resource is the UMLS MRCOC file, which provides information about pairs of MeSH terms that co-occur in each MEDLINE record related to a specific MeSH indexing year. We used the 2014AA release of the detailed MRCOC version with a size of 131 GB. Each line of this file (Table 3) contains, among other data, a pair of co-occurring MeSH terms, the subheadings assigned to them, and the identifier of the MEDLINE record where these MeSH terms co-occur. The number of subheadings is variable, depending on the content of the article. Each MeSH term points to one UMLS unique concept identifier (CUI), which is linked to one or more UMLS semantic types in the files MRSTY and SRSTRE\(^{1}\).

**Tools:** SemRep is a system that analyses text and extracts semantic predications as triples. Their subjects and objects are represented as UMLS CUIs and the predicates correspond to one of the 54 UMLS SN relations. The output of SemRep is classified into three categories: TEXT, ENTITY and RELATION. TEXT describes the textual section analyzed by the system. ENTITY is related to a particular UMLS concept identified in the text, and RELATION describes a semantic relation between two entities found in the text.

**Methodology:** The creation of predications from MEDLINE metadata consists of five main phases: (i) aggregation of the co-occurring concepts and their MeSH subheading information; (ii) filtering of the aggregated co-occurrences based on their log-likelihood rates\(^{20}\) (LLRs); (iii) clustering of the co-occurring concepts based on the accumulated MeSH subheadings; (iv) extraction of semantic predications from MEDLINE records associated with the co-occurrences of every resulting cluster using SemRep; and (v) identification of the statistically significant predicates of each cluster.

- **The first phase** is the aggregation of co-occurring concept pairs in order to select the most relevant ones. The input data is the list of co-occurrences from MRCOC described in Table 3, and the output will be the list of aggregated PubMed identifiers, the MeSH and UMLS IDs of the first term with a list of aggregated MeSH subheadings, the MeSH and UMLS IDs of the second term with a list of aggregated MeSH subheadings (Figure 1). Due to the large data volume in the detailed version of MRCOC, we have applied the MapReduce\(^{21}\) programming paradigm and the Amazon cloud services (Amazon EMR\(^{22}\) and Amazon S3\(^{23}\)) together with Apache Hadoop\(^{24}\) for generating the aggregated version of MRCOC. MapReduce provides two types of procedures: MAP and REDUCE. The functionality of MAP is to filter and sort elements, where REDUCE takes the output of MAP and performs certain operations on the processed values. The data is represented as key/values pairs, thus facilitating data access and distribution across several computers. Hadoop is a software framework that supports the distributed processing of large data sets across clusters of computers. Consequently, processing the MRCOC file using both, MapReduce and Hadoop, can be easily scaled up and parallelized.
The second phase of our methodology is the calculation of log likelihood ratios (LLRs) and the co-occurrence filtering based on such rates. LLR reflects the statistical relevance of a pair of concepts regarding their percentage in the dataset and the percentage of other concept pairs. The required parameters to calculate the LLR of concept C1 that co-occurs with concept C2 are:

1. Number of co-occurrences of C1 and C2 (#C1\(\cap\)C2);
2. Number of co-occurrences of C1 without C2 (#C1\(\cap\neg\)C2);
3. Number of occurrences C2 without C1 (\(\neg\)C1\(\cap\)C2);
4. Number of co-occurrences where neither C1 nor C2 occur (#\(\neg\)C1\(\cap\neg\)C2).

These parameters were obtained during the aggregation of list of MeSH subheadings using Amazon cloud services. The formula in Figure 2 explains how the log-likelihood ratio is computed. The function H represents the Shannon entropy. H(matrix) indicates the entropy of #C1\(\cap\)C2, #C1\(\cap\neg\)C2, #\(\neg\)C1\(\cap\)C2 and #\(\neg\)C1\(\cap\neg\)C2. H(mRows) is the sum of entropies of the pairs <#C1\(\cap\)C2, #\(\neg\)C1\(\cap\)C2> and <#C1\(\cap\neg\)C2, #\(\neg\)C1\(\cap\)C2>. Finally, H(mCols) is the sum of entropies of the pairs <#C1\(\cap\)C2, #C1\(\cap\neg\)C2> and <#\(\neg\)C1\(\cap\)C2, #\(\neg\)C1\(\cap\neg\)C2>. In order to filter the less significant co-occurrences we applied a threshold of 10.83, which corresponds to the chi-squared test with one degree of freedom and a p-value < 0.001.

\[
LLR = 2 \times (H(\text{matrix}) - H(\text{mRows}) - H(\text{mCols}))
\]

The third phase is the co-occurrence clustering. The resulting list of co-occurrences from the previous phase is firstly, filtered by the semantic types of both concepts and, then, clustering them by the list of aggregated MeSH subheadings. Thus, we obtain different sets of co-occurrences for each pair of semantic types, such as Disease or Syndrome with Organism Function, or Pharmacologic Substance with Pharmacologic Substance. We hypothesize that each pair of semantic types can be interpreted as one or more UMLS SN relations. Their number can be used as input parameter to define the number of clusters to obtain during the clustering process. We use WEKA, which provides a set of clustering and machine learning algorithms, which can be applied to data mining tasks, from which we chose the k-means clustering algorithm. The variables to be used to cluster the co-occurrences are the list of aggregated MeSH subheadings. The number of occurrences of each subheading in the list is normalized by the total number of co-occurrences found for its related concept pair, and, therefore, the value for each subheading will be in the range [0, 1]. As there are 83 types of MeSH subheadings and because each concept in the co-occurrence has a different list of subheadings, the total number of features is 166.

In our experiments, we have focused on the combination of the semantic types Disease or Syndrome with Pharmacologic Substance, for which UMLS SN defines six predicates: Diagnoses, Affects, Treats,
Complicates, Prevents and Causes (Table 2). The number of suggested predicates provided by UMLS SN can be used as the input parameter of the number of clusters to be produced by the k-means algorithm. Moreover, we can also investigate the use of clustering algorithms that can estimate the best number of clusters.

- In the **fourth phase** of the methodology, predictions are extracted from MEDLINE abstracts using SemRep. However, the accuracy of such predications is limited by the ambiguity and complexity of natural language. Nevertheless, we can use the outcome of this analysis as indicators for the most relevant predicates for each co-occurring concept pair. Subject to analysis are the abstracts of those MEDLINE records that are related to the co-occurrences of the resulting clusters from the third phase. This phase yielded a list of predicates directly related to each pair of co-occurring concepts.

- The goal of the final **fifth phase** is the association of the most relevant predicate to each resulting cluster. To this end, we analyze the predications generated by SemRep. The analysis is focused on the study of the frequencies of the predicates in each cluster. According to our hypothesis, the concept co-occurrences grouped together in a cluster are related with the same type of predicate. Therefore, the predicate frequencies found by SemRep for those co-occurrences should be also statistically significant.

We compared the results between clustering into five, six, and seven different clusters with the k-means clustering algorithm. The assignation of the relevant predicates to each resulting cluster must be consistent with the predominant types of MeSH subheadings. Besides, the inference of unrelated predicates for the same co-occurrences will be analyzed, i.e. if in the extracted predications two concepts are associated with both Treats and Cause relations.

**Results**

The total number of aggregated co-occurrences from MRCOC is around 99,000. However, the input dataset for clustering only includes the resulting list of co-occurrences with LLR > 10.83, which reduces the number to 15,886 co-occurrences. Examples of co-occurrences with higher LLRs in our dataset are < HIV infection, AIDS Drugs >, < Hypertension, Antihypertensive Agents >, or < Grippe, Influenza vaccines >. Such co-occurrences with a high LLR are very frequent in MEDLINE records for the analyzed period.

The k-means algorithm produced centroids for each cluster and, hence, we can classify the co-occurrences into the cluster with the smallest Euclidean distance to its centroid. Nevertheless, co-occurrences can be ranked depending on their distance to the centroid of each cluster, as a consequence, we could compare the ranks of co-occurrences of each cluster and discover which ones are representative of more than one cluster.

The parameter of the number of clusters for the k-means algorithm was, firstly, obtained from the six relations suggested by UMLS SN between our selected semantic types; and, secondly, we used the expectation maximization (EM) algorithm\(^\text{27}\), which gave us an estimated number of five or seven clusters depending on the provided minimum standard deviation. Thus, we compute the clustering using five, six, and seven clusters. The clustering is based on the list of aggregated subheadings of each co-occurrence. Consequently, some subheadings are more predominant than others are. In Table 4, Table 5, and Table 6, we show the list of MeSH subheadings that have higher frequency in the co-occurrences for each cluster.

Because of the clustering, we obtained the lists of co-occurrences that belong to each generated cluster. The identifiers of the MEDLINE records, which are related to each co-occurrence, are also included in the MRCOC file. During the aggregation of the list of MeSH subheadings, the identifiers of such records were also collected and, therefore, we can use them to gather abstracts that are going to be processed with SemRep.

The collected corpus contains around 1,500 abstracts related the top co-occurrences of each cluster where, at most, 50 abstracts of the same co-occurring concept pair were collected. Each abstract corpus was processed by SemRep. The results were analyzed to extract the percentage of each predicate from the resulting triples where the subject and object are identical with co-occurring concepts of the cluster. However, this exact match occurred only in roughly 10% of the abstracts. Nevertheless, we assumed this subset reasonably representative for the whole. Thus, we normalize the frequency of each predicate in each cluster by dividing the resulting frequency by the total number of predicates that match the co-occurrences in a cluster. In particular, SemRep could identify through the different corpora the following predicates: Treats, Prevents, Affects, Causes, Associated with, Predisposes, Augments, and Disrupts. The predicates Predisposes, Augments, and Disrupts do not belong to UMLS SN, but they were proposed by SemRep. Figures 3 - 5 visualize the percentage of each predicate per cluster.

The analysis of the results of SemRep produces the association of the predicates with the corresponding clusters that are indicated in Table 7. These associations were obtained by selecting those predicates that, at least, were present in 25% of the total predications extracted by SemRep. Using Table 7 we could generate predications such as: <Nesiritide — Treats — Heart failure>, <BCG vaccine — Prevents — Tuberculosis>, <Estrogen — Associated with — Endometrioses>, <Erythropoietin — Affects — Ischemia> and <Nevirapine — Causes — Stevens-Johnson Syndrome>. Moreover, when two or more predicates were assigned to a cluster we could generate predications such as <Anticoagulants — Treats — Arterial Obstructive Disease> and <Anticoagulants — Prevents — Arterial Obstructive Disease>. A first inspection of 50 predications by an expert did not spot any clearly wrong predication. However, due to the high threshold used (p-value < 0.001), we assume that the recall is rather low. A systematic assessment is still outstanding and will be done in the next round after the inclusion of more semantic types and improvements of the matching process.

Discussion and Conclusions

This study is mostly descriptive and refrains from a detailed quantitative analysis, as it constitutes the first important milestone of a larger research project. The inspection of Fig. 3 - 5 seems to be only partly discriminative, but exhibit some interesting aspects that will guide our further work:

- Only a few relations exhibit a clear profile, viz. Treats, Prevents, and Causes. However, there is a cluster that includes in similar proportion Treats and Prevents, which is easily explained by the fact that there are substances used for both treatment and prevention.
- There is a clearly different profile of the relation Causes, because what causes a disease, is rather unlikely to be used in its prevention or treatment.
- Augments and Disrupts are too infrequent to allow any statement. Associated with, Predisposes, and Affects are very little discriminative. This is not surprising, because these relations are very vague. Affects may include causation, prevention, and treatment, Predisposes is difficult to interpret for disorder – substance associations, and Associated with could be as the most generic predicate which subsumes all of the other ones. This shows that the predicates generated by SemRep, but which are not present in the UMLS SN are not helpful for a clear semantic interpretation of the clusters.
- We hypothesize that other relations are more important to describe disorder – substance associations, especially the relation Diagnoses, which describes a substance that can be used to diagnose a disorder.
- The lack of discrimination may also be due to the genericity of many MeSH concepts such as Dermatologic Agent or Vaccines, for which there might be specializations for all predicates under scrutiny. This may lead to the decision to ignore too general concepts in the future refinement of the method.

The main advantage of selecting the most relevant predicates for each cluster is that a low p-value of the predicate could reduce the errors in the resulting set of predications obtained with NLP. For example, from the text: “Even conventional immunosuppressive agents, such as glucocorticoids and cyclosporine, directly affect podocyte structure and function, challenging the immune theory; of the pathogenesis of childhood nephrotic syndrome in which disease is caused by T cells.” SemRep extracts the predication <Immunosuppressive Agent — Causes —
Nephrotic Syndrome. It is not surprising that a relation extractor fails with syntactically complex sentences like this one. This explains why a certain background noise is unavoidable when relying on NLP tools.

Another limitation is that the scope of SemRep is the whole UMLS Metathesaurus and not only its MeSH subset. This explains the low rate of matching between the concept pairs. This could be improved by inferring predications between MeSH concepts from predications between UMLS Metathesaurus concepts in general by traversal of hierarchical links. This approach can increase the number of matching predications and, thus, provide a bigger dataset.

The comparison between the inferred predicates (Table 7) and the resulting clusters from the three clustering experiments (Table 4, Table 5, and Table 6) allows us to identify the combination of MeSH subheadings that are closely related to each particular relation. From our experiments we obtained: (1) Treats is related to co-occurrences that the disease term is annotated with Drug Therapy and the substance with Therapeutic Use; (2) Prevents is associated with co-occurrences that the disease term is annotated with Prevention and Control, and Immunology and the substance with Immunology, and Administration and Dosage; (3) Causes is related to the co-occurrences that the disease term has Chemically Induced subheading and the substance has Adverse Effects, Therapeutic Use, and Administrative and Dosage; and (4) Associated with and Treats are related to the co-occurrences that both the disease and substance have the MeSH subheadings Metabolism and Blood.

Finally, an evaluation of the generated predications would be necessary to rate their plausibility. It is obvious that predicates that represent more than 80% of the extracted predications in a cluster by SemRep are more plausible that those which are closer to 25%. Besides, the evaluation of the distance of co-occurrences to the cluster centroid might detect weaknesses that could guide the generation of predicates.

Intelligent Simulation Model To Facilitate EHR Training

Vishnu Mohan, MD, MBI1, Gretchen Scholl, BS1, Jeffrey A. Gold, MD1

Abstract

Despite the rapid growth of EHR use, there are currently no standardized protocols for EHR training. A simulation EHR environment may offer significant advantages with respect to EHR training, but optimizing the training paradigm requires careful consideration of the simulation model itself, and how it is to be deployed during training. In this paper, we propose Six Principles that are EHR-agnostic and provide the framework for the development of an intelligent simulation model that can optimize EHR training by replicating real-world clinical conditions and appropriate cognitive loads.

Introduction

The growth of electronic health records (EHRs) in the United States in the last decade has been meteoric, primarily as a consequence of the Health Information Technology for Economic and Clinical Health Act (the HITECH Act), enacted under Title XIII of the American Recovery and Reinvestment Act of 2009. The reimbursements afforded to institutions and individuals as a consequence of “meaningful use” regulations have also added substantially to the impetus of EHR adoption1.

As EHR use has grown, the potential for improvement of healthcare delivery quality has also increased2, but so has the potential for causing patient harm associated with EHR use3,4. This phenomenon can be attributed to a number of reasons, primarily because the addition of technological innovations into complex healthcare systems appear to be associated with a new breed of errors, a process which has been termed “technological iatrogenesis”5.

EHR training plays a critical role not only in fostering end-user EHR adoption, but also in their ability to efficiently use the EHR while delivering clinical care6. This realization led the Office of the National Coordinator for Health Information technology (ONC) to endorse the creation of curricular materials for entry-level HIT professionals that included hands-on learning with an EHR7. However, a standardized learning plan is not available to healthcare organizations that are implementing EHRs. Further, different EHRs, and even different implementations of the same EHR, tend to have variations in their interface, which makes the process of finding and reviewing information more difficult for end-users.

Typically, clinicians using the EHR need to find relevant information in a rapid fashion, often while they are multitasking, and operating in an environment that can be distracting8. Training clinicians to operate efficiently in such an environment while using the EHR in a manner that optimally facilitates medical decision making and patient care requires the development of EHR training protocols that best aid learning. Further, since the time clinicians spend in EHR training is in essence time they cannot devote to direct patient care, optimum EHR use training needs not only to be comprehensive but also efficient with respect to the use of clinicians’ time. Training must take into account the needs of all of the varying professional groups which interact with the patient. Finally, EHR training programs also need to consider the unique characteristics and assumptions of the community of practice they serve9, the degree of comfort that each individual clinician has with the EHR, and their baseline proficiency.

Many models of EHR proficiency training have been proposed, but the most commonly used formats are formal classroom/lab, and one-on-one/at-the-elbow training10. Most use a training or simulated EHR environment, since the use of real-life situations to impart EHR training has critical drawbacks, including the fact that imparting training in...
a production environment can introduce errors into a real patient’s chart, that no two real life cases are identical (i.e. the lack of replicability), and that training using actual patient records may violate Health Insurance Portability and Accountability Act of 1996 (HIPAA) privacy rules. An increasing body of literature describes the potential of simulation training to improve acquisition of clinical skills, training of health care teams to effectively navigate complex systems and improve teamwork, communication and shared decision making. While the technology to improve the fidelity (realism) of simulation activities has improved dramatically, there are still significant barriers and limitations to incorporating the EHR into clinician training regimens. Firstly simulation environments are often very different than their production counterparts, marginalizing their utility when provider knowledge and use of the actual operational clinical information system need to be emphasized. Second, EHR training environments are not populated with actual patient information (in deference to HIPAA privacy rules) and typically contain just a few cases populated with sparse data. Typical cases within EHR training environments rarely recapitulate the complexity and specific clinical information encountered by end-users providing clinical care within the scope of their training, and rarely replicate the level of data density encountered in real-world utilization. Third, EHR simulations are typically not associated with the “cause-and-effect” real-time cascade of events that is seen in real life clinical settings – for example ordering an antibiotic for a febrile patient with an infection results in the normalization of their temperature and a change in their clinical status which results in the discontinuation of the antibiotic after an appropriate period of time.

In this paper, we describe a model for developing and building realistic, clinically complex simulations that can be used for optimizing end-user EHR training, in a manner that facilitates the simulation of realistic clinical cognitive loads as end-users participate in simulated activities.

The case for simulation

The primary advantage of using simulations for training is that they allow learning activities to be absolved of any risk of harming real patients. Simulation tools and technologies have advanced dramatically over years, and now allow both the training of classical procedural skills such as airway management of trauma patients in the prehospital setting\textsuperscript{11} or advanced cardiac life support (ACLS)\textsuperscript{12}, as well as more innovative learning, such as the use of simulation in teaching clinical judgment skills\textsuperscript{13} or in disease management and prevention\textsuperscript{14}.

By replicating complex real-life situations\textsuperscript{15}, simulations allow the evaluation of clinical skills and competence in a comprehensive manner\textsuperscript{16}. Further, we have used simulations to assess EHR safety\textsuperscript{17} and demonstrated that participation in EHR simulation helps clinicians better recognize patient safety issues\textsuperscript{18}.

Characteristics of an optimal simulation-based EHR training protocol

However there is still a need to develop an optimal EHR training protocol that utilizes simulation effectively. There are three primary barriers to optimal simulation use at present which will need to be overcome. First, default “training” cases included with most EHR distributions are overly simplistic, and contain sparse data. This is very different than real life patient records, which are often complex and contain a plethora of data. For example, a patient admitted to a typical ICU may generate more than 1,500 data points each day they are in critical care\textsuperscript{19}. Optimally training an ICU physician would require the use of simulation cases that replicate at least a significant proportion of the data complexity that they would be expected to encounter when they are providing direct patient care.

Second, EHR training should also be able to replicate the cognitive load that clinicians are subjected to when they peruse the patient chart. These will allow the clinician to understand and mitigate the errors of cognitive that are closely associated with their task load and EHR use patterns\textsuperscript{20}. For example, while EHRs can reduce errors associated with physician order entry, they may also paradoxically increase them\textsuperscript{21, 22}. Typical EHR training cases focus on entering one, or at most a few orders into the system in a setting where cognitive load is minimized, thus
minimizing the likelihood of any errors occurring during the training process, and missing a rich opportunity to emphasize a specific training objective that would allow end-users to identify, correct and mitigate a common potential cause for patient harm.

Third, the current EHR training paradigm continues to focus on the structure of the EHR as the prime anchor for training, rather than the function of the EHR within the context of the cognitive tasks the clinician needs to perform using the EHR. A clinical simulation scenario is better suited to contextualize the use of the EHR in clinical settings than the traditional classroom approach where a specific topic of EHR functionality is first identified, followed by a demonstration of the task(s) required to achieve the desired functionality. By migrating away from a “learn-by-rote” model of EHR training towards “case-based” model of EHR training, learning objectives are better reinforced and clinicians are able to translate the concepts they have learned in their EHR training session much more effectively to their clinical practice.

**Building the infrastructure**

In order to achieve an effective training paradigm, the EHR simulation environment itself should be capable of achieving the necessary degree of fidelity that replicates the system in the clinical setting. To accomplish this in an optimal fashion, one would employ a simulation version of the clinical EHR that would allow for full utilization of system functionality without risking either breach of patients' protected health information or potentially impacting other connected systems (e.g. pharmacy or billing clinical information systems).

In our experience, the simulated instance of the EHR should contain the following characteristics: first, it should be routinely “cloned” from the existing production environment (with all patient identifiable information deleted) thus allowing users to have the most up to date version of the EHR, as well replicate the individual provider's user-specific customizations, macros and order sets. Second, the system must be populated with simulated medical records that have been designed specifically for the workflow being assessed, with cases that reproduce the clinical complexity and scenarios encountered in actual practice. Third, cases must be temporally aligned with the proposed exercise. Specifically, complex cases need to be carefully designed and built into the system in advance of any training exercise. Rather than populate the simulation environment with patient data that exists in the distant past (as perceived by the end-user), it is essential that patient data, if appropriate, be carried forward to the day of training. Finally, real time report results need to be generated directly into the EHR rather than be verbally communicated to the end-user during the simulation activity. Ensuring this feature is often the most difficult; depending on the exercise, results may need to be customized “in the moment” and informed by the performance of trainees. However, this functionality is essential for replicating realistic EHR use patterns in high-stress situations, especially when considering end-user information processing, as well as subsequent diagnostic reasoning and shared decision making.

Once the simulation environment of the EHR is created, it must be deployed in a manner similar to its clinical use. When incorporating the EHR into other simulation activities, it is important to ensure that the simulation workstations resemble, at least in terms of form and function, the actual workstations used in the clinical environment. This includes replicating monitor size, the use of mobile workstations and ergonomics similar to the clinical care environment when applicable. This is important to not only eliminate potential confounders introduced by unfamiliar hardware, but also fosters cognitive thinking in a fashion that mimics real life conditions. Ideally, once established the actual simulation center itself could be EHR agnostic, allowing multiple EHRs to be utilized in simulations depending upon the needs of the organization, the tasks at hand and the learners themselves.

**Conceptualizing an Intelligent Simulation Model**

Engaging in simulation activities allows learners to move from the knowledge or comprehension levels of Blooms taxonomy to application and analysis. The provision of high fidelity simulation that replicates a level of cognitive
load comparable to real life clinical situations may also allow learners to synthesize knowledge for subsequent application in real life patient care.

Simulation activities promote learning without endangering patient safety, utilizing standardized replicable scenarios. High fidelity simulations allow learners to engage in scenarios that are closely reminiscent of real life situations, and thus engage in analogical reasoning that integrates new information learned during the simulation to prior accrued experiential clinical knowledge, thus improving competency.

We have previously described a model for intelligent case design that emphasized a patient-centric record and utilized an interprofessional team-based approach to designing complex cases. Additionally we have also described a framework that allowed us to test how high fidelity simulations can be utilized to test new EHR training models or interface designs in a manner that facilitates error recognition and improves patient safety. We built upon this framework and utilized intelligent cases to facilitate a model that allowed the generation of realistic cognitive loads as learners participated in the simulation activity. The intelligent cases designed by us specifically allowed end-users to identify both normal as well as abnormal patient data by recognizing low and high-end cutoffs in the context of the patient’s clinical presentation rather than depending on the traditional defined range. Our cases included both common as well as rare data, at a level of density that reflected real-life clinical situations. The data also allowed end-users to not only find relevant data, but also to recognize when relevant data was missing from the user interface screens they were expected to use. And finally, our cases incorporated best practice and meaningful use criteria to emphasize the need to incorporate standards of care into efficient EHR use.

Deploying cases designed using the principles delineated above allows end-users to be trained using a model that closely replicates the cognitive load they encounter while taking care of patients, and allows them to anchor simulation-based EHR training in the context of providing clinical care. However these cases are best deployed using a simulation paradigm for EHR training that is also based on intelligent design principles.

**Building intelligent simulations**

We propose Six Principles for effective Intelligent Simulations that foster effective EHR training. These Principles emphasize the need to provide a training experience that closely mimics real-life cognitive and decision-making paradigms, and allow EHR training to occur in the context of the clinical care that the end-user is trained to provide. They are independent of the EHR being used to conduct the simulation.

1. **EHR training should be conducted in the form of a simulation exercise that describes a clinical scenario familiar to the learner.** The training session should be anchored utilizing the clinical context of the simulation, rather than on specific elements of EHR functionality. The simulation exercise should focus on pre-determined optimal clinical outcomes that define efficient EHR use, rather than the EHR-specific tasks themselves. For example, if the simulation trains the end-user to learn order entry functionality for prescribing medications, the clinical context (for example a patient develops an abnormal heart rhythm necessitating the prescription of a specific medication to counter it) should drive the training session, and success should be aligned to the end-user's ability to visualize and examine specific information within the EHR, rather than focus only on the EHR itself -- in the case of the example noted above, one success measure could be the ability of the end-user to visualize and recognize the patient's changes in clinical and vital signs after prescribing the appropriate medication.

2. **Simulations should replicate real life processes.** This implies that cases should not be too simplistic (as is the case with most current training cases) or divorced from reality. Clinicians should be immersed in the environment as much as the simulation infrastructure allows, and cognitive skills utilized in real-life settings should be brought to bear as the simulation training progresses.

3. **The simulation should use a standardized case structure and format.** Most importantly, these cases should replicate both the clinical complexity as well as the workflows of the clinician being trained, with adequate data...
density and complexity. In addition, two vital characteristics of real-life cases need to be included within the intelligent simulation. First, the structure of simulation cases should replicate real-life conditions. Clinical scenarios should be plausible, and documentation within the patients chart (such as clinical notes, X-rays or laboratory tests) should reflect the clinical condition in a manner that replicates real-life considerations. Second, the diagnostic reasoning processes that the trainee brings to bear should mimic real-world cases, thus attempting to maintain intellectual fidelity in addition to data fidelity.

[4] Each simulation needs to address the routine “cause-and-effect” phenomenon that characterizes EHR use in the clinical setting, specifically with respect to the temporal sequencing of data. Typically, training EHR cases showcase events that have occurred in the past (typically on the day the cases were incorporated into the instance). This creates an artificial temporal sequence that end-users usually find unrealistic. By utilizing “rolling” cases that allow patient data to be accessed as they would in real life (i.e. yesterday’s lab values can be accessed by the end-user scrolling back by one day, and last week’s vitals by going back a week in time) the cognitive load placed on the learner is realistic and sustained. Complex cases will need careful design to reflect this, and patient data will need to be routinely carried forward up to the day of testing. End-users will also need to access real-time reports as they engage in training. This allows appropriate information processing and use of the EHR in a manner that fosters diagnostic reasoning.

[5] Simulations should be conducted using an instance of the EHR that has been replicated from the production environment. The training instance should incorporate all the individual customizations applicable to the end-user receiving training, and also allow the use of protocols (for example logins, macros) that are identical to those utilized in the production environment. This allows end-users to learn using the same screens and customized features that they are familiar with when they take care of patients, thus optimizing their level of learning with the EHR.

[6] Simulation training protocols should be developed by an interprofessional team. The practice of medicine today is clearly a team activity. We believe that the perspectives of members of an interprofessional team are invaluable in developing simulation cases and protocols for specific disciplines of clinicians. For example, a nurse may have insight that allows a more sophisticated EHR training protocol to be defined for a group of physicians, or a pharmacist may contribute significantly to the EHR training of nurses. Involving multiple disciplines in the development of EHR training protocols also fosters collaboration, and strengthens patient safety.

A summary of the six design principles delineating the focus and evaluation paradigm associated with each individual principle is presented in Table 1.

**Tailoring simulations**

Intelligent simulation designs incorporate clinical scenarios that replicate the cognitive load that clinicians experience when they are actively utilizing the EHR to provide patient care. This requires not only calibrating the amount and complexity of data presented during the simulation, but also customizing the simulation to the specific role of the clinician. For example, a case targeted to physicians may need additional customization to ensure that it retains adequate high-fidelity and cognitive complexity for nurses, pharmacists on other non-physician clinicians who may participate in simulation activities. Cases will need to be tested to ensure that pertinent and appropriate data elements are displayed not only on physician EHR screens, but also on role-specific EHR screens for any non-physician clinicians who may participate in the activity.

Further, the level of cognitive load that can be assumed by individual clinicians is also dependent on their clinical competency, and experiential factors such as their level of training. A medical student participating in a high fidelity EHR simulation assimilates and processes clinical data differently than an attending physician. Developing
intelligent simulation requires designers to acknowledge the importance of calibrating both the complexity and the cognitive load of the simulation to match the level of competency and experiential learning of individual subjects.

</table>
Conclusion

Using simulation infrastructure deliver end-user EHR training can optimize learning, clinician efficiency and promote patient safety. Rather than continuing to utilize current training models, developing a strategy that incorporates intelligent simulation within clinician EHR training programs has the potential to improve how clinicians use the EHR, reduce patient harm, and promote superior clinical quality of care.

Developing the Pathologists’ Monthly Assignment Schedule: A Case Study at the Division of Anatomical Pathology of The Ottawa Hospital

Amine Montazeri, MSc, Jonathan Patrick, PhD, Wojtek Michalowski, PhD, Diponkar Banerjee, MBChb, FRCP, PhD

1 Telfer School of Management, University of Ottawa, Ottawa, ON; 2 Division of Anatomical Pathology, The Ottawa Hospital, Ottawa, ON

Abstract
In the Division of Anatomical Pathology of a teaching hospital at the beginning of each month, clinical managers assign expected daily pathology requests to the pathologists on duty. Since the number of these requests is usually large and a division employs a number of pathologists with different sub-specialties, the size of the problem is significant and finding a feasible assignment schedule manually is time-consuming. Moreover, every time there is a need to change, a new assignment schedule needs to be developed taking into account all the pre-defined constraints including pathologists’ availability, sub-specialty mix, teaching/research releases, etc. In this paper we describe an analytics optimization model embedded in a decision support tool that helps the clinical managers of the division determine the optimal monthly assignment schedule. The decision support tool has been validated using data from the Division of Anatomical Pathology at The Ottawa Hospital in Ottawa, Ontario, Canada.

Introduction and Problem Statement
Developing an assignment schedule for the pathology laboratory at a teaching hospital is a process that assigns the individual pathologists to pathology requests taking into account pathology sub-specialties, the volume of requests, and any teaching/research functions that impacts each pathologist’s availability. As the complexity of clinical pathology grows, the time spent on creating the pathologists’ assignment schedule increases creating a need for a computer-aided scheduling support tool. In this paper we describe a support tool that was developed in collaboration with the clinical managers and pathologists from the Division of Anatomical Pathology (DAP) at The Ottawa Hospital (TOH). TOH is a teaching hospital affiliated with the University of Ottawa that provides inpatient and outpatient services on three campuses located in different parts of the city. The DAP is located on one of these campuses (General Hospital campus) and serves the entire TOH. It also receives pathology requests from the community hospitals and from private pathology laboratories serving the City of Ottawa and surrounding areas. Each day about 200 pathology requests of differing complexity arrive from the operating rooms of TOH, the clinics affiliated with the hospital, the community hospitals, and from small laboratories. These requests are recoded as the “cases”, with each case involving the analysis of one or more specimens that are further subdivided into slides. In this paper we are concerned with the assignment schedule at the level of the specimen. We do not describe the process of creating the specimens from a tissue but want to stress that each specimen may include (depending on its type) anywhere from 3 to over 200 slides that need to be examined by a pathologist to whom a particular specimen is assigned. The 36 full time pathologists working at the DAP are salaried and their responsibilities, apart from clinical work include teaching and research that impact their availability in a given day, week, and month. These pathologists cover services spanning 26 sub-specialties (i.e. liver, breast, neurology, etc.).

In order to process all pathology requests, at the beginning of each month clinical managers develop the assignment schedule for the following month. This schedule assigns each type of specimen to a pathologist for each working day of the month. It must take into account the following requirements:

- **Pathologist’s sub-specialty**: Each pathologist can assess only those specimens that are within his/her expertise such as breast, head and neck, musculoskeletal, to name a few.
- **Pathologist’s availability**: Due to a number of clinical and non-clinical responsibilities, each pathologist’s availability needs to be assessed on daily and weekly basis. We measure availability in a given week using “full time equivalent (FTE)” fraction (i.e. for a pathologist working full time in a given week FTE = 1).
The service weight: The amount of time it will take to assess all slides of a given specimen type in a given day is clearly a stochastic variable. However, these times are estimated using pre-determined service weights that are different for each specimen (i.e., a service weight of 2.0 for neuropathology indicates that the expected workload on a given day for neuropathology should require the services of two pathologists). There is no agreement in the literature (and practice) as to how the service weights ought to be determined, but this discussion is beyond the scope of our research. Clinical managers at the DAP rely on weights that are based on the L4E indicator used in a number of North American laboratories to determine pathologists’ workload.

The above requirements define what we call “hard requirements” as they need to be satisfied by any assignment schedule. However, there is a number of “soft requirements” that should be considered when a reasonable assignment schedule is created and these requirements include:

- Consistent assignment in a week: It is desirable that within a given week a pathologist is assigned to work on specimens belonging to a single sub-specialty.
- Rotation of the specimens: In order to maintain the clinical skills required for the analysis of a given sub-specialty, each pathologist should regularly rotate through his/her areas of expertise.
- Prioritization of the specimens: Due to vacations and other absences, it is not always possible to cover every sub-specialty on every day. Faced with this dilemma, the DAP prioritizes between subspecialties in order to ensure that the crucial ones are covered. For instance, full coverage requires three pathologists to be assigned to a given sub-specialty. Faced with insufficient resources, the DAP will choose to reduce that coverage to two pathologists as a first step. This ranking of coverage priorities needs to be respected.

Currently the clinical managers at the DAP use a manual approach to scheduling that relies on data recorded in a spreadsheet. Since the size of the pathologists’ assignment schedule is large, finding a satisfactory assignment manually is time-consuming and can take a number of iterations over a number of days to complete. Moreover, every time there is a need to revise the schedule the process must start over again.

In this paper we describe a computer-based decision support tool for developing an assignment schedule. This tool has two main components – an analytics optimization model that is used to develop the optimal assignment schedule taking into account both the hard and soft requirements and a spreadsheet-driven interface that is similar to what is being used now in the division and allows the managers to manipulate and revise the assignment schedule in order to assess a number of scheduling scenarios or consider special cases.

The next section presents a brief review of the research on using the assignment problem in healthcare. This is followed by a description of the analytics model that we have developed. The decision support tool is described in the Implementation section. The comparison of the assignment schedules developed automatically with those used by the division is presented in the Results section. The paper ends with some concluding thoughts.

Related Work

The development of an assignment schedule is an important analytics problem that aims to find an optimal allocation of n available staff members to m positions or tasks in a system. During the last few decades, researchers have developed a number of assignment models for various settings such as industrial systems, educational institutions and healthcare organizations all designed to help managers allocate tasks to resources (including human resources and equipment). A number of assignment models, specific to healthcare, have been developed. The type of model developed depends on the type of organization and the specific characteristics of the problem to be addressed. Assigning nurses and physicians (mostly in the Emergency Department) to shifts so that staffing requirements are met represents one of the most common problems and the analytics models include stochastic programming, goal programming and genetic programming models. Home care staff assignments require the development of an assignment schedule connecting health providers with patients based on factors such as workload restrictions, provider qualifications and preferences, acuity levels of patients, an overtime penalty and staff satisfaction. The majority of the home care assignment problems use optimization models.

To the best of our knowledge, our work is the first attempt to apply analytics to develop the optimal assignment schedule in a pathology department. The proposed model is similar to those used elsewhere but has a number of
distinct features: it deals with a situation where each pathologist has multiple sub-specialties and explicitly considers
the need for pathologists to rotate through the types of specimens in order to maintain the required skills in a given
clinical sub-specialty. It is worth mentioning that there are commercial scheduling systems designed to develop an
assignment schedule for the pathologists. However, they are mostly concerned with implementing the existing
scheduling practice in terms of rules rather than developing the kind of optimal assignment schedule provided by the
system described in this paper. A good example of such assignment is Q-Genda’s pathologist scheduling software
(Q-Genda corporation) that allows the managers to develop different scheduling scenarios according to a set of
decision rules. However, because of the way that these scenarios are created, it is not possible to determine if
proposed assignment is truly the best one or if it just meets basic requirements.

Methods

The development of the pathologists’ assignment schedule is a decision-making problem that involves the analysis
and assessment of a number of alternative schedules each with different characteristics. This type of problem is
solved using analytics methods that allow the user not only to assess possible alternatives very quickly but also to
identify the optimal one based on the measurable criteria. In this paper we describe the use of an analytics approach
that involves the development of a mixed-integer optimization model that incorporates both hard and soft
requirements. This model has the following four components: decision variables, model parameters, objective
function, and constraints. Each component is described in greater detail below and the full model is provided in the
Appendix.

Decision variables: The decision variables represent the unknown (to be determined by the model) daily
assignments of the pathologists to specimens on each day. For the DAP, assuming that a monthly assignment
schedule needs to be developed for 20 business days on average (DAP does not work on the weekends and statutory
holidays), this implies that there are 18720 possible daily assignment combinations. However, the incorporation of
the soft constraints requires the creation of auxiliary decision variables bringing the total to 43649.

Model parameters: Every model requires known and measurable inputs that are called “parameters”. We use five
types of parameters:

- The FTE for each pathologist working full time has a value of 1 while for the part timer it can be any
  number between 0 and 1 (i.e. for a pathologist working two out of five days a week the value of his/her
  FTE is 0.4). Values for the FTE fraction parameters were obtained from the DAP.
- The service weights for each type of specimen were determined by the DAP clinical managers as explained
  earlier.
- The availability of a pathologist on a given day is captured by a binary parameter (value 1 if the
  pathologist is available and 0 if the pathologist is unavailable). These values change from month to month
  and reflect each pathologist’s workload taking into account teaching/research obligations, holidays, etc.
- Another binary parameter captures which specimens are within each pathologist’s area of expertise. (When
  a pathologist is able to diagnose a given specimen type then the value of this parameter is 1. It is 0
  otherwise). This information was provided by the DAP.

Objective function: The purpose of the objective function is to establish a performance measure for assignment
schedules in order to derive the optimal solution. In our model the objective function is created by amalgamating the
soft requirements outlined earlier. Thus, the objective function has three parts, each with a specific weight of
importance that can be assigned by a clinical manager. In the case study described later in the paper the values of
the weights were determined experimentally so the resulting assignment schedule best matches the expectations of
the clinical managers.

Constraints: The constraints describe in a formal way the constraining factors that limit the development of an
assignment schedule. Model constraints include hard requirements as well as a number of additional constraints
related to the need to produce feasible daily assignments over 20 days. The model we developed for the DAP has
52057 constraints excluding binary and non-negativity constraints imposed on the decision variables.

The model was solved using variant of Simplex algorithm implemented in IBM ILOG CPLEX Optimization Studio
running on a Dell T7600 desktop computer with Windows7. On average it took seven to ten minutes to obtain the
optimal assignment schedule for a given month.
Implementation

Responding to the clinical managers request that the user interface to the model should have a “spreadsheet – like” feel, we embedded the model within a customized Microsoft Excel platform that provides a user-friendly interface. The resulting scheduling decision support tool was named the Automatic Pathologists’ Scheduler (APS) system. It integrates the analytics model and the Microsoft Excel spreadsheet using a number of macros. The APS system has a hierarchical structure with a main menu (see Figure 1) that allows the clinical manager to access the different functions of the system.

In order to use the APS system, the clinical manager needs to enter the values of the parameters required by the analytics model. These parameters can be categorized into:

- **Dynamic parameters**: the values of these parameters have to be updated every month before solving the model. They include information about the holidays in a given month, pathologists’ availability and specific “hard-wired” assignments that task a given pathologist to a specific specimen type on a given day.
- **Static parameters**: the values of these parameters are updated infrequently (or do not need to be updated at all). They include the roster of pathologists working in a division, the list of sub-specialties, the FTE fractions and the service weights.

The APS system has the built-in functionality that allows for extended editing and control of the development of assignment schedules. This functionality includes:

- **Editing**: revising values of all parameters, including anticipated daily pathology requests. This function also allows for the manual development of a partial assignment schedule that is later used by the analytics model as a starting point, as needed.
- **Optimization control**: The user interface allows the manager to experiment with different values for the weights assigned to the components of the objective function. The purpose of this functionality is to provide the clinical manager with the ability to develop different assignment schedule scenarios depending on the changing importance of each of the soft requirements.
- **Schedule analysis**: A separate spreadsheet interface for analysing the schedule allows the clinical managers to evaluate and revise the schedule, if needed.

The output produced by the APS system is illustrated on Figure 2 (due to space limitations only a fragment of the spreadsheet is presented). The assignment schedule is organized by the days in a month (columns), types of the specimens (coded with the abbreviations used in the DAP and represented as the rows), and labels associated with individual pathologists (cell values). In the original schedule the cell values include pathologists’ initials, but for privacy reasons they are replaced here with P# labels. The dash (-) on the schedule indicates a non-business day. As an example pathologist P14 is assigned all cardiac specimens from April 7 to April 10. Starting on April 13 this type of specimen is re-assigned to pathologist P5 (until April 17, inclusive). In the schedule, two separate rows have been allocated to breast specimens (indicated by “Breast1” and “Breast2” labels) as historically two pathologists are required to analyze all daily breast specimen requests.
Results

The system’s performance has been validated by the clinical managers at the DAP and also by comparing manually developed assignment schedules with those created by the model. The results show that the APS system is effective in developing a schedule that meets most of the pre-defined scheduling criteria and as such represents a significant step forward in managing the pathologists’ scheduling problem. To illustrate, below we present and compare the assignment schedules generated by the APS system for the months of October and November 2014 against the schedules that were developed manually for those same months and implemented in the DAP. When conducting these comparisons, following the advice of the clinical managers, we looked at:

- Percentage of unassigned specimen types: in the schedule developed by the APS system, higher priority sub-specialties are assigned to the pathologists first. This may result in some lower priority sub-specialties being left unassigned due to an insufficient number of pathologists available. This measure is calculated as the percentage of all unassigned specimen types within a month in relation to all the assignments in this month.

- Percentage of inconsistent assignments: this measures the consistency of assignments within a given week. It is calculated as the percentage of all assignments that are not consistent within a week in relation to all the assignments in this week. An assignment schedule that has a lower value for this measure is preferred.

- Percentage of missed rotations: each pathologist ought to cycle through all sub-specialties within his/her area of expertise. This is accomplished by rotating what specimen type a pathologist is covering each week. Missed rotations (in %) are the number of sub-specialties within each pathologist’s area of expertise that is not covered in a given month divided by the total number of sub-specialties for each pathologist. This metric is aggregated over all pathologists to derive a single measure. It is important to note that it may not be possible to cover all sub-specialties in a given pathologist’s area of expertise while still maintaining consistency with the week as some pathologists have 5 or more sub-specialties. However, an assignment schedule that has less missed rotations is clearly better.

Looking at the results presented in Table 1, we note that the APS system consistently outperforms the manually developed assignment schedule when considering the percentage of inconsistent assignments. The differences between the APS and the manual schedule on the other measures are negligible indicating that the model quite accurately reflects current practice.

Discussion

In this paper we describe the APS system that helps clinical managers of the DAP to develop a monthly assignment schedule. The system creates the schedule by solving an analytics model that takes into account all hard and soft scheduling requirements considered currently by the managers. Providing the clinical managers with such an easy to use support tool has value for a number of reasons. First, the APS system helps to create the optimal assignment schedule very quickly. Secondly, the proposed schedule can be used by the managers to either make additional adjustments taking into account intrinsic requirements or to create a number of scenarios considering different staffing possibilities, specimens’ volume levels, etc. Finally, the APS system gives flexibility in establishing and revising all model parameters to reflect for example a sudden change in the pathologists’ availability.

Currently we are using the system to develop assignment schedules for the next couple months of 2015 and at the same time we are working on improving and customizing the user interface. While the APS system was created for DAP and using data from that division, it can be easily customized and ported to different pathology departments provided that there is data to revise the model’s parameters. A possible extension of the model would be to consider non-deterministic character of daily requests for pathology services. This extension requires additional data of different granularity and type that, at present, is not easily available at the DAP.

Appendix

Mixed Integer Linear Programming Model

Decision Variables

\[ X_{ijt} = \begin{cases} 1, & \text{if specimen of type } j \text{ is assigned to pathologist } i \text{ on day } t \\ 0, & \text{otherwise.} \end{cases} \]

\[ i=1,2,3,\ldots,36 \quad j=1,2,3,\ldots,26 \quad t=1,2,3,\ldots,25 \]

\[ Y_{ijk} = \begin{cases} 1, & \text{if pathologist } i \text{ is given specimen of type } j \text{ in week } k \\ 0, & \text{otherwise.} \end{cases} \]

\[ i=1,2,3,\ldots,36 \quad j=1,2,3,\ldots,26 \quad k=1,2,3,4 \]

\( \beta_{ij} \): Auxiliary variable for “Rotation of the specimens” that keeps track of the number of different types of specimens that have been assigned to each pathologist.

Model Parameters

- \( b_i \): the FTE fraction of pathologist \( i \) availability per week
- \( a_j \): the proportion of a full day’s work required for daily pathology requests of type \( j \)
- \( \alpha_{ij} \): equals 1 if specimen type \( j \) belongs to one of the sub-specialties that pathologist \( i \) posses.
- \( T_{it} \): equals 1 if pathologist \( i \) is available on day \( t \), otherwise 0
- \( S_{ij} \): equals 1 if pathologist \( i \) is able to review specimen type \( j \), otherwise 0
- \( C_1, C_2, C_3 \): weights for each part of the objective function

Objective Function

\[
\min z = C_1 \sum_{i=1}^{n} \sum_{j=1}^{m} \sum_{k=1}^{K} Y_{ijk} - C_2 \sum_{i=1}^{n} \sum_{j=1}^{m} \beta_{ij} + C_3 \sum_{j=1}^{m} \sum_{t=1}^{T} d_{jt}
\]

The objective function consists of three parts. The first part penalizes assignment schedules each time a pathologist is given a different specimen type in the same week. The second part rewards assignment schedules every time they cover another specimen type that lies within their expertise. The final part penalizes assignment schedules for every uncovered assignment. The weights \( C_1, C_2, C_3 \) allow the user to adjust the importance of the three components to the performance of an assignment schedule. Typically the third component is deemed the most important.
Constraints

1. Consistent assignment in a week (4 weeks within a month, 5 business days within a week):

\[ \forall (i, j) \]
\[ \sum_{t=1}^{5} X_{ijt} \leq MY_{ijt} \]
\[ \sum_{t=6}^{10} X_{ijt} \leq MY_{ij2} \]
\[ \sum_{t=11}^{15} X_{ijt} \leq MY_{ij3} \]
\[ \sum_{t=16}^{20} X_{ijt} \leq MY_{ij4} \]

where \( M \) is a very large number. Each time a new specimen type is assigned to a given week, the above constraints for a new \( Y_{ijk} \) to be positive. Ideally, a pathologist is given only one specimen type in a week so that, for each week, there is only one \( Y_{ijk} \) that is positive.

2. Rotation of the specimens

\[ \forall (i, j) \]
\[ \sum_{t} \alpha_{ij} X_{ijt} \geq \beta_{ij} \]
\[ \beta_{ij} \leq 5 \]

The ideal schedule would give a week’s worth of one specimen type to a pathologist and then switch to a different specimen type for the subsequent week in order to rotate through his/her areas of expertise. This set of constraints rewards schedules that assign a specimen type with a pathologist area of expertise up to a maximum of a reward of 5 for any particular specimen type. This encourages the model to give full weeks of a given specimen and then switch.

3. Weekly assignment

The FTE fractions are per week, but in a scale of 0 to 1, so their values \( (b_i) \) have to be multiplied by 5 in order to derive the number of days that each pathologist works per week (5 business days in a week).

\[ \forall i \]
\[ \sum_{t=1}^{5} \sum_{j=1}^{m} a_{ij} X_{ijt} \leq 5b_i \]
\[ \sum_{t=6}^{10} \sum_{j=1}^{m} a_{ij} X_{ijt} \leq 5b_i \]
\[ \sum_{t=11}^{15} \sum_{j=1}^{m} a_{ij} X_{ijt} \leq 5b_i \]
\[
\sum_{t=16}^{20} \sum_{j=1}^{m} a_j X_{ijt} \leq 5b_i
\]

These constraints force the number of assignments (weighted by the service weight) to respect the number of days that a given pathologist is available based on their FTE fraction.

4. Daily assignments

\[
\forall (i, t) \sum_{j=1}^{m} a_j X_{ijt} \leq 1
\]

This set of constraints ensures that no pathologist is given more than a full day’s work on any given day.

5. Demand coverage

\[
\forall (j, t) \sum_{i=1}^{n} X_{ijt} + d_{jt} = 1
\]

This set of constraints ensures that if a given specimen on a given day (j,t) is not assigned to a particular pathologist then the value of \( d_{jt} \) is forced to be one and thus the objective function captures the number of unassigned slots.

6. Availability

\[
\forall (j, t) \quad X_{ijt} \leq T_{it}
\]

These constraints allow the manager to explicitly state what days a given pathologist may not be available.

7. Skill set

\[
\forall (i, j) \quad X_{ijt} \leq S_{ij}
\]

These constraints again allow the manager to explicitly state which type of specimens a given pathologist is unable to analyse.
Reading and Writing: Qualitative Analysis of Pharmacists' Use of the EHR when Preparing for Team Rounds

1Department of Veterans Affairs, Salt Lake City, UT; 2University of Utah, Salt Lake City, UT; 3Intermountain Healthcare, Salt Lake City, UT

Abstract

In the collaborative hospital environment, pharmacists are important members of the healthcare team, yet compared to physicians and nurses, little is known about pharmacists' information needs or how they interact with the electronic health record (EHR). We directly observed seven clinical inpatient pharmacists as they interacted with the EHR preparing for clinical rounds using an eye-tracking camera and contextual inquiry. Pharmacists spent 50% of their time reading information from the EHR, such as notes and medication lists, and 27% of their time copying EHR data onto paper, such as patient history and laboratory results. In an environment where minutes count, the results of this study can help inform the development of CDS tools and/or EHR designs to facilitate the information needs of the pharmacists in providing care for their patients.

Introduction

Pharmacist hospital services, such as medication reconciliation and adverse drug event (ADE) monitoring, are time-intensive processes associated with improved patient care and decreased mortality, making pharmacists integral members of the healthcare team.1-5 Meaningful Use core measures, such as electronic health record (EHR) and computerized provider order entry (CPOE) adoption have impacted the ways pharmacists work and care for patients.6-9 In 2007, only 5.7% of pharmacy departments reported that their institution had a fully electronic patient record;10 this number grew to 26.5% in 2013, with 92.6% reporting having a partial or basic EHR.11 Medication and pharmacy information are critical components of the EHR, and are related to many of the safety features and benefits of EHR use.12 In addition, EHRs have become an important communication tool for interaction between pharmacists, physicians, and nurses.13 Therefore, pharmacists should be included during the development and implementation of EHRs.13-14 Many studies have looked at information needs and seeking behavior of physicians and nurses in the EHR,15-19 but none have evaluated pharmacists. Additionally, the lack of usability or design considerations of health information technology for pharmacists can lead to human-computer interaction problems, increased workflow complexity, loss of productivity, and a decrease in the quality of patient care.15,20

In the Veterans Health Administration (VHA), clinical pharmacists attend clinical patient rounds and participate in patient care planning, which goes beyond medication consultation in many cases. Having a pharmacist present on clinical rounds is a common practice, with over half of all hospitals, and 85% of hospitals with more than 200 beds, having pharmacists attend rounds.11 Pharmacists involvement in clinical rounds has been associated with a significant reduction in ADEs, improved patient care, and reduced costs.3,21-23 In preparation for clinical rounds, pharmacists spend large amounts of time using the EHR to evaluate or “work up” their patients. These evaluations typically consist of identifying potential medication problems, medication regimen review, drug-drug and drug-disease interaction checking, ADE monitoring, therapeutic effectiveness evaluation, dosing appropriateness of medications based on the context of disease states and laboratory values, medication therapy management (MTM), medication reconciliation, and evaluation of patient medication adherence.24 During patient evaluations, pharmacists need to have access to real-time patient information, as other studies have shown that timely information retrieval is important in patient care.25,26 Missing, incomplete, or inaccurate information can lead to medication errors, adverse drug events, failure to provide prophylactic treatment, and other potential patient harm, whereas too much information can cause information overload.15,27 Additionally, distributed and disjointed data can lead to longer times for finding, filtering, and organizing information along with a higher risk of missing important information and cause an increased burden on available resources.16

Due to the abundant and distributed nature of patient data in the EHR, the difficulty of obtaining some data, and time constraints facing pharmacists, an understanding of what information pharmacists need and how they go about finding that information is important. Such an understanding could lead to improved EHR designs or clinical decision support (CDS) tools targeted to pharmacists. Therefore, the purpose of this study is to explore pharmacists’ use of the EHR and information needs in real clinical practice settings using direct observation.
Methods

Study setting and participants
This study was carried out at the George E. Wahlen Department of Veterans Affairs Medical Center in Salt Lake City, Utah. The VHA has a long-established EHR as well as advanced clinical practice for pharmacists, such as independent prescribing privileges within their scope of practice since 1995. The VHA uses the Veterans Health Information Systems and Technology Architecture (Vista) as its EHR, with the Computerized Patient Record System (CPRS) as the clinician interface. A more detailed description of CPRS is available elsewhere. In 2009, the VHA accounted for half of all US hospitals with a comprehensive EHR, and has been associated with improvements in quality of care. Study participants were clinical inpatient pharmacists. We recruited a convenience sample of seven pharmacists from a wide range of inpatient sites such as post-op care, acute medicine, telemetry, rehabilitation, and an intensive care unit. Pharmacists had on average 6.4 years experience with CPRS (range: 1-18, median: 6). Pharmacists were recruited through presentations at staff meetings, demonstrations of the study methods, and referrals from other study participants. We were not able to capture all of the rounds preparation time, but we collected data of the pharmacists evaluating 13 new and 19 familiar patients. We did not collect patient data. This study was approved by the University of Utah Institutional Review Board and VA Research Service.

Procedures
Prior to the observation sessions, pharmacists were given minimal explanation of the study and asked to prepare for clinical rounds as they normally would. Sessions were carried out in the pharmacists' usual environment and time of preparation for rounds, but were limited to approximately the first 45 minutes. We used mixed-methods approach with direct observation in the clinical setting, eye-tracking capture, and contextual inquiry. Direct observation was used because it is difficult to get unbiased responses from providers by directly asking them what their information needs are, or conducting surveys. We encouraged participants to describe their goals or the information they are looking for. However, we did not depend on think-aloud techniques for data collection because in the clinical setting, experts tend to function with system 1 level thought, most people stop talking when they are thinking or processing complex information, and it is difficult for experts to verbalize their goals and tasks. During the session, a researcher would ask clarifying questions to better understand goals, mental models, responsibilities, perceived usefulness of different sources of information, and task. The researcher would wait to ask questions until the pharmacist completed a task, as to not disrupt the cognitive process of complex tasks. In order to capture the rapid, dense, and variable study data, and information sources outside of the EHR, we used an eye-tracking camera from Pupil-Labs to capture video and an iPad to capture audio and additional artifacts. Pupil-Labs is a mobile eye-tracking device with affordable hardware and open source software written in python. The hardware consists of a 3D printed headset that the user wears like a pair of glasses, and has a camera to record the field of view and a camera to record eye movements. The Pupil-Labs camera even allows the researcher to see the pharmacists' gaze positions in real time. The software was run on MacOS, but can be installed on Linux or Windows computers. In addition to the audio and video recording, the researcher would also document field notes during the session and ask deepening questions about information needs and goals after the session. Audio and video from the session were merged and loaded into Atlas.ti 7 (Scientific Software Development GmbH, 2015) for coding and analysis.

Analysis
The analysis of the data was mainly qualitative and descriptive using Atlas.ti for coding and times, and interquartile ranges (IQR) for descriptive statistics. Because of the qualitative and descriptive nature of the study, we estimated that the sample size of seven pharmacists would be sufficient to describe a range of information needs across the inpatient setting. After the observation sessions, the researcher would then code the video using high-level codes to describe what the pharmacist was doing, where they were looking, and what they were writing down. The codes were reviewed and verified by a second researcher. During piloting, we found that the pupil tracker did not provide the precise location of the pharmacist's gaze, but was able to provide a general area of where the pharmacist was looking, which helped in review of the verbal and observational data. This was because the camera calibration suffered when it was taken on and off to visit with patients, and the distance between the tracker and the information source (i.e. computer monitor) changed when the pharmacist moved. Therefore, we did not pursue direct analysis of the eye-tracking data, but rather used gaze data in the context of the rich descriptions in the audio and field notes.

Results
The average time of recorded observation per session was 39 minutes. The average time it took each pharmacist to evaluate a new patient was 11:31 (mm:ss) (median: 10:42, IQR: 9:51 to 14:46). Patients familiar to the pharmacist had an average time of 3:47 (median: 1:46, IQR: 0:56 to 4:51) for review and evaluation in the EHR.
**Reading and writing**

In preparing for rounds, pharmacists spent 50% of their time reading information in the EHR and 27% writing information onto paper, with the rest of their time performing other tasks such as communicating with the team or managing patient lists or notifications. The most predominant information use pattern was the back and forth of reading and writing. Of note, pharmacists switched between reading and writing an average of 4.35 times per minute. In terms of reading, pharmacists spend the most time reading notes in the EHR (such as admission notes, history and physical notes, etc.), followed by medication lists, printed papers (typically print outs of active inpatient and outpatient medication lists), laboratory results (such as reviewing recent results), provider orders (especially over the last 24 hours), and others. However, twice as much time was spent reading EHR notes compared to medication lists. Within the notes, the most time was spent reading the assessment/plan and patient history sections, followed by laboratory results or notes section. The average time spent reading each section was 2.45 minutes, which is significantly higher than the average time spent on medication lists (such as outpatient medications not restarted upon admission), and other medication or historical notes (such as highlighting changes in therapy or identifying preventative treatments). Table 1 shows a list of reading locations and length of time.

As for writing, significant paper records were kept, including active inpatient medication lists, outpatient medication lists, and medication reconciliation notes. Most information was written down on the active inpatient medication list printed from VistA, not CPRS, and was the main document used on rounds, as shown in Figure 1. Pharmacists spent the most time writing the patient's past medical history (such as problem lists), laboratory results, reminders (such as recommendations or questions for the medical team), medication doses administered (such as frequency of PRN doses, insulin requirements, and IV infusion rates), medication lists (such as outpatient medications not restarted upon admission), and other medication or historical notes (such as highlighting changes in therapy or identifying preventative treatments). Table 2 shows a list of topics written down and times spent writing.

**Searching for information**

Search and review strategies varied most in terms of whether the patient was new or familiar. New patients were typically evaluated before familiar patients. When evaluating a new patient, pharmacists typically started in the notes section of the EHR, followed by going to the medication or laboratory results section, followed by the coversheet, orders, or printed medication lists. When evaluating a familiar patient, pharmacists typically started in the orders section to look for updates in treatment, followed by laboratory results or notes section. The average location sequence length was 10 sections of the EHR for new patients, and 5 sections for familiar patients. Additionally, we observed that pharmacists used many different programs in addition to CPRS, such as BCMA, Essentris, VistA, VistA Imaging, and used different non-EHR sources, such as other papers, clinicians, whiteboards, etc. Some information was easier to find than others, for example, in order to find the patient's QTC interval (or even if they had an ECG done) pharmacists had to log into VistA Imaging, which took 51 seconds just to log in.

**Information Tasks**

There were many tasks that the pharmacists performed when preparing for rounds. Some of the most common were comparing medication lists for medication reconciliation, correlating indications/treatments and treatments/indications, managing/optimizing drug therapy (such as insulin or warfarin management), verifying medication administration, monitoring for ADEs, and documenting notes in the EHR (such as medication reconciliation notes). Generally, there was a considerable amount of task switching and multitasking, such as checking for drug-drug interactions, drug doses, medication indications, changes in therapy, etc. when reading the medication list. In this paper, we present managing insulin doses and verifying medication administration as examples of tasks the pharmacists performed in the EHR.
Figure 1. Integrating EHR information by writing notes on an active inpatient medication list printed from VistA. 
A, check list for admission medication reconciliation note and deep vein thrombosis (DVT) prophylaxis. B, reason for admission. C, past medical history or problem list. D, complete blood cell count (CBC) shorthand. E, complete metabolic panel (CMP) shorthand. F, place holders (memory aids) for laboratory results that are pending. G, outpatient medications that have not been restarted. H, triangles in the medication list signal to continued outpatient medications, but with changes compared to outpatient use. I, highlighting DVT prophylaxis. J, circles in the medication list signal to new medications since admission. K, planned duration of antibiotic therapy (some pharmacist would also record which day of regimen). L, "H" in the medication list signals to outpatient medications that were continued on admission. M, items on the list that the pharmacist is not following or going to use on the discharge medication reconciliation note. N, a note that signals to changes in therapy as compared to outpatient.
Example 1. Managing insulin doses

The pharmacists at this institution managed insulin doses, which required an average of 80 seconds to gather needed information to support this task, even though the patients in this study had relatively low insulin requirements. Figure 2 shows a schematic of this task, which required the pharmacist to go to the medication section (or orders section), find one of the insulin orders (such as rapid acting insulin), double click the order, scroll down to the bottom of the popup window to the BCMA data section, and then write down the ancillary blood glucose levels entered as free-text by the nursing staff and write down the insulin doses administered (also free-text entries), as shown in Figure 3. Then they would search for additional insulin orders, such as long-acting or basal insulin, and repeat the above process. The pharmacist would then go to the laboratory results section and write down additional blood glucose levels (which were sometimes different from the results reported in BCMA), and open a laboratory search (or a report) to find the most recent HbA1c lab result, and search for the patient's diet (in the orders or the notes). The pharmacist would then sum the insulin requirements for the last 24 hours, look for trends in the blood glucose values, and provide a recommendation to the team, take no action, or modify the insulin order. To complicate the process, we found that there were multiple insulin orders (such as sliding scale, scheduled, baseline, IV drip, etc.) sometimes using different types of insulin (such as insulin aspart, regular insulin, NPH, or insulin glargine) and that not all blood glucose values were documented in the EHR.

![Example 1. Insulin management process](image)

Figure 2. Example 1. Insulin management process. BG = blood glucose

Example 2. Verifying medication administration.

To verify medication administration, the pharmacists typically had to find the medication order, double click on the order, scroll down to BCMA data and write down times and doses administered. They would check if 'as needed' medications were administered in order to assess pain control or the patient's ability to sleep, check administration times to correlate with drug levels, follow up on medication orders (such as making sure the patient received their warfarin dose), checking when antibiotics were started in order to calculate the treatment duration, and going to the patient's bedside to check IV infusion rates. However, there were some limitations identified. For example, medications administered in the Emergency Department (ED) were not documented in BCMA, so the pharmacists would have to read the ED notes to find doses and administration times. Additionally, BCMA would only pull in the drug concentration and nursing would have to input the dose administered as free text. This was a challenge for one pharmacist when they were trying to find when, or if, the active 80 mg furosemide dose was given to the patient, as shown in Figure 4.
Figure 4. BMCA drug administration data. BCMA data displays drug concentration, but nursing would have to input the dose administered as free text. The pharmacist was searching for 80 mg dose of furosemide.

Discussion

In this study we observed pharmacists as they interacted with the EHR preparing for clinical rounds. We found that pharmacists spent a considerable amount of time searching for and reading information from the EHR and integrating EHR data by writing it down from printed medication lists, suggesting that the way information is stored or displayed in the EHR does not meet the cognitive model or needs of pharmacists.

We observed that not all information in the EHR was useful for pharmacists, or easy to obtain, even when it had been recorded to answer anticipated information needs. For example, CPRS calculates and displays the patient's estimated kidney function using the MDRD creatinine clearance equation. One pharmacist noted that "the MDRD equation is not helpful for me because medication dosing recommendations use the Cockcroft-Gault equation", so he would use an Internet calculator to calculate creatinine clearance using the Cockcroft-Gault equation, which took about 53 seconds. The pharmacists also commented on the not being able to run drug-drug interaction checks on demand when evaluating patient lists. Additionally, the pharmacists typically did not trust the vital signs, fluid balance, or IV infusion rates reported in the EHR, as they were documented infrequently or missing in the EHR.

Other studies of physicians' use of the EHR show that they tend to focus more on the “Assessment and plan” part of clinical notes, and give very little attention to the “Medication profile” part. Ancker et al. also studied physician use of the EHR and found significant physician level variation in utilization of EHR features. Using EHR log data, they found that problem lists were updated in only about 20-25% of encounters, almost always by adding problems instead of removing them. Additionally, problem lists and medication lists were marked as reviewed less than 10% of the time. Given the pharmacists' training and role, it is understandable why pharmacists focus more on medications and medication lists in the EHR. Additionally, pharmacists' focus on medication lists and problem lists to perform daily medication reconciliation and search for drug related problems, such as underdosing or overdosing of medications, ADEs, drug-drug and/or drug-allergy interactions, medication use without an indication, improper medication selection, and untreated medical problems. Similar to physicians, we observed that pharmacists obtained information from a variety of different non-EHR sources, and they typically had multiple systems open at the same time in addition to CPRS. However, having multiple programs open at the same time was problematic as pharmacists tend to jump from one patient to another, and there were instances where the other programs did not update and change patients to be in sync with CPRS, which could have lead to errors.
It was interesting to observe the extensive use of paper and that pharmacists spent about 1/3 of their time transcribing information from the EHR onto paper, especially in an environment that has had a comprehensive EHR in place for over a decade. The persistence of paper is not a new concept, and in 2009, Saleem et al. proposed several reasons for the persistence of paper in the VHA environment, and other benchmark institutions with EHRs. Similar to their study, it seemed that pharmacists mainly used paper because of its ease of use and it helped with efficiency, memory, awareness, task specificity, task complexity, and data organization. For example, most of the pharmacists only had one computer monitor and having information written down on paper helped reduce the need to jump back and forth between tabs in the EHR. The use of paper helped memory by writing things down such as patient history, recommendations, check boxes, medication lists, and placeholders for pending laboratory results. Additionally, paper helped with identifying changes or new information, and allowed for highlighting and quick annotation. Russ et al. suggested that healthcare workers need information to be customizable, prioritized, trendable, locatable, and accessible, requirements that the pharmacists in our study used paper to satisfy.

One study assessed providing pharmacists with tablet computers during rounds, and found many advantages such as the ability to enter/modify/or delete medication orders in real-time, perform complicated calculations, review up-to-date and comprehensive patient data, and access information databases, patient education materials, guidelines, and institutional protocols. However, there were challenges with limited battery life, having to carry around a heavy device, and the limitations of the rigid EHR design, such as searching for information. Even though paper is static, it is cheap, light, flexible, easily carried on team rounds, and not limited by power supply or battery life. The use of paper has important and powerful advantages that cannot be replicated in the EHR and it can help to fill gaps in the EHR design or information; therefore, perhaps we need to better support paper processes using the EHR, such as designing better paper using reports, or bringing related, yet disparate, information in the EHR together to reduce searching/reading time, or tools for associating medications, problem lists, and/or laboratory values. Pharmacists in this study constructed their own custom paper worksheet to help serve as memory aids and facilitate the evaluation process, as shown in Figure 4. In the clinical environment, every minute counts, and tools that can reduce time or increase efficiency are important. The findings in the study, and others, suggest that EHRs provide little cognitive support for clinicians or their workflows.33, 48

![Figure 4. Examples of custom paper worksheets](image)

One limitation of the use of paper by the pharmacists was the creation of handwritten notes and memory aids were more up-to-date than the information in the EHR, and were not available to be handed-off to other pharmacists. When one of the pharmacists was asked about patient handoffs, she said that the other pharmacist will usually call and give a verbal handoff if it is a complex patient, but it is 50:50 if they get a handoff or not, thereby losing the valuable information that the pharmacist spent so much time compiling. Technologies could be developed, such as...
EHRs or EHR apps, that are easily developed and customized, allowing clinicians to create dashboards or reports that are relevant to their setting or role, thereby becoming part of the information system instead of persisting alongside it.\textsuperscript{50} Some have reasonably suggested that it is not possible to meet the information needs of all users, as different users have different workflows;\textsuperscript{51} however, making the EHR customizable for different use cases, such as through apps or CDS tools that access core services and data in the EHR, could make it possible to meet the information and workflow needs of a spectrum of various users.\textsuperscript{52, 53}

Lastly, Millonig\textit{ et al.} suggested that pharmacists need to have access to patient-specific health information to improve patient outcomes, including a medication profile with refill history, vital signs and laboratory test results, diagnoses and current conditions, and medical history and physical assessment data.\textsuperscript{39} While our project focused on the inpatient setting, the availability of patient-specific information to help satisfy pharmacist information needs in the ambulatory and community settings could help improve patient outcomes, especially since pharmacists are more likely to detect and prevent errors by having more access to patient information that provides the overall context of the patient.\textsuperscript{54, 55} Pharmacists, and other clinicians, should have access to the entire patient record, regardless of where care was received, such as potential outpatient medication lists and problem lists.\textsuperscript{5} As pharmacists’ scope of practice continues to expand, especially in other institutions, so too does their need for adequate patient information as meaningful users and contributors to the EHR.\textsuperscript{54, 56-58}

\textbf{Limitations}\n
There are some limitations to this study that should be mentioned. Frist, we had a small sample size from only one institution, and we were not able to explore site-specific cultural needs or additional individual user preferences. Additionally, the generalizability of our results to non-VHA institutions is limited due to the unique characteristics of CPRS and the exemplary example of progressive clinical pharmacy practice in the VHA. The practice of pharmacy, roles of pharmacists, and EHR data collected or reported may be different at other institutions. However, anecdotal experience at local surrounding non-VHA hospitals suggests similar information needs and use of paper. Additionally, we were not able to have independent coding by the second researcher. The first researcher had significantly more knowledge and context of the sessions because he was a pharmacist and he was the one present for the observations; however, both coders had to agree on consensus for the coding procedures. While this project focused on the actual user workflow, future research could compare these results with the pharmacists’ perception of an ideal workflow in their clinical area of focus.

\textbf{Conclusion}\n
Pharmacists spend a significant amount of time searching for patient information in the EHR, and writing it down onto paper. This study suggests that current EHR designs do not readily support the information needs or workflow requirements of pharmacists. In an environment where every minute counts, the results of this study can help inform the development of CDS tools and/or EHR designs to facilitate the information needs of the pharmacists in providing care for their patients.

Assessing the Utility of Automatic Cancer Registry Notifications Data Extraction from Free-Text Pathology Reports

Anthony N. Nguyen, PhD1, Julie Moore2, John O'Dwyer1, Shoni Philpot2
1The Australian e-Health Research Centre, CSIRO, Brisbane, Australia
2Queensland Cancer Control Analysis Team, Queensland Health, Brisbane, Australia

Abstract
Cancer Registries record cancer data by reading and interpreting pathology cancer specimen reports. For some Registries this can be a manual process, which is labour and time intensive and subject to errors. A system for automatic extraction of cancer data from HL7 electronic free-text pathology reports has been proposed to improve the workflow efficiency of the Cancer Registry. The system is currently processing an incoming trickle feed of HL7 electronic pathology reports from across the state of Queensland in Australia to produce an electronic cancer notification. Natural language processing and symbolic reasoning using SNOMED CT were adopted in the system; Queensland Cancer Registry business rules were also incorporated. A set of 220 unseen pathology reports selected from patients with a range of cancers was used to evaluate the performance of the system. The system achieved overall recall of 0.78, precision of 0.83 and F-measure of 0.80 over seven categories, namely, basis of diagnosis (3 classes), primary site (66 classes), laterality (5 classes), histological type (94 classes), histological grade (7 classes), metastasis site (19 classes) and metastatic status (2 classes). These results are encouraging given the large cross-section of cancers. The system allows for the provision of clinical coding support as well as indicative statistics on the current state of cancer, which is not otherwise available.

Introduction
Cancer notified from pathology is the primary method of identifying population based cancer incidence and is an important and fundamental tool for cancer monitoring, service planning and research. The Cancer Registry receives cancer specimen reports from pathology laboratories, which are subsequently abstracted by expert clinical coders for key cancer characteristics. The information is often trapped in the language of these reports, which are in the form of unstructured, ungrammatical and often fragmented free-text. The effort required for information abstraction can therefore be an extremely labour and time intensive exercise. Furthermore, the abstraction is also subject to errors and inconsistent interpretations due to the need for repeated interpretation of the results by coders with differing levels of experience and training potentially leading to differing conclusions, repeated data entry into collection systems, and when cases are misinterpreted or keywords are missed.

An approach whereby reports are electronically received and automatically processed, abstracted and analysed has the potential to support expert clinical coders in their decision-making and assist with improving accuracy in data recording. Improving the cancer notifications process would provide significant benefits to oncology service providers, health administrators, clinicians and patients.

An automated medical text analysis system that extracts cancer notifications data from any notifiable electronic cancer pathology report is proposed. A rule-based approach utilising natural language processing (NLP) and symbolic reasoning using SNOMED CT were adopted in the system. Selected Queensland Cancer Registry business rules were also incorporated to mimic the interpretations and coding standards that expert clinical coders would adopt. The system was deployed to process pathology HL7 feeds from across the state of Queensland in Australia. The utility of the system was assessed and showed promising results on a set of reports containing a large cross-section of cancers.

Background
There has been a number of clinical language processing systems or studies relating to the extraction of key cancer characteristics from pathology free-text. Most research has focused on data extraction tasks for specific cancers such as colorectal, breast, prostate and lung.

* Systematized nomenclature of medicine - clinical terms
The medical text analysis system/pathology (MedTAS/P) proposed by Coden et al. uses NLP, machine learning and rules to automatically extract or classify cancer characteristics. Selected cancer characteristics were evaluated and showed promise with F-measures ranging from 0.9–1.0 for most extraction tasks including histological type, primary site, and grade on a corpus of colon cancer pathology reports.

Martinez and Li, similarly, used a colorectal cancer database to automatically predict cancer characteristics using machine learning (and in some cases complemented with rules) with 5 of the 6 multiclass problems achieving an F-measure above 74.9% using simple feature representations. Primary site, however, proved difficult to predict with an F-measure of 0.58.

Ou and Patrick extracted pertinent colorectal cancer information from narrative pathology reports using supervised machine learning and automatically populated the cancer structured reporting template using rule-based methods. They achieved an overall F-measure of 81.84% over a large range of structured reporting data fields.

Currie et al. presented a method of automated text extraction using specific rules and language patterns to extract over 80 data fields from breast and prostate cancer pathology reports with 90-95% accuracy for most fields.

Buckley et al. studied the feasibility of using natural language processing to extract clinical information from over 76,000 breast pathology reports from 3 institutions. They reported that there was widespread variation in how pathologists reported common pathologic diagnoses. For example, 124 ways of saying ‘invasive ductal carcinoma’, 95 ways of saying ‘invasive lobular carcinoma’ and over 4000 ways of saying ‘invasive ductal carcinoma was not present’. Reported sensitivity and specificity of the system were 99.1% and 96.5% when compared to expert human coders.

The Medical Text Extraction (Medtex) pipeline proposed by Nguyen et al. used a symbolic rule-based approach to parse pathology reports using NLP to identify SNOMED CT concepts of relevance, and tested whether these concepts were subsumed by concepts relating to cancer staging factors. Lung cancer staging and synoptic reporting were used to illustrate the symbolic rule-based approach. The symbolic rule-based system performed within the bounds of human staging accuracy as observed in studies of registry data.

As these studies are cancer (or tumour stream) specific, more generalized approaches are needed to extract cancer characteristics for all cancers. More recent research using Medtex has been applied to the extraction and coding of cancer characteristics such as basis of diagnosis, histological type and grade, cancer site and laterality from pathology free-text for all cancers. Preliminary results on a small evaluation set of 61 cancer notifiable reports comprised of a range of cancers have shown that cancer characteristics can be extracted with an overall accuracy of 80%.

In this paper, we present the architecture and deployment of Medtex on streaming pathology HL7 feeds from public pathology laboratories across the state of Queensland, Australia. Challenges here included the vast individual pathologists and institutional variations in the textual contents of the reports. A subset of 220 pathology reports from the deployment was selected from patients with a range of cancers to evaluate and analyse the performance of the system over seven cancer characteristic categories, each potentially containing a large number of possible classes, namely, basis of diagnosis (4 classes), primary site (330 classes), laterality (5 classes), histological type (1036 classes), histological grade (9 classes), metastasis site (330 classes) and metastatic status (2 classes). In contrast to previous work, the work presented here evaluated the utility of a Medtex deployment using a different and larger evaluation dataset and, unlike all previous tumour stream specific studies, this paper presents cancer characteristic extraction results on a wide range of cancer sites and types. The robustness of the system is also presented by comparing the evaluation results against those obtained from the development set and from a majority class classifier. An error analysis of the poorer performing cancer characteristic categories was also performed to determine the underlying limitations of the system.

Method

System Description

The medical text analysis system, Medtex, is a Java-based NLP software platform created for the development of clinical language engineering analysis engines to support data-driven analytic tasks. Medtex incorporates a (1) free-text to SNOMED CT mapping engine to normalize the free text (i.e. unify the language of the reports) by identifying medical concepts, abbreviations and acronyms, short-hand terms, dimensions and relevant legacy codes, (2) relate key medical concepts, terms and codes using contextual information and report substructure, and (3) use formal semantics, via a SNOMED CT ontology server, for medical text inference and reasoning. Additional analysis
engines can be incorporated to infer or classify complex clinical notions relevant to a particular health application using handcrafted algorithms and rules and/or machine learning techniques. Medtex has been applied to small scale datasets for research purposes; however its utility on real-time data streams and larger datasets may be inadequate if the computational time for the analysis of reports cannot keep up with the demands of the incoming data stream.

To address this issue, the Java messaging service (JMS) was chosen as the messaging broker for providing an intermediary to allow Java applications to be loosely coupled and reliably create, send, receive and read messages. This messaging service is built on the concept of message queues, producers (senders), and consumers (receivers). A message producer is used for sending messages to a specific queue. The message consumer is then used for receiving messages from a specified queue. Multiple message consumers can be set up in parallel to receive messages from the same queue such that only one message is received by only one of the consumers. Furthermore, consumers acting on data can publish their results to another queue called a message topic, whereby other consumers wishing to register and subscribe to the topic can receive messages from the topic. This scenario allows for multiple consumer applications to act on the same messages published from a given consumer.

The proposed Medtex service for analysing HL7 messages from a statewide pathology information system is illustrated in Figure 1. It aims to automate a number of Cancer Registry tasks such as the notification of cancer reports and the coding of notifications data. Apache ActiveMQ, an open source message broker, which fully implements JMS, was used to implement the messaging service. The message producer (HL7 Producer) accesses pathology HL7 messages and through the selection of report types that are relevant for subsequent processing, messages are sent to a specified queue (REPORTS_QUEUE). Multiple Medtex consumers can be set-up such that each consumer will take a message from the queue in turn. The results from the Medtex analysis are encoded in JSON format and published to a message topic (RESULTS_SUBSCRIPTION) where the topics can be subscribed to by end-user applications (Results Consumer), for example, to consolidate patient results and store them in a database and/or provide support for clinical coders to abstract clinical information from medical reports.

Within Medtex itself, the system would automatically process and analyse free-text HL7 pathology reports. The system selects from the pathology feed, histology and cytology reports, and filters non-notifiable cancer reports. For notifiable cancer reports, cancer characteristics extracted for a Cancer Registry notification consist of basis of diagnosis, primary site, laterality, histological type, histological grade, metastasis site, metastatic status, among others. Those relevant for the evaluation in the current study include:

- **Basis of diagnosis** encodes the method by which the cancer was diagnosed. For cytology and histology reports, the basis of diagnosis can either be encoded as cytology or haematology (06), histology of metastasis (07), histology of primary (08), or autopsy and histology (09). The basis of diagnosis is often used to assess the reliability of the cancer diagnosis, where the most conclusive information is found from histological reports.
- **Histological type** records the characteristics of the tumour. It is encoded using an ICD-O morphology code, which consist of a prefix M followed by a five-digit code ranging from M-80000 to M-99893. The cell type and behaviour make up the morphology code. The first 4 digits refer to the histology, while the last digit is

---

‡ [http://www.json.org/](http://www.json.org/)
the behaviour code and identifies whether the neoplasm is benign (0), uncertain and unknown behaviour (1), in situ (2), malignant (3), secondary or metastatic (6), or malignant but unknown whether it’s a primary or metastatic site (9). Behaviour codes 6 and 9 are not used by Cancer Registries but are instead flagged or derived from other cancer characteristic data elements such as basis of diagnosis, metastatic site or metastatic status.

- **Histological grade**, differentiation or phenotype describes how much or how little a tumour resembles normal tissue. It is encoded using a one-digit code. Only malignant tumours are graded and are represented by code numbers 1 to 4, designating grades I (well differentiated) to IV (undifferentiated), respectively. For a lymphoma or leukaemia, separate code numbers 5 to 8 are used to identify immunophenotype differentiation such as T-cell, B-cell, Null cell, and NK cell origin, respectively. If grading is unknown, not applicable or cannot be determined, then a code number of 9 would be assigned.

- **Primary site** describes the origin of the cancer in the body and is represented by an ICD-O topology code ranging from C00.0 to C80.9. It is encoded using a four-character code using a prefix C to identify topography codes. The first two digits represent the site (e.g. C34 for Lung), while the last digit defines the sub-site (e.g. C34.1 for Upper lobe of lung).

- **Laterality** indicates the side affected by the tumour for cancers of paired organs (e.g. breast, lung, kidney, etc.). It is encoded using a one-digit code: right (1), left (2), bilateral (3), not applicable (8) and unknown (9).

- **Metastasis site** describes the site of spread from which the cancer originated. In this study, it was proposed to assign an equivalent ICD-O topography code to represent the metastatic site, although ICD-O is not usually used for this purpose.

- **Metastatic status** is a flag to reflect whether the behaviour of a tumour indicates a metastasis (including lymph node metastasis).

The cancer characteristic codes were defined from ICD-O Third Edition for primary site, histological type and histological grade; and other notifications data according to classification codes recorded in the Queensland Cancer Registry. Table 1 summarises the list of the cancer characteristics along with their codes (or classes). In general, the cancer characteristic categories are multiclass where there are more than 2 classes within the category. The vast number of histological types and primary sites for classification show the complexity of the extraction tasks involved.

An expert clinical coder analysed the development set (see Corpus Description) to help build the ground truth and extraction modules for each of the cancer characteristic categories. A combination of NLP, domain knowledge and rules, and in particular SNOMED CT manipulation and querying were used to classify cancer characteristics. The
algorithm and rules were iteratively refined based on measuring and analysing the performance of the system on the development data set. Examples of the cancer characteristic classification sites are tabulated in Table 2.

Corpus Description

Access to the Queensland statewide pathology data was obtained from the Queensland Oncology Repository with research ethics approval from the Queensland Health Research Ethics Committee. The data covers HL7 pathology feeds from public pathology laboratories in the state of Queensland. A corpus consisting of 500 pathology reports was used for system development of which 201 of them were notifiable cancers (and thus relevant for the current cancer characteristic extraction task). Non-notifiable cancers such as non-malignant cancers, and squamous cell carcinoma (SCC) and basal cell carcinoma’s (BCC) of the skin were identified, but removed and flagged by the system; a separate study addressed these issues by filtering notifiable reports from non-notifiable reports. For system evaluation, a separate 220 pathology reports from the deployment of the system for processing the backlog of pathology feeds was selected from patients with a range of cancers (i.e. tumour-stream stratified sampling) to evaluate and analyse the performance of the system. The ground truth used for system evaluation was based on the reference data set annotated by the same expert clinical coder who helped develop the system. Table 3 shows the cancer characteristic statistics from the development and evaluation corpus.

Dev., development set (N=201); Eval., evaluation set (N=220); Std Dev, standard deviation; NA, ‘Not Applicable’ class

The distributions between the development and evaluation set for each cancer characteristic category were quite similar. However, within the categories the class frequencies can vary quite significantly, with large variation in ranges and standard deviations, e.g. basis of diagnosis, histological grade, laterality, etc. On the other hand, in some categories, there are a large number of small frequency classes resulting in low means and standard deviations, e.g. histological type and primary site, due to the large and diverse number of cancer types and sites, respectively.
Furthermore, there is a large portion of classes contained in the evaluation set that were not found in the development set (e.g. histological type, primary site and metastatic site). The corpus and cancer characteristic category statistics show the challenges and complexity of the extraction tasks. In addition, the varied writing style and language contained within the reports from different pathologists and laboratories creates additional challenges that will test the robustness and generalizability of the extraction modules when measuring the performance of the system on the evaluation set.

**Performance Measures**

The measures used to evaluate results are based on the counts of true positives ($TP$), true negatives ($TN$), false positives ($FP$), and false negatives ($FN$) resulting from the classification decisions. The multiclass classification performance for a given cancer characteristic category, $C$, is measured using the micro-average recall ($R_{micro}$) or sensitivity), precision ($P_{micro}$ or positive predictive value), and balanced F-measure ($F$).

$$R_{micro} = \frac{\sum_{i=1}^{C} TP_i}{\sum_{i=1}^{C} TP_i + FN_i}; \quad P_{micro} = \frac{\sum_{i=1}^{C} TP_i}{\sum_{i=1}^{C} TP_i + FP_i}; \quad F = \frac{2PR}{P + R}$$

Overall system performance is reported as the macro-average measure across all the categories, with equal weight to every category.

A majority class classifier was used as a baseline to determine whether the system’s results were significantly better than one that naively classifies results simply based on the majority class. In addition, to assess the generalizability of the system, the system’s results from the evaluation set were compared with that from the development set. Other cancer notification extraction systems are tumour specific and thus were not suitable for use as a benchmark.

**Results**

The Medtex messaging service was applied to a statewide pathology HL7 message feed. The backlog and new incoming HL7 messages from pathology laboratories in Queensland, Australia were used to analyse the pathology reports as well as test the load on the service. Using 3 instances of Medtex, the system’s average processing rate was 3.6 seconds per message and achieved the processing of a year’s worth of messages within just under 5 days.

An increase in report analysis throughput was achieved by using the messaging framework and multiple instances of Medtex consumers in parallel. The use of 3 Medtex instances in parallel resulted in a 2.5 times speed-up over the sequential single instance of Medtex in operation. Depending on system resources, further speed-ups are possible if additional instances of Medtex and/or multiple instances of Medtex’s shared resources such as the SNOMED CT ontology and concept-mapping servers were made available.

The classification performances of the system with respect to the cancer characteristic categories are shown in Table 4. Figure 2 summarises the F-measure comparison of cancer characteristic categories between the development and evaluation set.

Discussion

Overall system performance on the evaluation set reported as F-measure was 0.80. At a cancer characteristic level, the F-measure performances within each category were 0.93 for basis of diagnosis, 0.64 for histological type, 0.79 for histological grade, 0.61 for primary site, 0.82 for laterality, 0.90 for metastatic site and 0.93 for metastatic status. The results are promising given the challenges previously discussed regarding the large number of classes from certain categories, varied and skewed distributions within each cancer characteristic category, and the large number of unseen classes being classified in the evaluation set. The results show the system’s robustness and generalizability by achieving extraction performances on the evaluation set that is comparable with that obtained from fine-tuning the system using the development set, and also its superiority to that obtained when using a majority class classifier. When compared to previous studies that focused on certain tumour streams, the results show that generalizing the extraction algorithms to accommodate for all tumour streams has its challenges and therefore is sub-optimal to the tumour stream specific results. However, it would be a very costly exercise to build specific tumour stream cancer characteristic classifiers for each and every possible cancer. The trend in extraction performances across the categories are also consistent with previous works where primary site was found to be the most challenging.

The results between the development and evaluation set were in general not significantly different. Only the histological type and histological grade generated results that exhibited non-overlapping 95% confidence intervals suggesting that the algorithms and rules adopted in these extraction modules likely over-fitted the development data. That said, there was a large number of histological types in the evaluation set that were not seen in the development set; despite having almost 70% of the histological types unseen by the system during development, the system was able to classify the category with a recall of 0.58, precision of 0.71 and an overall F-measure of 0.64. In terms of the
free-text to SNOMED CT mapping engine, it was observed that 83.2% of the histological types from the
development set could have been found within the mapped concepts. This provides an upper bound to the
classification performance by the system, unless other methods are introduced to infer the histological type.

For histological grade, error analysis revealed that at a per-class level, all classes had non-overlapping 95% confidence intervals, except for the histological grade of 3 (poorly differentiated). The errors were more pronounced for histological grades 4 through to 6, from which 5 and 6 relate to lymphoma or leukaemia histological types.

The extraction of primary site was also a challenge for the system as evident from its performance. Despite having 45% of the cases in the evaluation set unseen by the system during development, the results between the development and evaluation set had overlapping 95% confidence intervals. One source of error was due to the lack of co-referencing of specimens between the macroscopic and microscopic sections of the pathology report. As a result, the relation between different evidences in the free-text could not be classified correctly. Again in terms of the free-text to SNOMED CT mapping engine, 70.3% of the primary sites (excluding unknown primary C80.9 sites) from the development set were found in the mapped concepts. This suggests that the use of the current concept-mapping algorithm has its limitations in giving the system the ability to correctly identify primary sites. Further inspection of the errors also revealed that many of the cases actually classified the ICD site = C34 for Lung) but not the sub-site (Cxx.x; e.g. sub-site = C34.1 for Upper lobe of lung). Figure 3 illustrates this effect where results at a site level (Cxx) were significantly better than that classified at a sub-site level (Cxx.x) with non-overlapping 95% confidence intervals.

![Figure 3. Primary site classification performances at a site (Cxx) and sub-site (Cxx.x) level along with 95% confidence intervals.](image)

The metastatic site and metastatic status data items are also worth deeper analysis. Although, performing well with high F-measures, the large bias towards the majority class did not make the system perform much better than the majority class classifier. As a result, it is likely that there is poor recall and precision for the minority classes.

Future research will need to focus on iteratively improving the system’s performance, especially for critical cancer notifications data such as primary site and histological type. Preliminary error analysis have revealed areas of focus for further system improvement such as histological grade for lymphoma and leukaemia cancers, including the need to investigate other concept-mapping algorithms for improving both histological type and primary site categories. These error analyses facilitate the identification of the relevant Queensland Cancer Registry business rules to be incorporated, abstraction errors by human experts, and also feedback the type of errors generated for further system development.

Other limitations of the system include limited number of development reports given the large number of possible histological types and primary sites. The evaluation corpus is also biased towards uncommon cancers due to the tumour-stream stratified sampling that was applied to ensure that a range of cancers were represented in the evaluation set. In addition, the system at present cannot distinguish between multiple cancers reported within a single report.

In a clinical coding workflow setting, the system could be used to support clinical coders and hence improve data collection capture at Cancer Registries by highlighting and pre-populating cancer notification items for validation (for example, see Figure 4). Here, the free-text report is shown in the leftmost panel. The highlights shown over the
free-text report correspond to the evidence used to generate the system’s suggested coding, which is shown in the rightmost panel. Clinical coders can then use the system’s suggestions to either accept (using the arrows in the rightmost panel) or enter in an alternate code to populate the fields within the clinical coder’s coding panel (as depicted by the middle panel). Investigations into the utility of a guided and interactive annotation process on cancer characteristic abstraction tasks is reserved for future work.

Figure 4. The Medtex software can process narrative pathology reports and generates structured data to aid clinical coders in cancer abstraction tasks.

The proposed architecture for the processing and analysis of streaming pathology reports has potential to overcome the multi-year delay in the reporting of cancers by providing indicative population-level statistics on the current incidence of cancer. The system supports future data extension requirements such as cancer stage, and also can be applied on other sources of cancer data with free text, e.g. death data and radiology reports.

Conclusion

Analysis of the contents of electronic pathology reports will have a profound impact on cancer care. As a result, a number of automatic cancer data extraction systems have been developed, however their utility in automating Cancer Registry tasks has to be adequately assessed. In this study, the Medtex system was assessed and showed promise in terms of stream processing at a statewide level and also in terms of cancer characteristic extraction performances and its ability to track and identify specific system limitations for future improvements.

The use of Medtex’s messaging technologies that take advantage of the parallelism of consumers/producers can be an effective real-time processing solution for data streams. These technologies greatly increase the throughput of medical text analytics for clinical decision support and/or research activities involving real-time data streams or large datasets.

The cancer notifications data extraction results from Medtex show promise with an overall F-measure performance of 0.80 on a broad range of cancers and cancer characteristic categories. Despite some cancer characteristic categories performing well, with an F-measure score of above 0.90, the histological type and primary site extraction results proved more challenging due to its large number of possible classes. The system is extensible and cancer stage including other synoptic data can also be incorporated. Future work will analyse errors between the system and the reference standard to feedback into the iterative development process.

The system is proposed to streamline and support the clinical coding workflow at Cancer Registries by identifying cancer notifiable reports and then highlighting and pre-populating cancer notification items for clinical coder validation. It is hoped that such automation would help overcome the multi-year delay in the reporting of cancer
statistics with Cancer Registries able to have access to up-to-date population-level statistics on the current state of cancer.

Abstract

Nutrition care and metabolic control contribute to clinical patient outcomes. Biomedical informatics applications represent a way to potentially improve quality and efficiency of nutrition management. We performed a systematic literature review to identify clinical decision support and computerized provider order entry systems used to manage nutrition care. Online research databases were searched using a specific set of keywords. Additionally, bibliographies were referenced for supplemental citations. Four independent reviewers selected sixteen studies out of 364 for review. These papers described adult and neonatal nutrition support applications, blood glucose management applications, and other nutrition applications. Overall, results indicated that computerized interventions could contribute to improved patient outcomes and provider performance. Specifically, computer systems in the clinical setting improved nutrient delivery, rates of malnutrition, weight loss, blood glucose values, clinician efficiency, and error rates. In conclusion, further investigation of informatics applications on nutritional and performance outcomes utilizing rigorous study designs is recommended.

Introduction

Biomedical informatics applications have been shown to improve efficiency and quality of health care delivery in management of diseases such as diabetes, cardiovascular disease, mental illness, and pediatric asthma, among others.¹⁻³ Clinical decision support (CDS) systems also have demonstrated improvements in practitioner performance.⁴⁻⁶ For instance, a systematic review by Garg et al. found that the majority of the reviewed electronic health record systems (EHRs) improved clinicians’ performance in drug prescribing and dosing, preventative care, and disease management.⁶ Likewise, Jaspers et al. concluded that CDS systems have a positive effect on provider performance regarding drug prescribing and preventive reminders.⁴

In the clinical setting, studies have found that poor nutritional support can contribute to impaired patient condition and therapeutic complications.⁷⁻¹⁰ For example, incidence of blood glucose (BG) dysregulation is associated with adverse outcomes and increased mortality.¹¹⁻¹² Alternatively, carefully monitored nutritional support providing adequate kilocalories and protein leads to lower rates of mortality and improved clinical outcomes in observational studies.¹³⁻¹⁸ Despite the benefits, nutritional monitoring can be a complex task, requiring management of multiple data inputs, mastering complex calculations, and consuming significant time from clinicians.¹⁹

Despite the growing body of research regarding health informatics technologies in medical patient management, no systematic reviews have been published describing the evidence for medical nutrition informatics applications. This paper aims to address that gap by summarizing the evidence of the effect of informatics applications containing CDS and computerized provider order entry (CPOE) features on 1) clinician workflow and error rate; 2) patient outcomes such as nutrient delivery, blood glucose management, malnutrition and weight loss; and 3) quality of nutrition support in various clinical settings. We use the term CDS to cover a broad variety of tools, from simple calculators to advanced algorithms. Where this use might cause confusion, we clarify the type of tool being discussed.

Methods

We conducted a systematic review of the peer-reviewed literature using three search databases: MEDLINE/PubMed, Scopus, and CINAHL (the Cumulative Index to Nursing & Allied Health Literature). Search criteria were designed broadly to include as many results as possible and employed keywords to search title, abstract, and MeSH (Medical Subject Heading) terms. A search was conducted on CINAHL using the keywords “nutrition AND informatics.” The following search terms were used for PubMed and Scopus databases: ("Nutrition Therapy"[Mesh] OR...
For all searches, we further limited relevant results to those published in the English language within the past ten years (January 1, 2004 and onward). Papers were accepted if they contained a clinical and a dietetic focus, an emphasis on CDS and/or CPOE applications, and human subjects of any age or disease state. Four reviewers independently assessed the set of returned titles and abstracts using those predefined inclusion criteria. Publications deemed irrelevant were excluded and duplicates were removed. Any discrepancies in the review process were resolved through unanimous consensus. We conducted a hand search of article bibliographies and related citations for additional sources. Upon completion of the initial abstracts search, we screened each paper in full for applicability, and identified final articles to be included in the systematic review. In total, sixteen studies were selected for analysis. The search process is illustrated in Figure 1.

**Figure 1.** Schematic of Search Strategies

**Results**

**General Overview**

A diverse set of locations and healthcare systems around the world are represented in this review. Of the sixteen included studies, three were conducted in Greece, two in the Netherlands, two in the United States, one in Switzerland, one in France, one in the Philippines, one in Norway, one in Denmark, one in Belgium, one in Austria, and one in Spain.

Of these studies, eleven examined the impact of a variety of CDS tools and CPOE systems on clinical patient outcomes and quality of nutrition care, two described features and validation of a computerized tool, four discussed effects on clinician workflow (for example, time saving features), and four assessed impact on rates of calculation and order error. Of the articles assessing the effect of informatics applications on patient care, five studies examined effects on BG values, related to use of computerized tools, four addressed energy or macronutrient delivery and achievement of prescribed nutritional support rate, one discussed unintentional clinical weight loss, and one studied recognition of malnutrition.
Systems varied regarding decision support and ordering features. Thirteen programs recommended nutrition and/or insulin interventions based on patient data, five contained computerized nutrition support ordering capabilities, five produced electronic alerts and reminders, three reported daily energy delivery totals from multiple sources, three conducted computerized patient screening, two produced feedback based on patient progress, and one developed automated meal plans based on patient needs.

The focus of these research articles generally fell within three major groupings: nutrition support for adults and neonates, BG management, and other nutrition applications. The design and duration of these studies varied widely among these three groups. Of the studies addressing impact of computerized interventions on patient outcomes, some featured a control group, though many did not. Others assessed features based on simulations, system descriptions, validation studies, or reductions in rates of calculation error.

**Adult Nutrition Support**

The ability to integrate and display nutritionally relevant patient data from multiple sources is a unique feature of computerized information systems. One CDS system synthesized data from delivered enteral or parenteral nutrition as well as macronutrient contributions from patient medications to provide a complete picture of nutrient delivery. Similarly, Berger et al. described one system able to synthesize energy totals from multiple sources, including glucose, lipids, and protein from medications and feeding, in addition to inputs from nutritional support. As a result of these data management features, clinicians responded well to the better graphical display of weight curves, energy balances, and total lipid, glucose, and protein deliveries with computerized systems. This display resulted in acceleration of nutrition support infusion rate when a deficit was observed. The assimilation of multiple data sources contributed to coordination and continuity of patient care when this information was available over prolonged time periods. Furthermore, some systems allowed the user to extract data to be analyzed by other computer programs for spreadsheet creation or statistical analysis.

Error rates were demonstrated to be lower in calculations performed by CDS in contrast to manual methods. Paschidi et al. developed a software tool for computation of parenteral nutrition prescriptions in adult patients based on validated estimated nutrient needs calculations. When compared to calculations completed without the assistance of a computer program, researchers observed a significant decrease in errors among a random selection of 21 patients. In general, use of computer-based nutritional support applications were shown to save time spent performing calculations.

Multiple studies employed use of computerized alerts, warnings, and feedback features to aid in selection and maintenance of nutrition support prescriptions. Decision support systems acted as a guide for the prescriber, monitoring delivered nutritional therapy, and warning of mismatched calculations and potential complications. Electronic warnings were implemented into nutrition support applications to identify values outside a normal range and/or in need of correction. Clinicians could take the initiative to seek out assistance, clicking on an “advice” button to receive recommendations for type and amount of nutritional formula. Alternatively, some feedback features were automatic. One system contained programmed informative messages intended to supplement clinician knowledge. Another sent the patient’s care team a daily email containing a comparison of delivered nutrition support to recommended calculations.

Patient outcomes were clearly and positively improved by informatics tools. The number of patients achieving early and adequate nutritional support increased significantly after the deployment of computer-aided support, in some cases nearly doubling, along with decreases in ICU (intensive care unit) length of stay after utilization of an “advice” button and daily feedback regarding achievement of nutrient delivery. In a study examining a total of 166 patients, higher numbers of critically ill patients received at least 80% of prescribed nutrition therapy for kilocalories (79% vs. 45%, p<0.001) and protein (37% vs. 3%, p<0.001) when a computer system was used for calculation of nutrition support prescriptions, with continued improvements over time. The same authors also reported that the group receiving computer input had increased percentages of patients prescribed at least 120% of recommended kilocalories. Berger et al. described the impact of an EHR on quality of nutritional support among 109 adult intensive care and burn patients. Though energy delivery was below target in both a unit containing a computerized system and one without, it was significantly higher and closer to desired level in the unit with computer support providing recommendations and feedback for discrepancies between calculated needs and actual energy delivery. Additionally, moderately and severely burned patients exhibited lower levels of weight loss when on the unit containing an EHR with these decision support features.
Improved energy delivery and avoidance of weight loss were not the only benefits observed in electronic CDS and CPOE systems. Llido reported that among 135,888 patients, malnourished individuals were recognized promptly based on a computerized screening program, leading to an increase in rates of referrals of these underweight patients to dietitians and nutrition support professionals from 37% to 100% . The percentage of critical care patients seen by nutrition support teams also increased from 10% to 99% . Computer systems used to calculate appropriate parenteral nutrition orders contributed to early identification of metabolic complications (25% increase in identification post-implementation). Additionally, one study reported a significant decrease in occurrence of ICU-acquired infection among a group of 95 patients whose nutrient needs were calculated using a computer program. However, the same study found no significant difference in mortality or length of ICU stay between the intervention and control group. Nutrition support findings are summarized in Table 1.

### Neonatal Nutrition Support

Premature and sick neonates frequently require nutrition support for adequate hospital recovery. Nonetheless, therapeutic errors can result in serious complications, so impacts on patient safety are routinely studied in neonatal nutrition support applications. A summary of the reviewed neonatal nutrition support applications is found in Table 2. Lehmann, Conner, and Cox researched an online CPOE system allowing for automated total parenteral nutrition (TPN) calculations in a neonatal ICU. Two years after implementation, an 89% reduction in total calculation errors was observed, amounting to a total of 1.2 errors per 100 orders vs. the initial rate of 10.8 errors per 100 orders. Likewise, Skouroliaikou et al. developed a computer program to assist in formulating and administering TPN to preterm and sick-term neonates. TPN orders prepared by the computer program contained no errors, compared to physicians’ orders, which had an error rate of 2.98%.
Further, CPOE systems in the neonatal ICU setting were met with enthusiasm from clinical staff. Results from staff-administered questionnaires rated computer systems as easier to learn and to use than paper systems, and as a better protection against errors.27 Changes in clinician workflow were also noted, with an average decrease from 7 minutes to 1 minute spent completing TPN orders, representing a reduction in clinicians’ workload.21

**Blood Glucose Management**

A substantial number of studies investigated CDS and CPOE systems on BG management during nutrition therapy, as shown in Table 3. In general, informatics tools were utilized to balance delivery of nutrition with management of BG levels. Hoekstra demonstrated a viable method for initiating nutrition support while managing target BG values in 23 predominantly surgical ICU patients.24 By utilizing an incremental step-up method of PN initiation in addition to a CDS system for continuous monitoring of insulin infusions, adequate caloric and nutrient allocation was achieved within 24 hours while consistently maintaining BG levels under acceptable parameters for the greatest majority of measurements in patients.25 Similarly, another CDS system in a neurotrauma ICU allowed for provision of 93.5% of estimated resting energy expenditure for adult patients (n=6) vs. 129.5% in the control group (n=6) while also maintaining BG levels at an average lower than that of the control group.22

In addition to adequate nutrient delivery, CDS aided in the management of BG levels. Pachler et al. described a computer algorithm for management of mechanically ventilated adult ICU patients.36 Taking into account current BG concentration, insulin dosage, and carbohydrate content of nutrition support formula, calculations were determined for insulin infusion rate and timing of next BG sample. Under these conditions, the intervention group exhibited lower average BG concentrations and hyperglycemic index levels compared to the control group.36 Among these same patients, the total carbohydrate administration rate was no different between intervention and control group. Meyfroid et al. found that a glucose alert system for adult ICU patients employing pop-up alerts in response to abnormal values decreased mean BG values, decreased hyperglycemic index levels, decreased glycemic penalty index levels, and decreased proportion of measurements within the hyperglycemic range.35 There were no significant differences in hypoglycemic index, or proportion of measurements in the hypoglycemic range, however.35 Another study found that a CDS and CPOE system for neonatal patients had no effect on instances of hypo- or hyperglycemias pre- and post-intervention, despite a modest reduction in time for simple calculations, and major reduction in time for complex calculations.27

**Other Nutrition Applications**

Apart from parenteral and enteral nutritional support informatics applications, several programs have been developed to assist with patient screening and oral feeding, as illustrated in Table 4. de Ulibarri et al. implemented a nutritional risk screening and referral system based on laboratory parameters in an adult hospital population not undergoing aggressive therapeutic procedures or suffering from severe diseases.35 Compared to validated measures, the system had a screening sensitivity of 92.3% and a specificity of 85%.35 In a related study, Fossum et al. found that a CDS system used for risk screening in nursing homes for the elderly resulted in significantly reduced rates of malnourishment among a baseline of 491 individuals when compared to institutions without such a program.31 However, the same study found no effect on rates of pressure ulcer formation,31 even though nutritional status is considered an important predictor of the condition.

CDS=computerized decision support, NS=nutrition support
Skouroliakou et al. published an implementation brief describing an application of nutrition informatics in oral nutrient delivery for hospitalized patients. This system was developed to prepare dietary prescriptions, calculate nutritional requirements, store patients’ dietary records, produce automatic daily menus, and generate reports on food lists and menu costs for patients receiving nutritional support by mouth. As a result of that implementation, a reduction in errors occurred during data recording, during calculation of daily requirements, and during menu planning. Additionally, authors reported a minimization of time spent by dietitians on menu planning after program implementation. For patients, no significant effect on days of hospitalization was found related to use of this tool.

Discussion

This systematic review examined a wide range of medical CDS and CPOE informatics applications in clinical dietetics. Overall, the benefits described in the reviewed articles were numerous. Specifically, improved patient outcomes included lower rates of weight loss, increased nutrient delivery, fewer acquired infections, more stable BG values, and lower rates of malnutrition, in addition to increased referrals to nutrition support teams. Furthermore, improved clinician workflow and fewer calculation errors were noted in multiple studies. Researchers reported high rates of acceptance of CDS and CPOE systems among clinical staff. However, studies produced conflicting results regarding the influence of computerized interventions on length of hospital stay, with a tendency toward no effect. Only one study assessed mortality outcomes; here, researchers found no significant effect. Taken together, these results suggest that use of informatics applications contribute to an improvement in metabolic management, but they offer a conflicting and incomplete picture of overall patient outcomes.

Although reviewed studies showed significant improvements in error reduction among adult and neonatal nutrition support ordering, in only one study was the absolute error number reduced to zero. One might argue that any level of error is unacceptable, particularly among system-generated calculations. It is important to note the synergistic relationship between CDS and CPOE systems and clinical care providers. Though CDS systems may generate automated calculations, this result is dependent on completeness of input patient data as well as clinicians’ adherence to suggested electronic alerts and reminders. Regardless of the demonstrated value of CDS systems, there is no substitution for qualified human clinical judgment in delivery of healthcare. Even the most well designed system might not produce perfect results without accurate human knowledge and attention to detail. Clinician oversight in regards to prescription and delivery of adult and neonatal nutrition support is always necessary to ensure best patient outcomes.

Interestingly, there was a more effective reduction of errors in the neonatal nutrition support systems than in adult nutrition support systems. It could be that neonates and sick term infants are more likely to have a similar set of clinical needs and treatments than is seen in the large variety of adult patients of various disease states. However, the authors are more inclined to think that user interface may have the greatest impact on error reduction. For example, the system described by Skouroliakou generates a set of yes/no questions for the user to answer to determine parameters for preparation of TPN. This type of simplification of input may clarify the most important clinical parameters when prescribing nutrition support. Particularly in hectic environments such as an adult or neonatal ICU, simplified but thorough CDS systems will be the most useful in assisting nutrition support prescription.

Some tools may be better suited to particular clinical situations than others. In particular, the reviewed studies have demonstrated that clinical applications for TPN ordering are well suited for delivery of neonatal care. Additionally, blood glucose management systems have a potential application in all clinical areas, from ICU to medical floors to neonatal care. Likewise, nutrition informatics applications have a place in multiple types of hospitals; for rural hospitals, CDS systems may supplement and inform clinical decision making when specialized nutrition professionals may not be readily available. Although every clinician can benefit from use of CDS systems, CPOE is best suited for ordering providers such as physicians, physician’s assistants, and pharmacists. EHRs designed with multiple CDS features will fulfill the greatest number of needs, with access privileges for clinicians specific to need.

Although this review discusses nutrition informatics applications in clinical practice, the potential of informatics goes beyond inpatient use. Recent technological innovations targeting patient self-management, especially through mHealth apps, suggest clinical efficacy. Oenema et al. reported that an Internet-delivered computer-tailored lifestyle intervention program resulted in lower saturated fat intake based on a validated food-frequency questionnaire (p<0.01). In addition to modifications to patient behavior, computerized systems have the potential to impact outcomes such as weight management. For example, research has suggested that online “feedback” features such as
progress charts and physiological calculators are the best predictor of weight loss in internet-based weight control programs.\textsuperscript{38}

There are also implications for chronic disease management. Albisser described a Web-based graphical user interface designed to provide decision support regarding medication dosing and lifestyle factors such as diet and exercise for individuals managing insulin-dependent diabetes.\textsuperscript{25} Any actions taken by the user were documented by the system and linked back to an online registry, where these data were available for review and/or intervention by the patient’s provider. This application suggests the potential integration of patient-facing technologies and clinical care coordination,\textsuperscript{39} particularly in diseases requiring joint patient-provider supervision. These findings seem to suggest that decision support features in online programs and applications designed for patient self-management might contribute to positive clinical outcomes in a variety of diseases.

This study had several limitations. First, results included only those published in English, potentially excluding meaningful studies written in other languages. Second, this paper is necessarily limited by the methods used in the primary research reviewed. The largest majority of the studies reviewed in this paper employed a quasi-experimental study design (n=10, 62.5\%). Several other papers were published as a system description,\textsuperscript{20,26} proof of concept study,\textsuperscript{24} or validation study.\textsuperscript{25} Only two studies employed a controlled trial method, one with group randomization,\textsuperscript{32} and one an “open” design.\textsuperscript{34} As such, overall results should be considered preliminary findings in the area of nutrition informatics applications and interpreted with some caution. Future research should consider more rigorous methods, including randomized controlled trials utilizing large sample sizes. Finally, a meta-analysis was impossible due to significant differences in reported outcomes. However, the positive results described herein suggest that further research examining the benefit of informatics interventions, specifically those incorporating CDS and/or CPOE, will strengthen the case for nutrition informatics applications in the clinical setting.

Furthermore, it is important to note the stage of development of each informatics approach when assessing reported results. Though studies showed positive outcomes, not all computer systems had been implemented in an actual clinical patient-care setting.\textsuperscript{20} It is possible that systems that look promising in the early stages may not translate to practical use in patient care. Therefore, studies set in a clinical venue are needed for further conclusions. Although the studies included in this review provide examples of informatics tools used in nutritional management, very few specifically addressed patient health outcomes. The effect of CDS and CPOE systems on length of hospital stay, weight loss, wound healing, and mortality represent important markers of nutrition care efficacy. Overall, the impact of informatics on patient outcomes remains an understudied area of research in all medical informatics applications, including those used for nutrition care.

Use of informatics applications is relevant for Registered Dietitians as well as other nutrition care professionals. Specifically, the integration of informatics systems into clinical practice may increase practitioner efficiency as well as improve the quality of nutrition care. For example, Skouroliakou described an informatics application developed to specifically improve efficiency and performance of dietitians in meal planning and menu assessment.\textsuperscript{22} Lildo demonstrated that use of an informatics system resulted in increased involvement of clinical dietitians in all aspects of patient care, including referrals to nutrition support services.\textsuperscript{30} Additionally, in the application described by Mirtallo et al., Registered Dietitians were consulted throughout the development and initiation process for system evaluation and feedback, ensuring optimized nutrition care functionality.\textsuperscript{26}

For Registered Dietitians, CDS systems present an opportunity to enhance quality of patient care as well as number of malnourished and critically ill patients seen by nutrition care practitioners. Many healthcare institutions implement a screening procedure for patients who qualify for a dietitian referral; often dietary technicians or the dietitians themselves complete this screening task. Automated systems such as the one described by Lildo\textsuperscript{22} may be helpful in identifying these at-risk patients and initiating nutrition care contact sooner while reducing the workload of hospital personnel. Among critical care patients, nutritional status is often an area of concern as many patients are unable to meet nutrition needs for at least some portion of their hospital stay depending on the severity of their medical status. Increased referrals to nutrition services likely represent an early identification of potential need for alternative support in at-risk patients especially susceptible to malnutrition. When tailored to reflect the screening parameters set forth for a particular hospital, systems developed to correctly identify patients in need of nutrition intervention ensure that the standard of nutrition care is upheld.

We would argue that nutrition professionals can use the research from this review to advocate for informatics systems to assist in delivery of nutrition support and metabolic management, to improve calculation accuracy when writing prescriptions, and to assist in screening and early identification of nutritional concerns. Furthermore, these
applications make possible the direct integration of evidence-based recommendations for clinical nutrition care into ordering systems, including standardized processes for nutrition support ordering, delivery, and monitoring. In conclusion, acceptance of nutrition informatics applications is increasing in inpatient and outpatient healthcare, both nationwide and worldwide. Appropriate nutrition monitoring and support is an integral part of ensuring hospital recovery and positive patient outcomes. Given this, computerization of the nutrition care process in particular could impart significant benefits for patient outcomes, practitioner performance, and institutional cost. Further research is recommended to provide evidence for integrating informatics applications into routine clinical nutrition practice.

Abstract

The National Drug File – Reference Terminology (NDF-RT) is a large and complex drug terminology. NDF-RT provides important information about clinical drugs, e.g., their chemical ingredients, mechanisms of action, dosage form and physiological effects. Within NDF-RT such information is represented using tens of thousands of roles. It is difficult to comprehend large, complex terminologies like NDF-RT. In previous studies, we introduced abstraction networks to summarize the content and structure of terminologies. In this paper, we introduce the Ingredient Abstraction Network to summarize NDF-RT's Chemical Ingredients and their associated drugs. Additionally, we introduce the Aggregate Ingredient Abstraction Network, for controlling the granularity of summarization provided by the Ingredient Abstraction Network. The Ingredient Abstraction Network is used to support the discovery of new candidate drug-drug interactions (DDIs) not appearing in First Databank, Inc.'s DDI knowledgebase.

Introduction

We present a new method for the discovery of candidate drug-drug interactions (DDIs). Conceptually, this method is based on comparing a large commercial knowledgebase of DDIs with small groups of drugs where all members of one group contain similar ingredients. These groups of drugs were derived from an independent drug terminology, the National Drug File – Reference Terminology (NDF-RT) [1]. The challenge is that the NDF-RT in its source format does not provide appropriate groups of drugs. Finding such groups by hand is difficult, because the NDF-RT is composed of approximately 43,000 concepts connected by 67,000 IS-A roles and 73,000 other roles, e.g., has ingredient and has mechanism of action. Thus, we are using algorithms, based on a well-developed body of work on abstraction networks (AbNs) [2], to derive small groups of similar drugs. Intuitively, if most but not all members of such a group have known drug-drug interactions according to a DDI knowledgebase, then the remaining group members should be reviewed by an expert to determine why they don’t have (known) DDIs. The challenge is that none of our previously developed AbNs could be applied to the NDF-RT. In this paper, we present a new AbN, expressly developed for the NDF-RT and for the purpose of discovering candidate DDIs.

NDF-RT uses a description logic-based concept model to define drugs according to various aspects, e.g., active chemical ingredient, mechanism of action, physiologic effect, therapeutic intent, and dosage form. Each aspect is represented by a separate concept hierarchy and the aspects of each drug are expressed via roles. For example, the drug concept Aspirin/Caffeine has two has ingredient roles, to Aspirin and to Caffeine.

Abstraction networks (AbNs) [2] are compact, visual terminology summaries, based on grouping “similar” terminology elements together into groups. (The meaning of “similarity” is terminology-dependent.) One type of AbN that was previously applied to description logic-based terminologies is the partial-area taxonomy [3], thus one would expect that this AbN could be applied to the NDF-RT. However, due to NDF-RT’s highly specialized structure, our previously developed methods for deriving AbNs are not applicable to it, because the majority of NDF-RT’s hierarchies have no roles emanating from their concepts. The existence of such roles is the basis for our previously developed AbNs for description logic-based terminologies.

In this paper, we describe the derivation of a new kind of AbN called an Ingredient Abstraction Network (IAbN), which summarizes NDF-RT’s chemical ingredients and their associated drug concepts. The NDF-RT distinguishes between different dosage forms of the same drug. However, for the purpose of the discovery of potential DDIs we can safely ignore such distinctions in our algorithms. The resulting IAbN turned out to be not sufficiently compact, which is a desirable feature. Thus, we developed a secondary abstraction mechanism (“Aggregate IAbN”) that creates an IAbN with fewer groups and each group stands for a collection of groups from a “complete” IAbN (i.e., a non-aggregate IAbN). The Aggregate IAbN derivation algorithm is parameterized to allow users control over the degree of summarization that is achieved.
Background

NDF-RT is a formal representation of the VHA National Drug File (NDF) [4], which is a drug classification hierarchy used to group orderable drug products into one of 579 drug classes. NDF is used to support VHA’s clinical applications. NDF-RT’s Mechanism of Action, Physiologic Effect and Chemical Ingredients hierarchies were created by matching VHA drug ingredient names to terms from the National Library of Medicine (NLM)’s Medical Subject Headings (MeSH) [5]. Specifically, the Chemical Ingredients (CI) hierarchy was derived from MeSH’s Chemicals and Drugs Category. The Mechanism of Action and Physiologic Effect hierarchies were also initially created based on MeSH [6] and then extended. NDF-RT organizes concepts around the Pharmaceutical Preparations (PP) hierarchy, the largest one in NDF-RT, with 25,093 concepts (July 2014 version). Besides IS-A roles, PP concepts can have roles to concepts in other hierarchies to define drugs according to their various aspects. For example, the drug concept Aspirin in PP has the role has ingredient to Aspirin in CI, the second largest hierarchy in NDF-RT with 10,118 concepts.

An abstraction network [2] (AbN) is defined as a compact network of nodes that summarize groups of “similar” concepts in a terminology to capture its “big picture.” The definition of “similar” is based on the type of terminology and the specific kind of abstraction network. AbN nodes are organized in a hierarchy derived from the hierarchical IS-A links of the terminology. In previous work, we have derived various [3, 7-10] kinds of abstraction networks for many different terminology systems, e.g., the Systematized Nomenclature of Medicine – Clinical Terms (SNOMED CT) [11], the National Cancer Institute thesaurus (NCIt) [12], and the Gene Ontology (GO) [13]. These AbNs were shown successful in supporting the identification of concepts with a high likelihood of errors. For a review of different kinds of AbNs and their properties, see Halper et al. [2].

Extensive research has been done on NDF-RT, e.g., on its content coverage, the adequacy of representation, drug normalization and classification. Rosenbloom et al. [14] investigated the adequacy of the representation of the Physiologic Effect hierarchy. The results suggested that the concepts in the Physiologic Effect hierarchy are appropriate for medications. Carter et al. [15] studied drug class names from three sources to understand how drugs were classified, and evaluated NDF-RT’s semantic coverage. They found that NDF-RT can cover more than 90% NDF drug categories. Pathak et al. [16] evaluated the applicability of RxNorm [17] and NDF-RT for classification of medication data extracted from electronic health records (EHRs). Their study demonstrated that the two terminologies can be used together for drug classification.

Methods

Definition: An Ingredient Abstraction Network (IAbN) is an AbN where the nodes summarize (1) the ingredients in the Chemical Ingredient hierarchy and (2) those drug concepts in the PP hierarchy that have no dosage information but that do have at least one has ingredient role to a drug ingredient in the Chemical Ingredient hierarchy.

Refer to Figure 1 for the following definitions that will be used throughout the whole paper. We distinguish between four types of concepts in the Chemical Ingredients (CI) hierarchy. (1) A drug ingredient in CI is the target of has ingredient role(s) from concepts in the Pharmaceutical Preparations (PP) hierarchy. Drug ingredients are chemical ingredients that are used in prescription drugs. (2) A classification ingredient in CI is a concept that “organizes” other drug ingredients. It has drug ingredients as children. (3) A dual use ingredient in CI is both a drug ingredient and a classification ingredient. Note that this is “dual use” in the terminology, not for prescription. A classification ingredient that is not also a drug ingredient is called a strict classification ingredient. (4) Some concepts in CI are neither a drug ingredient nor a classification ingredient. No specific name was chosen for such concepts, as they are not used in this work. The right side of Figure 1(a) illustrates these definitions for an excerpt of 12 CI concepts.

The design of an AbN for the CI hierarchy poses a challenge for several reasons: (1) A lack of roles emanating from CI concepts prevents the derivation of AbNs called partial-area taxonomies [3]. (2) The need to distinguish between drug ingredients and classification ingredients is further complicated by the dual use of many CI concepts. (3) There is a need to summarize the drug concepts, which in NDF-RT are parts of the PP hierarchy, according to their ingredient concepts in CI. (4) To obtain a “big picture” of the classification ingredients, one needs to identify distinct groups of drugs and organize them in a way that supports DDI discovery. (5) A method is needed that allows a user to control the granularity of summarization, so that s/he is not overwhelmed.

IAbN derivation begins with identifying all of the drug concepts in the PP hierarchy with a has ingredient role but with no has_DoseForm role. PP concepts with dosage information are ignored since an ancestor concept, typically a parent (a PP generic drug ingredient) introduces the has ingredient role, which is inherited to such concepts. All of the PP concepts in Figure 1(a), except Pharmaceutical Preparations, have one has ingredient role to a concept in
the CI hierarchy. Different drug concepts in the PP hierarchy can have a has ingredient role to the same CI concept, e.g., both Aspirin and Acetylsalicylic acid have the ingredient Aspirin. PP concepts may also have multiple has ingredient roles, e.g., Aspirin/Caffeine has has ingredient roles to both Aspirin and Caffeine.

**Figure 1.** (a) An excerpt of concepts from NDF-RT’s Pharmaceutical Preparations (PP) and Chemical Ingredients (CI) hierarchies. On the left, drug concepts in the PP hierarchy with no dosage information have a shaded background. On the right, seven drug ingredients are outlined in pink and five classification ingredients have a pink background. Two concepts, Aminosalicylic acid and Warfarin, are both drug ingredients and classification ingredients, i.e., they are dual use ingredients. Ethyl Bicoumacetate is neither a drug ingredient nor a classification ingredient. (b) CI revisited: Drug ingredients (not shaded) and their has ingredient roles (shaded). Each drug ingredient is color-framed according to its lowest common ancestor classification ingredient according to its lowest common ancestor classification ingredient. (c) The final IABN for the excerpt of Figure 1(a). Ingredient groups are shown as white boxes that are labeled with the name of the lowest common ancestor from 1(b). Also shown are the total number of ingredient concepts summarized by the group, and the total number of drug concepts [with no dosage information in the PP hierarchy] with has ingredient roles pointing to the CI hierarchy. Child-of links between ingredient groups are shown as upward directed arrows.

Next, drug ingredients (see definition above) are identified by collecting the target concepts of all the has ingredient roles. Classification ingredients (again, see definition above) are identified by analyzing the parent concept(s) of each drug ingredient. Additionally, for each drug ingredient, the lowest ancestor(s) that are a strict classification ingredient(s) are identified, with the intention of finding lowest common ancestor classification ingredients for groups of drug ingredients. For example, for the Aspirin CI concept, the lowest ancestor that is a strict classification ingredient is Salicylates. Salicylates is the lowest common ancestor for Aspirin and Magnesium salicylate. For Warfarin Sodium its parent concept, Warfarin, is a classification ingredient but it is also a drug ingredient (i.e., it is dual use). Thus, the lowest ancestor of Warfarin Sodium that is a strict classification ingredient is Warfarin’s parent, 4-Hydrocoumarins. Many CI hierarchy concepts have multiple parents, thus, a given drug ingredient may have more than one lowest ancestor which is a strict classification ingredient.

Drug ingredients are grouped together according to their lowest common ancestor(s) that are strict classification ingredients. For example, Aspirin and Magnesium salicylate both share Salicylates as lowest common ancestor. Similarly, Warfarin and Warfarin Sodium share 4-Hydrocoumarins as a lowest common ancestor. Figure 1(b) models the right side of 1(a) and shows the drug ingredient groups induced by the lowest common ancestors.
Next, each strict classification ingredient is made into a root for its ingredient group. Thus Salicylates becomes the root of the group with Aspirin and Magnesium salicylate in it. The CI root concept, Chemical Ingredients, is also a root. Figure 1(c) shows how roots stand in for their groups. The line “2 Ingredients” under Salicylates indicates how much information is summarized. Ingredient groups are not disjoint; drug ingredients with multiple parents may be summarized by multiple ingredient groups. With this we have achieved a summary of the “right side” (the Chemical Ingredients) of Figure 1(a). In the next step, we include information from the left (PP) side into Figure 1(c).

For each ingredient group, the PP drug concepts that have a has ingredient role to a drug ingredient in the ingredient group are identified. For example, the Aspirin and Acetylsalicylate Sodium drug concepts in PP both have Aspirin in CI as the target of their has ingredient roles. The Aspirin drug ingredient belongs to the Salicylates ingredient group, thus, the Aspirin and Acetylsalicylate drug concepts from PP are also summarized by the Salicylates ingredient group. This is expressed by the line “3 Drugs” under Salicylates in 1(c). (The third is Magnesium salicylate). Since ingredients may belong to multiple ingredient groups, a given PP drug concept may be in multiple ingredient groups.

Within the IAbN, ingredient groups are organized into a hierarchy according to child-of links derived from the underlying IS-A hierarchy. An ingredient group A is a child-of another ingredient group B if A’s root has B’s root as an ancestor and there are no other roots on any path from A’s root to B’s root. An ingredient group may be child-of multiple ingredient groups. In the visualization of an IAbN it is necessary to organize the ingredient groups in a way that helps the summary reflect the “big picture.” Thus, ingredient groups are organized into color coded levels according to the length of the longest child-of path to the root ingredient group (Chemical Ingredients). Figure 1(c) shows the IAbN derived from the NDF-RT excerpt in Figure 1(a).

We note that there are CI concepts that are neither drug ingredients nor classification ingredients, e.g., Ethyl Bicoumacetate. (See case (4) in the above definitions and Figure 1(a).) This occurs when the drug ingredient is modeled in CI but no PP drug concept has a has ingredient role to this drug ingredient. For the current research, such concepts are not summarized by any ingredient group and are not considered part of the IAbN. In the Discussion we propose methods for extending the IAbN to include these concepts. Additionally, we note that drug concepts with dosage information are not associated with an ingredient group. However, the ingredient group(s) of these drug concepts can be identified via their parents, which are grouped into at least one ingredient group.

**Aggregate Ingredient Abstraction Network (Aggregate IAbN)**

One significant issue we encountered when deriving the IAbN for the complete CI hierarchy (“complete IAbN”) was its large size. While the complete IAbN is significantly smaller and less complex than the underlying CI hierarchy, there are still too many nodes, many of which “summarize” only one drug ingredient. To improve the efficacy of the IAbN to function as a summary, we now introduce a parametric method for controlling the granularity of summarization. This secondary summarization approach is based on the following heuristic: An ingredient group that summarizes a relatively large number of drug ingredients is more important within the CI hierarchy than an ingredient group that summarizes relatively few drug ingredients.

However, controlling the granularity of summarization provided by the IAbN requires more than just hiding small ingredient groups. Simply hiding these groups leads to a loss of information and inconsistencies in the child-of hierarchy. To obtain a more compact secondary summary of the CI hierarchy’s content we have developed a parametric IAbN called an Aggregate Ingredient Abstraction Network (“Aggregate IAbN”) that aggregates “small” ingredient groups into their larger direct ancestor ingredient groups.

Given a bound b (a natural number), an Aggregate IAbN is derived in the following way. Starting from the root ingredient group, Chemical Ingredients, the hierarchy of ingredient groups is traversed downwards using a Topological Sort; that means, an ingredient group is processed only after all of its parent ingredient groups have been processed. We define a) aggregate ingredient groups, b) removed ingredient groups, and c) regular ingredient groups. A removed ingredient group is an ingredient group in the complete IAbN with fewer than b ingredients. The root ingredient group, Chemical Ingredients, is by definition not a removed ingredient group. Approximtely speaking, an aggregate ingredient group is an ingredient group that summarizes itself and one or more removed ingredient groups. A regular ingredient group is not changed when going from a complete IAbN to an Aggregate IAbN. Thus the Aggregate IAbN consists of aggregate ingredient groups and regular ingredient groups.

More precisely, in an Aggregate IAbN, a removed ingredient group i is included into an aggregate ingredient group a if i is a descendant of a in the complete IAbN and there is no other aggregate ingredient group on any child-of path from i to a. Removed ingredient groups are “hidden” in the Aggregate IAbN. Consider the IAbN excerpt in Figure 2 and a bound b=10. Chemical Ingredients has two child ingredient groups with fewer than ten drug ingredients.
(Glycosides and Heterocyclic Compounds) and several further descendants with fewer than ten drug ingredients (e.g., Glucosides and Piperidones). Some of these further descendant ingredient groups may be direct descendants of other ingredient groups that have more than ten drug ingredients, e.g., Piperidones is child-of Piperidines, which summarizes 47 ingredients.

Consider the two removed ingredient groups that are children of Chemical Ingredients in the IAbN of Figure 2(a), with \( b = 10 \): Glycosides and Heterocyclic Compounds. There are no intermediate aggregate ingredient groups, so these children are included into Chemical Ingredients in the Aggregate IAbN of Figure 2(b). Furthermore, the removed ingredient group Glucosides is a child of Glycosides. The closest aggregate ingredient group above Glucosides that is not a removed ingredient group, via the path through Glycosides, is Chemical Ingredients. Thus, Glucosides is included into the Chemical Ingredients aggregate ingredient group as well. Note: \( I = 14 \) in Chemical Ingredients in Figure 1(b), summarizing the removed ingredient groups, while \( I = 3 \) in Chemical Ingredients in 1(a).

**Figure 2.** (a) An excerpt of 13 ingredient groups from the complete IAbN. Child-of links are shown as arrows. Removed ingredient groups (fewer than ten ingredients) have a red background. (b) The Aggregate IAbN (\( b = 10 \)) for (a). Aggregate ingredient groups are shown as rounded-corner white rectangles, labeled with the numbers of ingredients, drugs and groups they summarize. (\( I = \) Ingredients; \( D = \) Drugs; \( G = \) Groups that were removed). Regular ingredient groups are white rectangles. They have the same \( I \) and \( D \) value in (a) and in (b).

Aggregate ingredient groups are not necessarily disjoint in terms of which removed ingredient groups they summarize. There may be two or more paths to different aggregate ingredient groups that satisfy the above condition. In Figure 2(a) Pipecolic Acids is a child-of Piperidines and Acids, Heterocyclic. On the path from Pipecolic Acids to Chemical Ingredients via Acids, Heterocyclic there are only removed ingredient groups. Thus, in the Aggregate IAbN of Figure 2(b), Pipecolic Acids is summarized by both Piperidines and Chemical Ingredients.

The child-of links between ingredient groups in the Aggregate IAbN are established according to the ingredient group hierarchy of the complete IAbN. If an aggregate ingredient group or a regular ingredient group is a child-of a removed ingredient group, then its child-of link(s) in the Aggregate IAbN go to the aggregate ingredient groups above the removed ingredient group. In other words, the child-of link is redirected to the aggregate ingredient group that summarizes the removed ingredient group.

**IAbN Supporting the Discovery of New Candidates for Pharmacodynamic-based DDIs**

One application of the IAbN is the discovery of new candidate drug-drug interactions (DDIs) not appearing in a DDI knowledgebase. Given is a set of DDI rules in the form (Drug1, Drug2, Clinical Consequence), such that Drug1 and Drug2 can be coded by NDF-RT drug ingredient concepts. In pharmacology, drugs with the same chemical ingredients tend to have similar DDIs [18]. By reviewing the DDIs associated with the drug ingredients in an IAbN ingredient group one may uncover new candidate pharmacodynamic-based DDIs.

To illustrate this process, we use an example from First Databank, Inc.’s DDI knowledgebase [19]. Consider the 18 drug ingredients in the Aggregate IAbN’s Salicylates ingredient group (Figure 5(b)), 13 of which appear in FDB’s DDI knowledgebase. The DDI interactions between ten of these salicylates and seven anticoagulant drugs are “Avoid concurrent use when possible” (AVD) and “Increases the effect of latter drug” (INL), for a total of 70 DDIs between these two groups. However, three extra Salicylates (balsalazide, mesalamine, and salsalate) have no DDIs with any anticoagulant in the FDB DDI knowledgebase. This raises doubt regarding the existence of DDIs between the seven anticoagulants and these three salicylates. Indeed, upon investigating the DDIs between the three extra salicylates and these seven anticoagulants in another source [20], we discovered DDIs between the three salicylates and three of the anticoagulants. The 70 old and nine new DDIs are described in Figures 3(a) and 3(b), respectively. The reason FDB did not include these new candidate DDIs in their knowledgebase is that in these cases the drug formulation has a low potential for interaction. Nevertheless, FDB staff (JKU) confirmed that this example
demonstrates the fact that summaries of NDF-RT have the potential for supporting the discovery of new candidate DDIs. Of course, pharmacological investigation is required for each potential DDI.

Results

We derived a (non-aggregate) IAbN for the February 2015 release of NDF-RT’s Chemical Ingredients (CI) hierarchy which consists of 10,144 concepts. The complete IAbN consists of 859 ingredient groups which summarize 2,664 drug ingredients and 6,850 PP hierarchy drug concepts. We define the abstraction ratio of the IAbN to be the average number of drug ingredients per ingredient concept. The abstraction ratio of the February 2015 IAbN is 3.1 (=2,664/859). There are 813 drug ingredient concepts summarized by more than one ingredient group and each such drug ingredient is summarized by an average of 2.25 ingredient groups.

Figure 3(a). Illustration of 70 DDIs. There are 10x7=70 AVD and INL DDIs between the ten salicylates on the left and the seven anticoagulants on the right listed in Figure 3(a). Nine new candidate DDIs not appearing in FDB’s DDI knowledgebase. (b) Nine new candidate DDIs not appearing in FDB’s DDI knowledgebase. The DDIs of (a) combined with the aggregate ingredient group of salicylates in the IAbN of NDF-RT supported the discovery of nine DDIs that were confirmed by another source.

Figure 3(a). Illustration of 70 DDIs. There are 10x7=70 AVD and INL DDIs between the ten salicylates on the left and the seven anticoagulants on the right listed in Figure 3(a). Nine new candidate DDIs not appearing in FDB’s DDI knowledgebase. (b) Nine new candidate DDIs not appearing in FDB’s DDI knowledgebase. The DDIs of (a) combined with the aggregate ingredient group of salicylates in the IAbN of NDF-RT supported the discovery of nine DDIs that were confirmed by another source.

… drug concepts summarized by each ingredient group is 7.97. Figure 4 shows an excerpt of 149 of the IAbN’s ingredient groups, as the complete IAbN is too large to fit on one page. By reviewing the ingredient groups of the IAbN one can see the major types of drug ingredients used in NDF-RT’s drugs. For example, the Polymers group (Level 2: green) summarizes 26 ingredients and 81 drugs, Piperidines (Level 3: blue) summarizes 47 ingredients and 73 drugs, Tetracyclines summarizes 17 ingredients and 26 drugs, Ethanolamines summarizes 45 ingredients and 232 drugs, and Penicillins summarizes 34 ingredients and 64 drugs.

One deficiency of this complete IAbN is the relatively large number of “small” ingredient groups. For example, there are 312 (36%) ingredient groups that “summarize” only one drug ingredient. This is the reason why we developed the Aggregate IAbN methodology. The Aggregate IAbN can be used to combine these small “groups” into larger aggregate ingredient groups. We derived a few Aggregate IAbNs using bounds (b=) of 2, 6, 11, and 15, and investigated the structural properties of each resulting Aggregate IAbN (Table 1). The Aggregate IAbN in Figure 5(a), created using b=11, is composed of 30 regular ingredient groups (e.g., Ergotamines) and 88 aggregate ingredient groups (e.g., Saliycylates) which summarize 711 removed ingredient groups. Figure 5(b) illustrates how an aggregate ingredient group can be “dynamically expanded” with a software tool, so that its “summarized” removed ingredient groups can be recovered and viewed on demand.

IAbN-Based DDI Discovery Results

Table 2 shows the results of looking for new candidate DDIs using the Aggregate IAbN. Column 1 lists the interaction type. Column 2 represents the number of concepts of Group 1 (e.g., Salicylates) in NDF-RT. Column 3 represents the number of concepts in FDB among those in Column 2. Column 4 shows the number of concepts of Group 2 (e.g., Anticoagulants) interacting with Group 1 according to information in FDB’s knowledge base. Column 5 describes the number of concepts of Group 1 having no interactions with Group 2 in FDB. Column 6 describes the number of concepts among those in Column 5 for which we have found drug interactions from public sources. Column 7 lists the number of drug interactions found in those public sources.
Figure 4. An excerpt of 149 (17%) ingredient groups from the February 2015 CI hierarchy’s IABN. The smaller ingredient groups have been hidden. Child-of links are hidden for readability and longer ingredient group names are truncated. The number of ingredients and drugs summarized by each ingredient group is shown in parentheses and prepended with I: and D:, respectively. Salicylates and Aminosalicylic acids, from Figure 1(c), are highlighted in yellow.
Figure 5. (a) The Aggregate IAbN (b=11) for CI. (b) The Salicylates aggregate group expanded.

</table>
Table 2 lists five new candidate ingredient pairs (rows) for Salicylates. For each such pair Column 5 lists the number of salicylates from NDF-RT appearing in FDB but not having such a DDI. From those, Column 6 lists the number of salicylates that have DDIs with drugs of Group 2 in a public source and Column 7 lists the number of such DDIs. For example, row 1 reports the case described in Figure 3. However, the three extra salicylates e.g. mesalamine have no interactions with dicumarol, warfarin, and anisindione in FDB because their drug formulations produce localized concentrations in the gastrointestinal tract but not systemic blood levels where they will interact with anticoagulants.

In the last five rows of Table 2, we list ingredient pairs with hydantoins. Looking for hydantoins in NDF-RT that also appear in FDB but have no DDIs, a base formulation representation of the fosphenytoin ingredient in NDF-RT is found, for which public sources list DDIs. A review of FDB’s knowledge base by a coauthor (JKU) found the DDIs associated with the salt formulation representation of this ingredient, fosphenytoin sodium, rather than with fosphenytoin. In this case, the candidate base ingredient does not exist in pharmaceutical formulations and thus there is no clinical data gap. However, there may be other instances, e.g., erythromycin base with physical dosage forms that would be considered candidates for inclusion in DDIs. Hence, these DDI candidates are legitimate.

Discussion

The development of the IAbN (Ingredient Abstraction Network) represents an important first step in the summarization of NDF-RT’s drug concepts according to their various classifications. The IAbN makes it possible to compactly visualize the major types of ingredients, and the drugs which contain them, as they exist in NDF-RT. One reason that the IAbN derivation methodology works well for the CI hierarchy is that the majority of drug ingredient concepts in NDF-RT are leaves (i.e., have no children) or are near the bottom (leaves) of the CI hierarchy.

The IAbN derivation approach is applicable beyond the CI hierarchy. For example, it is possible to apply the IAbN derivation methodology to the Mechanism of Action (MOA) hierarchy, summarizing NDF-RT’s drugs according to their mechanisms of actions, rather than their chemical ingredients. In a future study, we will investigate the structural properties of IAbNs derived for NDF-RT’s other classification hierarchies.

The Aggregate IAbN provides a secondary summarization mechanism that allows control over the granularity of summarization provided by an IAbN. The Aggregate IAbN lets a user see a very compact representation of a terminology hierarchy. Fine control is possible by choosing different values for b (the bound). The software tool (under development) for displaying IAbNs lets the user “re-expand” aggregate ingredient groups and lets her/him inspect previously hidden removed ingredient groups. In other words, the knowledge in the removed ingredient groups is not lost; it is just hidden and can be displayed by the tool upon demand. One issue to consider in future research is when one should use an Aggregate IAbN versus the complete IAbN. A usability study of the software tool and a study of the trade-offs between different abstraction ratios in Aggregate IAbNs will be performed.

In future research, we will investigate the use of alternate methods for controlling the amount of information of an IAbN that is displayed. This will include generating IAbNs that are created, e.g., by choosing a specific ingredient group and then viewing all of its ancestor and/or descendant ingredient groups. Additionally, we will investigate the creation of Aggregate IAbNs according to the number of PP drug concepts, rather than the number of ingredient concepts. This approach would provide an alternate secondary summary that highlights which ingredient groups summarize more PP drugs. Different users with various professional profiles may prefer different options according to their emphasis on ingredients or on drugs.

One significant difference between the IAbN and our previously developed abstraction networks is that not every concept in the CI hierarchy is summarized by an ingredient group. In our previous AbNs, every concept was always summarized by at least one AbN node [2]. However, since a CI hierarchy concept may be neither a classification ingredient nor a drug ingredient, it may be omitted from the IAbN, e.g., Ethyl biscoumacetate in Figure 1. In fact, the majority (6,621, 65.3%) of concepts in the CI hierarchy are not summarized by any ingredient group. This situation occurs for several reasons. The CI hierarchy was primarily imported from MeSH and many of the concepts from MeSH are too general and do not represent ingredients that could be used in drugs. Other ingredient concepts may not be relevant to the drugs in NDF-RT, as no drug includes them as an ingredient.

The goal of the IAbN is to summarize NDF-RT’s drugs according to their ingredients. Thus, it is not necessary to summarize CI concepts that are not used as ingredients in drugs. However, it is conceivable that there may be applications which need access to these concepts. In a future study we will investigate ways of summarizing non-classification/non-drug ingredient concepts. One potential idea is to associate each such concept with its closest classification ingredient. Using such an approach, Ethyl biscoumacetate would be summarized by the 4-Hydroxycoumarins ingredient group.
Conclusions

In this paper, we introduced the Ingredient Abstraction Network (IAbN) to summarize the concepts in NDF-RT’s Chemical Ingredients hierarchy. A parametric method for controlling the level of summarization in a secondary abstraction network, called Aggregate IAbN, was introduced. The IAbN was shown to support the discovery of new candidate drug-drug interactions in a DDI knowledgebase.

Machine Learning Approaches for Detecting Diabetic Retinopathy from Clinical and Public Health Records

Omolola Ogunyemi, PhD,1,3,4 Dulcie Kermah, MPH,2,3

Abstract

Introduction: Annual eye examinations are recommended for diabetic patients in order to detect diabetic retinopathy and other eye conditions that arise from diabetes. Medically underserved urban communities in the US have annual screening rates that are much lower than the national average and could benefit from informatics approaches to identify unscreened patients most at risk of developing retinopathy.

Methods: Using clinical data from urban safety net clinics as well as public health data from the CDC’s National Health and Nutrition Examination Survey, we examined different machine learning approaches for predicting retinopathy from clinical or public health data. All datasets utilized exhibited a class imbalance.

Results: Classifiers learned on the clinical data were modestly predictive of retinopathy with the best model having an AUC of 0.72, sensitivity of 69.2% and specificity of 55.9%. Classifiers learned on public health data were not predictive of retinopathy.

Discussion: Successful approaches to detecting latent retinopathy using machine learning could help safety net and other clinics identify unscreened patients who are most at risk of developing retinopathy and the use of ensemble classifiers on clinical data shows promise for this purpose.

Introduction

Diabetic retinopathy arises when excess glucose in the bloodstream resulting from diabetes mellitus causes damage to the blood vessels of the retina. Among US adults between the ages of 20 and 74 years, diabetic retinopathy is the leading cause of blindness.1,2 Diabetes affects an estimated 29.1 million people in the United States.3 In a Centers for Disease Control and Prevention (CDC) assessment performed between 2005 and 2008, 4.2 million or 28.5% of people with diabetes aged 40 years or older in that time period had diabetic retinopathy.3

Annual eye examinations for diabetic patients are recommended in order to detect and treat diabetic retinopathy in a timely manner, since blindness from this condition is preventable with early detection and the use of laser photocoagulation therapy. While the US national annual eye screening average for diabetic patients is 60%,4-8 some studies of the urban safety net setting have shown annual screening rates for inner-city diabetic patients to be lower than 25%.9-11 Previously, we presented findings from a study that sought to examine issues affecting that disparity between national and urban safety net screening rates by highlighting the feasibility and challenges of implementing teleretinal screening for diabetic retinopathy in an urban safety net setting facing eyecare specialist shortages.12-15

We also examined the potential for developing predictive models for detecting diabetic retinopathy on safety net clinic data. Here, we build on knowledge gained from our earlier diabetic retinopathy predictive modeling work;16 and we also examine the utility of using National Health and Nutrition Examination Survey (NHANES) public health data collected by the CDC in our model development effort, inspired by a study from South Korea that utilized similar public health data from that country to create predictive models for diabetic retinopathy.17 Our long-term goal is to develop predictive models for diabetic retinopathy that are appropriate for the safety net setting.

Risk factors for diabetic retinopathy cited in the literature include duration of diabetes,18-20 high blood glucose/poor blood sugar control,18-21 high blood pressure,18-21 dyslipidemia,18 high cholesterol,19 pregnancy,18 nephropathy,20 and obesity.18 Other known risk factors for diabetic retinopathy include inflammation,18 puberty (in Type 1 diabetes),18 ethnicity,18 insulin treatment (for Type 2 diabetes - related to poor blood glucose control), tumor necrosis factor receptors,22 and smoking23 (in one study, pack-years of smoking were found to be borderline significant in predicting retinopathy in younger adults;24 however, other studies have found the relationship between retinopathy and smoking to be inconsistent25, 26). Risk factors such as high blood glucose, duration of diabetes and high blood pressure are considered to be stronger predictors of retinopathy than other risk factors.18 Models that
incorporate some or all of these known risk factors as well as other factors that may not have been considered in the literature could be useful for prediction. Aside from tumor necrosis factor receptors, most of the risk factors listed above are routinely collected and stored in electronic health records in the course of care for a diabetic patient and thus could be used to create predictive models to screen for latent retinopathy in diabetic patients who have not received an annual eye examination as recommended in clinical practice guidelines.

There are different stages of diabetic retinopathy, which in order of increasing severity are: mild non-proliferative diabetic retinopathy (NPDR), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy. On eye examinations, there are visible developments in the retina as diabetic retinopathy progresses that aid clinicians in distinguishing one stage of retinopathy from another. These include micro-aneurysms, intra-retinal hemorrhages, retinal ischemia (cotton-wool spots), venous beading, and finally, the proliferation or growth of fragile new blood vessels that can bleed on the retina’s inner surface.27 For the present study, our goal is to develop methods to identify patients at high risk of diabetic retinopathy in order to have them come in to a care site for a teleretinal eye screening or an in-person eye examination. This means that the methods developed will predict the presence or absence of retinopathy generally; retinopathy staging is not attempted (to accurately stage retinopathy, data from digital retinal images would be required).

For the CDC NHANES dataset utilized in the present study, which contains merged data from 2005-2006 and from 2007-2008, we found that only 13% (158 instances) involved patients who had diabetic retinopathy, while 87% (1081 instances) did not. In our earlier predictive modeling work, the dataset collected from urban safety net clinics corresponded to 513 diabetic patients, with approximately 25% of instances (130 instances) having an outcome of diabetic retinopathy and roughly 75% of the instances (383 instances) having an outcome of no diabetic retinopathy. The diabetic retinopathy rate of 25% in that clinical dataset is roughly in line with the projected US rate of 28.5% between 2005 and 2008 referenced above. Using standard classifiers, the best classification result on the clinical data from 513 patients was achieved with a Bayesian network that had a sensitivity of 26.2%, a specificity of 94.5%, an Area Under the ROC Curve (AUC) of 0.71, a negative predictive value of 79%, and a positive predictive value (precision) of 61.8%.16

One of the difficulties with predicting diabetic retinopathy solely from clinical or public health data for screening outreach purposes (without the benefit of digital retinal imaging features that are clearly only associated with retinopathy) is that there is some overlap between the classes corresponding to “retinopathy” and “no retinopathy,” which makes the two classes difficult to separate. Additionally, as described above, datasets based on clinical or public health records may be mostly skewed towards “no retinopathy.” A class imbalance is said to occur when one of the outcomes of a learning problem, especially the outcome of interest, is underrepresented in the dataset from which predictive models are to be learned.28 As each dataset used for the present study exhibits a class imbalance and we have previously had modest results on the clinical dataset with standard classifiers, we turn to machine learning approaches designed to deal with the class imbalance problem in this study. Galar et al identify four key approaches to dealing with the class imbalance problem: (1) techniques that modify existing algorithms for a standard classifier in order to emphasize the significance of satisfactorily classifying the minority class; (2) data preprocessing methods, such as undersampling the majority class or oversampling the minority class; (3) cost sensitive approaches that combine both algorithm and data preprocessing methods, and, (4) ensembles of weak learners (classifiers) that take advantage of data preprocessing and other methods.28 For this study, we focused on the use of ensembles of weak learners that take advantage of data preprocessing methods.

Methods

Approval to use clinical data for the study was obtained from the Charles Drew University Institutional Review Board.

Data sources:
Clinical data for the study were previously obtained from six federally qualified health centers that serve as primary care clinics for un- and under-insured patients in South Los Angeles. This was done through a retrospective review of medical records for 513 patients with type 2 diabetes who received an eye examination for diabetic retinopathy from ophthalmologists via teleretinal screening and who obtained care at the clinical sites in 2011.
Public health data for the study was obtained from the US NHANES cross-sectional data set. The National Health and Nutrition Examination Survey is conducted by the National Center for Health Statistics, using a stratified multistage probability design to obtain a representative sample of the total civilian, non-institutionalized US population. Since 1999, the NHANES has released data at 2-year intervals. The NHANES collects questionnaire data during face-to-face home interviews and includes a physical examination, as well as the collection of laboratory data. We used data from 2005-2006 and 2007-2008. These years had the only datasets that matched 95% of the variables utilized in the previously mentioned Korean study.\textsuperscript{17}

Sample from NHANES:
There were a total of 20,497 participants from NHANES 2005 to 2008. For this analysis, we only included persons with diabetes (N=2,874). Of those who had diabetes, participants who had complete data on the presence or absence of diabetic retinopathy were included in the analysis. Our analytical sample was based on a total of 1239 people with diabetes who had been told whether or not they had retinopathy. Participants were identified as being diabetic if they met at least one of the following criteria; plasma fasting glucose ≥ 126 mg/dL, serum glucose ≥ 200mg/dL, glycohemoglobin ≥ 6.5%, responding “Yes” to the question “Other than during pregnancy, have you ever been told by a doctor or health professional that you have diabetes or sugar diabetes?,” responding “Yes” to the question, “Are you now taking insulin?,” responding to the question “Are you now taking diabetic pills to lower your blood sugar? These are sometimes called oral agents or oral hypoglycemic agents.”

Classification Methods:
Variables with 50% or more of their values missing were not included in the datasets used for machine learning. Missing data for the remaining variables (less than 50% of values missing) were handled by using imputation techniques. For the datasets analyzed, we performed feature subset selection using the Lasso.\textsuperscript{29} Since we used standard (single) classifiers in our previously published study, for this study, we use ensembles, which combine classifiers and may perform better than a single classifier approach. We learned ensemble classifiers based on decision tree learners designed to handle class imbalances such as RUSBoost,\textsuperscript{30} which utilizes majority class undersampling. For contrast, we also learned ensemble classifiers using AdaBoost.M1,\textsuperscript{31} which uses adaptive boosting to combine the weighted output of several weak learners to produce a boosted classification output. On its own, AdaBoost.M1 has no special accommodation for class imbalances. The ensemble classifiers were learned on the full feature set as well as the feature subsets obtained. We reserved 20% of each dataset for testing and then performed 10-fold cross validation on the remaining 80% of the dataset, selecting the best classifier from the cross-validation process for use on the reserved test set. Analyses were performed using MATLAB\textsuperscript{32} and Weka.\textsuperscript{33}

For each classifier, we measured sensitivity or the true positive rate (the total number of cases classified as having diabetic retinopathy divided by the total number of cases actually involving retinopathy), specificity or the true negative rate, the AUC, which represents the trade-off between the true positive rate/sensitivity and the false positive rate or 1 – specificity, and accuracy (the total number of correctly classified cases divided by the total number of cases).

Discussion

The results show that the clinical dataset was moderately predictive for diabetic retinopathy, with the best RUSBoost ensemble having an accuracy of 73.5%, sensitivity of 69.2%, specificity of 55.9%, and AUC of 0.72 on previously unseen instances (the test data set aside). As the AdaBoost ensemble results show by comparison, there is a trade off of an increase in sensitivity with majority class undersampling in RUSBoost for a decrease in specificity. For the purpose of identifying individuals who have not yet received an annual eye examination but may have latent retinopathy, the increase in sensitivity provided by RUSBoost is important. In previous work on the same dataset, the best standard classifiers achieved stellar specificity (>90%) but poor sensitivity (<28%), which made them less suitable for screening purposes. The best AdaBoost ensemble achieved better sensitivity than a standard Bayesian network classifier (34.6% versus 26.2%) but much worse specificity (63.7% versus 94.5%). A greater improvement in sensitivity and reduction in specificity was also seen for the best RUSBoost ensemble results (sensitivity of 69.2% versus 26.2% for the Bayesian network classifier and specificity of 55.9% versus 94.5% for the Bayesian network classifier). The improved sensitivity results on the clinical data with RUSBoost are encouraging, since the data include features that are routinely collected by and available to clinics treating diabetic patients and could provide the basis of targeted outreach to noncompliant patients.

The classifier ensembles developed on the public health data were not useful, with AUC’s indicating that they were no better than flipping a coin at discriminating between cases of retinopathy and cases of no retinopathy. While the accuracy results for AdaBoost were high on the public health dataset, it is clear from the best AdaBoost sensitivity results (3.2%) and the best specificity results (85.8%) that the ensembles tended towards predicting “no retinopathy” in almost every situation and was not as adaptive in adjusting to misclassifications as might have been expected.

The NHANES dataset utilized relies on physical examinations as well as patient questionnaires for some key variables; poor responses to the questionnaires may have led to poorer quality data for learning. For example, duration of diabetes, which is known to be a major risk factor for retinopathy had to be derived from questionnaire responses about the age at which a patient was diagnosed with diabetes (subtracting the age of diagnosis from the current age). There were negative durations in some cases and over 70% missing data for this key variable; these inaccuracies meant that we were not able to include duration of diabetes for the public health data analyses in the present study. It is likely that a public health dataset with more variables related to retinopathy measured clinically and fewer missing data would produce better results. However, a recently published study that looked only at a subset of 266 people over the age of forty from NHANES who were newly identified by the paper’s authors as having diabetes had more promising results with regards to predicting retinopathy, with a best AUC of 0.74, a low positive predictive value (precision) of 22% and a high negative predictive value of 99%. 34

Future work includes collecting additional clinic data, applying novel methods for learning with a class imbalance to the data and developing software from the predictive models developed. The software is intended for clinics to use for targeted outreach to patients who have not received an annual eye examination (in addition to their usual outreach to diabetic patients). Predictive models that are able to accurately identify individuals with diabetes who may have developed retinopathy but are not yet aware of it would be invaluable for outreach purposes in order to prevent avoidable blindness from diabetic retinopathy.

Understanding patients’ health and technology attitudes for tailoring self-management interventions

Abstract
Healthcare providers are moving towards tailoring self-management interventions to include the communication technologies patients use in daily life. Accurate understanding of patients’ attitudes towards both technology and involvement in managing chronic conditions will be critical for informing effective self-management strategies. The tailoring of these interventions, however, could be undermined by providers’ implicit biases based on patient age, race, and education level that have been shown to negatively affect care. To inform the design and tailoring of self-management interventions, we elicited attitudes toward technology use and participation in care of 40 participants in a maximum variation sample. The analysis revealed three participant clusters—“Proactive Techies,” “Indie Self-Managers,” and “Remind Me! Non-Techies”—that represent varying attitudes toward health behaviors and technologies that were independent of race, education level, and age. Our approach provides insight into how people prioritize important values related to health participation and technology.

Introduction
Self-management of chronic conditions, such as diabetes and asthma, creates considerable burden for patients. Effective self-management requires patients to be active participants in treatment by taking medications, making lifestyle changes, and regulating emotions¹,². The day-to-day skills involved in self-management include identifying problems, selecting solutions, using information sources, collaborating with providers, changing behavior, and evaluating results². This dynamic process goes well beyond adhering to treatment plans, and considers the patient holistically in the context of the attitudes and values that influence their everyday behaviors.

Self-management interventions are designed to alleviate some of the burden of chronic illness care. Self-management support through the internet, over the phone, and in person have proven effective, and the delivery of programs via SMS and other mobile platforms are promising³–⁸. However, tailoring and personalization of self-management interventions is limited by the lack of methods for understanding how patients prioritize health information and tools to accomplish self-care goals. Moreover, implicit biases of providers, such as ascribing preferences for health information and treatments on the basis of age, race, literacy, and gender, can differentially affect provision of chronic care for underrepresented minorities⁹–¹⁶. Therefore, understanding patients’ attitudes toward health and technology is especially important for informing unbiased and patient-centered interventions that augment patients’ health self-management strategies in everyday life.

To address the lack of understanding of the attitudinal factors that influence patients’ preferences for health information and technology, we studied how patients prioritize tools (e.g. email, cell phones, paper tools) to strengthen their accountability for health self-management. We found that patients’ attitudes toward mobile technology, accountability, and goal-setting were the most distinguishing and influential attitudes on patients’ approaches to health self-management. We also found that patients’ attitudes and values were more influential than demographic characteristics—especially race, age, and education level—on defining health self-management behaviors. We contribute a description of a method for eliciting preferences for self-management support, including attitudes toward adopting technology to attain health goals. Our empirical evidence from this study can inform new approaches to clustering patients and tailoring appropriate self-care support based on the tools, information, and goals they perceive to be essential to managing their health.

Related Work
Previous research on self-management, disparities in use of e-health services, and patterns of technology adoption inform our work. Below, we briefly summarize this literature and describe how our approach to clustering patients based on health and technology attitudes contributes new insights for supporting self-management.
Patient Self-management

Studies show that self-management interventions are effective in supporting patients to manage chronic illness\(^1\)\(^7\)\(^-\)\(^9\). In particular, interventions that systematically support patients to build skills in the three major domains of self-management—medical, role, and emotional—offer the most comprehensive support for self-care\(^1\)\(^2\). Within all three domains, self-management interventions are more likely to succeed if they target problems and strategies that patients perceive as most significant to their health, because the focus on patients’ strategies and concerns is motivating, engaging, and empowering\(^2\). Our approach provides researchers with a holistic perspective well-suited to tailoring self-management programs based on what patients perceive as essential to managing their health. As many healthcare providers are beginning to engage patients in care activities online and over mobile devices, we investigated both health and technology attitudes to understand technology adoption in support of patients’ overarching health goals.

Intervention research

Research on targeting self-management interventions has focused on understanding the sources of variation in the use of e-health services. For example, Goel et al\(^20\) investigated racial disparities in e-health services enrollment, and found that barriers to internet access did not explain these disparities; rather attitudinal barriers were significant. Similarly, Clark et al\(^21\) found that understanding attitudes and health priorities is particularly important for tailoring self-management interventions for socioeconomically vulnerable older adults. Finally, Lyles et al\(^22\) found that differences in portal use by race and ethnicity were not fully explained by differences in age, sex, sociodemographics, health status, or provider factors—particularly for black patients. Therefore, demographic characteristics provide limited help in understanding differences in portal use and how to tailor self-management support programs to the technologies patients use. Our approach to investigating values that influence patients’ use of e-health services can provide alternative perspectives on the attitudes that drive patient engagement in self-management programs.

The importance of understanding the attitudes and beliefs that influence engagement with health technologies may become even more important as intelligent information systems are deployed to support self-management. For example, recent approaches to mHealth care include intelligent systems that adapt to users depending on the patient’s beliefs about illness, medication, and information needs\(^23\). Researchers like Clark et al\(^21\) and Koch et al\(^24\) have called for a greater emphasis on the “self” in self-management, and have brought attention to the importance of understanding patient’s priorities, expectations, and expertise in the care process. Moreover, Valdez et al\(^25\) recently emphasized a “patient work approach” to designing applications aligned with patients’ and their family members' health-related activities. As mHealth service design becomes more adaptive and personalizable, the “self” in self-management will become a focal point for tailored interventions. We demonstrate an approach for “getting to know” the patient that provides insight into how patients prioritize different values related to health and technology.

Finally, Pew\(^26\) data suggests that people from underserved populations, such as people with low education and ethnic minorities, are highly engaged with technology, even compared to privileged populations. These findings undermine implicit assumptions about correlations between low education level or racial minorities and low technology use. However, research by Sarkar et al\(^27\) also suggests that these populations are less likely to use technology to manage their health, which points to the need for researching the disparity between technology adoption for everyday life compared to health management. We demonstrate that qualitative research may provide important insights into the social and attitudinal barriers to adopting e-health services that can explain low technology adoption for health.

Methods

We used a mixed-methods approach that combined in-depth, semi-structured interviews with 40 participants, using a card sorting procedure called Q-methodology\(^28\)\(^,\)\(^29\) to elicit attitudes and opinions from persons managing a chronic illness. Q-methodology has been used in health\(^30\),\(^31\) and technology\(^32\) settings to understand patient perspectives. We conducted the interviews and Q-methodology procedure in participants’ homes, usually at their kitchen tables. Each interview lasted 1.5 to 2 hours and focused on understanding the participants’ health goals, priorities, and attitudes. The interviews were transcribed, and identifiable information was redacted to protect participants’ confidentiality. The study was reviewed and approved by the Internal Review Board of the Group Health Research Institute.
Participants
We recruited older adults with diabetes Type 1 and Type 2 (n=20), and mothers of children with asthma (n=20). We recruited these two distinct samples to maximize the variation in attitudes toward health self-management and technology use. We sampled mothers of children with asthma (rather than fathers or both parents) because women in this age group have ongoing health care needs relevant to reminders, such as screening for cervical cancer. All participants (see Table 1) were sampled from Group Health Cooperative, a large integrated healthcare delivery system in Washington State. We purposely oversampled racial and ethnic minorities, who would substantially benefit from improvements in care related to technology and chronic illness management. These interviews were the second round of interviews for 34 of the 40 participants. We had recruited these 34 participants by mail and phone from a bank of 586 people for this three-year multi-part study. The remaining 6 people were recruited from a new bank of 99 people (25 older patients, and 74 mothers). Older adults (10 of 20 were male) had a median age of 73 years, and mothers had a median age of 38 years. After the interview, they received $50 for completing the study.

In-depth Interviews and Q-methodology
The interview protocol contained open-ended questions about health goals, and a reflection on the challenges and personal significance of nationally recommended health tasks appropriate to the age and diagnoses of each participant. The Q-methodology procedure was conducted at the end of the interview. The data collection procedure for Q-methodology consists of a set of subjective statements printed on cards that the participant arranges according to what is most personally significant to them. It is a highly structured data collection procedure wherein participants arrange the statements in a grid that is shaped in a normal distribution. The extremes of the distribution represent the statements that the participant feels most strongly about (See Figure 1): “Most Agree” to “Most Disagree” are located at either end of the Q grid, with “Neutral” in the middle. The statements that participants place at the extremes receive the most weight in the cluster analysis of the data, revealing the health and technology attitudes that distinguish unique patient perspectives (See Table 2).

Our Q statement set consisted of 27 statements based on a health-sciences theoretical framework. The statements were categorized into two groups: (1) attitudes toward health self-management, especially related to core self-management skills; and (2) attitudes toward using and adopting technology. We developed statements in the first category on self-management attitudes based on the three large domains of work in chronic illness care originally identified by Corbin and Strauss\(^1\) and incorporated into self-management support programs by Lorig and Holman\(^2\). These included the work of medical management, emotional support, and redefining life roles. We used prior instruments of patient activation to inform statements representing patients’ attitudes towards self-management in these domains. These include the Patient Activation Measure (PAM)\(^3\) and the Patient Assessment of Chronic Illness Care (PACIC)\(^5\). The PAM assesses patients’ self-management beliefs, knowledge, skills, and confidence. The PACIC scale assesses the extent to which the patient has received care congruent with the Chronic Care Model and includes a subscale of patient activation. We used both of these scales to inform a set of statements on a continuum of patients’ self-management beliefs, confidence, and practices\(^6\). These statements allowed us to observe how patients prioritize health and technology behaviors for health self-management. We derived the wording of statements from qualitative data from a previous round of interviews with these participants\(^\_3\).
Analysis
We analyzed the data with PQMethod\textsuperscript{38}, a widely used application for conducting exploratory cluster analyses of Q-methodology data. We conducted a principal components analysis that extracted 8 components, 3 of which explained 53% of the variance in the data. We chose to retain only 3 components for interpretation based on the standard criteria for factor rotation (i.e. proportion of variance, scree test, and interpretability)\textsuperscript{39,40}. We rotated the three components using varimax, a standard orthogonal rotation method.

We used the distinguishing statements—statements that distinguish each cluster based on statistical significance—to inform the qualitative analysis of the interview data (See Table 2). By checking the themes that emerged from the distinguishing statements in the cluster analysis against the qualitative data, we were able to interpret the clusters in the context of each participant’s health goals, and to report on their attitudes and beliefs using their own words. Moreover, this method of qualitative validation is especially important when working with marginalized populations\textsuperscript{41}. Participant quotes are incorporated into our results, with A\# identifiers denoting the words of mothers with children who have asthma, and D\# identifiers denoting quotes from diabetes patients.

Results
The principle components analysis resulted in three clusters that represent three unique perspectives on both health attitudes and tools that are essential to health self-management. These three components yielded excellent interpretability and a “simple structure,” with only 4 participants whose views are excluded from analysis due to their loading significantly onto more than one component. Clusters 1 (n=14), 2 (n=13), and 3 (n=9), do not correlate with age, race, educational background, portal use, gender, or disease. Rather, each cluster represents a unique attitude towards health self-management held by a diverse subset of the sample (see Table 1). We describe each cluster below, and characterize them as: (1) Proactive Techies; (2) Indie Self-Managers; and (3) Remind Me! Non-Techies. We denote the distinguishing statements for each cluster with the ranking assigned to it, on a scale of Most Agree (+3) to Most Disagree (-3), by participants of the cluster.

Table 1. Participant demographics by attitude cluster and cohort. A=asthma cohort; D=diabetes cohort.

Cluster 1: “Proactive Techies”
Fourteen participants (3 male) define this cluster, including six participants from the diabetes cohort (ages 63-74) and eight from the asthma cohort (ages 32-49) (see Table 1). This cluster has a high technology profile. The participants who define this cluster strongly agree that cell phones (+2), electronic communication (+3), and knowledge of the science behind health advice (+2) are essential to health self-management. They somewhat agree that electronic reminders will reduce the stress of managing their health (+1) and that online calendars are the best way to manage their health (+1). Consistent with their preference for electronic methods, they strongly disagree that paper calendars (-3) and reminders (-3) are useful for health self-management.

Patients in this cluster were distinguished by their emphasis on the connection between health self-management and technology use. These patients used technology to take the initiative with their health care by proactively tracking health indicators, understanding scientific health information, and setting personal goals. This health tracking behavior supported these patients to set health goals for themselves and to take responsibility for their health outcomes. In particular, older adults with diabetes described using technology to track self-care activities. For example, D15, a black man with some college education, recounted how he used a spreadsheet to track his blood glucose levels, and sent it in an email to give his doctor a “heads up”:

“It's going back about 18 months ago, I went and got it [blood glucose] on Excel in a nice little graph that looked good to me ... when we had my primary care doctor and we met, she was able to say okay, you need to up your medication...[the doctor] had a heads up before I got there, not only from her examination but from me sending her information.”

Similarly, D6, a black woman with a 4-year degree, described how she used the patient portal to track a detailed history of her A1C test results:

“[On the patient portal] there's information about the test, why they take the test, what the numbers are, whatever it is. So you know where you should be, and then they keep it - I think mine started 2008, they keep it for a long time and they have a chart so you can see where your ups and downs are.”

D7, another black woman with a 4-year degree, described how she uses her cell phone for keeping track of her health, “I keep my appointments in there [cell phone]. I have my pacer in there to track the number of steps I walk. I have things on my calendar, what days I do certain exercises and stuff on there.” Another older patient, D11, a white man with a high school education, described a very different reason that his cell phone helped him to take control of his health, “They [providers] got our home phone number and there's times they call and leave a message on there, I've always got my cell phone with me and then if we're out for the day or something, I won't miss a message.” This patient used a cell phone to check his voicemail messages on his home phone while he was away. Although this patient may not be considered a typical example of a “high tech” self-manager, from the perspective of this patient, cell phones were explicitly prioritized for managing his health.
Many of these “proactive techies” placed a high value on health information, and especially prioritized scientific evidence to enhance accountability for acting on doctor recommendations. A20, a white woman with more than a 4-year degree, described the importance of health information and the value of email for enabling her to proactively communicate with her doctor about the accuracy of her research, "like "I read this about my child's condition, is this even accurate, would you agree, disagree?"...I need someone to double-check the information that I'm finding and give me an answer."

A12, a Hispanic woman with a high school education, also emphasized the value of health information. She expressed not having enough information, and wanted to learn more detailed scientific health information from her doctors, however: “They're [providers are] not prepared to have details about what are the studies behind this, what were the outcomes of that study and the percentages of side effects and that kind of thing. They're not ready at hand with that kind of thing.” This patient had the desire to have more scientific evidence for the health tests, medications, and behaviors that were recommended by her doctor. She recalled how, in the past, she had used different resources to get the information that her doctors could not provide, “The oncologist that I had connected with, I guess, told me what the options were. I researched what the options were and people who've gone through those options, and then came back with a decision on how to move forward with it.”

D6, a black woman with a 4-year degree, also described wanting more information so that she could be a better judge of her health status relative to the norms for her age and race,

“Unfortunately, they [providers] can't give you information you need on genetics and heredity and stuff like that, especially for African Americans, because we may be at some point of African descent but that's not all we are. For the majority of us, that's not all we are, so we're just grouped, and because this country has a 1/8 rule, we're just grouped... if you're African American and Asian your [A1C] numbers are higher because of the genetics there. That's what I'm getting at - so it really matters.”

Although six patients in this cluster were over the age of 60, and five had a high school education or less, all patients in this cluster used technology to be proactive about their health. Regardless of age, race, and ethnic background, these patients prioritized technology for tracking health indicators, communicating with providers, and finding scientific health information.

Cluster 2: “Indie Self-Managers”

Thirteen participants (5 male) define this cluster, including seven participants from the diabetes cohort (ages 62-89), and six from the asthma cohort (ages 28-43) (see Table 1). This cluster has high accountability for health self-management, expressing a strong belief that they have an active role in care (+3). Patients in this cluster considered technology to be a low priority for health. They are strongly independent (“indie”) and rely on keeping track of health tasks in their heads (+2). They disagree with the idea of needing follow-up from the doctor to stay on track with their health (-2), and with the idea that someone should check in with them to help remind them (-2). They strongly disagree that use of mobile technology is linked to better health outcomes (-3).

In contrast to cluster 1, patients in cluster 2 did not prioritize health information, nor did they connect technology use with health outcomes. Although all patients in this cluster described using a cell phone, and used it for other aspects of their lives, they did not consider it essential to their health.

For example, A4, a black woman with a high school education, said, “I use my cell phone and email and stuff, but I personally don't see how that affects my health.” Similarly, D8, an Asian man and the oldest patient in our sample, described why his cell phone was not linked to his health outcomes, “a cell phone is just another convenience, you know. I don't need it on the list of things I feel essential for managing my health. “A14, a white woman with more than a 4-year degree, made an even more explicit distinction between the use of her cell phones for everyday activities versus health activities. She described how her cell phone was directly at odds with the nature of her health self-management strategies, “my health needs me to be peaceful and relaxed and meditate and dealing with my emotional issues ... a cell phone's just a tiny little thing and it's actually a little bit detrimental. It's starting to become a little bit of a problem for me.” This patient noted the potential negative impacts on her health of communication technologies.
Although there was a weak link between technology and self-management for patients in this cluster, there was a strong sense of accountability. These patients felt strongly that they were responsible for their health, a statement that distinguished this cluster from others. D3, a black woman with more than a 4-year degree, gave a powerful example of how she took control of her health outcomes during a disagreement with her provider, “She [the doctor] wasn’t as receptive as I wanted her to be so I said some things at the end – it wasn’t in anger, but like ‘I’ll tell you,’ and because I said that she told me some things that’s been very beneficial to me.” Similarly, A14 described herself as an empowered patient, “I am confident, I have ownership. I feel like it’s my job to take care of that area of my life, I’m not passive, I’m an active player.” A9, a black woman with more than a 4-year degree, shared a similar sentiment about her role in care, “Just that, because it’s my body and I think I’m the expert. I know what’s going on with it versus someone that’s telling me what’s going on with it.”

Patients in this cluster prioritized health education because it helped them to be accountable for their health. The explicit connection between health education and accountability was unique for these patients. For example, A4 explained:

It empowers you, it holds you accountable versus thinking - I don't know, I've seen people who are like this is what's wrong, and they're constantly running to the doctor type of thing, but not really fixing what the issue is, just treating it constantly. I think it is good to be educated so that you could take care of it.

A9 had a similar view, “Getting the quality of the office visits we’re getting, the education that the doctor’s able to provide...It's nice to know what you're talking about and be able to help a child, based on what you actually know rather than guessing.”

For these independent self-managers, their “mental attitude,” as D8 put it, was more essential to health self-management than the technologies they used in everyday life. Their low adoption of technology specifically for health self-care was due to perceived negative impacts of reliance on cell phones, and an emphasis on autonomy from both technology and provider authority. They emphasized accountability and empowerment through health education.

**Cluster 3: “Remind Me! Non-Techies”**

Nine participants (2 men) define this cluster, including six from the diabetes cohort (ages 63-88) and three from the asthma cohort (ages 38-45) (see Table 1). This cluster has low accountability for self-management, and a low technology profile. They strongly agree that their health will improve if they set health goals with their doctor (+3), and that they need follow up from the doctor to stay on track with their health (+2). They dislike using electronic communication with their doctor (-1), and prefer phone calls (+1). They strongly disagree with keeping track of health tasks in their heads (-3), and do not believe in using online calendars (-1) or that mobile technology will improve health outcomes (-1). They agree that their health will improve if follow-up notices are clearer (+1).

Cluster 3 was characterized by their strongly positive attitudes toward goal-setting with their doctors and follow-up care. They placed a low priority on email and mobile technology and instead preferred phone calls with providers to stay on track with their health. Although they expressed agreement with being responsible for health, these patients were distinguished by their greater reliance on health care providers to guide and motivate healthy lifestyles.

The follow-up phone calls from providers were highly prized, if not relied upon, by these patients. For example, when asked about why she preferred phone communication, A18, a woman with some college education, said, “That's when I know I need to take action. Like if I've procrastinated for a while.” Similarly, A17, a white woman with more than a 4-year degree, found it difficult to prioritize health goals without the doctor checking in:

I get home and in my own brain, I sort of prioritize what was important and if life gets busy, I will prioritize other things above my health. If someone is calling you and holding you accountable to it, you feel if there's a priority for that person to call me, I'd better respect that, and keep it a priority.

Prioritizing health goals was a common challenge among these participants. A18 explained how follow-up could help her to stay on track, “If she [doctor] could have a goal, eating better or eating more fruits or whatever it is. And then once in a while if she sends me a thing that says ‘how's it going with this?’ – Oh yeah, I'm supposed to be doing this!”
Patients also perceived follow-up as an important source of motivation for staying on track with health goals. For example, D16, a black man with a high school education, talked about needing motivation from his provider. When asked how his doctor could motivate him, he said “Be there on me...My doctor's cell phone, he can do more.” This patient had several health complications, including two leg amputations, and limited speech due to a stroke. D5, a Hispanic woman with a high school education, who also had complications from comorbidities, described how better follow-up from her doctor could motivate her health management, “He'd [the doctor] make sure I go to the gym. He'd make sure I'm getting dialysis. He'd make sure he checks me once a month, they check everything I have to be doing.”

Finally, D14, a white woman with a high school education, expressed the value of having health goals with a provider, “If you go ‘that's the way life is,’ that's not helping anybody, but if he [the doctor] sets a goal – ‘okay, do more exercise, drink more water,’ then you know - I've got goals that will help me.” This echoes a statement from D2, a black woman with more than a 4-year degree, about the importance of health goals, “I think everybody needs goals, whether health or in anything, and goals would be a motivating factor.”

Discussion
The most surprising finding from this study is that it revealed attitude clusters that each contained a broad spectrum of patients in terms of race, age, education, patient-portal use, and diagnosis. Studies confirm that providers rely on these kinds of observable cues, especially race and age, to assess patients’ health attitudes and make treatment recommendations. In contrast, our findings provide evidence that patients’ attitudes toward health information and technology are not correlated with any of those observable cues. These attitudes and values are more influential than demographic characteristics on health self-management behaviors.

Our work can inform new approaches to clustering and understanding patients to inform tailored self-management interventions. In particular, our work suggests that attitudes toward health and technology can interact in unexpected ways, such as the “Indie Self-Mangers” who engage with technologies in everyday life but do not connect their technology competency with health self-management. Another example of unexpected interactions of health and technology attitudes is in “Cluster 1: Proactive Techies”, wherein six patients over the age of 60 years agreed that electronic communication and cell phones were essential to managing their health. Furthermore, A12 and A19, both women of color with high school educations, were “Proactive Techies” who expressed a strong sense of self-efficacy and technology use for health self-management. These examples are especially significant given that socio-economic status, which encompasses education status, has been shown to have the broadest effect on physician’s perceptions of patient competence, compared to race and age.

Researchers have extensively explored effects of race, gender, and literacy on clinician behavior, but have not investigated differences in the attitudes of a diverse set of patients’ toward self-management and technology. We found that patients’ attitudes have a strong influence on technology adoption and accountability for health that have implications for patient-provider relationships. In addition, those relationships extend through at-home, patient-centered self-management programs. For example, the “Remind Me! Non-Techies” had a passive attitude toward health self-care, and relied upon providers for reminders and monitoring of progress toward health goals. Moreover, members of this cluster contradicted stereotypes of white patients with high education, who are often perceived by providers as highly motivated and effective self-managers. For example, A17, a white woman with more than a four-year degree, did not use the patient portal, and relied on the doctor to keep her on track, “if the doctor's office is calling, you feel like oh! – okay.” Our results suggest that self-management programs for these low-technology users could leverage their respect for provider authority by delivering self-management content that encourages the feeling of being mentored by a provider. In contrast, interventions for “Proactive Techies” are more likely to be adopted if they support patient-initiated exploratory approaches to health tracking and goal-setting. Similarly, interventions for “Indie Self-Mangers” can be tailored to suit their strong preference for control over decision-making in care, providing tools that encourage autonomy and self-improvement through health education.

Finally, our work suggests that patients’ attitudes toward health information and technology may be important for understanding why patients adhere to, or fail to adhere to, treatment recommendations. Differences in these attitudes may have implications for health outcomes because these attitudes affect patients’ participation in care. Moreover, understanding the attitudes that distinguish different approaches to self-management can help providers to develop nuanced approaches to tailoring interventions for patients across a spectrum, from fully "activated" to fully "passive." Traditional scales that provide insight into patients’ perceptions of their role in care, like the PAM, can
be complemented with methods like ours that provide insight into patients’ strategies and motivations for developing their self-care capacity. We demonstrate the advantages of observing the interaction of health and technology attitudes for providing a holistic view of the attitudes and tool-use strategies that influence self-management.

Conclusion
Our findings demonstrate three unique clusters of self-managers based on different health and technology values. These three clusters demonstrate the limitations of a “one-size fits all” approach to self-management interventions, especially when these interventions are mediated by electronic communication tools like cell phones and email. We demonstrate that Q-methodology can be a useful approach for understanding patients’ attitudes toward technology and self-management. In addition, it could inform new approaches to clustering patients and matching them with appropriate self-care support. Prior research shows that raising clinician awareness of biases mitigates the effect of those biases, thus reducing healthcare disparities\textsuperscript{16}. This study suggests that an understanding of patients’ attitudes toward self-management and technology could inform unbiased, patient-centered interventions. Moreover, our approach has highlighted different values that influence technology adoption for health self-management, and this work could inform new scale development for assessing the appropriateness of computer-mediated interventions for patients. Overall, a greater awareness of the health and technology priorities of patients can help clinicians to leverage patient’s values and strategies for enhancing self-management. This work encourages clinicians and technology developers to combat implicit biases based on race, age, and education by eliciting patients’ values that define health self-management.

Understanding the acceptance factors of an Hospital Information System: evidence from a French University Hospital

R. Ologeanu-Taddei, PhD¹, D. Morquin, MD¹², H. Domingo¹², MSM, R. Bourret, PhD²
¹Montpellier Research Management (MRM), Montpellier University, France; ²Montpellier University Hospital, Montpellier, France.

Abstract
The goal of this study was to examine the perceived usefulness, the perceived ease of use and the perceived behavioral control of a Hospital Information System (HIS) for the care staff. We administrated a questionnaire composed of open-end and closed questions, based on the main concepts of Technology Acceptance Model. As results, the perceived usefulness, ease of use and behavioral control (self-efficacy and organizational support) are correlated with medical occupations. As an example, we found that a half of the medical secretaries consider the HIS is ease of use, at the opposite to the anesthesiologists, surgeons and physicians. Medical secretaries reported also the highest rate of PBC and a high rate of PU. Pharmacists reported the highest rate of PU but a low rate of PBC, which is similar to the rate of the surgeons and physicians. Content analysis of open questions highlights factors influencing these constructs: ergonomics, errors in the documenting process, insufficient compatibility with the medical department or the occupational group. Consequently, we suggest that the gap between the perceptions of the different occupational groups may be explained by the use of different modules and by interdependency of the care stare staff.

Introduction
The implementation of Healthcare Information Systems, such as Computerized Physicians Order Entry (CPOE), Clinical Information Systems (CIS) or Electronic Medical Records (EMR) and, more recently, Hospital Information System (HIS), is supposed to have various benefits for the medical practices, as providing easy access to documentation of patients records and accurate them¹², billing management³, reducing potential medical errors⁴, and improving the quality of patient care⁵. However, previous studies have shown the use of HIS has led to unintended consequences in the actual work practices, such as increased documentation time⁶,⁷, incompatibility with clinical workflow⁸, increasing more interruptions in medical work⁹ and system-introduced errors in patients care¹⁰. How can we explain the gap between the expected benefits and the conclusions of these different studies? We suggest an explanation related to the fact that the acceptance factors are not taken enough into account by the hospital management during the post implementation stage. We argue this idea based on a survey driven in a French University hospital using a HIS. This survey is based on the main concepts of the Technology Acceptance Model (TAM)⁹.

Theoretical framework
TAM is considered a “gold standard” in the information systems research¹⁰. This model aims to identify determinants (perceived ease of use and usefulness) of attitude and usage intention. While it provides useful insights into why people adopt a technology, this model and its evolutions (known as TAM2 and TAM3¹¹), has several limitations. First, it works especially in voluntary contexts and not mandatory ones¹²,¹³. Thus, intention to use is not a relevant concept in mandatory contexts.
Second, it assumes that users face no impediments in the course of information system uses. Besides, users often do not have a total control over situations of use, especially as employees. This argument led TAM authors to improvement in the initial model¹¹.
Third, the parsimony of the TAM concepts, whereas it was considered for a long time as a strengthens of the model, has been evaluated recently as weakness because its misfit to different organizational contexts¹⁴.
Fourth, these concepts are linked to binary variables (use or not use), which may be described for simple technologies uses⁹,¹⁵ but not for complex ones. However, complex information systems, including Enterprise Resource Planning (ERP) and, consequently, HIS, give rise to more or less advanced uses. Some features may be used, while others not. In addition, the professional context of usage is not considered enough¹⁶.
Fifth, the main potential benefit of TAM, which is its explanatory and predictive power, seems to be partial. Sixth, previous research in the healthcare, based on the TAM use and focused on physicians, have found a positive relationship between perceived utility and acceptance but a non-significant relationship between ease of use and acceptance or ease of use and intention to use.

We suggest that these limitations are related to the deterministic use of the TAM, that is, measures of causality relations between the determinants, the attitude of acceptance and the intention of use. Beyond this deterministic use, the main construct of TAM may provide better understanding about HIS acceptance. In order to take into account the criticism we have summarized above, we add the construct of perceived behavioral control, which is driven by the theory of the planned behavior and has been used in the healthcare. This construct includes perceived internal control, which is named self-efficacy by the TAM authors, and perceived external control, which is linked to another concept of TAM, that is, facilitating conditions.

The table below summarizes the constructs of the survey and their definitions.

<table>
<thead>
<tr>
<th>Perceived Utility (PEU)</th>
<th>“the degree to which a person believes that using a particular system would enhance his or her job performance”</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perceived Ease of Use (PEOU)</td>
<td>“the degree to which a person believes that using a particular system would be free of effort”</td>
</tr>
<tr>
<td>Perceived Behavioral Control (PBC)</td>
<td>“The degree to which an individual believes that he or she has the ability to perform specific task/job using computer” (self-efficacy)</td>
</tr>
<tr>
<td></td>
<td>“The degree to which an individual believes that an organizational and technical infrastructure exists to support use of the system.” (facilitating conditions)</td>
</tr>
</tbody>
</table>

Table 1. Definitions of the constructs

Methodology and context

We designed a questionnaire based on these three constructs. We used the items tested by Chau & Hu. All items were measured in a 7-point Likert’s scale, with 1 as strongly disagree and 7 as strongly agree. We added two open questions in order to investigate users’ perceptions about the advantages and the disadvantages of this information system.

This questionnaire was sent for pre-test to a panel of 20 volunteers. This pre-test and adaptation of the questionnaire prevented the definition of indicators according to the representations of researchers and thus allowed the contextualization of the issues. The main adaptation consists on the contextualization of the HIS name: as suggested by the pre-test answers, we decided to use the software’s name instead of the generic term “HIS”.

The questionnaire was developed and administered online to the care staff, during the month of December 2013. The survey was conducted in a large French University hospital. The target was composed by the care staff (9 000 employees with care occupations). The aim was to measure the users’ perceptions related to the daily use of the HIS, 18 months after the HIS implementation. This information system includes computerized physicians order entry, medical and nursing observation, laboratory tests results, medical prescription, operating room process management, drugs logistics management, consultation program and appointment, billing management.
Data analysis and results

1,942 questionnaires were collected. The distribution of the occupations is detailed in the table below:

Figure 1: Occupational characteristics

We use the across-method triangulation, consisting in the combination of three methods:

- Statistical correlations between the responses to the closed questions, which were assessed by Chi-Square test, using the Sphinx software.
- Content analysis using a French textual data analysis software named Alceste, which identifies classes of speech.
- Content analysis of the open answers, which were coded independently by two researchers (the reliability was measured by the kappa coefficient).

We also used internal validation, which consists in the “truth value” of the findings and their credibility for the care staff. We presented the findings to the hospital management, to the medical managers of the hospital units or services and to the care staff.

We found a very significant correlation of all the constructs with occupations. We resumes bellow the main rates (1-3 for disagree and 5-7 for agree. We do not mention the middle rate (4 on the Lickert’s scaledivided):

1. **Item Perceived Ease of Use (PEOU):** \( \chi^2 = 160.48, \quad ddf = 30, \quad P < 0.01, \quad Cramer’s V : 20.42\% \). Generally, 48% of the staff care agree (vs. 35% disagree) with the statements related to the construct “the HIS is ease of use”. The majority of anesthesiologists (61%), of physicians (56%), of midwives (55%) and of surgeons (52%), and of the residents (51%), the half of nurses, 45% of care managers, 39% of auxiliary nurses, 35% of physiotherapists disagree. Only 25% of anesthesiologists, 27% of physicians, 27% of midwives, 30% of surgeons, 33% of nurses, 35% of residents, 37% of care managers, 42% of auxiliary nurses, 45% of physiotherapists agree with this statement. Furthermore, 50% of the medical secretaries (vs 32%) consider the HIS is ease of use. Pharmacists are more divided: 41% disagree and 40% agree.

2. **Item Perceived Utility (PU):** \( \chi^2 = 168.61, \quad ddf = 30, \quad P < 0.01, \quad Cramer’s V : 19.65\% \). The staff care consider the software is useful or very useful (42% agree vs. 34% disagree). More precisely, 48% of auxiliary nurses (vs. 31%), 38% of anesthesiologists (vs. 38%), 57% of care managers (vs.13%), 47% of surgeons (vs. 27%), 44% of residents (vs. 27%), 41% of physicians (vs. 38%), 43% of physiotherapists (vs. 27%), 74% of pharmacists (vs. 15%), 31% of midwives (vs. 23%), 63% of medical secretaries (vs. 16%)
agree with the statement “the HIS is useful”. Besides, nurses (30%), midwives (31%) and anesthesiologists (38%) have the lowest rate of PU. Only the nurses disagree (46% vs 31%) with this statement. In contrast, pharmacists (71%), medical secretaries (63%), residents (61%) and nurses managers (57%) state the software is useful or very useful.

3. **Item Perceived Behavioral Control (PBC):** chi² = 154.32, ddl = 30, 1-p = >99.99%. The staff care is divided (46% agree while 36% disagree), as surgeons (45% agree vs. 41% disagree). More precisely, 52% of anesthesiologists (vs. 32%) and 43% physicians (vs. 37%), 44% of pharmacists (vs. 39%), consider they have only little behavioral control or not at all. At the opposite, 65% of medical secretaries (vs. 20%), 64% of residents (vs. 34%), 63% of physiotherapists (vs. 22%), 56% of auxiliary nurses (vs. 25%), 45% of nurses (vs. 31%) and 42% of nurses managers (vs. 35%) states that they have behavioral control.

Furthermore, we identified 4 classes of speech by the Alceste software:

- **Class 1 (majority) "Treatment plan".** Key words: prescription - care - treatment sheet - validation - error - transmission - treatment - sign - readability. At the center of this class are prescription and treatment plan, related to the difficulty to understand the computerized prescription and treatment sheet, which may lead to errors of treatment.

- **Class 2 "Lack of ergonomics".** Key words: unfriendly - tool - person - think - Computer - true - Software - design. These speeches are related to the ergonomics software, considered as flawed. Some users describe "a disaster" loss of staff time to the detriment of his care tasks. Software bugs are also highlighted.

- **Class 3 "Laboratory results and examinations".** Key words: report - post - results - classify - archive - imaging. The speech emphasized results and schedule modules, which are described as unusable, as well as the non-readability of biological results.

- **Class 4: "Find and view information".** Key words: Input - Support - File - information - structure - Psychiatry - enter - check. This class focuses on the difficulties of entering and viewing documents external to the University Hospital and the difficulty to find relevant information. Many people feel that the information is misfiled.

The difficulties related to the HIS may be classified into three categories, as follows:

- **Software ergonomics.** The HIS is viewed as a usability-faulty system. Overload of information on the screen drowns relevant information and increase the risk of error. Users mention also bugs and software failures.

- **Insufficient use of documentation rules in the clinical workflow and misfiled information driving to errors in patient care.**

- **Insufficient compatibility with the clinical workflow in the departments (e.g. Hematology, Emergency, Pediatrics and especially Psychiatry) and for different medical occupations (anesthesiologists, physicians, surgeons, midwives), because the possibility of settings and customization was not effectively made.**

In addition, the words occurrences analysis shows that the mains words are: time – especially “waste of time” (727 occurrences); difficulties or difficult (402 occurrences); waste (383 occurrences); prescriptions (257 occurrences); incompatibility – of the information system to the clinical work (199 occurrences); prescription errors (182 occurrences); training (insufficient) (164 occurrences); errors – especially, bugs (154 occurrences).

**Discussion**

The low score of PEOU and PBC or the anesthesiologists, the surgeons and the physicians may be explained by the answers to the open questions. Based on the classes of speech, we have to consider the prescription module and the treatment plan module as the critical issues of the HIS use. The lack of ergonomics of the prescription and laboratory results modules, related to the information overload, may lead to prescription or treatment errors (especially for the drugs dosage and their frequency). In this context, anesthesiologists assess the lowest score of PEOU because they are the clinical occupation for which the medical error (especially prescription error) may have the most rapid dramatic consequences. Basically, anesthesiologists, physicians, surgeons and midwives are the most concerned by this issue, contrary to the medical secretaries.
Otherwise, the findings highlight errors in the documenting process associated with the misuse of indexation rules for patients’ files and the insufficient compatibility of the HIS to the clinical process for each medical department.

We have to mention that ergonomics, errors in the documenting process and the insufficient compatibility with specific medical processes have already been identified in the literature as a medical error risk. Our mixed method shows these factors are very connected. Furthermore, ergonomics and usability, correlated to a lower rate of PEOU, are a main issue, in contrast with studies suggesting physicians’ ability to learn to use the technology by themselves and their relative disinterest in usability. Moreover, the PBC rates suggest that the medical staff (especially anesthesiologists) considers that organizational support (as training) is not sufficient during the post-implementation stage. This result is consistent with the literature on the ERP success which is conditioned by the managerial and technical support.

In addition to these issues supported by the literature, our study adds to the literature the gap between the HIS perceptions according to the occupational groups. As an example, we found that a half of the medical secretaries consider the HIS is ease of use, at the opposite to the anesthesiologists, surgeons and physicians. Moreover, they reported the highest rate of PBC and a high rate of PU. It would be easy to conclude that this result is the expression a conflict between the administration and the professional logics, knowing that accountability and planning are the main aims associated to an ERP and, consequently, to a HIS. Nevertheless, an in-depth look at the results emphasizes a gap inside the clinic and care occupational groups perceptions. Thus, pharmacists reported the highest rate of PU but they are more skeptical about the PEOU and PBC. Answers to open questions suggest that this result is related to the drugs traceability, which is on expected benefit of the HIS, under the condition of the improvement of both the ergonomics and the indexation rules for patients’ files. Otherwise, the different clinical and care occupational groups do not need to use the same features. Anesthesiologists, surgeons and physicians use the prescription module, while nurses and auxiliary nurses use the care sheet. Nurses are very impacted by the misuses of the prescription module by the clinical staff, which may explain their low rate of PU and PEOU. In line with this argument, we suggest that the most nurses state that they have PBC because the right use of prescription module is not their task. Thus, we may consider our results in relation to the use of the different modules and features according to the occupational groups (e.g. use of the office module for medical secretaries, use of the prescription and the results laboratory modules for the physicians and surgeons) and the exposure to the medical liability and medical malpractice.

Although each occupational group uses different modules or feature of the HIS, they are interdependent, meaning that an error in the information workflow may have consequences on the clinical and care professionals involved in the workflow (related to a patient). Thus, medical secretaries have to use the indexation rules for the patients’ files for physicians, surgeons and anesthesiologists to find the relevant information related to the identity and the admission file. Clinical occupational groups have to use the right features for medical observation and prescription for pharmacists to deliver drugs and for nurses to administrate drugs and care delivery. Consequently, the PU, PEOU and PBC may influence these constructs for the other occupational groups.

**Conclusion and future directions**

Our study shows that perceived usefulness, ease of use and behavioral control are correlated to medical occupations. Furthermore, it outlines three main points that may explain this correlation: ergonomics, errors in the documenting process and insufficient compatibility with specific clinical care process. Generally, information systems are implemented according to a standard vision of clinical workflow. Our research results suggest that the HIS have to be settled and customized taking into account particular clinical care process. In addition, these results can help planners, managers and healthcare software editors to understand key issues affecting HIS perceptions and use.

This research provide better understanding inside the HIS care staff perceptions. Besides, the generic items of the questionnaire, driven from TAM, may be completed by more specific items considering each feature and module of the HIS (medical observations, prescriptions, care treatments, laboratory results), as suggested by the answers to the open questions. Indeed, medical secretaries, nurses managers, nurses or physicians do not use the same features; thus, theirs perceptions and their expectancy about the HIS are different.

Further research have to provide also more insight into the various features and modules used by the medical and the care employees, in different departments, and on their interdependency in both the information and care chain.

ABSTRACT:
User frustration research has been one way of looking into clinicians’ experience with health information technology use and interaction. In order to understand how clinician frustration with Health Information Technology (HIT) use occurs, there is the need to explore Human-Computer Interaction (HCI) literature that addresses both frustration and HIT use. In the past three decades, HCI frustration research has increased and expanded. Researchers have done a lot of work to understand emotions, end-user frustration and affect. This paper uses a historical literature review approach to review the origins of emotion and frustration research and explore the research question; Does HCI research on frustration provide insights on clinicians’ frustration with HIT interfaces? From the literature review HCI research on emotion and frustration provides additional insights that can indeed help explain user frustration in HIT. Different approaches and HCI perspectives also help frame HIT user frustration research as well as inform HIT system design. The paper concludes with a suggested directions on how future design and research may take.

INTRODUCTION:
One of the overarching goals of Human-Computer Interaction (HCI) research has been to increase the good experiences and possibly reduce or mitigate horrible first experiences with technology. Licklider, in his “Man-Computer Symbiosis” [14] article decades ago, envisioned how a perfect, and relatively mutual relationship between humans and computer systems should be. When we think of times or experiences when we had to use technology for the first time or switch to a different technology, the thought may not always be pleasant. In fact, mostly unpleasant. Generally speaking, depending on one’s generation and “mental model”
of the new technology, the thought of this experience will generate either a happy or not so happy feeling. When technology is used, regardless of the type of technology used and reason for use, there is a formation of an initial relationship with the technology. Should the initial relationship last, a long-term relationship is sustained as well. Frustration which has long been defined by Lawson [25] as an “emotional state resulting from the occurrence of an obstacle that prevents the satisfaction of a need”, summarizes what the lasting relationship may entail.

RESEARCH PROBLEM:

As the American healthcare system slowly moves through technology adoption, implementation and meaningful use of Health Information Technology (HIT), one of the main areas of concern is the Human-Computer Interaction (HCI) and user experience of clinicians as they adopt, implement and use HIT. The problem here is that there has been research showing that frustration is one of the top unintended consequences that occur during Electronic Health Records (EHR) implementation and also through the first few months of post-implementation usage [5, 21, 22, and 25]. With literature repeatedly confirming the incidence of frustration in HIT system usage, there should be work done to finding successful approaches to solving frustration in HIT interfaces. This paper attempts to use such HCI research to explain and possibly inform design that could reduce frustration in HIT use.

ORIGINS AND EARLY RESEARCH ON END-USER FRUSTRATION:

With this concept of human-technology relationships, HCI research has re-defined itself to explore first experience interactions to find interdependencies, shared workload and address different emotional states such as frustration in technology use. HCI research has gone into issues such as why humans develop emotions towards technology and how to mitigate negative emotions towards technology. Domains like emotional design, affective computing and frustration research are born out of researching into these kinds of problems.

One of the main HCI research disciplines for some time now has been exploring ways in which human feelings towards technology can defined, quantified and monitored. The basic goal of this field is to know more about HCI and how to sustain and maintain this ‘relationship’ as ethically as possible [1]. The beginning of a shift in focus of emotion design and end-user frustration research started with cognitive and social research. Before the 2000s, research was already being done on frustration, affective computing as well as studying emotional states. Researchers such as Rosalind Picard and the likes, have spent years in Massachusetts Institute of technology (MIT) Media Lab studying the recognition, measurement and description of affect [9, 11, and 12]. Her work over time, especially on affective computing explores how computing relates to emotion.

RESEARCH IN THE 2000s:
The early 2000s saw research on emotional design such as works by Don Norman [17, 18, and 19]. Don Norman’s article “Emotional design: Why we love (or hate) everyday things” and his book on “Emotional Design” started a way of thinking that suggested that good design was imperative and that bad design not only generates a negative feeling like frustration but is also was not cost effective. Norman also collaborated with Ortony in “Designers and users: Two perspectives on emotion and design”. The goal of this article was to find out and share perspectives of emotion and design by both designers of technology and users of technology [19]. This research explains how a shared needs analysis between designers and users is essential to understanding what emotions are and how emotion is experienced with technology.

Lazar et al[13], also did some work that explored frustration focusing on what influenced a frustration experience. They wanted to find out more about causes and effects of frustration and so they looked at a bunch of users’ frustration events and reported on incidental (happening at one time) events versus session (over a period) events. These frustration events were the generic HCI frustrations or annoyances experienced when using a computer anywhere and were measured in levels. In the research, the authors found out that although a lot of user factors accounted for frustration, more people are angry at the computer than they were angry at themselves or even determined to fix the problem. Whether or not a frustration event was incidental or session was really critical in terms of the rating of frustration severity. Findings also included the fact that the user’s mood before and after a frustration event played a huge role in frustration severity.

In terms of emotional design research, round about the same time as Lazar and team were working on frustration experience research, Boehner et al [4] put out a paper that was unlike the then current approaches which defined emotion as just a cognitive experience. They argued that emotion was not just a state of being but interactional as well. Emotion information could be captured processed and output just like Card et al’s Human Processor Model. This argument and their research as a whole not only made it easier to break down emotion information and measure emotion in the 3 phases of the IPO model( i.e. during input, processing and output) but their explanation of how emotion can be treated as both information and interaction helps define, understand and explain emotion as well as measure it. Emotion can be socially and culturally understood and interpreted and this means that we should be able to understand and define emotion as both internal and also expressed differently in different contexts by different people.

Two years before this research, Boehner et al [3] did some research on affect. In their paper “Affect: From Information to Interaction”. Similar to their work on emotion as information, they explained how affect in affective computing approached as merely processed and expressed as information leaves no room for the feeling part of affect. Their approach (interactional) was rather from a perspective where the emotion or human users in affective computing is not lost but understood and supported as well. They came up with reasons to support why and how the interactional approach will work better. In essence when you approach affective computing and define affect as interaction as well, then one is able to see affect from both a social and cultural
product which relies on and supports flexibility and is not confined or formalized. Their work also acknowledged some challenges in this kind of approach however, the understanding that emotion is one way of looking into interactions helps think about ways to design for a more broader population and use. Bickmore and Picard’s research article “Establishing and maintaining long-term Human-Computer Relationships” in 2005 expanded on what human–computer relationships were in the first place.

Their goal was to find out how personal and interpersonal social relationship constructs can be applied to human-computer relationships. It is interesting to note that they were able to identify that the same reasons for relationships in human-human interaction could be applied to human-computer interaction. So for example, people could form relationships with ATM machines for economic gains just as people form relationships with other people for economic gains. Human relationship communication and management also applied to human-computer relationships. The authors also introduced relational agents to help with long term human-computer relationships that focused on and sustained despite multiple interactions. In research like this, there is a new window opened for HCI designers and researchers to look into. It is easier to understand human-computer relationships if we can compare it with human relationships. User frustration research was still being done.

Research on general computer usage and frustrating experiences like those by Ceaparu et al[7,8] measured how often frustration occurred, what caused frustration and how bad the experience was. These research looking at user experiences on common applications on web platforms and how users handled it. They recorded that some common experiences were during mailing and word processes. The perceived causes of end–user frustration ranged from error messages to dropped network connections to hard-to-find features on interface. These research showed that frustration is a huge problem that needed to be addressed. Based on the data they received, it was evident that self-reported high levels of frustration and wasted time was among the top list of concerns in a frustration occurrence. These data also could be expanded into both financial and usage ramifications in the future. Knowing these causes, and frequencies of user frustration, research is a critical first step in exploring more about what could be done to reduce user frustration. Other researchers also studied how computer systems and interfaces could automatically detect frustration in users [11] and also how to design computers to respond to user frustration [12].

**RECENT RESEARCH ON HCI FRUSTRATION:**

More recently, research on frustration has focused on more dynamic aspects on end-user frustration like how we can harness frustration for the good. In fact, Frustration, sometimes referred to as confusion or anxiety or anger, is a special type of negative feeling or emotional state experienced not only in life but also in HCI. This is described as “A strong, negative emotional state” that users feel when they interact with technology or computer system interfaces [7, 9]. Frustration in HCI has been considered to hinder system
usability. For example, the research by Lazar et al [13] showed that there is a difference in frustration experience in student users versus worker users of a computer system. Which means a more tailored approach can be researched into so that narrowly focused research and design suggestions can be made for EHR design so as to mitigate frustration.

**A little bit of frustration is good!**

Baker et al [1] in their article on frustration compare the “cognitive-affective” states of students in different computer-based learning environments. Amongst other things, they found out that frustration was better than boredom in the different kinds of “cognitive-affective” states they evaluated. It can be inferred from the article that in any learning environment like what clinicians experience during the implementation of EHRs, confusion and a little bit of frustration may be better for the learning experience than boredom. This meant that it will be prudent to invest in system designs that randomly interrupted with routine boring processes but also monitor the amount of interference so as not to create a terrible experience for clinicians.

Riseberg et al [24] had long before researched on using frustration for the good. In their article “Frustrating the User on Purpose: Using Bio-signals in a Pilot Study to Detect the User's Emotional State”, they show how frustration could be induced in computer game interfaces in order to be able to detect and group frustration events that create similar emotional states making it a great approach to explore users’ states during human computer interaction. Current research [9, 10] refine what Riseberg et al did. Mentis [16] also did some work on interruptions in cognitive workflow that elicits the experience of frustration. She found out that in instances where people remember their frustration moments in interface interactions, those moments were times where the system had to respond to user needs/actions and not times when users were figuring out how to translate their thoughts to actions on the interface. This means that remembered frustration experienced occurred in the second half of an interaction mostly because there was a break in what interfaces were supposed to be displaying or executing to users.

**WHY HCI LITERATURE REVIEW IS NEEDED:**
The HCI literature reviewed provides an understanding of some basic parts to frustration as well as emotional design research. The literature review explores origins of end-user frustration, what has been done quite recently and future directions that researchers could take. From the literature, we know that man and computers can form a symbiotic relationship in which each contributes to the relationship [14]. This means that it is essential to know which parts of an HCI that humans take responsibility versus which parts a computer should be left to complete. Not only do we know that such human-computer relationships can exist we also know that we can apply human-human concepts, definitions and constructs to human-computer relationships as well [2, 6]. The same way human relationships involve emotions and sometimes frustrations, we are able to understand that there is the need to design for emotions and cater to frustration events should they arise [2]. User-frustration research which can also be found in affective computing research championed by people like Picard, Norman, Dourish, Bohner, Schneiderman etc. have been able to narrow down research to reflect specific
interface use, human factors, system factors, and perspectives. This is very helpful because then in thinking about using HCI use-frustration to explain and possibly influence future research and design in HIT, I will consider such finding and use their results as baselines to further research in HIT user frustration.

From the literature, we know what the right questions should be. For example, we know that the question in user frustration is not whether frustration is a good emotional feeling or not. We even know that in certain contexts, a little bit of frustration is good [1] and frustration has been used to find out more about emotional states [9, 24]. However, in thinking about what contributes to frustration and what HCI concepts helps better understand frustrations in HIT interfaces, a lot of factors come to play; long-term HCI relationship[2], definition of the affective state called frustration (information or interaction)[3,4], severity of frustration(self-reported or actual)[7,8], implications of severity of frustration in a system(economic, social, usage, perceived)[8,12], perspectives(system, user or designer) [11, 12, 13, 19], ways to measure user frustration with systems[9,11,16,22] come into the picture.

The solution to HIT clinician frustration is to first identify what makes clinician frustration different from the frustration events described in the literature. Specifically, what is causing frustration at that moment? From Bickmore and Picard’s work [2], it is safe to assume that overarching goal of any HIT implemented is to maintain a long-term relationship between clinicians and the systems after implementation. With the HITECH act and meaningful use, there is even a higher incentive to mitigate frustration which hinders such long-term relationships. This a broader picture of why frustration hampers the goal of IT adoption in healthcare.

There is also the issue of context and expectations from the clinician. In trying to address frustration, it will be better to consider what role the HIT is playing and the consequences of interruptions such as frustration. This means that technology which most ideally satisfies its reason for being, is subtle. Just like breathing, we wouldn’t know we are using it. He further explains that this evolution of technology adoption and implementation is only natural “a fundamental consequence not of technology but of human psychology....Whenever people learn something sufficiently well, they cease to be aware of it.” There is therefore a presumption that the initial phases of computer or technology interactions are not as unconscious or spontaneous as later phases where the technology is pervasive. Our experiences with technology, especially for the first times are memorable; either in a good way or a horrible one.

**Combined-approach to frustration research in HIT:**

In any HCI, there is a human and a computer system involved. A combined approach to frustration research in HIT will be to combine the human-side research with the computer-side design approach to mitigate frustration. In this case, issues like shared interaction and designing for human users are discussed jointly with HCI themes and theories. Interaction theories may be in the form of visualization, peripheral vision, affordances, human cognition, user preferences, abilities, capabilities, limitations, mental models, etc.
DISCUSSIONS AND FUTURE RESEARCH:

Over the timeline of frustration in HCI research, there is much discovered. We know what frustration is, what causes it, how we can measure it, how we can attempt to mitigate it both from user side and system design side, we know what other human states (pscho-/physio-/socio-, cognitive, mental, effective, affective etc. etc.) are involved in HCI frustration. The next phase of research should probably focus also on prior experiences that feed onto frustration and how that better tells the story of how frustration is experienced.

There is also the need to critically research into what makes frustration in HIT hypothetically more severe or relatively unbearable that frustration in other interactions. We may (or may not) discover that the frustration experience is just what it is regardless of the kind of technology or interface interaction. Assuming HIT interaction frustration proves more annoying (due to many other factors like safety, lives at stake, timeline crunch etc.), then research much begin to address it in a more ‘wholistic’ way like the combined approach. Perhaps it will be best to approach it will be by framing a scenario (see fig 1).

**Fig1: HIT frustration incidence model.**

**Framing a Scenario:**

This scenario is just a way to approach an instance of frustration that can be comparable to a use case in system design. Assuming you have a nurse¹ experiencing frustration with a computer order entry (CPOE) interface, what could be a logical HCI research-based explanation to such experience? We know that frustration can happen in all stages of technology use especially the initial phases.

To frame this scenario and better explain the frustration; let’s break the experience into three (3) phases: Pre-experience, inter-experience, and Post-experiences;

- **Pre-experience Phase:** The pre-experience phase of any HCI is the collection of knowledge, experience, ideas, mental models and skills that a user already has before he or she experiences frustration. Most at times, stress which is a higher determinant of frustration may play a major role in inducing frustration

  ¹Note that this model may illustrate several frustration circumstances.
during interaction. In our scenario, the nurse’s background, prior experience(or not) with interface, values and beliefs, physical and intellectual capabilities and time constraints could factor into her pre-experience that leads to frustration.

- **Inter-experience Phase:** This phase will be the particular moment when the clinician is in front of the interface interacting with the computer. Here the clinician’s physical, social and cognitive abilities, capabilities and limitations influence the severity, instance and overall frustration experience at the moment. The interface’s design, visualization features, affordances, display and feedback also contribute to the experience.

- **Post-experience:** After the frustration experience, a clinician acts upon one of three feelings (see fig 1) that they are left with. 1. A self-motivating feeling that makes them want to try again and not give up. 2. An indifferent feeling that makes him/her only use the technology or interface when necessary but avoid the interaction most of the time. A perfect instance is when clinicians are required to use hospital technology. 3. A worst-case scenario when a clinician gives up and decides not to use the interface any more.

These 3 post-frustration decisions are critical in that whichever one a clinician decides on: a) Determines the frustration threshold they have reached. b) Determines what mitigation steps to use. c) Could lead to insights on where the link broke.

**CONCLUSIONS:**

When user frustration is explained using HCI principles and themes, there will be a better way to address the issue. The US healthcare system still faces some push-back in adoption and use of HIT. Clinicians are frustrated by EHR systems; either by interface design or how these systems interrupt workflow. The goal is to move past current research into what frustration is, to applied research on how the knowledge of frustration can be applied to HIT. Unlike frustration in other interfaces like web navigation, HIT interfaces has the component of frustration by limited interface view.

There are other distinct differences that can be explored. Frustration in EHR interfaces occurs at all stages especially the initial implementation phase. When a clinician experiences frustration; there are three (3) phases involved: pre-experience, inter-experience and post-experience. All these three (3) phases have factors (especially HCI theories) that come to play. Health care interfaces may have certain distinct features or functions that makes frustration experiences in such HCI’s different.

Our interactions with the technology should be able to amount to a relationship that can be sustained rather that a relationship that makes it difficult to maintain due to experiences such as frustration.

Identifying the Clinical Laboratory Tests from Unspecified “Other Lab Test” Data for Secondary Use

Xuequn Pan, PhD¹,², James J. Cimino, MD¹,²
¹Lister Hill National Center for Biomedical Communications, National Library of Medicine; ²Laboratory for Informatics Development, NIH Clinical Center; Bethesda, MD

Abstract

Clinical laboratory results are stored in electronic health records (EHRs) as structured data coded with local or standard terms. However, laboratory tests that are performed at outside laboratories are often simply labeled “outside test” or something similar, with the actual test name in a free-text result or comment field. After being aggregated into clinical data repositories, these ambiguous labels impede the retrieval of specific test results. We present a general multi-step solution that can facilitate the identification, standardization, reconciliation, and transformation of such test results. We applied our approach to data in the NIH Biomedical Translational Research Information System (BTRIS) to identify laboratory tests, map comment values to the LOINC codes that will be incorporated into our Research Entities Dictionary (RED), and develop a reference table that can be used in the EHR data extract-transform-load (ETL) process.

Introduction

Laboratory test results are stored in electronic health records (EHRs) as structured data coded with local or standard terms. These formally coded laboratory tests can facilitate retrieval and reuse of EHR data. However, laboratory tests conducted at an outside laboratory are often simply labeled or coded as “outside test” or something similar, with the actual name included in the free text result, comment, or note (e.g. “Test requested: Lyme Disease Serology Test performed at: Mayo Medical Laboratories Rochester, MN Test result: Lyme Disease Serology, S - Negative”). As a result, these outside laboratory tests with nonspecific names cannot be differentiated during retrieval, impeding tasks such as patient care, data sharing, integration, analysis, and decision support. Manual clarification of such data is tedious and redundant.

Our goal is to develop a generalized method to make outside unspecific laboratory data available for secondary use. Our approach seeks to code nonspecific tests with appropriate codes and standard terms from the Logical Observation Identifiers Names and Codes (LOINC) using a fuzzy matching approach that comprises four steps: 1) identify outside laboratory tests results, 2) based on the text fields, map the test to a specific standard LOINC code, 3) develop local codes, 4) recode outside unspecific laboratory test results proactively when loading new data into the EHR. We demonstrate this approach with the Biomedical Translational Research Information System (BTRIS), a repository of EHR data at the National Institutes of Health (NIH).

Background

Logical Observation Identifiers, Names and Codes (LOINC)

LOINC, a standard for reporting clinical observations (including laboratory test results) used in EHR systems, includes names and identifiers for more than 68,000 medical terms. Approximately 300 LOINC codes cover more than 95% of laboratory test orders in the U.S. Based upon available laboratory information (e.g. name, unit of measure), we can use the LOINC Mapping Assistant (RELMA) to match LOINC codes with local codes. Over the past two decades, the benefits of LOINC mapping for EHR interoperability have been well discussed, as have the challenges in mapping practice. Basic LOINC mapping guidelines are derived from an accumulated experience with MIMIC-II lab codes.
The Biomedical Translational Research Information System (BTRIS)

BTRIS is a clinical research data repository at the National Institutes of Health (NIH) that collects EHR data from over 50 NIH sources. Laboratory data are obtained from multiple systems including the current hospital laboratory system, archived data from previous systems, and institutional clinical trials management systems. All of these sources include results from outside laboratories (e.g. Mayo Medical Laboratories).

All data in BTRIS are coded with the NIH’s Research Entities Dictionary (RED), a terminology resource that includes the concepts related to laboratory tests or panels in five categories (chemistry, hematology, immunology/flow cytometry, microbiology, and transfusion medicine). Like other RED concepts, laboratory test concepts have properties, roles, and associations to represent comprehensive knowledge about the tests they represent.

BTRIS uses a hybrid relational and Entity–Attribute–Value (EAV) database model, in which most laboratory data are represented with columns in two tables: Event_Measurable and Observation_Measurable. The Event_Measurable table contains laboratory order information with orderable laboratory tests and panels stored in the Event_Name column along with their RED concepts in the Event_Name_CONCEPT column. Laboratory test results are recorded in the Observation_Measurable table. Laboratory finding values (results) are in Observation_Value_Text or Observation_Value_Numeric columns. Additional textual information is stored in Observation_Note and Observation_Value_Name columns. Figure 1 displays a sample of the two tables. Additional information (e.g. status flags and reporting time) are stored in the corresponding EVA tables.

Figure 1. Sample data on the Event_Measurable and Observation_Measurable tables (selected columns only).

Fuzzy Lookup Transformation

Fuzzy matching or lookup uses mathematical processes to determine the similarities between strings and to find similar (non-exact) matches. We expect this method to be sufficient for matching newly received results with similar previously encountered results, since they typically share similar patterns and formats. Fuzzy matching can be expected to overcome minor differences such as unique numeric results, misspellings, or inconsistent abbreviation usage. For example “Aspergillus fumigatus Ab IgE 78.4 ku/l laboratory” and “Aspergillus Fumigatus Aby Ige 36 Ku/L” will be readily recognized as matching.

The development of fuzzy technology has a wide range of potential uses in health care (e.g. diagnosis, decision making); its role in EHR data cleaning and standardization is relevant to the current project. EHR data extract-transform-load (ETL) processes consolidate disparate clinical data into a data repository. Microsoft SQL Server Integration Services (SSIS) features a fuzzy lookup transformation in the ETL package for data cleaning and standardization. We plan to use the SSIS platform to perform fuzzy matching to recode unspecific laboratory data and incorporate it into the ETL processes to check new data during real-time data loading.

Methods

As previously described, the nonspecific laboratory tests are those conducted at an outside laboratory and the results are stored in clinical databases without specific test names. Our goal is to develop a generalized method that makes outside unspecific laboratory data available for secondary use. The following illustrates our four-step approach.

Step 1: Identifying nonspecific outside laboratory tests

To find unspecified outside (or reference) laboratory tests, we looked in the RED for suspicious local terms referring to outside laboratory tests (e.g. “ref lab”). We then obtained actual laboratory results from BTRIS that were coded with these terms.
Step 2: LOINC mapping

We selected samples from these laboratory test results and designed mapping strategies according to laboratory test types. For microbiology tests, our initial focus in the study, we extracted the laboratory test information from Observation_Value_Text or Observation_Note. After a simple normalization (e.g. spacing and capitalization), we used regular expression functions to parse comment strings into four parts: 1) Test requested; 2) Test results; 3) Laboratory location; and 4) Additional information. After removing duplicate “test requested” strings, we used test names, laboratory locations, and test results for LOINC mapping.

For tests performed at a known laboratory (e.g., Mayo Medical Laboratories), we reviewed the laboratory’s Web site to obtain test names, synonyms and LOINC codes where they were available. We used RELMA to map additional test terms to LOINC codes by matching main parts (e.g. components measured, the unit of amount of substance, timing and sample type) with available information found in test results. For example, for the test name “B. burgdorferi ELISA serum,” we obtained information from the result “IgM-Negative and IgG-Negative” and matched 4 LOINC parts: component (B. burgdorferi Ab.IgG & IgM), method (ELISA), system (serum), and Scale (Ord). We classified coding results as either “mapped”, “likely mapped (ambiguous match)” or “not mapped”.

Step 3: Developing local codes

We checked the RED for existing test terms with the corresponding LOINC codes; where they did not exist, we created new local test terms and annotated them with information about the outside laboratory tests.

Step 4: Developing a reference table for fuzzy lookup transformation

Based on the results of Steps 2 and 3, we created a reference table to associate the text results of outside laboratory tests to the mapped LOINC codes and local codes, which will be used for fuzzy lookup transformation in an ETL process to code new data.

Results

Identified unspecific outside laboratory tests in BTRIS

We found that the majority of outside laboratory tests had names that conveyed what the tests were being performed (e.g. “Anti-Influenza Virus B IgG Antibody Serum Test by Mayo”). We found that nonspecific tests most often included the word “other” in their names. Table 1 shows the summary statistics of distinct RED concepts and patient rows for all the records associated with RED concepts for outside laboratory tests in the Event_Measurable table.

We identified a total of 27 RED concepts used to code outside unspecific laboratory tests. Among them, 4 RED concepts are associated with microbiology tests: “other microbiology test,” “other mayo clinic microbiology Test,” “other micro mayo contract laboratory test,” and “other micro AML Test.”

We extracted patient rows from the joined tables of Event_Measurable and Observation_Measurable where the value of Event_Name_CONCEPT was one of these 27 concepts. As a result, we obtained 14,082 unspecified laboratory test results that are stored in Observation_Note and Observation_Value_Text columns. We found each of the microbiology tests had a specific, consistent report pattern, including units, and reference ranges, although naturally the values and interpretations varied.

LOINC mapping

From the “other microbiology test”, we selected 1,000 patient data rows as a convenience sample data set and extracted 342 unique laboratory test names from the comment fields. Of these, 298 test names were from 16 known laboratories (Table 2). We mapped 329 of 343 (95.9%) laboratory tests to 102 unique LOINC codes through laboratories’ Web sites and RELMA. No match was found for 14 tests because of the lack of minimal information, or a new LOINC code required (see examples in Table 3).

Developing local codes

We added 102 new terms to the RED when no laboratory test name had been represented in the RED, based on mapping and information from the outside laboratory.

Creating a reference table for fuzzy lookup transformation

Multiple columns are included on the reference table for fuzzy lookup transformation, including local code, local term, full text string, LOINC code and name for laboratory results. Table 4 shows the structure of the reference table with sample data.
Discussion

Data in EHRs are often encoded or coded to a level that is inadequate for re-use. Outside laboratory test results, such as those in our study, are commonly found in EHRs and are particularly troublesome, especially when attempting to merge such data with data that are more explicitly coded. In this study, we demonstrated that such tests do actually have appropriate LOINC codes and automated methods can be used to achieve mapping where neither the outside laboratory nor the receiving laboratory system are able to do so.

LOINC mapping. The LOINC code is an intermediate between local and outside laboratory tests. Our mapping is based on textual comments reported by the outside laboratory as results that actually include test names and results, which are different from mapping local laboratory tests based on the names from data dictionary. Our mapping strategy is a specific-general approach. We choose a specific LOINC code for the laboratory result with multi-part matching. Considering test results with less information, we prefer a relatively general code that can cover laboratory results with similar reporting patterns. The laboratory results from well-known laboratories use similar report formats for specific tests, so that the mapping results can be shareable within any laboratory system that obtains results from these laboratories. Our general mapping strategy produces a high success rate; however, we do not consider the possibilities of multiple LOINC codes and the influences of specific methods used in the laboratory tests. Although our mappings appear correct, we have not conducted a formal evaluation of their accuracy.

Local coding. We need to add new terms or codes into the list of laboratory tests, if these terms are not in an EHR system. In clinical data repositories within the i2b2 model, the i2b2 ontology management cell manages new test names under accurate concept paths. The RED concept structure allows the representation of outside laboratory test information in "synonym" properties and their associated attributes as local data sources. However, when we add as many new terms as we can identify from unspecified outside laboratory test results, we bear the burden of the need for additional concepts and an efficient method to manage the concepts.

Fuzzy lookup transformation. Microsoft SQL server integration services (SSIS) provides a platform for ETL processes that supports routines for outside laboratory test results transformation into the daily work flow. In BTRIS, we will apply the featured fuzzy lookup function in the ETL processes to identify unspecified laboratory results to match them with previously encountered test result (perhaps differing only by numeric result or punctuation). The input data source is the file with original outside laboratory results. The program will produce similarity scores for each sample in the reference table. The input data will be added to the output file with the specific laboratory test name with the highest similarity score above a given threshold. So far, we have worked on sample data retrieved from BTRIS. Additional experiments on new incoming laboratory data are needed.

Conclusion

We identified the meanings of outside unspecified laboratory tests results using medical standards and developed an outside laboratory test reference table for use in fuzzy lookup transformation processes. This study suggests that a
modest effort can lead to improved coding of these outside nonspecific laboratory data, such that we do not have to settle for having a portion of the patient’s records be unusable but rather can bring these additional data to bear on data re-use tasks. The heterogeneous and dynamic nature of EHR data reminds us of the challenges in the implementation of standards.

ABSTRACT

Online health communities provide popular platforms for individuals to exchange psychosocial support and form ties. Although regular active participation (i.e., posting to interact with other members) in online health communities can provide important benefits, sustained active participation remains challenging for these communities. Leveraging previous literature on homophily (i.e., “love of those who are like themselves”), we examined the relationship between vocabulary similarity (i.e., homophily of word usage) of thread posts and members’ future interaction in online health communities. We quantitatively measured vocabulary similarity by calculating, in a vector space model, cosine similarity between the original post and the first reply in 20,499 threads. Our findings across five online health communities suggest that vocabulary similarity is a significant predictor of members’ future interaction in online health communities. These findings carry practical implications for facilitating and sustaining online community participation through beneficial effects of homophily in the vocabulary of essential peer support.

INTRODUCTION

Many people use online health communities, such as WebMD and Facebook health groups, to exchange peer support and connect with others\textsuperscript{1}. Research on the benefits of online health communities highlights psychosocial benefits—such as reduced depression\textsuperscript{2,3} and stress\textsuperscript{4,5}—from active participation in online health communities. However, sustaining active participation remains a prominent challenge for online communities in general\textsuperscript{6-10} due to issues like lurking (i.e., participating without posting) and dropouts.

Sustained, active participation in online communities has been shown to positively correlate with a number of different factors. For example, receiving a response to a newcomers’ first post\textsuperscript{8}, receiving emotional support\textsuperscript{4}, obtaining a sense of community\textsuperscript{11}, and having familiarity with online interactive services (e.g., chat)\textsuperscript{6} have all shown to positively correlate with active participation or degree of effort and time spent with the community. Although these studies provide insight on how to sustain active participation in general online communities, only one study examined online health communities\textsuperscript{8}. In contrast to the typical online community, active participation in online health communities could have implications for quality of life due to the purpose of participation: exchanging health information and psychosocial support. In that study of an online health community,\textsuperscript{8} participation was measured by sign-ins, which includes passive behaviors like lurking\textsuperscript{10}. Lurkers not only gain fewer benefits than active participants\textsuperscript{4} but they also do nothing to promote community sustainability. In our study, we focus on active participation to better reflect the benefits of online health communities to members and community sustainability.

Homophily, the tendency for individuals to be attracted to others with similar characteristics such as attitude and behavior mimicry\textsuperscript{12}, is an important yet underexplored principle in studying online community participation. However, homophily is a well-established principle in the context of social network analysis\textsuperscript{13}, and it has been shown to positively correlate with credibility of authors in online health communities\textsuperscript{14}. Moreover, homophily expressed through unconscious mimicry was correlated with likelihood of liking the respondents\textsuperscript{15}. Similarly in language, verbal mimicry of function words (i.e., content-free parts of speech) has been shown to positively correlate with liking the respondents\textsuperscript{16} and positively functioning social dynamics\textsuperscript{17}. In online health communities, both function words and content words can serve as important cues for measuring homophily expressed in vocabulary usage. The function words are related to unconscious mimicry whereas the content words are related to similarity in health traits. Although homophily measured using all types of vocabulary usage—vocabulary similarity—could have effects on members’ active participation, vocabulary similarity has not been studied with respect to active participation in online health communities.
Based upon previous literature, we expect community members to appreciate responses in which respondents use similar vocabulary. Thus, we hypothesized that individuals are likely to sustain active participation if they receive replies written with similar vocabulary. We examined this issue within the context of five online health communities from WebMD.com to address the following research questions:

**(RQ1)** What is the relationship between receiving replies written using a similar vocabulary and original posters’ subsequent thread engagement?

**(RQ2)** What is the relationship between receiving replies written using a similar vocabulary in the early stage of joining the community and newcomers’ sustained community participation?

**(RQ3)** What factors other than homophily in vocabulary usage correlate with active participation in online health communities?

**METHODS**

Our overarching objective is to understand participation in online health communities, in particular the relationship between vocabulary similarity of received replies and the member’s future interaction in the community. We define **original post** as a post that starts a thread and **original poster** as the author of the original post. Similarly, we define **first reply** as the first post to reply to an original post and **respondent** as the author of the first reply. If the original poster or respondent uses multiple posts consecutively, we considered the accumulation of those posts as the original post or first reply, respectively. For example, original posters and respondents occasionally add comments in subsequent posts before any other member replies. Hence we included any supplementary posts as a part of the original post/first reply. We define **reengagement** as the behavior of original posters returning back to threads they started and having further conversation with the respondent (i.e., by posting a reply). Conversely, we defined **disengagement** as the behavior of original posters not posting a reply to that thread.

In our analysis, we restricted our focus to the first reply for two reasons. First, we wanted to pick the post with the highest chance of reaching the original poster. First replies appear for the longest time compared to other posts in the thread. Hence original posters have the longest time to read first replies. Second, systematically assessing who is responding to whom is difficult without analyzing the content of each post. For instance, the third person to post (the second replier) could be interacting with the respondent or the original poster. Those posts that are not replying back to the original post could skew the results; thus, we focused our analysis on first replies.

We reviewed common approaches from information retrieval that could be used to quantify **vocabulary similarity** that would represent homophily of vocabulary usage between original posters and respondents. We decided to use a vocabulary-based cosine similarity measurement without any feature reductions (e.g., removing common words) to quantify vocabulary similarity score. We chose to use cosine similarity because it is one of the most common and thoroughly studied measures. One advantage of cosine similarity over other text similarity measures, such as Jaccard similarity, is that cosine similarity normalizes the text length during the comparison. Thus, long first replies would not necessarily be considered to have higher number of shared words. To determine the cosine similarity between original posts and first replies, we first represent each post as vector in N-dimensional space, where N is the number of unique terms across all posts and the value is the frequency with which terms occur in that post. Cosine similarity measures the cosine of the angle between two vectors representing the posts. The resulting similarity score ranges from zero to one. A score of zero indicates no shared terms between the two posts, whereas a score of one indicates all terms and the relative proportion of the terms used are exactly equal.

**(RQ1)** What is the relationship between receiving replies written using a similar vocabulary and the original posters’ subsequent thread engagement?

To examine RQ1, we investigated whether original posters reengaged or disengaged in the threads given the vocabulary similarity score of first replies to original posts. We applied statistical tests (i.e., Pearson’s Chi squared test (X²) and Welch’s t-tests (t) for two unpaired samples with unequal variances) to determine whether original posters who received replies with higher similar vocabulary scores reengaged more often. Thus, we compared the mean vocabulary similarity score among original posters who reengaged with the mean vocabulary similarity score among original posters who disengaged.

Next, we used logistic regression to predict the likelihood of original posters reengaging in their threads given vocabulary similarity score. Logistic regression is a statistical technique for predicting dichotomous outcome variables (i.e., engagement) given one or more predictor variables (i.e., vocabulary similarity scores). Logistic
regression limits the range of outcome variables from zero to one, satisfying assumptions for dichotomous outcome. Then, we tested the overall effects of vocabulary similarity score using the Wald test.

(RQ2) What is the relationship between receiving replies written using a similar vocabulary in the early stage of joining the community and the newcomers’ sustained community participation?

We applied survival analysis to examine the relationship between newcomers receiving replies written using a similar vocabulary to their own posts in the early stage of joining the community and the newcomers’ sustained participation in the community over time. To identify newcomers, we selected members who contributed at least one original post and received at least one first reply in their newcomer stage. The threshold for the newcomer stage was defined as up to three original posts. We chose this threshold because members with less than three posts were considered lurkers, who are not yet a regularly contributing member, in a prior study10.

Survival analysis is a time duration analysis that models survival time until the failure event occurs. We define the survival object (i.e., “sustained participation”) as the period of time in which members continue to participate in the online health community. Defining survival time with respect to online participation can be difficult because the failure event cannot be as clearly defined as in other fields, such as biological and medical sciences where survival analysis has been widely used. In the context of online health communities, members can always return to the community after years of absence as long as the community is active. We adopted a definition of a failure event from Wang et al.5 to be a period of inactivity of three months without posting to the community. We considered members’ first post (i.e., either original post or replying post in threads) as the starting point of their participation in the community and their last post as the end of their participation. However, if members posted within three months of the data collection date, we considered them right censored (i.e., member who did not experience the failure event) because they might still be actively participating in the community. We calculated the survival time as the days between members’ first and last post.

(RQ3) What factors other than homophily in vocabulary usage are correlated with active participation in online health communities?

We selected a random sample of 100 original-first reply post pairs by selecting 10 pairs that reengaged and 10 pairs that disengaged in each of the five communities. We manually examined these 100 threads for other factors related to active participation. We drew on findings from previous studies to guide our content analysis. Previous studies have shown that types of social support19 sought by original posters (e.g., informational or emotional), types of social support that original posters received8, length of original posts and first replies20,21, and rhetorical elements (i.e., asking questions9) are associated with participation.

In addition, we considered coverage of information—whether replies address all of the concerns expressed in original posts. In information retrieval, cosine similarity is used to measure the similarity of two documents with respect to their subject18. Because cosine similarity can calculate homophily of vocabulary and similarity of two documents—a proxy for coverage of information—we investigate a possible correlation between information coverage and active participation to have a deeper understanding of the effects of homophily in vocabulary.

We blindly examined the effect of these factors on future interactions with respondents. Furthermore, we explored the purpose of original posters’ reengagement. The review of types of emotional support and the purpose of original posters’ reengagement followed an open coding process22, which is a method used to elicit unknown, emerging themes grounded in data. For informational support, we assessed whether the original posters were seeking information or not.

Data: Selection and Overall Characteristics

To meet our study aims, we restricted our analysis to five communities from WebMD.com for several reasons. First, we selected chronic disease-related communities. This criterion eliminated non-disease specific communities, such as parenting and baby’s first year or smoking cessation, with a possible correlation between short-term health issues and dropout rates of WebMD forums. Second, we selected highly active communities that ranked within the top 20 WebMD forums in total number of threads. This eliminated communities that could have member dropouts due to the low-activity of the community. Third, we selected communities with two or more moderators who helped as respondents. This eliminated communities that could have member dropouts due to the low-level of moderating. Lastly, we selected communities with a sufficient number of posts from members, at least 50 first replies from both members and moderators. After applying these inclusion and exclusion criteria, five communities remained eligible for subsequent analysis: (1) ADHD, (2) Diabetes, (3) Heart Disease, (4) Pain Management, and (5) Sexual Health.
communities (Table 1). We excluded two types of original posts: (1) original posts without replies and (2) original posts started by moderators. We removed these types of original posts to focus our analysis on members and their participation behavior when receiving replies. We sought review by University of Washington Institutional Review Board (IRB) and the data was exempt from review.

RESULTS

First reply distribution

First replies in our data set were posted within a day (mean of 21 hours), and 99% were posted within a week. Although replies posted later have an increased chance of not reaching the original posters, the reengagement rate for late replies that came after a week (9%) was comparable to the entire dataset’s reengagement rate (17%). Thus, all first replies were included in the following analysis.

Results for (RQ1): What is the relationship between receiving replies written using a similar vocabulary and the original posters’ subsequent thread engagement?

As shown in Table 2, we observed zero-inflated data distribution in which frequent zero vocabulary similarity scores were detected. Zero vocabulary similarity scores often resulted from the limited terms posted by respondents in first replies (e.g., “Find another doctor” or “no comment”). Original post and first reply pairs with zero vocabulary similarity scores had mean of 14 terms (Standard Deviation (SD)=29) in the first replies whereas the pairs with non-zero vocabulary similarity scores had significantly higher mean of 129 terms (SD=134; t(800)=70.21, p<0.0001) in the first replies. Because short generic replies are common in online communities, it was important that we keep the posts with zero similarity scores. We solved the high number of zero vocabulary similarity scores problem by fitting the data into a two-part model (i.e., zero-inflated continuous data model). We then analyzed original post and first reply pairs with zero and non-zero vocabulary similarity scores separately.

In the first part of the two-part model, we compared reengagement associated with vocabulary similarity score of zero versus non-zero. We compared the reengagement rate between the zero data set and the non-zero data set, which was significant ($X^2(1, N=20,499) = 15.27, p<0.0001$). Thus, having any vocabulary similarity score is associated with significantly higher reengagement.

In the second part of the model, we applied Welch’s t-tests to the non-zero portion of data to compare reengagement and disengagement by the original poster. Overall, Welch’s t-tests showed significantly higher vocabulary similarity score for reengagement compared to disengagement by the original poster in all communities except for Heart Disease (Table 3). Table 3 also shows the percentage of threads that original posters reengage later in the thread after multiple posters have posted. This data shows a full picture of original posters’ engagement behaviors. We suspect that no difference was found in the Heart Disease community because of its overall higher rate of disengagement. In the Heart Disease community, original posters disengaged 81% of threads, which is 20% higher than the average disengagement rate of 60% in the other four communities.

Next, we used logistic regression with one predictor variable—vocabulary similarity score—to predict the likelihood of original posters reengaging in their threads. Figure 1 shows the plot of the predicted probability with 95% confidence intervals of reengagement given the vocabulary similarity score between original post and first reply. This regression model was significant (X²(1)=91.43, p=1.55e-43) with odds ratio of 4.70. Using the vocabulary similarity score, we predicted future participation with 79% accuracy in a 10-fold cross validation. The Wald test indicated that for a one unit increase in vocabulary similarity score, the odds of original posters reengaging increased by a factor of 4.7 (X²(1)=188.60, p=6.43e-43).

**Results for (RQ2): What is the relationship between receiving replies written using a similar vocabulary in the early stage of joining the community and the newcomers’ sustained community participation?**

We applied survival analysis to test the effect of receiving replies written using a similar vocabulary on members’ sustained participation in the community. We partitioned members into three equally sized groups corresponding to members exposed to replies with a “High,” “Medium,” or “Low” vocabulary similarity score. For members with more than one original and corresponding first reply, we took the average vocabulary similarity score among the first three original and corresponding first replies. Low vocabulary similarity scores ranged from 0 to 0.28, Medium scores ranged from greater than 0.28 to 0.41; and high scores ranged from greater than 0.41 to 0.83, which was the highest vocabulary similarity score in our dataset. Examples of high and low replies are shown in Results section for RQ3.

![Figure 1. Predicted probabilities of reengagement graph with 95% confidence intervals.](image-url)
Figure 2 illustrates the effect of receiving replies written using a similar vocabulary on members’ sustained active participation. Members in the High group were most likely to stay active in the community, followed by members in the Medium group, followed by members in the Low group as least likely to stay active. These differences were sustained between the high and low groups for at least 300 days.

Results of two survival models are shown in Table 4. Model 1 reports the effects of the covariates. For instance, the hazard ratio of 0.75 for the total number of original posts indicates that those who initiate threads one standard deviation more have a 34% (i.e., (1/0.75) – 100%) higher survival rate. Similarly, Model 2 shows that members who received replies with a vocabulary similarity score of one standard deviation higher have a 5% (i.e., (1/0.95) – 100%) higher survival rate when controlling for covariates.

The hazard ratio indicates the odds of members dropping out of the community (encountering the failure event). We also considered a number of covariates and their relationship to sustained participation in two survival models. We selected covariates representative of each member’s intrinsic characteristics (e.g., sociable) as well as the amount of participation in the community. These variables include the total number of posts, total number of first replies provided, total number of first replies received, and total number of original threads. We normalized variables (i.e., (observation – mean)/standard deviation) to show predicted change in odds for a unit increase in the predictor.

Results for (RQ3): What factors other than homophily in vocabulary usage are correlated with active participation in online health communities?

Without any knowledge of their vocabulary similarity scores or reengagement status, we manually categorized original post and first reply pairs into three groups: high, medium, and low coverage groups. We categorized pairs with first replies that addressed all of the concerns expressed in original posts as high coverage, first replies that addressed some concerns as medium coverage; and first replies that did not address any concerns as low coverage. We then examined how well the vocabulary similarity measures performed compared to manual categorization. High coverage group compared to low coverage show significantly higher vocabulary similarity scores (t(19)=2.58, p=0.02) (Table 5). However, the difference between high coverage group and medium coverage group (t(20)=0.34, p=0.74) as well as the difference

</table>
between medium coverage group and low coverage group ($t(29)=1.63, p=0.11$) were not significant.

In the 50 reengaging pairs, we found that 86% provided high coverage, 8% provided medium coverage, and 6% provided low coverage. In contrast, of the 50 disengaging pairs, 52% provided high coverage, 24% provided medium coverage, and 24% provided low coverage. Comparison of high, medium, and low information coverage showed reengaging had a significantly higher proportion of high coverage replies ($X^2(1, N=100)=11.97, p=0.0005$). As well, disengaging had a significantly higher ($X^2(1, N=100)=5.02, p=0.03$) proportion of low coverage replies. However, medium coverage did not differ significantly ($X^2(1, N=100)=3.65, p=0.06$).

Similarly, when we compared pairs associated with reengagement and with disengagement, we found a noticeable difference in the length of the posts measured by number of words. The pairs associated with reengagement used more words in both original posts and first replies. On average in the reengaging pairs, original posters used 198 words (SD=152) while respondents used 181 words (SD=150). In contrast, in the disengaging pairs, original posters used 122 words (SD=116) while respondents used 137 words (SD=142). The difference between reengaging and disengaging pairs was significant in original posts ($t(92)=2.78, p=0.006$) but not significant in first replies ($t(98)=1.48, p=0.14$).

We also found differences in emotional support: whether respondents indicated an aspect of empathizing with or helping original posters. We found two themes of emotional support: acknowledgement of members’ experience of difficulty (e.g., “I know exactly how you feel [...] I’m in the same boat”) and encouragement for the current situation (e.g., “You’ve got a great attitude, and will do well”). In reengaging pairs, 30% of respondents acknowledged the difficulty of the original poster’s situation and 34% of respondents encouraged original posters. Conversely, in disengaging pairs, 18% and 28% of respondents acknowledged their difficulty and provided encouragement, respectively. However, differences in these propositions were not significant (Acknowledgement: $X^2(1, N=100)=1.37, p=0.24$; Encouragement: $X^2(1, N=100)=0.19, p=0.67$).

The overall exchange of emotional support was less frequent than informational support; this fits well with what original posters were seeking. Overall, 89% of the original posters asked for new information, while only 24% of the original posters showed any signs of requesting emotional support (e.g., “can’t take more” or “desperate!”). Exchanges of emotional and informational support were not mutually exclusive as some original posters sought both.

We also examined the effects of respondents asking questions to original posters in first replies. In reengagement, 32% of respondents asked a question in their reply, while only 20% of respondents asked a question in disengagement, however, difference in these proportions were not significant ($X^2(1, N=100)=1.30, p=0.25$). Similarly difference in the proportions of providing informational support was not significant ($X^2(1, N=100)=0.07, p=0.79$) between reengagement and disengagement. In reengagement, 84% provided informational support, while 80% provided informational support in disengagement.

In our qualitative analysis, we identified four themes for the purpose of original posters’ reengagement: (1) providing more information on their situation (82%), (2) thanking the original posters (62%), (3) asking more questions (20%), and (4) getting defensive (8%). These behaviors were not mutually exclusive.

In our sample, reengaging and disengaging pairs varied in the degree of information coverage. First replies that covered more aspects of the original post received higher vocabulary similarity scores than those that covered fewer aspects. The following is an example of a reengaging pair that received a relatively high vocabulary similarity score of 0.66.

**Original poster A:** “I’d much rather ask others that have a condition I may have... I’ve been pretty hyper all my life [...] and have been bouncing around the idea in my head that I may have some sort of ADHD. [...]I’ve noticed I can focus more when I am very tired. [...]”

**Respondent to A:** “You are describing Adult ADHD. You should make an appointment with a psychiatrist who was experience with adult ADHD. [...] My mind is usually all over the place bouncing from topic to topic [...] Things aren't like that now. [...] Go. Get tested. [...] If you do have ADHD, he may or may not prescribe medication. [...]You have nothing to loose as long as your honest with your doctors. Good luck. [...]”

Conversely, the following is an example of a disengaging pair that received relatively low vocabulary similarity score of 0.14.
Original poster_B: “been having muscle ache between upper left chest (near armpit) through shoulder [...] Did I strain a muscle/group of muscles, and what's best - heat, NSAIDs, chiropractic?”

Respondent_to_B: “Hello. No way for any of us on an internet message board to know what is causing your symptoms. You will need to see your doctor for an evaluation and treatment plan [...]”

In both examples, the respondents advocate seeking professional help. However, only in the first example, did respondent_to_A provide their experience and perspective. During this process, respondent_to_A covered a number of issues raised by original poster_A while using more shared vocabulary. This conversational pair resulted in a relatively high vocabulary similarity score and elicited original poster_A to reengage in further conversation. In the second example, respondent_to_B does not address the concerns original poster_B raised. This resulted in using less shared vocabulary with original poster_B and a relatively low vocabulary similarity score.

As mentioned earlier, other factors also correlate with original posters’ engagement. Respondent_to_A acknowledges the difficulty and encourages original poster_A while using more words (521 words) than respondent_to_B (34 words). Conversely respondent_to_B is succinct and does not provide any emotional support while neither respondent asked questions. Although a combination of many factors can influence engagement of the original poster, in our manual analysis receiving replies with more shared vocabulary appears to be associated with reengagement, which supports our quantitative analysis.

DISCUSSION AND FUTURE WORK

Prior research shows that sustaining active participation presents a prominent challenge for online communities6–10. In this paper, we showed the importance of homophily expressed through shared vocabulary associated with members’ ongoing engagement in online health communities. Members who received replies that contained more shared vocabulary with their own posts tended to continue their conversations with respondents.

Additionally, we created prediction models that estimate the likelihood that original posters will reengage with respondents. Although many factors can contribute to members disengaging from conversation, our logistic regressions showed that vocabulary similarity predicts future participation with the respondents. Similar prediction models could be one solution for the challenge of sustaining active participation. For instance, our prediction model could allow moderators to identify members who are most likely to disengage. This added knowledge could enable moderators to provide replies that encourage reengagement. Moreover, we discovered that receiving replies written in a similar vocabulary in the early stages of joining the community predicts long-term active participation within the community. One solution for sustaining newcomers’ participation in the community is to encourage community members to abide by a set of guidelines, which reflect ideal community member interactions with newcomers. Furthermore, measuring vocabulary similarity can be a basis for automatically alerting members when they deviate from posting replies that encourage reengagement. In contrast with targeting specific members to encourage reengagement, the environment of the community as a whole could be improved by filtering spam or abusive content through comparing terms with the common vocabulary of the community.

In our manual analysis, we found that a combination of many different factors could influence original posters’ engagement. Other factors, such as exposure to higher degree of information coverage and higher word counts by original poster20,21 were associated with reengagement in our data. All other factors had higher occurrences in reengagement, but they are not found significant. We suspect this is due to small sample size of 100 in our manual analysis. Investigating which factors had the biggest impact on original posters’ engagement is an important question for future work. However, measuring vocabulary similarity of first reply to the original post is a relatively easy and robust technique that seems to measure an important marker for member reengagement.

Furthermore, the vocabulary similarity of the first reply might not be the sole factor of member engagement with respondents. For instance, other components of life can influence online health community participation. Original posters could have gained the needed information through other sources and did not check back with the community. A serious medical crisis could prevent original posters from checking back with the community too, for example. Still, the consistent statistical results from examining the relationship between vocabulary similarity and participation show that homophily of vocabulary provides an important marker for member reengagement.

Our survival analysis examines members’ early stages of joining the community and uses a threshold of the first three replying posts that members received based on previous literature on lurking10. Understanding the transition point of members’ participation can provide a deeper understanding of how to sustain active participation in online communities.22,23
communities. Also, our analysis does not answer whether inactive members remained lurkers or completely dropped from the community. An analysis of these two different types of inactive members could further extend our findings.

Although overall our analyses showed consistent results in a diverse group of online health communities, we acknowledge that our large sample size could have inflated the significance levels or otherwise skewed results and raises questions to the practical significance of our findings. Also, how much vocabulary similarity is needed for a meaningful increase in reengagement remains an open question. Further investigation, such as surveys or interviews, analyzing members’ satisfaction and understandability of health information correlated to vocabulary similarity could further explore the significance of our findings.

In future work, we plan to investigate the correlation between actual users’ perceived qualities of replies and participation to further examine the challenge of sustaining participation in online health communities. Understanding these relationships could provide a more complete view of how to sustain participation in online health communities. The significance of this study goes beyond predicting members’ behavior in online health communities. For instance, our findings could generalize in non-health online communities and our automatic approach to analyze computer-mediated communication (CMC) could be applied to other CMC studies. Furthermore, our study showed a potential method to elucidate the process of forming social bonds through CMC in online communities.

CONCLUSION

We provide new insights regarding sustaining online health community participation through systematic analyses of five WebMD online health communities. Our findings suggest that homophily—the vocabulary similarity between members’ posts—plays a crucial role in sustained engagement in online health community. We provide new insights into how vocabulary similarity affects active participation in online communities. Furthermore, vocabulary similarity calculated with cosine similarity shows promising results in measuring the coverage of information in replies. Based on these insights, moderators, online community creators, and online community participants could tailor replies to encourage sustained, active participation by members. Findings from this study can improve member experience in difficult situations when online health communities provide essential support.

Approaches to Supporting the Analysis of Historical Medication Datasets with RxNorm

Lee B. Peters, M.S., Olivier Bodenreider, M.D., PhD
National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA

Abstract

Objective: To investigate approaches to supporting the analysis of historical medication datasets with RxNorm. Methods: We created two sets of National Drug Codes (NDCs). One is based on historical NDCs harvested from versions of RxNorm from 2007 to present. The other comprises all sources of NDCs in the current release of RxNorm, including proprietary sources. We evaluated these two resources against four sets of NDCs obtained from various sources. Results: In two historical medication datasets, 14-19% of the NDCs were obsolete, but 91-96% of these obsolete NDCs could be recovered and mapped to active drug concepts. Conclusion: Adding historical data significantly increases NDC mapping to active RxNorm drugs. A service for mapping historical NDC datasets leveraging RxNorm was added to the RxNorm API and is available at https://rxnav.nlm.nih.gov/.

Introduction

Many electronic medical systems identify a drug product by using a National Drug Code (NDC). For example, NDCs are used for identifying prescription drugs in the Medicare “Part D” database, as well as by many pharmacies, pharmacy benefit managers and health insurance companies [1-10]. NDCs represent not only the product’s characteristics (dosage strength and form), but also manufacturer and packaging information. Because of their specificity, NDCs tend to be less stable identifiers compared to other drug vocabularies, such as RxNorm. For example, NDCs can become obsolete not only due to the product discontinuation for the usual safety reasons, but also due to discontinuation by a manufacturer for business reasons, or due to changes in packaging (e.g., pack size). In some cases, the drug may still be produced (with the same identifier in RxNorm), but by a different manufacturer or with a different pack size (i.e., under a different NDC).

Because NDCs are widely used drug identifiers, there is a great need and interest in mapping the NDC for a drug product into a standardized RxNorm name for use in electronic medical systems. In fact, the most used function in the RxNorm API is findRxcuiById, used to map a variety of drug identifiers to RxNorm, and NDC is the type of identifier most often converted to RxNorm with our API. More specifically, our API received 155 million findRxcuiById requests in 2014, 123 million (79%) of which specify NDCs.

In addition to its own identifiers, RxNorm maintains a collection of curated, up-to-date NDCs and therefore supports the mapping of current NDCs to RxNorm. However, in addition to mapping NDCs to RxNorm for current datasets or transactions from health information networks, researchers have shown interest in analyzing historical medication datasets. One such dataset is the Medicare “Part D” dataset. While RxNorm maintains history information for its own identifiers, it does not keep track of obsolete NDCs and their connection to the drugs they referred to is lost. Similarly, the NDC database maintained by the FDA only contains currently valid NDCs.

Our objective is to investigate approaches to supporting the analysis of historical medication datasets with RxNorm. More specifically, we explore NDCs collected from earlier versions of RxNorm and NDCs provided by drug vocabularies integrated in RxNorm (but not curated by RxNorm), in their coverage of several large datasets of NDCs collected from various sources and time periods. Ultimately, our goal is to support the development of a new API function for mapping legacy NDCs to RxNorm, informed by the findings of this investigation.

Background

National Drug Code (NDC). The NDC is a universal product identifier for human drugs in the United States. The Drug Listing Act of 1972 requires registered drug establishments to provide the Food and Drug Administration (FDA) with a current list of all drugs manufactured, prepared, propagated, compounded, or processed by it for commercial distribution. Drug products are identified and reported using the NDC.

The NDC is represented by a unique 10-digit, 3-segment number. The first segment of the NDC identifies the labeler (manufacturer, distributor or re-packerager). The second segment is the product code, which identifies the specific strength, dosage form (i.e., capsule, tablet, liquid) and formulation of a drug for a specific manufacturer.
The third segment is the package code, which identifies package sizes and types. The first segment (labeler code) is assigned by the FDA and the second and third segments are provided by the labeler.

Examples of 10-digit, 3-segment NDCs:
- 54868-1048-1 (5-4-1 format)
- 55111-476-79 (5-3-2 format)
- 0179-0111-70 (4-4-2 format)

Many systems, including RxNorm, convert these forms into an 11-digit NDC derivative, which pads the labeler, product, or package code segments of the NDC with leading zeroes wherever they are needed to create a 5-4-2 format without the dashes. Examples of conversion:
- 54868-1048-1 => 54868104801
- 55111-476-79 => 55111047679
- 0179-0111-70 => 00179011170

RxNorm is a standardized nomenclature for medications produced and maintained by the U.S. National Library of Medicine (NLM) in cooperation with proprietary vendors [11]. RxNorm concepts are linked by NLM to multiple drug identifiers for each of the commercially available drug databases within the UMLS® Metathesaurus®. In addition to integrating names from existing drug vocabularies, RxNorm creates standard names for clinical drugs. RxNorm also contains NDC codes in the 11-digit NDC derivative format described above. The NDCs curated by RxNorm are derived from two terminologies – DailyMed and First Data Bank. Some other source vocabularies also contribute NDCs to RxNorm. However, these additional NDCs are not curated by RxNorm. RxNorm is updated monthly and each version only contains active NDCs, i.e., those NDCs which reflect the current state of availability of drug products. With each new version of RxNorm, some are added, while others that have become obsolete are removed. RxNorm does not keep track of obsolete NDCs.

The RxNorm API [12] provides functionality to access the RxNorm dataset, including mapping from NDCs to obtain the RxNorm concept identifier (RxCUI). It accepts the NDC in the 10-digit, 3-segment sequence or as the 11-digit derivative. Only active NDCs (curated by RxNorm in the latest release) can be mapped to RxNorm concepts.

Related work. Hanna et al developed a historical NDC dataset to use in the Drug Ontology [13]. While our objective is in part similar to theirs, their main goal was to harvest historical NDCs. In contrast, the specific contribution of this work is twofold. First we investigate the enrichment of a reference set of NDC not only with historical NDCs, but also with NDCs from other drug information sources. More importantly, we provide a comprehensive evaluation of the impact of using a richer set of NDCs by measuring the results on several large sets of NDCs from various sources and time periods.

Methods

Our investigation of approaches to supporting the analysis of historical medication datasets with RxNorm can be summarized as follows. First we describe two approaches to enriching RxNorm with additional NDCs:

1. Collect curated NDCs from earlier versions of RxNorm,
2. Collect NDCs from all drug vocabularies in the latest release of RxNorm (curated or not by RxNorm).

We then evaluate these two sets of NDCs in their coverage of large datasets of NDCs collected from various sources and time periods.

Enriching RxNorm with additional NDCs

To enrich RxNorm with additional NDCs, we need to acquire NDCs from some source and to associate each NDC with a valid RxCUI in the current version of RxNorm.

Collect curated NDCs from earlier versions of RxNorm. As mentioned above, the RxNorm dataset is restricted to currently valid NDCs and does not contain historical information regarding legacy NDCs. To create an NDC
history, we retrieved the monthly releases of the RxNorm dataset starting in July 2007 through the March 2015 release to track all the curated NDCs active at any time during this time period. For each NDC, the start and end times of the period of activity were recorded, as well as the concept identifier in RxNorm with which it was associated. For some NDCs, the RxNorm concept identifier originally associated with the NDC became obsolete and was remapped. For example, NDC 00002036303 (Darvocet-N tablets) was originally linked to RxCUI = 687241, but that concept was later mapped to 849692. We refer to this set of NDCs and related information extracted from historical RxNorm versions as the History data.

Collect NDCs from all the drug vocabularies integrated in RxNorm. There exist in the RxNorm dataset NDCs which are provided by drug vocabularies integrated in RxNorm, but not curated by RxNorm. These NDCs are not part of the active set of NDCs and are not retrieved by the RxNorm API. The reasons for these NDCs not being in the active set could be that they deal with products, such as needles or syringes or that they represent experimental or unapproved drugs by the FDA. Moreover, these NDCs may come from proprietary sources and may not be publicly available. In this investigation, we looked at the March 2015 release of the RxNorm dataset and harvested all the NDCs from all the drug vocabularies. We refer to this set of NDCs and related information extracted as the All Sources data.

Associating NDCs with active RxCUIs

To determine if an NDC is active, we used the RxNorm API method findRxcuiById. For active NDCs, the RxNorm concept identifier (RxCUI) is identified. For obsolete NDCs (NDCs that were once active but are no longer active), the last active time period is identified along with the last known RxCUI from the historical data. We use the RxNorm API to determine if the RxCUI associated with the NDC is active, has been remapped, or is inactive. For example, the obsolete NDC 0018202833 (Bacitracin Ointment) was last mapped to RXCUI=308509 but that RXCUI was later remapped to 1366116. NDCs which are not contained in historical data but are contained in All Sources (which we call “Alien” NDCs) have an RxCUI associated with them, and we use the RxNorm API to determine if that RxCUI represents an active RxNorm drug product.

Based on the presence of an NDC in the various sources, we determine the status of an NDC in the following way.

- **Active.** The NDC is currently recognized by RxNorm as an active drug code (i.e., is part of the curated NDCs from the latest release of RxNorm). All active NDCs are associated with an active RxCUI by definition, and can be found by using the RxNorm API. All active NDCs are also contained in both the History data and the All Sources data.

- **Obsolete.** The NDC is no longer active, but was in the past (i.e., was part of the curated NDCs from some earlier version of RxNorm). Some obsolete NDCs can be associated with an active RxCUI (e.g., if the RxCUI to which they were originally associated is still active or can be remapped to an active RxCUI). These NDCs are found in the History data.

- **Alien.** The NDC is not recognized by RxNorm as an active drug code, nor has it been in the past, but it is currently contained in at least one drug vocabulary. This indicates the possibility of an out of scope drug product. Most of these NDCs are not associated with an active RxNorm concept. These NDCs can be found in the All Sources data (and not in the History data).

- **Unknown.** The NDC is not found in either the History data or All Sources data.

The procedure for determining the NDC status goes through the steps listed above in order and stops when the NDC is identified. Once the NDC is identified from one of the datasets, we use the procedure outlined above to find the active RxCUI (if it exists) associated with the NDC. In order to facilitate the evaluation, we created an application for looking up the NDCs and their status from a database.

Evaluation

In order to evaluate the practical benefit of using additional NDC sources to the analysis of medication datasets, we acquired several large datasets of NDCs collected from various sources and time periods. We performed a quantitative evaluation of the coverage each dataset. Additionally, we performed a qualitative analysis of the NDCs from one of these sources for which no mapping to RxNorm could be found.
Quantitative evaluation. To test the NDC status function, we used sets of NDCs from three distinct sources:

- **Medicare NDCs.** This dataset came from a random sample of Medicare Part D patients who enrolled in 2009. The set contains 27,186 unique NDCs prescribed to these patients in 2011, as well as the frequency of prescription for each NDC.

- **Private insurance NDCs.** This dataset came from a large private health insurance group and corresponds to NDCs collected during the period January 2010 to May 2014. The set contains 51,490 unique NDCs.

- **API log file NDCs.** We took the NDCs specified in the RxNorm API calls to `findRxuiByld` for a single month (January 2015) from the API log files. This API call allows the user to find the RxNorm concept associated with the user specified NDC. We removed any input that was not in the 10-digit, 3-segment format or the 11-digit derivative format and converted all to the 11-digit derivative format. The resulting dataset contained 372,705 unique NDC entries.

- **FDA NDC list.** A reference list of approved NDCs for drug products exists from the FDA. We downloaded this list for http://www.fda.gov/Drugs/InformationOnDrugs/ucm142438.htm in our investigation to check against the NDCs in the History and All Sources data. The FDA list contained 167,748 NDCs.

Qualitative evaluation. One of the authors (OB), a physician, reviewed all the NDCs from the Medicare dataset for which no mapping to an active RxNorm drug could be found. This evaluation was made possible by the fact that this source provided a generic drug name for each NDC. In practice, we performed a manual review assisted by the use of regular expressions to capture frequently occurring words, corresponding to five major categories:

- Supplies (e.g., needle, syringe, lancet)
- Vitamins and dietary supplements (e.g., hyoscyamine, ferrous sulfate, carotene)
- Cold medicine (e.g., pseudoephedrine, methorphan, menthol)
- Other kinds of over-the-counter drugs (e.g., fluoride, glycerin, ointment)
- Potential prescription drugs (e.g., furosemide, insulin, nifedipine)

![Number of RxNorm NDCs](image)

Figure 1. Active NDCs in RxNorm
Results

*Enriching RxNorm with additional NDCs*

**Collect curated NDCs from earlier versions of RxNorm.** The number of unique NDCs in the History data totaled 445,039. As shown in Figure 1, the number of active NDCs in each monthly version RxNorm fluctuates over time, reflecting not only addition of new drugs, but also curation efforts to eliminate obsolete or unreliable NDCs. In recent years, the number of NDCs curated by RxNorm is about 200,000. The History data includes 418,287 NDCs which can be linked to active RxNorm concepts, which includes 214,876 NDCs not already covered by (active) RxNorm NDCs.

**Collect NDCs from all the drug vocabularies integrated in RxNorm.** The NDCs from the All Sources data include 607,451 NDCs. There are 178,284 (alien) NDCs not covered by the History data. Of these alien NDCs, only 6,485 are linked to active RxNorm concepts.

**Overlap between History NDCs and All Sources NDCs.** Figure 2 shows the overlap of the NDCs between the two datasets. The numbers in parentheses indicate the number of NDCs that are linked to active RxNorm concepts. There are 623,323 unique NDCs contained in the extended set of NDCs composed of the union of the History and All Sources sets, of which 424,772 (68%) are linked to active RxNorm concepts. The History data contains 71% of the total NDCs and 98% of the total NDCs which are linked to active RxNorm concepts. The All Sources data contains 97% of the total NDCs and 97% of the total NDCs which are linked to active RxNorm concepts.

![Figure 2. NDCs in History and All Sources](image)

(Numbers in parentheses denote NDCs linked to active RxNorm concepts)

*Evaluation*

**Medicare NDCs**

The results returned by the NDC status function for the Medicare NDC dataset are shown below (Table 1). Of the 27,186 NDCs in this dataset, 26,528 (97.6%) could be recognized when using the extended set of NDCs (“active”, “obsolete” or “alien” status), leaving only 658 (2.4%) unknown NDCs, compared to 22% unknown NDCs when only using the NDCs from the current release (“active” status). Moreover, 25,220 of all the NDCs could be linked to active RxNorm concepts, of which 24,924 (98.8%) were present in the History dataset (“active” or “obsolete” status).

Private insurance NDCs
The results returned by the NDC status routine for the private insurance NDC dataset are shown below (Table 2). Of the 51,490 NDCs in this dataset, 49,767 (96.7%) could be recognized when using the extended set of NDCs (“active”, “obsolete” or “alien” status), leaving only 1723 (3.3%) unknown NDCs, compared to 33% unknown NDCs when only using the NDCs from the current release (“active” status). Moreover, 43,713 of all the NDCs could be linked to active RxNorm concepts, of which 43,359 (99.2%) were present in the History dataset (“active” or “obsolete” status).

API log file NDCs
The results returned by the NDC status routine for the API log file NDC dataset are shown below (Table 3). Of the 372,705 NDCs in this dataset, 299,230 (80.3%) could be recognized when using the extended set of NDCs (“active”, “obsolete” or “alien” status), leaving “only” 73,475 (19.7%) unknown NDCs, compared to 63% unknown NDCs when only using the NDCs from the current release (“active” status). Moreover, 222,393 of all the NDCs could be linked to active RxNorm concepts, of which 218,216 (98.1%) were present in the History dataset (“active” or “obsolete” status). The high percentage of unknown NDCs in this dataset (compared to historical medication datasets) could be explained by the fact that these NDCs came from many users, whose intentions are unclear and whose sources may have included drugs and medical products that are out of scope for RxNorm. This dataset also has a much larger proportion of Alien NDCs.

FDA NDCs
We compared the NDCs in the History and All Sources data to an external source, the FDA NDC list. When we examined the coverage of these NDCs in the FDA list, we found that 99.8% of the FDA NDCs were contained in either the History or All Sources data. On examination of the missing FDA NDCs, we found several were not valid NDCs (they contained letters) and several others we examined were for drug products that are out of scope for RxNorm.

Qualitative evaluation. We reviewed a total of 1966 unique NDCs (from the Medicare dataset) with no mapping to RxNorm, corresponding to 313,659 prescriptions. As shown in Table 4, the overwhelming majority (82%) of these prescriptions correspond to supplies. While there are quite a number of potential prescription drugs among the list, these NDCs represent a minute proportion of the entire Medicare dataset.

Discussion
Findings. The results indicate there is much to be gained from the use of historical NDC data to allow obsolete NDCs to be linked to active RxNorm concepts. In the Medicare and private insurance datasets, 14-19% of the NDCs were obsolete, but 91-96% of these obsolete NDCs could be linked to an active RxNorm concept using the History data. In contrast, while the use of all sources of NDCs in RxNorm made it possible to recognize many additional NDCs, relatively few of these Alien NDCs were linked to active RxNorm concepts and the Alien data contributed very little in additional mapping to RxNorm concepts.

Comparison with the FDA list showed that the extensive coverage of the FDA NDCs eliminates the need for it to be included in our service that identifies NDCs.

Additionally, the qualitative analysis done on a set of NDCs without mappings to active RxNorm concepts indicate most of these NDCs correspond to entities other than drugs, mostly supplies.

Application. This investigation clearly demonstrates that the analysis of historical medication datasets can benefit from exploiting sources of NDCs beyond the active NDCs (i.e., the NDCs curated by RxNorm present in the latest release). Namely, we showed that a large number of obsolete NDCs in the History data can be linked to an active RxNorm drug. Moreover, additional recognition of NDCs is supported by the All Sources data.

Until recently, the RxNorm API only supported the mapping of active NDCs to RxNorm concepts. The findings of this investigation informed the design of a new API function, getNDCStatus, to support the mapping of historical NDCs to RxNorm. This function explores the History dataset and returns all RxNorm concepts ever associated with a given NDC, along with the period when this association was active. For example, the API indicates that the obsolete NDC 00364666854 was associated with the RxNorm concept 312656 (Promazine 50 MG/ML Injectable Solution) between June 2007 and January 2011. When an NDC is associated with several RxNorm concepts at different time periods, users can select the RxNorm concept corresponding to the date of prescription, if known. The function also indicates when an NDC is recognized as “alien” (i.e., is not curated by RxNorm). This API function was released in June 2015 and is available at https://rxnav.nlm.nih.gov/.
Conclusion
The large percentage of recovered active concepts from obsolete NDCs in the three datasets is a positive indication that a service to identify obsolete NDCs and their active concepts from the past will be beneficial for the analysis of historical medication datasets. An smaller added benefit is the identification of active concepts for NDCs from other sources in RxNorm.

Acknowledgments
This work was supported by the Intramural Research Program of the NIH, National Library of Medicine. We would like to thank Drs. Clem McDonald and Mallika Mundkur from the National Library of Medicine, who provided the Medicare use case. Similarly, our thanks go to Drs. Mark Homer and Ken Mandl from the Children's Hospital Informatics Program in Boston, who provided the use case with the private insurance.

Just One More Patient: Optimizing EMR Documentation in Ambulatory Care

Mark Pierce, MD, FAAP\(^1\), Tammy Toscos, MS, PhD\(^1,2\)
\(^1\)Parkview Health, Fort Wayne, IN; \(^2\)Indiana University School of Informatics and Computing, Indianapolis, IN

Abstract
The adoption of electronic medical records (EMRs) in primary care settings is on the rise in the United States and many are feeling the stress. The introduction of the EMR or transition to a new EMR is known to create workflow challenges for primary care providers and their office staff, as was the case in our health system. This study evolved out of an attempt to alleviate stress by defining the best practice or most optimal way to document office visits, allowing providers to see just one more patient each day. We leveraged a change management model that encourages looking for what is working vs. throwing resources at problem areas. By doing so we identified several distinguishing behaviors among providers who were doing exceptionally well with the EMR. We deployed an intervention aimed at enhancing the identified behaviors in a group of providers and it resulted marked improvement in efficiency.

Introduction
The transition to using an electronic medical record (EMR) in primary care offices can be quite difficult. In fact, several studies have shown that EMR adoption contributes to increased cognitive load, stress, burn out, and job dissatisfaction in primary care providers.\(^{1,2,3}\) In this paper we share the findings of a project aimed at identifying best practices for primary care office visits, as a means to improve the work experience of primary care providers working in our health system. We uncovered two key factors that differentiated providers’ use of the EMR for documentation. After implementing an intervention to enhance these two key factors, we found significant improvement in office visit documentation that occurred outside of business hours. Further, we found significant differences in specific EMR documentation actions of physicians who had the most successful office visits.

The Challenge
Parkview Health transitioned to a new EMR provider in the spring of 2012 and rolled out the application to all primary care offices in the system over the next two years. Going live with the EMR brought about much unhappiness. During the transition, providers were ‘slow and low.’ Providers complained of major delays in completing visit documentation and were becoming distressed about the impact on their office workflow and lengthy hours at work. Part of this was behavioral because there was not a strong pre-existing culture of EMR use, part was due to fatigue from the transition, and part was due to a reduction in productivity. Providers who had felt like an expert at all things medical before beginning use of EMR now struggled to get through basic work.

As Chief Medical Informatics Officer and a practicing primary care physician, the first author challenged the EMR company to provide a ‘best practice’ or most effective approach to completing all that needs to be done in an office visit. But when pressed for the best way the company could only respond by sharing what other organizations were doing – not an optimal method. In this particular EMR, there are many ways to complete a particular task, which allows for flexibility but also can create a cognitive burden and stress for the practicing physician.\(^4\) While the EMR training provided to primary care physicians was very task specific and technical, there was little attention paid to individual physician workflow. This left a gap in understanding what makes an office visit successful in the context of EMR use, what are the key metrics, and how do we get providers interacting with the EMR at an optimal level? The objective of our study was to enhance productivity, efficiency and quality of office visit documentation. In particular, the goal was to identify ways in which physician providers could spend less time in the system doing work and see just one more patient each day.

Interested in “What makes success?” vs. “What are the majority doing?”
It was a book on change management that inspired this work. In their book Switch, the Heath brothers describe a paradigm shift that can be affective when facing major obstacles against change, which they call finding the bright spots.\(^5\) In this analogy the authors describe a scenario where the problem solver looks in the community for successful efforts worth repeating instead of the common approach of deploying massive resources to those who
struggle. In the environment of change brought about by EMR adoption, a common approach is to focus all efforts towards low performers but this did not work for us. Things were not getting better and people who were doing well were being ignored. So we decided to look for the ‘bright spots’ in order to examine what was working well in the primary care practice use of the EMR. To do so, we identified several physician providers who seemed to be unfettered by the integration of the EMR in their practice. Importantly, we were not simply focused on what they did but rather on identifying what EMR practices were similar and which were true differentiators for those physicians practicing in the bright spots. In our data-driven approach we were careful not to use the words ‘high performers’ and ‘low performers,’ in order to avoid the obvious negative emotions that could be evoked. Rather, we relied on the metaphor ‘cheese finder’ used in another change management book, Johnson’s *Who Moved My Cheese* wherein finding cheese is synonymous with effectively navigating change.5

Methods
We conducted a 3-month study that included an observational pilot from which an intervention was designed. Outcome measures were collected in the final phase of the study to determine the impact of the intervention and to differentiate EMR actions of cheese finders when compared with controls.

Study Setting
Parkview Health is a system of 8 hospitals located in 6 counties in northeast Indiana. Parkview serves an area with a population of approximately 890,000. As a Health System, we have nearly 9,000 employees and 1,600,000 patient encounters each year. Parkview physicians group (PPG) has experience rapid growth and is currently comprised of 35 primary care service areas with 352 physicians (average age of 50) who are practicing across 120 locations. PPG serves counties in Northeast Indiana and Northwest Ohio with 1,253,000 clinic visits annually.

Observational Pilot
We started by identifying 12 cheese finders who met three criteria. 1) Productivity: Work Relative Value Unit (wRVU) ratio greater than 0.9; 2) Efficiency: less than two charts per week completed outside of regular office business hours; 3) Quality: content of note were complete and effectively communicated office visit events. We then matched 24 controls equally to the 12 cheese finders (2N:N) along specialty area and office setting (e.g. time since EMR deployed).

We developed a checklist of 35 items (see Figure 1) based discussion with cheese finders as to what they think makes them successful and also based on our observations of those doing well. Checklist information was obtained the information for all study subjects, either by direct observation in the office setting or by interviewing physician providers or their nurse. The objective of the checklist was to identify qualities that differentiated cheese finders from controls.

Intervention
The content of the intervention was focused on enhancing two actions that were identified in the observational pilot as a differentiating behavior of cheese finders. The intervention included two 5-minute educational videos deployed on Share Point. The videos were designed for everyone who was not a cheese finder as means to encourage behaviors that would lead to greater productivity. Participants were purely motivated by the potential to improve efficiency and recover personal time spent charting in the EMR. There were no other incentives to participate. Controls were individuals that either did not watch the videos describing the two interventions that could lead to higher productivity or they did watch the videos but chose not to change practice.

Outcome Measures
Outcome measures were selected keeping the end goal in mind: to enhance productivity, efficiency and quality of office visit documentation. In particular, the goal was to identify ways in which physician providers could spend less time in the system doing work and see just one more patient each day. Scope of EMR interaction was limited to documentation and ordering (to augment findings from observational pilot). Specific measures included the percentage of charts completed outside of office business hours and user interaction data collected with a tool offered by the EMR company – the user action log (UAL). The UAL tool allowed the capture of keystrokes, mouse clicks, menu interaction, and navigation sequences. So, this provided more detailed analysis of cheese finder behaviors than what was done in the observational pilot (e.g. time spent ordering, number of keystrokes per note). UAL data was collected for a 2-week period of time on both cheese finders and controls. Data analysis was completed using IBM SPSS Statistics for Windows, Version 21.0.
1. Is there any clinical "chart prep" completed? Example: Are charts reviewed prior to a scheduled appointment to look for recent test results or other missing data?
2. Does information get scanned prior to patient appointment or do you leave on paper for physician to review on paper for office visits?
3. Are there perceived bottlenecks at the front, impeding timely rooming of patient?
4. Does rooming staff fill in chief complaint?
5. Does rooming staff document vital signs every time?
6. Does rooming staff review and update allergies every time?
7. Does rooming staff do med rec?
8. Does rooming staff review smoking status?
9. Does rooming staff start the history of present illness (HPI)?
10. Does provider reference a snapshot view prior to entering exam room? Fill in blank
11. Are providers updating the problem list in the exam room?
12. Are smart sets being used?
13. For progress note documentation, is provider using a smart phrase for a whole note template?
14. Is provider using Dragon for HPI?
15. Is provider using Dragon for assessment/plan?
16. Is provider using Dragon for prescriptions?
17. Is provider using a system smart phrase to pull in lab results in the note?
18. Is provider using a personal smart phrase to pull in radiology results into the note?
19. Is provider using a prescription smart phrase?
20. Is provider using a review of systems (ROS) smart phrase?
21. Do you use a personal preference list for ordering?
22. Is provider using a macro for ROS?
23. Is provider using a macro for physical exam?
24. Is note being completed before seeing the next patient?
25. Does provider enter all of his/her own orders?
26. Is Dragon used for placing orders?
27. Are orders placed by provider in exam room?
28. Is visit diagnosis completed in exam room?
29. Is the problem list utilized for quick documentation of the diagnosis?
30. Is the level of service documented in exam room?
31. Is follow-up appointment documented prior to patient leaving?
32. Are notes routed by provider?
33. Is provider able to close the encounter at end of visit?
34. Does provider print own after visit summary?
35. Does clinical staff enter any orders in the system?

**Figure 1. Observational Checklist**

**Results**

The observational pilot findings uncovered two EMR actions that distinguished cheese finders from the rest of the cohort. A chi-square test was performed and a relationship was found between cheese finders and the frequency of using Dragon software to document the history of present illness, \( \chi^2(2, N = 32) = 5.722751, p = 0.016746 \). Likewise, a chi-square test revealed a relationship between cheese finders and the frequency of placing orders in the exam room, \( \chi^2(2, N = 32) = 4.097354, p = 0.04295 \). There were no other relationships found from the observational/ self-report data.

The intervention (two 5-minute educational videos) was deployed, focusing on encouraging the use of Dragon to document history of present illness and placing orders while in the exam room. Post-intervention measures showed a marked improvement of roughly 50% fewer charts being completed outside of office business hours (Figure 2).

![Figure 2](chart.png)

*Outside of time range 0800-1759 hours

**Figure 2. Percentage of Charts Completed Outside of Office Business Hours (OOBH) Pre- & Post- Intervention**

The findings from the UAL also revealed significant differences between the actions of cheese finders when compared to controls. Visit documentation metrics show cheese finders spent significantly less time \( p=0.028 \), fewer keystrokes \( p=0.002 \), and less clicks \( p=0.014 \) when documenting office visits (see Figures 3-5, respectively). Office ordering metrics show that while there was no significant difference in time spent ordering...
(p=0.126), cheese finders spent less time clicking (p=0.062) and had fewer clicks (p=0.061) in the process of placing orders when compared with controls (see Figures 6-8, respectively).

Figure 4. Difference between “Cheese Finders” and Control: Visit Documentation Keystrokes (p=0.002)

Figure 5. Difference between “Cheese Finders” and Control: Documentation Clicks/Visit (p=0.014)

Figure 6. Difference between “Cheese Finders” and Control: Ordering – Total Time (p=0.126)

Figure 7. Difference between “Cheese Finders” and Control: Ordering – Time Clicking (p=0.062)

Figure 8. Difference between “Cheese Finders” and Control: Ordering – Clicks/Visit (p=0.061)
Discussion
In this study we were able to demonstrate the value of applying change management philosophies during the aftermath of EMR implementation in primary care office settings. Namely, looking for the bright spots and uncovering exactly what efforts make an office visit successful and how we can communicate these practices to other physician providers who want to improve and/or simply reduce their cognitive load and stress from interacting with the EMR. Taking this alternative approach (the Switch model) to allocate resources toward the bright spots vs. toward those who were struggling allowed us to uncover two differentiating behaviors (using Dragon for HPI documentation and placing orders while still in the exam room) that were then leveraged in a successful intervention. The video education intervention resulted in a marked reduction in documentation completion outside of regular office hours. Additionally, we found that cheese finders spend less time documenting and completing notes with fewer keystroke and clicks. Although there was no real difference in provider time ordering, there was a tendency for fewer clicks among cheese finders. Drawing a connection between the findings from the observational pilot and the UAL findings we are left to wonder if using Dragon for documenting HPI can explain the time documenting and keystroke gap between cheese finders and controls.

There were confounding factors that impacted the findings of this study, namely organizational pressure to make things better right away. There was also a time barrier presented by an update in the EMR software and the looming deadline for the next go-live date. Additionally, there were contentions around allocating resources to examine behaviors of successful physician providers. There are limitations to the findings of this work in that our sample size was quite small. Further, we could not account for the time, clicks, and keystrokes entered by office RNs, LPNs and medical assistants.

We are currently looking at this opportunity to identify best practices for optimal EMR use with a larger, more formal study. In this we hope to define specific criteria to be considered a cheese finder, beyond the three criteria used for this study. This will include defining targets for documentation time, keystrokes for specific visit types, and ordering time. Expanded UAL data may include studying in-basket work, data gathering activity (e.g. navigation sequences) and behaviors when documenting care for inpatients. We also plan to expand our lens beyond the physician provider actions to better understand the role of support staff in the efficiencies we identified in cheese finders. We hope that we can identify more ideas for goal oriented training and optimization, as we found in this study. Finally, we hope to validate our findings with those from other organizations.

Conclusion
Are there times when “what everyone else does…” is not the right approach? We believe this is the case and have found value in applying activation resources to the bright spots in our own organization to determine what is right for us. Ultimately, this approach allowed us to quickly develop an effective intervention and allowed for more effective utilization of our resources.

Casting a Wider Net: Data Driven Discovery of Proxies for Target Diagnoses

Dusan Ramljak, Adam Davey PhD, Alexey Uversky, Shoumik Roychoudhury, Zoran Obradovic PhD¹

¹Center for Data Analytics and Biomedical Informatics, Temple University, Philadelphia, PA, USA

Abstract

Background: The Hospital Readmissions Reduction Program (HRRP) introduced in October 2012 as part of the Affordable Care Act (ACA), ties hospital reimbursement rates to adjusted 30-day readmissions and mortality performance for a small set of target diagnoses. There is growing concern and emerging evidence that use of a small set of target diagnoses to establish reimbursement rates can lead to unstable results that are susceptible to manipulation (gaming) by hospitals.

Methods: We propose a novel approach to identifying co-occurring diagnoses and procedures that can themselves serve as a proxy indicator of the target diagnosis. The proposed approach constructs a Markov Blanket that allows a high level of performance, in terms of predictive accuracy and scalability, along with interpretability of obtained results. In order to scale to a large number of co-occurring diagnoses (features) and hospital discharge records (samples), our approach begins with Google’s PageRank algorithm and exploits the stability of obtained results to rank the contribution of each diagnosis/procedure in terms of presence in a Markov Blanket for outcome prediction.

Results: Presence of target diagnoses acute myocardial infarction (AMI), congestive heart failure (CHF), pneumonia (PN), and Sepsis in hospital discharge records for Medicare and Medicaid patients in California and New York state hospitals (2009-2011), were predicted using models trained on a subset of California state hospitals (2003-2008). Using repeated holdout evaluation, we used ~30,000,000 hospital discharge records and analyzed the stability of the proposed approach. Model performance was measured using the Area Under the ROC Curve (AUC) metric, and importance and contribution of single features to the final result. The results varied from AUC=0.68 (with SE<1e-4) for PN on cross validation datasets to AUC=0.94, with (SE<1e-7) for Sepsis on California hospitals (2009 – 2011), while the stability of features was consistently better with more training data for each target diagnosis. Prediction accuracy for considered target diagnoses approaches or exceeds accuracy estimates for discharge record data.

Conclusions: This paper presents a novel approach to identifying a small subset of relevant diagnoses and procedures that approximate the Markov Blanket for target diagnoses. Accuracy and interpretability of results demonstrate the potential of our approach.

Objective

Identify a small subset of diagnoses (Markov Blanket) that can serve as highly accurate proxies for the set of target diagnoses used to establish reimbursement rates under the Hospital Readmissions Reduction Program (HRRP). Identification of these subsets has applications to problems such as providing more stable hospital quality estimates, estimating the extent of diagnostic “gaming,” identification of potential “upcoding” or fraudulent claims, and fuller understanding networks of diseases and medical procedures.

Introduction

As of October 1, 2012, §3025 of the Affordable Care Act (ACA) dictates that hospital reimbursements have to be based on performance relative to preventable 30-day Medicare hospital readmission rates observed in hospitals with similar predicted risk profiles. Three specific diagnoses in particular are used to track reimbursement rates: acute myocardial infarction (AMI), congestive heart failure (CHF), and pneumonia (PN). In October 2014 chronic obstructive pulmonary disease (COPD) was added to the list of diagnoses with two additional procedures, but we did not include it in our experiments since its value in this context has been criticized²⁹. This policy change may have introduced an incentive for hospitals to under-diagnose these illnesses by substituting related diagnoses for which they will not be held accountable. Burgess and Hockenberry (2014)³¹ provide a historical perspective on current attention to hospital readmissions and consider the potential for gaming of readmissions, but not via subtle changes in diagnoses themselves. In addition to the three diagnoses we decided to analyze (AMI, CHF, and PN), we
included sepsis as a diagnosis for studying in our experiments, given that it is one of the most prevalent diagnoses, and is currently the diagnosis with the highest mortality rate in the US.

Our method is aimed at approximating Markov Blankets consisting of small subsets of diagnoses and procedures that frequently co-occur with, and can shield, each of our four target diagnoses from the rest of the disease/procedure network (in other words, the Markov Blankets for each target diagnosis node consist of diagnosis and procedure nodes that contain the only information required to accurately predict the behavior of the target diagnosis in question). We chose to use a Markov Blanket for this task since several studies have already shown that using only a small set of features that constitute the Markov Blanket for a dependent variable is sufficient to accurately predict the value of the variable. Hence, each target diagnosis can be accurately identified and inferred from a small subset of related diagnoses and procedures, which can then be used to identify true cases with target diagnoses, estimate the extent of gaming via substitute diagnoses/procedures, and also suggest related sets of diagnoses and procedures which, in combination, may provide more stable methods for setting reimbursement rates. We have observed that the most frequent co-occurrence by itself is necessary, but not sufficient, to establish an accurate approximation of a Markov Blanket.

We built a directed weighted network of diagnoses and procedures from the hospital records that contain our target diagnoses, and adjusted the weights in that network according to co-occurrences of diagnoses and procedures in the records that don't contain our target diagnoses. We apply Google’s PageRank algorithm and use the PageRank value as a criterion to identify important nodes which will belong to the Markov Blanket, and set the number of the “important” nodes to be selected based on the distribution of the number of diagnoses and procedures in the records.

We attained preliminary results that were accepted for presentation at SDM-DMMH 2015 Workshop which were tested on a very small subset of CA data. We have since then refined our approach to make it more scalable, and evaluated its validity on a much larger set of data, spanning two states (CA and NY) and several years. We found that our approach is both accurate and stable in both states, even when trained on a relatively small sample of CA dataset. Given its simplicity and interpretability, we are confident that it can be used effectively for any target diagnosis, not just the four that we focus on in our experiments.

**Background**

As a direct result of the change in the structure of Medicare reimbursements, there is now more focus on problems such as the ability of health care providers to identify changing predictors of 30-day hospital readmissions, as well as to identify characteristics of individuals and providers associated with above-average levels of readmission risk. Hospitals that perform below expectations will see a reduction of up to 1% in Medicare-based reimbursements for services related to all diagnostic-related groups (DRGs). Based on performance levels in 2010, these targets would have placed half of all hospitals in the under-performing group. In coming years, additional diagnoses will be added to the list used to determine reimbursement rates. A focus on 30-day readmission rates has been criticized for a variety of reasons, including concerns about the validity of diagnoses, sparse evidence that decreased readmissions translate into improved health outcomes, an assumption that most readmissions are preventable, and disproportionate penalization of hospitals serving “safety-net” hospitals. Joynt and Jha (2013) found evidence that large teaching hospitals and safety-net hospitals are more likely to be penalized under the HRRP. Kansagara et al. (2011) performed a systematic review of readmission risk models. They found that specific medical diagnoses were the most universally used predictors appearing in 24 of 26 prediction models they considered. This same study also found that the range of the Area Under the ROC Curve (hereinafter AUC) metric for predicting readmission ranged from 0.50 (nurse/case manager predicted risk of readmission) to 0.83 (administrative model plus self-report).

Several potential methods of “gaming” have been suggested, including enriching the population admitted with a target diagnosis with individuals assessed to have low readmission risk, using extended “holding areas” for patients to receive hospital care without being readmitted, and selectively coding target diagnoses among patients with expected low readmission risk. Such gaming strikes us as particularly likely given the narrow range of criteria that factor into reimbursement rates under the HRRP. Because hospitals cannot be penalized for diagnoses they do not make, physicians are incentivized to choose similar, but distinct, diagnoses for criterion diagnoses. For example, a patient who is admitted to a hospital with AMI may initially be diagnosed as having chest pains or coronary atherosclerosis. If this patient was subsequently readmitted within the following 30 days, this diagnosis could not be used to penalize the hospital for poor performance. Similarly, PN may initially be diagnosed as acute bronchitis or an upper respiratory infection, and CHF may instead be diagnosed at first as chronic obstructive pulmonary disease. In addition to studying the three aforementioned diagnoses used by the ACA, we also study Sepsis using our approach, since it is one of the most prevalent diagnoses, and is currently the diagnosis with the highest mortality.
rate in the US. It can be diagnosed initially as a bacterial infection, pneumonia, urinary tract infection, peritonitis, or a skin ulcer. In practice, only those assessed as having the lowest risk of 30-day readmission may be likely to receive the target diagnosis.

However, several specific diagnoses are likely to co-occur with the target diagnosis, and some procedures (e.g., angioplasty) may be strongly indicative of a specific underlying true diagnoses (e.g., AMI), serving as good proxy indicators of the true diagnosis. Evidence for changes to clinical practice, diagnoses, and associated procedures in response to changes in reimbursement has been well-documented for more than 30 years⁵ and there is reason to suspect that similar changes are already occurring due to the most recent changes enacted under the ACA. Rothberg et al. (2014)¹⁹ suggested that, by more liberally applying diagnoses of sepsis and respiratory failure, hospitals might improve their reported performance under the HRRP. Another way of estimating the extent of these changes, and identifying cases that represent the true diagnoses of criterion diagnoses, is considering diagnoses as a set of connected nodes in a graph (connected by aspects such as co-occurrence). The Markov Blanket (MB) for a node is the set of nodes that shield it from the rest of the network. Previous studies have shown that knowing the Markov Blanket of a diagnosis node is all that is required in order to predict the value of the criterion, either by classification or regression⁶,⁷,⁸. If the MB of a specific diagnosis can be identified prior to a policy change, it may be used to more accurately identify the set of criterion diagnoses following the policy change, which can in turn be used to estimate true cases, as well as the extent of gaming of diagnoses which will occur due to the policy change.

Our experiments used discharge data from the California and New York State Inpatient Databases (SID), obtained from the Healthcare Cost and Utilization Project (HCUP) provided by the Agency for Healthcare Research and Quality.⁶ The SID is a component of the HCUP, a partnership between federal and state governments and industry, which tracks all hospital admissions at the individual level. We included all data from January 2003 through December 2011. Patients were excluded from the analysis if they did not have Medicare or Medicaid as the primary payer and if they were younger than 19 years of age. The final dataset included 16,736,927 discharge records for CA and 12,717,787 discharge records for NY, with the primary set of features used in our experiences being the Clinical Classifications Software (CCS) diagnoses for ICD-9-CM. CCS codes, developed as part of the HCUP, are designed to cluster patient diagnoses (hereinafter DX) and procedures (hereinafter PX) into a manageable number of clinically meaningful categories (272 diagnoses and 231 procedure codes).

Some prior research has examined the role of comorbid conditions with the aim of identifying longer-term effects and mortality risk with a single target diagnosis in mind. Each of our target diagnoses has been considered in this fashion: AMI⁹, CHF¹¹, PN¹⁴, and sepsis¹⁵. To the best of our knowledge, ours is the first study concerned with identifying co-occurring diagnoses and procedures that can serve as a proxy indicator of the target diagnosis, something necessary to identify potential instances of hospitals gaming the system to reduce risk exposure.

Methods

Our goal was to find a minimum subset of the most informative DX and PX (accurately predict the presence of Target DX in the records) associated with the Target DX. We decided to build a directed weighted ego-centric network for each Target DX where weights are calculated from counts of co-occurrences of DX and PX. We calculated the PageRank for each DX, PX to obtain ranked list. We used the PageRank value as a criterion to rank the importance of DX, PX in the above defined Target DX ego-centric network. Number of features for PageRank approximation of MB identified as the maximum number of DX, PX in the records. This way obtained PageRank approximation of MB then serves as feature set for logistic regression with a default setup.²²,²³,²⁵. Generated software will be available at [https://github.com/dusanramljak](https://github.com/dusanramljak)

Target Diagnosis Ego-centric Network of Diagnoses and Procedures

We started with identifying DXs and PRs that most frequently co-occur with the Target DXs. The most frequent co-occurrence by itself is necessary, but not sufficient, to establish an appropriate approximation of the Markov Blanket. For example, some diagnoses might co-occur with a Target DX simply because they are frequently diagnosed. Meanwhile, other frequent diagnoses might co-occur with our Target DX and also contribute significantly in discriminating between the classes when viewed in combination with other diagnoses or procedures. Making that distinction is not possible by looking only at the frequencies of co-occurrences with a Target DX.

To that end we have built directed weighted networks of DX and PR from the hospital records that contained each of our Target DX. The starting weights in this network were counts of co-occurrences of the nodes. In order to build directed weights we followed the following intuition: the “level of trust” of a node (source) in a connection with another node (destination) should be scaled by the counts of occurrences of the source in the network – the source
can “trust” the destination only to an extent that is proportional to the ratio between the count of the occurrence of the link between them and its own count of occurrence. Since we also have the counts of occurrences of the nodes in the records that don’t contain our Target DX, we adjusted the weights in the network according to occurrences of destination in the records that don't contain our Target DX. Following this intuition, the “level of trust” should be scaled with the count of occurrences of the destination in the records that don’t contain our Target DX. The formula for setting the weights is $w = \frac{c_i}{c_s + c_d}$ where $c_i$ is the count of co-occurrences for the source and destination nodes, $c_s$ is the count of occurrences of the source node in the network, and $c_d$ is the count of occurrence of the destination node in the records that do not contain Target DX.

PageRank Approximation of Markov Blanket

Since we defined weights by co-occurrences, as well as by additional information from the structure of the network of DXs and PXs that co-occur with our Target DX, we could use the PageRank value as a criterion to identify important nodes. For a subset of highly important nodes, we could say that the nodes with highest PageRank represent an approximate Markov Blanket for our Target DXs.

PageRank gives us a ranked list of important DX and PX, but we are not able to determine if there are any redundancies. Redundancies in this context mean that several DX and PX might not provide information to discriminate between classes. In our earlier experiments we used a feature selection method to help us decide the number of DX and PX that will be provided by our PageRank approximation of MB, but our more recent experiments follow a different path. Because our goal is to have all the important DX and PX that could represent our Target DX in our MB, we determined the maximum number of DX and PX that could be present in individual records. That number is then used to determine the number of nodes with the highest PageRank included in the MB.

Results

The data we used in our experiments comes from the HCUP family of databases, and the raw data consists of patient hospital visit records from California’s and New York’s SID in the period from January 2003 up to December 2011. Each record consists of a number of attributes, which are explained in detail on the HCUP website\textsuperscript{26}. The California and New York database contain more than 50 million inpatient discharge records over the specified 9 years. The information is not specific to a group of hospitals, but rather represents the data for the entire state.

The database also includes demographic information for each patient (such as age, birth year, sex, race), DX (primary and up to 24 secondary for CA, primary and up to 14 secondary for NY), PX (up to 21 for CA, and up to 15 for NY), information about hospital stays, and other information (including length of stay, total charges, type of payment and payer, discharge month, and survival information). For the purposes of our experiments, we used only the procedure and diagnosis information since our earlier work showed its potential, and since one of our primary concerns is preserving privacy (which could be breached if we used the more specific demographic and hospital stay information). Each of the 4 Target DXs we examined in this study was fairly prevalent. As shown in Table 1, CHF was most common (17.37% CA, 16.51% NY), followed by PN (9.43% CA, 7.77% NY), Sepsis (6.13% CA, 4.91% NY), and AMI (3.25% CA, 3.14% NY). There were also considerable seasonal and secular trends (similar in both datasets) in these Target DXs. For example, the prevalence of sepsis increased steadily across the study period. The three other Target DXs showed gradual decreases in prevalence over time, but also very strong seasonal trends.

We chose to use 20 combined DX and PX in this study, since this covered 95% of California and 98% of New York state data. We divided the data into two parts in order to show that the model generalizes well over both space and time. We used the first part, containing data from California in the years 2003 – 2008, for training and validating our models, and report the results of using 5-fold cross-validation. The second part consists of 2009 – 2011 records for both NY and CA data, and is used exclusively for testing. Since a previous study\textsuperscript{27} suggests that accuracy is
maximized when both training and test sets are balanced, used the same number of positive (Target DX present in the record) and negative (Target DX not present in the record) examples during training and testing. Since the four Target DXs appear at different rates (as shown in Table 1), the sample sizes we chose were different for each Target DX, but in each case we chose sizes with a roughly logarithmic progression such that the largest sample size covered the majority of the available cases. We used three sample sizes of different scale for each Target DX, and refer to these sample sizes using the general terms small, moderate, and large (for example, for CHF (2003-2008) in California, these sample sizes were 100k, 300k, and 1 million, respectively). We gathered 10 random samples for each sample size, and used 5-fold cross-validation for training and validation, resulting in 180 distinct training datasets per Target DX. When testing, we used the maximum possible size of the positive class for each Target DX, and performed 10 replications for each of the two states we have available, resulting in 20 distinct testing datasets for each Target DX. We opted to use 10 random samples that, when taken together, covered the entire dataset, rather than using the entire dataset as one big sample to increase the number of replications. To this end, we sampled cases with replacement with no overlaps within samples, and minimal to nonexistent overlap between samples.

For each of our Target DX, 150 out of 180 models were included in 5-fold cross-validation and tested once on an appropriate 5th fold holdout. 30 models were tested on all of the 20 test sets, and the results indicate high out-of-sample accuracy, scalability, and stability of the method. The fact that adding more features always increases the accuracy supports the idea that we are dealing with a challenging problem, though the diminishing returns on accuracy improvements suggest that using a smaller set of features can be sufficient. Furthermore, although diagnoses are the most commonly used features across different hospital readmission models, many other individual characteristics are also important but either not considered here (e.g., age, sex, race) or not available in the data we used (medications, laboratory tests ordered, laboratory test results). We include results using all diagnoses and procedures as features, rather than using only the significantly smaller subset of diagnoses and procedures selected by our method, to show that we attained comparable accuracy using only the subset of features that are strongly relevant to the Target DXs. Furthermore, experiments showed the somewhat surprising fact that having more data for training doesn’t offer much improvement in accuracy, but does affect the stability of both the achieved accuracy and the chosen features.

We evaluate the “stability” of the features selected by our method by examining how often each one appears in each of our training models. That is, after acquiring the ranked list of PageRank values for each of the features during each experiment, we selected the 20 highest-ranked features in each experiment (giving us 60 potentially overlapping sets of 20 features for each sample size), and then took the intersection of those feature sets to find features that appear in all experiments. We labeled these features as stable, since they were shown to be in the top 20 PageRank lists over the course of all experiments.

This procedure was repeated for each of the three sample sizes for each of the four target diagnoses, yielding the results summarized in Tables 2 and 3. These tables portray the features that were selected as the most influential by PageRank over each set of experiments, for each of the Target DX, as well as the sample size for which each feature was stable. In other words, features that are stable in all three sample sizes are the most frequently occurring and therefore are the best candidates for the MB approximation, while those that only appear during the experiments in the largest sample size are less frequent.

While accuracy is an important criterion for our task, interpretability and relevance of the selected features also play key roles in the utility and acceptability of the approach, and our results are very encouraging in this regard. For AMI (Table 2), the two selected diagnoses, cardiac arrest and shock, are two of the most common consequences of a heart attack. Similarly, the selected procedures all align directly with common clinical practice, representing a variety of cardiac imaging, diagnostic, and surgical procedures. CHF (Table 2) is a complex condition reflecting the intersection of cardiac and pulmonary systems. These are well represented among the selected diagnoses and procedures, as is the overlap (in terms of cardiovascular disease) with AMI. For PN (Table 3), one recent study found that readmissions rates for PN could be made more accurately and stably when sepsis and respiratory failure were also included. Both of these diagnoses are selected for PN, along with a range of respiratory procedures. Finally, the expected overlap between Sepsis (Table 3) and PN emerges for diagnoses and procedures when the former is considered as the target diagnosis. Additionally, there are more serious diagnoses relating to injuries and abscesses along with various stoma.

In addition to validating the relevance of the small subset of features we selected for each diagnosis, we also tested their representative power by comparing the predictive accuracy (measured in AUC) obtained using only this small subset of features against the accuracy obtained when using all (approximately 500) features for the same task.
These results are presented in Figure 3 as boxplots for each Target DX at each sample size, with variance obtained from the 10 repetitions of each experiment. Several observations can be made from these plots, the first being that while using all 500 features offers the best accuracy, we can attain very competitive predictive accuracy using a significantly smaller number (20) of features which have the added benefit of being relevant to the Target DX in addition to being useful for discriminating between the two classes. The gap between accuracies using the subset vs using all features varies among the four Target DX, but even in the case of the most difficult to predict diagnosis, PN, the AUC we attained using only 20 features was very respectable (in the 0.68-0.75 range). In the case of the easiest to predict diagnosis, Sepsis, we were able to attain a nearly perfect level of prediction using a very small number of features, which we believe to be particularly important given the frequency and deadliness of this diagnosis. A somewhat more surprising finding was that varying the sample size did not have as big of an impact as expected. Although a general trend of AUC being higher when the sample sizes are larger can be seen, there is a noticeable variability in the results, while the mean values of AUC are quite close between sample sizes. While we expected sample size to play a bigger role in increasing accuracy, these findings suggest that the features we chose were representationally powerful enough to offer good performance even when the sample size is limited, further proving their relevance to the target DXs.

Conclusion

The US healthcare system is rife with opportunities for perverse incentives. The implementation of any new healthcare policy results in changes within the healthcare system in order to minimize the adverse consequences of the policy change for healthcare providers. Changes that began in 2012 under the Affordable Care Act can be expected to reduce the number of individuals receiving target diagnoses of AMI, CHF, and PN as healthcare providers move to reduce their exposure to adverse consequences of hospital readmissions. Beginning in October 2014, the HRRP was extended to three additional conditions: acute exacerbation of chronic obstructive pulmonary disease (COPD), patients admitted for elective total hip arthroplasty (THA), and total knee arthroplasty (TKA). Early models of readmissions are being presented for COPD30, but they suffer from the same low predictive value (AUC=0.65) as earlier work with AMI, CHF, and PN, and the value of COPD as a criterion measure has received some criticism.

In this paper, we propose a novel approach to the problem of under-diagnosing, specifically, approximating Markov Blankets by PageRank. Performance using this subset of diagnoses shows performance that is generally quite high in terms of both accuracy and precision. Additionally, these diagnoses and procedures often point to clinically meaningful patterns. However, it is unclear which will ultimately prove most useful as the network of diagnoses and procedures surrounding a Target DX changes in response to policy. To some extent, this problem is likely to pose a
continuously moving target and so future research should more fully develop an understanding of the temporal forces to determine whether, for example, the indicators of PN depend on month of admission.

**Figure 1.** AUC values of the model using the top 20 features selected by PageRank (blue boxes) and using all features (dotted red line). Each row represents one of the Target DX: AMI, CHF, PN and Sepsis. Each column represents a different subset of data that was used for testing purposes. Results obtained from the three sample sizes described above are shown for each setting.

The approach used here is likely to be useful in the analysis of healthcare data in several ways. First, it provides a set of associated diagnoses and procedures that can be used to “impute” missing or unobserved data in an effort to estimate true prevalence of various diseases. Second, it can be used to estimate the extent of “gaming” of diagnoses in response to policy changes. Several authors consider the potential for gaming. Multiple potential methods of “gaming” have been suggested, including enriching the population admitted with a target diagnosis with individuals...
assessed to have low readmission risk, using extended “holding areas” for patients to receive hospital care without being readmitted, and selectively coding target diagnoses among patients with expected low readmission risk. Such gaming strikes us as particularly likely given the narrow range of criteria that factor into reimbursement rates under the HRRP. Enriching the pool of related diagnoses has been shown to provide more accurate and stable estimates in the case of PN19.

Extending Rothberg et al. (2014)19, Sjoding et al. (2015)20 performed a Monte Carlo study using 2009 Medicare data. They found that hospitals could substantially improve their pneumonia readmission and mortality rates by converting pneumonia diagnoses to sepsis or respiratory failure. The improvements are often substantial. From a sample of 100 hospitals with pneumonia readmission rates above the 50th percentile, 66 improved their readmissions rate, and 15 dropped below the 50th percentile. Changes were even more dramatic when mortality was considered (90 and 41 hospitals, respectively). This suggests that our approach may also prove useful in order to adjust estimates for this kind of gaming and could also provide more robust methods to estimate true hospital readmission rates where intentional under-diagnosis of such diagnoses is likely. Historically, there are several precedents for this kind of under-reporting. The effects of the Omnibus Budget Reconciliation Act of 1987 (OBRA87) was observed to have considerable impact on medical practice in nursing home settings21. Considerable decreases in the per capita diagnosis of AMI can already be seen leading up to implementation of the HRRP (Gerhardt, et al., 2012).

Going forward, several areas of inquiry are likely to be fruitful. For example, future work should consider the conditions newly added in October 2014. Related to this, now that a reasonable amount of data are available following the implementation of the HRRP, researchers should evaluate evidence for shifting of diagnoses away from the targets. Another related area of critical importance has to do with the way in which individual hospital reimbursement rates are set and risk-adjusted. There is some evidence that building a larger network of related diagnoses may produce more stable and accurate performance estimates. Thus, a direct extension of this work is to consider the performance of a model trained on historical data, but used to predict performance of individual hospitals. Given how well our models generalize across time and state, we have reason to expect strong performance. Finally, models such as the ones we present here may have direct application to fraud detection and upcoding (Suresh et al., 2014)28.

Abstract

There has been rapid growth in the purchase of surgical robots in both North America and Europe in recent years. Whilst this technology promises many benefits for patients, the introduction of such a complex interactive system into healthcare practice often results in unintended consequences that are difficult to predict. Decision making by surgeons during an operation is affected by variables including tactile perception, visual perception, motor skill, and instrument complexity, all of which are changed by robotic surgery, yet the impact of robotic surgery on decision making has not been previously studied. Drawing on the approach of realist evaluation, we conducted a multi-site interview study across nine hospitals, interviewing 44 operating room personnel with experience of robotic surgery to gather their perspectives on how robotic surgery impacts surgeon decision making. The findings reveal both potential benefits and challenges of robotic surgery for decision making.

Introduction

Technological innovation has led to great advances in surgical practice over the past two decades, resulting in improvements in patient outcomes1. In the 1990s, traditional open surgery was challenged by the introduction of minimally invasive surgery (MIS). With MIS, the surgeon performs operations using small ‘key-hole’ incisions, through which cameras and laparoscopic instruments are passed. This removes much of the abdominal access trauma, resulting in numerous benefits for patients, including less postoperative pain, shorter hospitalisation, quicker return to normal function, and improved cosmetic effect2-4. In addition to patient benefits, laparoscopic surgery is also cost-effective for healthcare providers5, due to shorter inpatient stay and decreased wound care costs4. However, laparoscopic surgery can be technically challenging to perform, as a result of the 2-dimensional operative image and instruments that have limited freedom of movement and require awkward and non-intuitive handling. As a consequence, uptake of laparoscopic surgery has been slow6.

Robotic surgery overcomes some of the limitations of laparoscopic surgery, potentially making the benefits of MIS available to a greater number of patients. The Da Vinci surgical robot (Intuitive Surgical, California, USA) is currently the only commercially available robot for soft tissue surgery. The surgeon sits unscrubbed at a console that provides them with a magnified pseudo 3-dimensional (3D) view of the surgical site. From the console, the surgeon is able to control the robot arms that hold the laparoscopic instruments inserted into the patient. Robotic surgery enables the surgeon to achieve increased precision through intuitive instrument handling, tremor elimination, and motion scaling. There has been rapid growth in the purchase of Da Vinci robots in North America, despite the cost of the latest model being almost $2 million and annual maintenance costs of $125,000, and Europe is quickly following suit. Between 2007 and 2011, the number of Da Vinci robots installed in the United States increased from 800 to 1,4007, while the number of Da Vinci robots installed worldwide had reached 2300 in 20118. Whilst robotic surgery is primarily used in urology, its use is expanding across the surgical specialties, also being used in gynecology, ear nose and throat, colorectal, cardiology, and pediatrics.

Decision making is an important component of surgical expertise9, yet there is a paucity of research on decision making in the operating room (OR)10, 11. Theories of decision making highlight the importance of previous experience with particular situations, to enable the development of patterns or mental models which draw attention to relevant cues, provide expectations, determine plausible goals, and suggest typical responses to the situation12. In the OR, factors that impact surgeons’ decision making include tactile perception, visual perception, motor skill, and instrument complexity13, all of which are affected by robotic surgery, and may therefore impact on the surgeons’ ability to use their experience (mental models) to inform decision making. Similarly, the separation of the surgeon
from the rest of the OR personnel may also be significant, as there is strong evidence, both in the OR and in other contexts, that physical proximity of team members and technology influence the gathering of information that is used to inform decision making. Again, disruption of these patterns of information seeking may impact if and how surgeons are able to use their experience to inform their decision making. However, evaluation of robotic surgery to date has understandably focused on patient outcomes and the impact of robotic surgery on decision making has not previously been studied.

This is the first study to explore how robotic surgery impacts decision making, through interviews with surgeons and OR personnel. Interviews were conducted using the teacher-learner cycle, where interviewees are presented with ideas from the literature and asked to reflect on the extent to which those ideas fit with their experience. We first review relevant literature on decision making before describing the methods of our study and presenting the results. We conclude by discussing the implications of the findings for the implementation of robotic surgery.

Background

Klein, in his recognition primed decision (RPD) model, highlights the importance of context or situation in ‘triggering’ mental models that guide decision making in numerous complex decision situations. Situation awareness is defined as the perception of elements in the environment, the comprehension of their meaning, and the projection of their status in the near future. Situation awareness is also an important factor in understanding information behavior, the manner in which decision makers seek and use information to guide their choices. As highlighted in the RPD model, situation awareness is an important component of surgeons’ intra-operative decision making and better situation awareness of the surgeon is associated with fewer surgical errors. One model of intra-operative decision making suggests a continuous cycle where, with the preoperative plan in mind, the surgeon assesses the situation, reconciles new information with existing information, and subsequently implements a revised course of action. In this cycle, through the use of existing mental models, information may be actively sought or, by remaining observant of what is happening in the OR, perceived without active seeking. Robotic surgery potentially changes the nature of the information that the surgeon has available to them. The magnified, surgeon-controlled, 3D view of the surgical site may support the surgeon in visually perceiving anatomic information. However, because the surgeon sits at a console away from the patient and the rest of the OR team, they may not be able to see the patient or the robot arms directly and access to auditory information is also likely to be reduced. One report of the introduction of robotic surgery described a tendency for surgeons to ‘bury themselves in the console,’ thereby blocking out the OR. Consequently, the surgeon is dependent on the rest of the OR team communicating information that they previously obtained through visual perception. This has led some to argue that intra-operative decision making in robotic surgery is more collaborative than open or laparoscopic surgery.

Robotic surgery also changes the ability of the surgeon to use tactile perception to determine anatomic information. In open surgery, surgeons work primarily with visual and tactile information. In laparoscopic surgery, tactile information is reduced but, by touching with the instruments, surgeons are still able to determine features of objects such as shape, texture, and consistency. In robotic surgery, the surgeon receives no tactile information and this is considered to be a major limitation of robotic surgery. Some surgeons have suggested that the lack of tactile information means that surgeons move more slowly because they have to rely on visual information only. However, research suggests that, as experience of robotic surgery increases, surgeons find visual information sufficient for informing their intra-operative decision making, and this is supported by surgeons’ own reports.

While robotic surgery changes the visual and tactile information that is available to the surgeon, potentially reducing their situation awareness, it has been argued that the surgeon’s position inside the console and the 3D image create a sense of immersion and that the subsequent reduced ‘distractibility’ of the surgeon could be a benefit of robotic surgery. Certainly, if robotic surgery does reduce the number of distractions that the surgeon experiences, this could have positive impacts on decision making and subsequent patient outcomes; research reveals that distractions in the form of case-irrelevant communication are linked to an increase in surgeons’ mental fatigue and intra-operative stress and excessive levels of intra-operative stress compromise not only technical skills but also non-technical skills such as decision making. However, it has also been found that equipment and work environment distractions are more frequent in laparoscopic operations than in open operations, due to the more complex technology, suggesting that robotic surgery may also introduce new distractions.

The ergonomic benefits of robotic surgery may also impact surgeons’ stress and fatigue. Robotic surgery removes the awkward and unnatural movements required during laparoscopy and the surgeon is able to sit down comfortably at the console, potentially reducing physical stress and associated fatigue. This has led some surgeons to argue that, with stress arising from a difficult operation being an indirect cause of conversion to open surgery, robotic surgery
may result in a lower rate of conversion. However, results from experimental studies are inconclusive; while two studies found robotic surgery to result in lower mental and physical stress than laparoscopic surgery, in another study the difference was not statistically significant.

Methods

This study was undertaken as part of a process evaluation, running alongside ROLARR, a multicenter randomized controlled trial comparing laparoscopic and robotic surgery for the curative treatment of rectal cancer. Realist evaluation, an approach that is increasingly popular for the evaluation of complex interventions in healthcare, provides an overall framework for the process evaluation. Realist evaluation involves building, refining, and testing users’ ideas and assumptions, or ‘theories’, of how an intervention produces its outcomes. From a realist perspective, interventions in and of themselves do not produce outcomes. Rather, interventions offer resources to users; outcomes depend on how users choose to respond to those resources, which will vary according to the situation or ‘context’. Thus, rather than just asking ‘what works?’, realist evaluation seeks to answer the question of ‘what works, for whom, in what circumstances, and how?’. Realist evaluation involves gathering data in order to explain how different contexts trigger particular changes in the reasoning and responses of users (‘mechanisms’) which, in turn, give rise to a particular pattern of outcomes. While general qualitative approaches can only provide a catalogue of possible contextual factors thought to impact the process and outcomes of interest, the advantage of realist evaluation is that it increases the specificity of our understanding of the relationship between context, mechanisms and outcomes. As part of the first phase of the process evaluation, we undertook a multi-site interview study, interviewing OR teams to elicit their theories of how robotic surgery impacts decision making during surgical operations.

Participants

All English hospitals participating in the ROLARR trial were invited to participate in the interview study. English hospitals not participating in the trial but using the robot for colorectal surgery were identified by the trial team and through personal contacts of one of the team members (DJ), and all were invited to participate in the interview study. In this way, geographic spread and variation in level of experience of robotic surgery was achieved. A snowball sampling strategy was used; at each hospital, one of the surgeons was interviewed first, who then assisted in identifying other members of the OR personnel to interview (surgeons, trainee surgeons, anesthesiologists, OR nurses, and OR practitioners).

National Health Service (NHS) study-wide ethical approval was granted and research governance permissions were obtained from each hospital. All participants gave informed consent.

Data collection

Interviews were conducted, either face-to-face or by telephone, using the teacher-learner cycle. Teacher-learner cycle interviews are advocated within realist evaluation as a way to uncover users’ ideas and assumptions (theories) about how an intervention works and thus understand how user responses (mechanisms) are triggered in different circumstances (contexts) and produce certain outcomes. These theories can then be expressed as context-mechanism-outcome configurations (CMOs). In contrast to standard qualitative interviews, in teacher-learner cycle interviews, the researcher’s theories are the subject matter and the purpose of the interview is to confirm, falsify, or refine that theory. Using a semi-structured interview schedule, the interviewer presented the interviewee with theories from the literature concerning how robotic surgery is thought to impact surgeons’ decision making. Interviewees were asked to reflect on whether or not, and in which ways, these theories fitted with their experience.

From our review of the literature, we started with the following theories:

1. When the team is more experienced in robotic surgery, they understand that the surgeon’s situation awareness is dependent on them orally communicating information and they respond by using more oral communication about the patient’s state which in turn improves the surgeon’s situation awareness.
2. Surgeons progress more slowly through a robotic procedure because they do not have tactile information to inform their assessment of the situation and to determine whether to persist with or revise their course of action, but this effect becomes less pronounced as experience with robotic surgery increases.
3. The sense of immersion that the robot provides means that the surgeon is more focused, resulting in improved decision making and patient outcomes.
4. The ergonomics of the robot mean that the surgeon is less stressed and tired, resulting in better decision making and reduced conversion to open surgery.
As the literature provided limited information on the contexts in which robotic surgery impacts decision making, and the mechanisms through which those impacts are achieved, the interviews sought to elicit further detail about this. An iterative approach to data collection and analysis was taken, with the theories being revised as the interviews progressed. Interviews were audio recorded and transcribed verbatim.

**Analysis**
The interview transcripts were anonymized and entered into NVivo 10. Framework analysis, an approach developed for analyzing qualitative data for applied policy research, was used. Informed by the interview schedule and reading of preliminary interviews, codes for indexing the data were identified and agreed by three members of the research team (RR, NA, SH). They then indexed four transcripts to test the applicability of the codes and assess agreement. Where there was variation in the indexing, the codes were refined and definitions were clarified. The refined codes were applied to all transcripts. The indexed data was summarized in a matrix display to build up a picture of the data as a whole. In the final stage, mapping and interpretation, the matrix was used to identify similarities and differences in participants’ responses.

**Results**
Forty-four interviews were conducted across nine hospitals between January and August 2014. Interviews ranged from 29 minutes to 1 hour 40 minutes, with an average (mean) length of interview of 53 minutes. Table 1 provides a summary of participants and settings. The findings are organized around the main theories discussed.

**Theory 1: Situation awareness**
The majority of surgeons perceived that their situation awareness is potentially reduced during robotic surgery, stating that they are focused on a small area and therefore are less aware of their environment; they have ‘tunnel vision’. One surgeon provided the example of ‘sucking fluid’; the surgeon can request that their assistant provide suction, but they are unaware if the assistant experiences difficulties fulfilling their request or the reasons why. Attitudes to the seriousness of this varied. One surgeon described operating with a second surgeon as a ‘wing man’ to counteract the problem of reduced situation awareness and stated that he would be very concerned about reduced situation awareness if he operated without a second surgeon present. Another surgeon described being ‘vastly less aware’ of what is going on in the OR but he had not been ‘hindered’ by this and did not think it made any difference to the operation. Only two surgeons felt that their situation awareness is not reduced. One described still listening to the ‘banter’ amongst the team in the OR, while the other surgeon made a conscious effort to intermittently ask the team about the patient’s status.

Team members also perceived that the surgeon’s situation awareness is reduced due to their position in the console e.g. the surgeons do not have lateral vision and their sensory feedback, which can indicate problems, is reduced. Consequences of the surgeon’s reduced situation awareness described by the team include the robotic arms impinging upon each other, which could damage the robot or prevent the surgeon achieving their aim. Respondents explained that the surgeon only realizes that the robot arms are clashing when they are unable to manipulate the instruments as desired. On one occasion the robot arms nearly collided with a patient’s head; this problem was averted by the OR nurse who intervened.
The overarching strategy described by the surgeons to increase situation awareness, in line with our initial theory, was to establish good communication links between the surgeon and the team. Good communication was seen as an essential part of robotic surgery. Trust between the surgeon and the team was also emphasized, as the surgeon has to rely on the rest of the team to communicate information outside of their field of vision to avoid complications. If the surgeon trusts their team to communicate problems to them, their concern over their reduced situation awareness is lessened. One surgeon commented that a more experienced team might be better able to communicate the necessary information to them.

Communication was also described by the OR teams as the main strategy to increase situation awareness, who saw it as their responsibility to act as the ‘surgeon’s eyes and ears’. In contrast to our initial theory, the information that they described communicating to the surgeon was less about the patient state and more often about the robot, as in the examples described above. Some noted that they just ‘tell the surgeon’ when there are problems and that everyone in their team knows to do this whether it is themselves or the robot that is struggling. Others described that it is important, because of the physical separation of the surgeon from the team, that team members have voices that are ‘strong enough for the surgeon to hear’. Good communication was seen as dependent on the relationship between the surgeon and team. While this is dependent on individual personalities and approaches, training together as a team and having a dedicated team were strategies that were considered by interviewees to increase team members’ confidence to speak up. As one nurse said about training as a team:

‘I just think having been away, just you got to know the surgeons better and […] you’re just that much happier saying, can we start, can we slow down a bit, can we do this or we need to get that, it just sort of levels the hierarchy so much, which made it much easier to work with people.’

Another strategy described by the OR teams was positioning the console so that the surgeon has a direct view of the patient and the assistant when they look up from the robot, i.e. they are ‘not hidden in a corner.’

Theory 2: Lack of tactile information

Several surgeons described initial experiences with the robot where, due to the absence of tactile information, they had not realized how much force they were applying and consequently had, for example, snapped a suture. However, none of the surgeons considered the lack of tactile information a significant problem. While a couple of the surgeons described being ‘a bit more careful’, ‘a bit more hesitant’, the surgeons we interviewed did not consider that the lack of tactile information led to a longer operation duration. They felt that they had adapted quickly to relying on visual cues, learning to look for tension. Several surgeons related this to their experience of laparoscopic surgery; with laparoscopic surgery, they had already learnt to work with reduced tactile information. As one surgeon described, ‘from previous experience you know what you’re looking for, so you know the tension that you’re putting on the tissues from what you can actually see.’ Interviewees contrasted this with the experience of urology surgeons who had moved straight from doing open prostatectomies to doing them robotically.

Theory 3: Immersion

The majority of the surgeons we interviewed agreed that the robot produces a sense of immersion. One surgeon described how they can ‘lose themselves’ during the operation and, referring to level of concentration, he described this feeling as ‘quite intense’. Other surgeons commented that it is not that the robot creates a sense of immersion but just that they have to concentrate more because they have less experience with robotic surgery than with laparoscopic surgery. Two surgeons refuted the idea that the robot produces a sense of immersion, commenting that they are immersed in the procedure regardless of whether it is laparoscopic or robotic and that technology should not determine whether the surgeon is immersed.

A number of theories about the contexts in which a sense of immersion occurs were suggested by the participants. One surgeon anticipated that, while he already experiences a sense of immersion when using the robot, the feeling will probably increase when the ‘mundane’ and routine tasks related to using the robot, e.g. port positioning, have been mastered. In contrast, another surgeon commented that he feels immersed using the console, particularly during complex cases, but that this feeling would probably lessen over time, i.e. that it was a feature of his limited experience with the robot. One surgeon described immersion as being dependent on who he has assisting i.e. if he trusts the assistant he can be immersed as the assistant fulfils requests with ‘silver service’, whereas otherwise he is ‘constantly looking’ as there is anxiety about where the assistant is ‘pointing the instrument’. The creation of trust was also associated with training as a team, as one surgeon described:
'We learned to trust each other. We came back from [the training] with that certain knowledge that between us we knew what we knew and [...] we would each remember something and we would be able to pull it off.'

Some surgeons described the OR as quiet during robotic surgery, enhancing their concentration, and that there are no distractions. In comparison, in open and laparoscopic cases, the surgeon can chat with the assistant and team.

Perceptions of the impact of the sense of immersion varied. Some respondents commented that heightened concentration might lead to better decision making, but how or why was not articulated. One surgeon described the sense of immersion as making him more focused, which should enable a more precise dissection. Others felt unable to comment on whether immersion would be reflected in patient outcomes. One surgeon said he felt the sense of immersion would not impact his decision making, except that he may persevere longer with an operation because he is less aware of time. However, this could cause concern if the patient is operated on for an ‘excess amount of time’.

**Theory 4: Impact of ergonomics**

The surgeons discussed their experiences of using the robot and the extent to which ergonomics affected their levels of stress and tiredness in comparison to laparoscopic surgery. Some surgeons discussed that, for them, performing operations using the robot is more stressful than laparoscopic surgery because they are in the early stages of implementation i.e. have not used the robot on many occasions. In this context the surgeons stated that they shared the operation with a colleague. They explained that sharing the operation reduced their levels of stress, as opposed to the ergonomics of the robot. Other surgeons felt that the robot was an improvement on laparoscopic surgery (ergonomically); how and why it was an improvement was not fully explored although one surgeon described that they were in a ‘less awkward position’. The surgeons also discussed that using the robot might be physically less tiring than laparoscopic surgery, but it is mentally more so because they have less experience of robotic surgery than laparoscopic surgery. For this reason, they have a higher level of concentration for a longer time using the robot; in comparison, they could relax on occasion during laparoscopic cases.

Two surgeons described how the level of stress is affected by the how the team acts; as one surgeon described it:

‘I think it probably makes you physically less tired. I think you’re probably mentally more tired [...] We’ve all done less robotics than we have laparoscopic, so you’re carrying more of a burden I think robotically. And sometimes you feel like you’re only the person in theatre that knows what’s going on. [...] Because you’re there, and you’re the only one there looking.’

The extent to which the robot reduces surgeons’ stress levels was also described as dependent on the stage of the procedure. For example, talking about suturing, one surgeon said:

‘If I was doing that laparoscopically, it would be a nightmare. It’s just a joy to do it robotically because of the ergonomics.’

In contrast, this surgeon described how with dissection his ‘fear’ of bleeding is increased, because the magnified image means that he notices tiny blood vessels that he would not notice otherwise. It was also noted that stress can be dependent on the type of operation performed e.g. a low anterior resection is stressful using both approaches, whereas operations that do not go down to the pelvic floor are less stressful and demanding. However, being able to take breaks when using the robot was noted as a benefit.

The extent to which the ergonomics of the robot impacted on decision making, particularly the decision to convert to open surgery, was difficult to ascertain. It was suggested by some respondents that if the surgeon is more comfortable during surgery he or she might persevere with a difficult operation rather than convert to open surgery. It was also noted that the surgeon can ‘take five minutes’ to consider their decisions during robotic surgery, whereas they might feel more pressure in decision making during laparoscopic surgery. However, it was also acknowledged that the decision to convert to open surgery is often due to circumstances outside the surgeon’s control, e.g. conversion was described as a ‘technical’ matter that was not linked to ergonomics or how stressed the surgeon was. One surgeon stated that, if anything, he would persevere longer with laparoscopic surgery because that is the technique with which he has more experience and so feels more confident.

How and why the ergonomics of the robot reduced surgeons’ stress levels was also postulated by the wider surgical team. Team members discussed a number of ergonomic benefits of the robot, e.g. because the surgeon is sat down must mean that they are more relaxed, the surgeon can adjust the console’s head piece, the console is padded, and it is easier to have coffee breaks as no scrubbing or de-scrubbing is required to step away from the console. However, it was also suggested that stress might be dependent on the surgeon’s experience i.e. those learning how to use the
robot do not seem as relaxed using the console. Participants also noted that if a surgeon found a stage of the procedure difficult, this would cause stress regardless of the ergonomics of the robot. The difference between mental and physical tiredness was also highlighted by the team; some described that the surgeon gets tired looking at the 3D image, that robotic surgery is stressful for their eyes and requires more mental concentration. It was also noted that the surgeon can be hunched in the same position for hours.

Discussion

Robotic surgery is a complex interactive system. Whilst this technology promises many benefits for patients, the introduction of interactive systems into healthcare practice often results in unintended consequences that are difficult to predict. We have drawn on the experience of OR teams to understand the impact that robotic surgery has on surgeons’ intra-operative decision making. Using the approach of realist evaluation, we have not only identified some of the consequences of robotic surgery for the processes and outcomes of surgeon decision making but have also begun to unpack how these impacts are achieved and the contexts in which these impacts are likely to occur.

The findings suggest a number of revisions to the theories discussed in the interviews. They highlight the role of the team in maintaining the surgeon’s situation awareness, fitting with ideas previously postulated in the literature. We anticipated this would involve teams providing surgeons with information about the patient state but the state of the robot also needs to be communicated. However, the findings also suggest that, for this to occur, there needs to be a positive relationship between surgeon and team. That relationship may be impacted by the way in which robotic surgery is introduced, with training as a team and having a dedicated robotic team being associated with positive relationships between the surgeon and team so that team members feel confident to speak up. The findings also reveal the intertwined nature of surgeon situation awareness and the surgeon’s level of concentration when undertaking robotic surgery; when the surgeon trusts the team to make him aware of changes outside of his field of view, he feels confident to remain in the console, resulting in reduced distraction and increased concentration. What is less clear is how this impacts patient outcomes. The ergonomic console can reduce stress and tiredness, enabling the surgeon to persist longer with the operation and potentially reducing the number of conversions to open surgery, but this is only when the surgeon is experienced in robotic surgery. Interestingly, in contrast to some of the literature, lack of tactile information did not present a concern for the surgeons in our study. A revised set of theories, formulated as CMO configurations, is presented in Table 2. Given realist evaluation’s concern with identifying what works, for whom, in what circumstances, these theories describe what is needed to produce a positive outcome. The implication is that, in the absence of the necessary contextual factors, the mechanism that produces the desire outcome will not be triggered. For example, if there is not a positive relationship between the surgeon and the OR team so that the team communicate information to the surgeon, this could lead to complications and increased distraction for the surgeon.

These findings have a number of implications for the design and implementation of surgical robots. While there is recent research exploring how to provide haptic feedback in robotic surgery, from the perspective of the users the lack of tactile information does not, after a short learning period, hinder their ability to assess the situation and...
determine the appropriate course of action. Concerns that are more persistent relate to the impact on the surgeon’s situation awareness and, where this is not addressed, potential benefits of robotic surgery in terms of reduced distraction and increased concentration will not be obtained. We suggest that, to realize the benefits of robotic surgery for surgeon decision making and avoid any negative consequences, implementation of robotic surgery should involve (a) training for teams that acknowledges the need for the team to maintain the surgeon’s situation awareness, and (b) whole team training and/or a dedicated robotic team to establish positive strategies of communication between the surgeon and the team.

Limitations

A limitation of this research is that, although conducted over nine different hospitals, it has been concerned with one surgical specialty, colorectal surgery. However, informal discussions with urology and gynecology surgeons suggest that they experience similar impacts of robotic surgery. In future research, we will be conducting interviews across a range of surgical specialties to assess the extent to which are findings are specific to colorectal surgery and to revise our CMO configurations to reflect the experience of a broader range of surgical specialties.

Another limitation of this research relates to the challenges associated with conducting interviews to understand decision making. Decision making in the OR has predominantly been studied through interviews but to develop a rich, nuanced understand of the complexity of clinical decision making requires comprehensive data, gathered through multiple methods. Consequently, in the next phase of this research, we will be testing our revised theories through a multi-method multi-site case study. We will be conducting structured observations of both robotic and laparoscopic operations using OTAS (Observational Teamwork Assessment for Surgery), which will provide a quantitative measure of the situation awareness of the different sub-teams in the OR. Post-operation, we will ask participants to complete questionnaires to gather their perceptions of the mental and physical demand and the extent of distractions. This will be complemented by detailed analysis of video data that allows us to understand how these impacts are achieved, interviews with participants to understand their reasoning, and ethnographic observations to understand the contexts that influences these mechanisms.

Conclusion

This is the first study to explore how robotic surgery impacts decision making. It reveals both potential benefits and challenges of robotic surgery for decision making, which could have consequences for patient outcomes. While the assumption underlying the introduction of robotic surgery is that the increased precision provided by the robot results in improved patient outcomes, our findings suggest a more complex picture. This is a topic that needs to be considered and addressed by healthcare providers when implementing robotic surgery into their organization.

Abstract

The health information technology (HIT) implementation listserv was conceived as a way to combine a substantial portion of American Medical Informatics Association (AMIA) members who belonged to four working groups (WGs): CIS, Evaluation, ELSI, and POI. Other AMIA members joined in significant numbers. It immediately became a major forum for discussing medical informatics, informatics policies, and discussion of the purpose of AMIA itself. The listserv membership approximates 25% of AMIA’s members and has generated over 6,000 posts. We report on a survey of the listserv’s members: what members think about the listserv; what participants want for medical informatics; how they think those goals should be achieved, and what AMIA’s role should be in this process. The listserv provides vital signs about AMIA and hopes for informatics. We combine qualitative analysis of members’ comments and responses about the listserv using ATLAS.ti qualitative text analysis tool and a word cloud generator.

Introduction

The lifeblood of a membership organization like the American Medical Informatics Association (AMIA) is, not surprisingly, its members. Among the reasons members join is because they value interacting with other members through conferences, journals, committees, working groups, and listservs. Each AMIA Working Group (WG) has its own listserv, through which members exchange information, carry on discussion, post announcements, organize conference sessions, and keep in touch with each other. In addition, one cross-group listserv serves these functions for the large section of the membership interested in implementation issues.

Twelve hundred members from AMIA (~25% of the organization’s members) subscribe to the AMIA “Implementation and Optimization Forum” listserv (hereafter, the “listserv”). This listserv was created in 2012 when multiple cross-postings to the four separate AMIA WGs’ listservs frustrated participants with overlapping and redundant conversations. The postings’ high volume and engaging content motivated the four groups to form a new combined listserv to which all members of the four WGs – the Clinical Information Systems WG, the Evaluation WG, the Ethical, Legal and Social Issues WG, and the People and Organizational Issues WG – were automatically
subscribed. Other AMIA members also were invited to join. By October of 2014 the participants had posted 5392 messages in 824 separate discussion threads. As expected, there is a Pareto-like distribution of members’ postings, i.e., some members post far more frequently than many others.

The lively discussions and frequent interchanges reflect the pulse of AMIA membership. Informaticians from different disciplines, countries, and traditions discuss a range of topics, including implementation experiences, ethical conundrums, change management, organizational issues and politics, regulatory environment, workflow, open source, influential publications, design, and cutting-edge content that has not yet reached medical informatics textbooks or journals. Moreover, the listserv was intended to create synergy and energy across working groups. This has apparently been accomplished. Many from outside of the previous four groups have joined the new listserv.

While listservs are not new, they still create community, enhance communication, enable sharing information and resources, and provide a venue for engaging discussion. [1-9] However, there is little research on how they can be used to support knowledge dissemination and how individual scientists use a listserv for various purposes, including education, conversation, and knowledge dissemination. In December 2014, we surveyed members of the listserv to gain insight into their use of and perceptions about the listserv itself. The survey solicited members’ views on what they most appreciated about this listserv, their suggestions to improve it, and topics they would like to have discussed. We report responses from over 200 AMIA listserv subscribers who responded to fixed-choice and open-ended questions.

We previously reported on some of the listserv content and discussions [10-11] and also have reported some preliminary survey findings from early respondents that focused on the fixed-choice survey responses [12]. This paper complements that work in that we focus on the free text comments. They indicate the reasons AMIA members find the listserv of considerable value and ways they think it might be improved. Our survey results indicate how a significant proportion of AMIA members interact, and would like to interact, suggesting ways AMIA can augment on-line member benefits and services. They also point to topics members consider important for improving implementation of health information technologies (HIT), and, ultimately, health care, that AMIA members, and AMIA as an organization, can address. The survey results indicate what members consider important, showing the vitality of both the listserv and of members’ interest in expanding both its functionality and discussion. The survey, therefore, as well as the listserv, measures some of AMIA’s “vital signs.”

Methods

Three methods were used. First, a survey was conceived to gain insight into AMIA members’ perceptions about the listserv. The authors developed the survey instrument between July and September 2014. The survey was pre-tested starting in mid-September 2014 with a group of 50 volunteer AMIA members who were asked to answer the questions and provide suggestions for revising them. Based on the feedback from the pretest, the authors then formulated and iteratively refined the questions via pretesting with 17 of the volunteers. The final version of the survey had 8 questions that ranged from how often people read and make listserv postings to what they like and dislike about the listserv, as well as what they would like to see improved. With the exception of Question 8, all questions were fixed-choice, and Questions 4, 5, 6, and 8 also asked people for free text comments. The fixed choice questions were not limiting in choices, so a respondent could select as many choices as they wish. The survey was IRB approved and respondents were offered anonymity. The survey was officially launched on December 2, 2014 via SurveyMonkey®. [13] All 1200 Forum members were invited to participate and, after several reminders, by February 1, 2015, 223 people responded to the survey.

Second, the numerical data was analyzed by SurveyMonkey® using descriptive statistics. Third, the free text comments were exported into ATLAS.ti [14] and analyzed to identify themes related to the numerical data. Three of the authors (BK, KR, and CK) used ATLAS.ti to independently code the free text data for Questions 4, 5, and 8, focusing on what people most appreciated about the listserv and their suggestions for improvement. After completing their independent coding the three authors then integrated their analyses and used an iterative process to develop thematic consensus. Free text quotations are used throughout the findings to emphasize or further illustrate certain themes. The other authors (MA, SA, and RK) also analyzed the free text data from Questions 4, 5 and 8 questions to identify respondents’ suggestions for AMIA. The four comments to Question 6, which asked participants if they referred others to the listserv, were not analyzed and are not germane to this paper.
For further clarity, a word cloud provided a visual display of each of the Questions 4, 5, and 8 free text comments. For this analysis, the word cloud only gives size as a visualization of word frequency, not necessarily the importance of the words, a task that falls to the authors for the interpretation. [15]

Results

The response rate for the survey was 18.5% and the final number of participants was 223. The findings are structured according to the data from questions 4, 5, and 8. For each question we briefly summarize the fixed choice responses, rounded to the nearest integer, then describe the themes from the free text responses, and conclude with a Word Cloud that illustrates the free text responses. When we describe the themes from the free text data we use quotations from the data to emphasize or clarify certain themes.

The first question about the listserv asked “What aspects of the listserv do you most appreciate?” Two hundred and twenty three fixed choice responses were received and were overwhelmingly positive: Approximately 60% of the respondents said the value of the listserv is in “interesting comments from colleagues (64%), “different perspectives” (64%), and “learning about important issues” (59%). Others commented on “the relative absence of political discourse” and the benefit of access to an international perspective. Moreover, in answer to Question 6, 52% said they have recommended the listserv to others.

While many respondents favored leaving the listserv as is (27% said “don't change a thing”), the survey responses also indicated that some see room to improve. The answers to a subsequent open-ended question regarding how the listserv could be improved revealed three broad categories of recommendations: content of discussions, social rules, and technological improvements. We later discuss each of these in turn.

The free text (additional) comments expanded on the themes noted above. Twenty-one free text comments were received for the question of what respondents most appreciated. Seven of the 21 comments from this question highlighted how much people appreciated getting different perspectives from reading listserv postings. They liked reading different points of view and “the chance to discuss possible different way of doing things….” Perhaps most important is that the interdisciplinary perspective of the listserv was something that both clinical and non-clinical participants appreciated.

(Example response) As a clinician, it shows me how non-clinicians and academic personalities view issues...and helps me understand what physician informatics leaders are thinking.

Participants also reported reading real life experiences from actual HIT implementations. Some noted “real world experiences…show how the grass is not always greener across the pond.”

The second most appreciated value of the listserv was keeping readers informed of current developments. Four comments: new publications, “what’s hot,” upcoming webinars, AMIA activities, and instant dispersion of information.
Figure 1: Word cloud reflecting responses (both fixed choice and free text) for Question 4: “What aspects of the listserv do you most appreciate?”

Fig. 1’s word cloud reflects the sentiments expressed in both the fixed choices and free text comments about the aspects most appreciated in the listserv. Predominant terms are generally positive and welcoming: “learning,” “new developments,” “funny,” “humor,” “informs me,” “new developments,” “experiences” (explained, related), “value,” “discussions of problems,” “helps me understand,” “shows me,” (discusses) “reasons for actions,” “studies,” “publications,” “rapid information,” and “collaboration.”

In tabular form, the most common responses were:

<table>
<thead>
<tr>
<th>What aspects of the listserv do you most appreciate?</th>
<th></th>
</tr>

</table>

Note: Respondents could choose multiple items.
The next question asked for “Suggestions for improving the listserv” (N=209). The most popular fixed choice response requested that we “Ask people (politely) to make the headers reflect the actual topic,” which was chosen by 57% of respondents. As noted above, however, 27% of respondents selected “don’t change a thing” as a suggestion for improvement.

Of the 19 free text responses, some addressed technical issues, such as links not loading from postings, but most primarily referred to social aspects of the listserv: certain people dominating the discussions, some “rants” and “rock throwing,” and too many interpersonal discussions.

People’s suggestions to improve the social issues were varied. Many loved the freedom and spontaneity of the listserv, but some felt this led to tangents of limited interest. Respondents were equally divided on whether the list should be moderated. For some, the volume, repetition, and negativity made the listserv less attractive, while others thought it is a “must read.” While some wished for more intervention and listserv moderating (12 of the comments mentioned this) to improve netiquette and reduce the “bashing” and “beating the same drum over and over again,” they were equally split (11 of the comments) because others liked the “spontaneity.” Many welcomed new perspectives and the “frank exchange” of problems being exposed via the “savvy” postings.

(Example response) A few suggested the use of “providing polite training for those with knowledge gaps of how to respond to single individual vs all.”

Figure 2: Word cloud reflecting comments (free text) in response to question 5, about improving the listserv.

The word cloud for this question (Fig. 2) reflects both the joy and frustration of the readers. On the joy side – the predominant side – we see terms like: “useful,” “original,” “great sprit(ed),” “constructive,” “discussions,” “conversations,” and “communications.” On the “frustrated” side, we find terms such as: “header” (as in fails to keep headers up to date), “attacks,” “personal,” “soapbox,” and “personal” (as in responses to personal comments or the rounds of congratulatory messages that some experience as clogging the list).

Finally we inquired: “What else would you like to tell us? For example, some have suggested we encourage more discussions of: cyber security of EHRs and PHRs; the role of the CMIO; specific concerns about the cost of
healthcare IT (both initial software and the cost of implementation); inclusion of clinicians at key decision points in HIT design and implementation.” This question had only free text responses and 97 were received. Suggested topics included: improving EHRs and their implementation, usability or lack of it, HIT errors, standards (e.g., interoperability standards), the continuum of change (from talk to change), liability for lost data, HIT risks, change management, measurement and improvement of quality and safety, the barriers between IT and clinical and fiscal or monetary influences, gaps between technical people and healthcare professionals, and the topics listed in the question itself. Some suggested a topic of the month, while others liked that topics evolved, responded to the news, and reflected member interests and issues. A few commented that they liked the political discussion and ways to effect change, while others wanted less or no political discussion. Some also believe more presence of vendors as well as healthcare students who are currently trained using EMR systems in the listserv could be helpful. Overall, the freedom and spontaneity of the listserv was appreciated by some users but disliked by others who believe it leads to less meaningful dialogue.

(Example response) The beauty of the listserv is the spontaneous presentation of topics represented based on what's relevant to all of us in the field and front lines. Attempting to influence the content detracts from this. You always have the choice to ignore a post or present a topic.

However, others would prefer to have set topics to focus the discussion.

(Example response) I wish it could somehow be focused, as the volume is far (!) too great. Really limit it to implementation and optimization issues, not every topic under the Sun. Some people seem to spend virtually all their time posting to the list...a more circumspect approach would be better.

More specifically, the diversity of participants meant that there were different ideas for selected topics. One idea was topics with a greater academic focus such as social or economic theories or foundations in applied informatics research. Another suggested topic was more perspectives for CMIOs. Other requests were for either more moderator involvement (help focus topics, encourage polite behavior) or for less moderator involvement.

Several commented on the volume of postings and the chaotic or vestigial headers (they don’t change when topics change). Some asked for summaries, search and visualization tools, and more digest options. Some wanted previous messages to be repeated, finding it easier to make sense of the thread, while others “hated” it and wanted them either eliminated or “snipped.” Others argued for mobile apps and greater access via the AMIA website.
In Fig. 3 we see a reflection of the themes noted above: on the one hand, an appreciation of the freedom and evolving nature of the listserv, on the other, a desire to focus and control the discussion.

**Discussion**

The listserv evolved from the intersection of several AMIA WGs. The informality continues in this combined service and is clearly appreciated by members who enjoy the natural development and evolution of topic threads. Nonetheless, some members indicated that they missed specific (types of) HIT implementation topics or that some topics were not discussed adequately and suggested that the list moderator could ensure that these topics were raised, for example by posting a “topic of the month.” Recurring themes in the suggested topics were gaps in applied informatics research, theories and frameworks, standards, interoperability, EHRs/PHRs, and the role of the CMIO. Other members suggested not trying to influence content because one of the listserv’s benefits is its spontaneity of posting topics and the evolution that threads take.

Several respondents felt that just exchanging ideas on the listserv is not enough. In the free text, respondents indicated that the list members should try to move from merely discussing barriers or problems to finding solutions (“moving from talk to change”). Suggestions for doing so included AMIA members collaborating to develop a medical record system, picking up a Quality Improvement initiative or study, and trying to resolve the seemingly ever-present gap between professionals (e.g., technicians versus physicians).

**Social rules**

Some respondents further indicated that the added value of the listserv can become clouded by the amount or nature of posts from a few users with personal agendas. They suggested that a moderator or others should say what types of posts are appropriate for a listserv and what types of posts might be more appropriate via, for example, personal email, blog, or tweet. Moreover, the respondents suggested a level of mutual respect – recognizing that others may have a different opinion from one's own and that some members might be more critical than others in their...
comments. That said, there were far fewer negative comments than positive, and respondents split on the desirability of a moderator.

Additional social rules included awareness of the tone of messages, indicated in statements such as “I really don’t appreciate the sarcastic humor,” and the need to discourage “rants” or “beating the same drum.” Some respondents were careful to say that they do not explicitly favor censorship except in extreme cases where the postings are detrimental to what readers can get out of the list or involve personal attacks.

To address these concerns, some members suggested solutions such as establishing rules of engagement for newcomers to the list or distributing a regular operational message to the list with a policy statement. An additional suggestion was to offer training (to new and existing members) regarding proper listserv etiquette. There were also suggestions to let the moderator play a stronger role, both in the discussions and behind the scenes by explicitly discussing problematic behavior with the person posting to the listserv.

**Technology**

Some responses also indicated that the flurry of discussion that naturally evolves should be balanced against email overload. These respondents therefore asked AMIA administrators to examine technical solutions to help reduce the volume of messages in people’s inboxes. Some members favor a periodic summary of trending topics.

One of the most prominent comments involved threading and individual posting behavior vis-a-vis thread/header hygiene. Few pay attention to the headers even when the topic shifts. Fifty-seven percent indicated that as discussion evolves headers should be adjusted to reflect the actual topic. However, respondents also indicated that this is sometimes difficult within the current listserv software and ease of use with headers. They ask for personal accountability and/or improvement to the current email interface.

**Conclusions**

The implementation listserv, within less than a year, became a major forum for discussing medical informatics, informatics policies, and of the purpose of AMIA itself. At the time of the survey, the listserv was subscribed by 25% of AMIA’s members and, by March 12, 2015 had generated over 6,000 posts. In summary, the survey results analysis serves to advance research evidence about knowledge dissemination, particularly how members interact and what they consider priorities for the topics under discussion and for the listserv itself. This report has relevance both to AMIA and to a more general audience interested in sociotechnical aspects of online knowledge transfer, engagement among community-of-practice members, organizational use of IT, and implementation and optimization issues in deploying and using IT.

For the respondent sample size, 18.2%, we make no claims of representativeness – in part because we turned off the email tracing function as part of our promise of confidentiality and anonymity, and thus cannot report on the identities of individual respondents. We also did not collect demographic data out of the same concern, as we personally know respondents we might have been able to identify. We do know that AMIA membership includes clinicians, researchers, HIT practitioners, and vendors, no doubt reflected in the pool of subscribers to this listserv. In addition, we may assume that those more engaged in the listserv’s discussions were more likely to respond to the survey. We note, however, that some respondents said they seldom if ever contributed to the listserv, which may indicate at least some inclusion of "lurkers."

Of course, the usual limitations of question wording apply. We also know that some for whom English is not a mother tongue may be especially reluctant to contribute to the listserv. On the other hand, we doubt that many members of the listserv are illiterate, making this concern less relevant.

Next steps will be more in depth studies of the listserv and its data such as social network analysis and studies of specific topics (e.g., data standards, workflow, HIT evaluation, international contexts). Our plan is to engage the listserv participants to form groups corresponding to topics of interest.

Public Perspectives of Mobile Phones’ Effects on Healthcare Quality and Medical Data Security and Privacy: A 2-Year Nationwide Survey

Joshua E. Richardson, PhD, MLIS, MS, Jessica S. Ancker, MPH, PhD
Department of Healthcare Policy and Research
Weill Cornell Medical College, New York, NY

Abstract

Given growing interest in mobile phones for health management (mHealth), we surveyed consumer perceptions of mHealth in security, privacy, and healthcare quality using national random-digit-dial telephone surveys in 2013 and 2014. In 2013, 48% thought that using a mobile phone to communicate data with a physician’s electronic health record (EHR) would improve the quality of health care. By 2014, the proportion rose to 57% (p < .001). There were no similar changes in privacy concerns yet nearly two-thirds expressed privacy concerns. In 2013 alone, respondents were more likely to express privacy concerns about medical data on mobile phones than they were to endorse similar concerns with EHRs or health information exchange (HIE). Consumers increasingly believe that mHealth improves healthcare quality, but security and privacy concerns need to be addressed for quality improvement to be fully realized.

Introduction

Healthcare researchers and industry leaders perceive mobile phones (mHealth) as having the potential to revolutionize the ways in which consumers self-manage their health and interact with their healthcare providers. It represents an informatics intervention that is fundamentally different from electronic health records (EHRs) or personal health records (PHRs) because of the ability for consumers to capture, process, and share personal health information without being tethered to an Internet browser.

In particular, smartphones and their applications (“apps”) offer novel opportunities for remote patient data gathering such as tracking exercise and sleep patterns or medication adherence. This could be a valuable tool that helps manage chronic disease. It is also encouraging that mHealth is being widely adopted by various consumer groups regardless of race, gender, or socioeconomic status. In fact, there is evidence to suggest that those with lower socioeconomic status may be more willing to accept mHealth than other groups. That may provide a host of new opportunities to engage patients in health care and research. Taking together these trends, mHealth offers exciting opportunities for delivering services in ways that can potentially improve overall healthcare quality. However, along with its rise in availability and use, mHealth may be subject to unintended consequences such as increased threats to data privacy and security.

Informatics researchers and developers are not only applying mHealth strategies to track patients with highly prevalent conditions such as diabetes, but also conditions that may be considered socially sensitive. Examples of those applications include monitoring activities in the context of care for sexually transmitted infections, drug treatment support, mental health care, and delivering healthcare services for patients living with HIV/AIDS. With the continued increase in smartphone adoption, the emergence of wearable devices, and personalized/genetic medicine it is likely that in the near future mHealth data will be collected for a myriad of other sensitive patient conditions in far greater quantities than today. This raises numerous challenges that informaticians will have to address.

One particular challenge is gauging consumer perceptions of mHealth privacy and security with respect to any potential for improvements in healthcare quality. If consumers believe that the gains from mHealth in terms of improved healthcare quality outweigh the costs associated with risks to patient data privacy and security, it is reasonable to assume consumer adoption of mHealth would be broad and therefore the impact would be widely felt. Capturing consumer attitudes will help identify potential opportunities and barriers to mHealth adoption, with implications for mHealth, public policies in the form of new regulations, industry investment and market development, and mHealth research.
Our objective for this study was to gauge consumer perceptions of the effects of mobile devices on medical data security and privacy and healthcare quality.

**Methods**

The Cornell National Social Survey is an annual random-digit-dial telephone survey conducted by Cornell Survey Research Institute. Every year, the sample size of 1000 provides a margin of error of plus or minus 3.1 percentage points. The Cornell University Institutional Review Board approved the study, and respondents provided oral consent.

**Sampling strategy**

The Cornell National Social Survey is conducted annually with a random sample drawn from a dual frame of landline and cell phone numbers in the continental United States not stratified by geographic region, race, or other variables. The proportion of cell phone numbers is calculated from county-level data on prevalence of cell phone-only households. Listed and unlisted numbers are both included in the sample list; known business, disconnected, and non-household numbers are excluded. When the telephone is answered, the adult with the most recent birthday is interviewed to ensure that each adult has equal chance of selection.21

**Survey development and administration**

Researchers from Cornell University and Weill Cornell Medical College submit potential questions that are competitively reviewed by the Cornell Survey Research Institute. Three questions about “cell phones or smartphones” were included for 2 consecutive years: 2013 and 2014. Initial question wording was based on EHR and health information exchange (HIE) questions, which were included within the same survey in 2013 only and are the focus of a separate publication.22 There were slight wording variations based on between-year pilot testing (boldface below) but testers did not note any difficulties with respondent comprehension in either year. In each year one question asked about perceived impact on quality, and two questions asked about perceived impact on privacy and security with regard to sharing health data and storing health data.

Do you think it would:  
  • (5-point Likert scale from “greatly improve it” to “greatly worsen it,” midpoint at “no effect”) |
Data analysis

Data are summarized with descriptive statistics. Chi-squared tests were used to compare frequencies from year to year. In bivariate analyses, there were small but statistically significant associations between some of the demographic characteristics and the 3 mobile phone questions. For multivariable logistic models (with dichotomized response variables) characteristics significant at .05 were included to determine whether the year-to-year changes remained statistically significant while controlling for participant characteristics. Analyses were performed in SAS (version 9.3).

Results

A total of 1000 respondents were included in 2013 and 2014 with a 3.1% margin of error in each year. The cooperation rate (using the American Association for Public Opinion Research definition of number of eligible participants reached by telephone who participated) was 70% in 2013 and 79.1% in 2014. The samples were somewhat more likely to be white, non-Hispanic, and highly educated than the US population, but were otherwise fairly representative.

Each year, there was strong support for being able to use mobile phones to share data with a doctor’s EHR. The proportion of respondents who thought this would improve healthcare quality rose from 48% to 57% (p < .001; Figure 1). However, each year the level of privacy and security concerns was also very high. About three-quarters of individuals believed that storing medical information on the phone would threaten privacy and security (74% in 2013, 75% in 2014, p = 0.64). About two-thirds thought that sharing data between a mobile device and a doctor’s EHR would threaten privacy and security (69% in 2013, 67% in 2014, p = .45)
Each year, several characteristics had modest but statistically significant bivariate associations with the 3 mobile phone questions. These are listed in Tables 3-5 and were included in multivariable models. The multivariable models confirmed that there was a statistically significant increase in the proportion that believed mobile phone-EHR communication would improve healthcare quality, with no year-to-year differences in the other 2 mobile phone questions. Younger individuals, those with more education, and nonwhites were significantly more likely to endorse the belief that mobile phone-EHR communication would improve quality. Non-Hispanics were significantly more likely to express privacy concerns about storing data on mobile phones.

*AOR, Adjusted Odds Ratio

In 2013 only, participant opinions about mHealth could be compared to their opinions about physician use of EHRs and HIE. In this year, respondents were markedly more likely to believe that health care quality would be linked to physicians using EHRs or HIE (61% and 74%, respectively) than to patients using mobile devices to communicate with EHRs (48%). They were also markedly more likely to express concern about worsened privacy and security with storing data on mobile phones and mobile phone-EHR communication (74% and 69% respectively) than with EHRs and physician HIE (41% and 47%).

Respondents who believed that EHRs would improve healthcare quality were nearly 3 times as likely to believe that using a mobile device to share data with an EHR would improve healthcare quality (OR 2.94; p < .001).

**Discussion**

Our nationwide survey found increasing year-over-year consumer sentiment that healthcare quality would improve as a result of using mobile phones to share personal health information with doctors’ EHRs. Nevertheless, participants in each year were highly likely to believe privacy and security would worsen as a result from using mobile devices to store and share their personal health information, with no year-to-year change. Of further note is that privacy and security concerns remained high even though the questions posed arguably benign patient scenarios (cholesterol scores and physical activity levels) as opposed to more socially sensitive scenarios, e.g. sexually transmitted infections. In specific, these results strengthen the argument that consumers place high value on privacy and security of health data on mobile phones. These results in general provide important insights that inform informatics research, healthcare policy, and the growing mHealth industry.

Consumers are increasingly optimistic that mHealth can have a positive affect on healthcare quality. This suggests the possibility that consumers are becoming familiar with the idea that mobile devices can be used for user-specific technologies to support overall health or disease-specific tracking: examples include activity monitoring, calorie tracking, and communicating with doctors. The fact that there were no increased concerns about privacy and security may indicate that consumers are not only becoming more familiar with mHealth, but may be more welcoming of mHealth in their personal care. In addition, given that consumers perceived privacy and security as separate from healthcare quality is in itself an interesting finding, for many might argue that privacy and security of mHealth are important features of overall quality. We hope to delve further into this area so to report if and how consumers may perceive the costs and benefits to quality improvement versus threats to privacy and security, and how that may influence future adoption and use of mHealth. In general, researchers may do well to pose future health data privacy and security questions to consumers from within the context of broader health services so that consumers must weigh the costs and benefits for privacy and security.

Despite the generally positive perception of the potential for mHealth, our 2013 comparison found that consumers were more likely to believe that physician-oriented information technologies (EHRs and EHRs with HIE) would improve healthcare quality. It will be interesting to see if consumer perceptions of mHealth and healthcare quality rise to the levels of EHRs and HIE alone in the years ahead.

A large majority of consumers consistently reported that using mHealth to store and share personal data would worsen privacy and security. Researchers, policy makers, and mHealth developers should take note of this result as it indicates possible concern within the general population. Although it did not seem to affect perceptions about how mHealth improving healthcare quality in this study, consumers’ concern could manifest itself in other ways that impact future trends in adoption and use. Also, consumer groups may find cause for concerns in these findings because an increasing amount of informatics research is demonstrating that mobile devices have multiple security threat vectors including data leaks and loss. There may be cause to educate the general public about how to...
securely store and share their protected health information, and for standards bodies to push for more robust mHealth security standards.\textsuperscript{26-28}

Younger individuals and individuals with more education were more likely to endorse the idea that mHealth would improve healthcare quality. These findings may support a view that mHealth is an intervention primarily for the tech savvy. The fact that nonwhites were significantly more likely to endorse that data sharing would improve quality is consistent with research outside of health care showing that nonwhites and those with lower socioeconomic status are just as likely to use smartphones to access the Internet as are whites.\textsuperscript{29} We therefore believe that these findings support future efforts to understand the mHealth user population and how mHealth may cut across traditional lines of race and class. Our finding that non-Hispanics were significantly more likely to express privacy concerns about storing data on mobile phones supports this.

The following are limitations to this study. Sampling coverage and non-response bias are known limitations to random-digit dial surveys. We did not apply survey weights in order to match demographic characteristics of the country because the sampling strategy was random. As a result our sample was fairly representative in gender, age, and employment, but more educated and affluent, more likely to be white, and less likely to be Hispanic than the national population. The survey questions were not separately validated; however, the survey developers piloted the questions for cognitive comprehension and the interviewers did not report any respondent difficulties with the questions. The size and scope of the survey limited our ability to probe particular attitudes regarding privacy and security or mobile devices; we hope to investigate those issues in future work. The study design was cross-sectional, and association does not imply causation.

**Conclusion**

The growing availability of mHealth offers consumers new and exciting opportunities to improve healthcare quality but, as with any informatics intervention, improvements in quality need to be appropriately balanced against potential threats to data privacy and security. Consumers are one of the stakeholder groups, perhaps the key stakeholder group, for determining that balance between potential quality improvements and potential threats to privacy and security. Our 2-year survey found consumers increasingly perceived that using mHealth to share patient data with doctors would improve healthcare quality. Although consumers did not exhibit a year-over-year increase in privacy and security concerns, consumers have strong concerns nonetheless. These findings add encouragement to mHealth advocates but also support the need for informatics researchers, policy-makers, and mHealth developers to improve mHealth privacy and security.

Automatic Extraction and Post-coordination of Spatial Relations in Consumer Language

Kirk Roberts, PhD, Laritza Rodriguez, MD, PhD, Sonya E. Shooshan, MLS,
Dina Demner-Fushman, MD, PhD
National Library of Medicine, Bethesda, MD

Abstract

To incorporate ontological concepts in natural language processing (NLP) it is often necessary to combine simple concepts into complex concepts (post-coordination). This is especially true in consumer language, where a more limited vocabulary forces consumers to utilize highly productive language that is almost impossible to pre-coordinate in an ontology. Our work focuses on recognizing an important case for post-coordination in natural language: spatial relations between disorders and anatomical structures. Consumers typically utilize such spatial relations when describing symptoms. We describe an annotated corpus of 2,000 sentences with 1,300 spatial relations, and a second corpus of 500 of these relations manually normalized to UMLS concepts. We use machine learning techniques to recognize these relations, obtaining good performance. Further, we experiment with methods to normalize the relations to an existing ontology. This two-step process is analogous to the combination of concept recognition and normalization, and achieves comparable results.

Introduction

Medical ontologies are fundamentally limited in the number of concepts and terms they contain. The range of potential problems, treatments, tests, biological processes, and other concepts encountered in medicine is far too vast to encode directly as concepts in an ontology. Instead, ontologies generally rely on attributes and relations to handle on-the-fly concept creation. Further, for a given concept, it is often impossible to enumerate all the textual strings that can be used to refer to that concept in natural language. The ontological solution for this problem is known as post-coordination, where simple concepts are composed (or coordinated) into a more complex concept. Making full use of an ontology when interpreting unstructured text therefore necessitates natural language processing (NLP) techniques.

The need to perform post-coordination is particularly strong in consumer language. Non-experts lack the breadth of vocabulary that experts often use to describe medical concepts. Instead, consumers often rely on lengthy descriptions with a reduced vocabulary when describing symptoms or conditions. This results in an increased need for post-coordination. Consider the following three examples of consumer language:

1. I am experiencing pain in my left leg.
2. They measured his blood pressure and found it to be above acceptable levels.
3. During the accident I sustained an injury to the back of my head and neck.

The first example corresponds to the UMLS concept Pain in left leg (C0564822 in UMLS 2014AB), yet the presence of the word “my” in the middle of the phrase prevents the concept from being recognized by a simple lexicon lookup. Instead, the concept Pain (C0030193) and Left leg (C0230443) need to be composed to find the pre-coordinated concept in UMLS. In the second example, the patient has Hypertension (C0020538), but this has to be inferred from the result of the high measurement. This is an example of where consumer language would likely differ from that of medical professionals, who might simply state, “He has hypertension.” In the third example, no concept in UMLS corresponds to the problem “injury to the back of the head and neck”. Instead, the problem concept Injury (C3263722), the direction Back (C0205095), and anatomical locations Head (C0018670) and Neck (C0027530) must be post-coordinated into an on-the-fly concept.

Unfortunately, short of complete natural language understanding, there is no general-purpose NLP technique for performing post-coordination. Rather, methods must be used that target specific domains or linguistic phenomena. In this paper, we limit our scope to a vital phenomena for understanding consumer-described symptoms and conditions: the spatial relationships between disorders and anatomical locations. These are generally expressed in one of two ways: (i) a noun compound (e.g., arm pain), or (ii) a grammatical relation between an indicator term such as a spatial
preposition (e.g., *in*, *on*, *at*) and two or more concepts. While noun compounds describing spatial relationships are quite common, they are often pre-coordinated in an ontology and are easier to automatically recognize due to their contiguous nature. The grammatical relations describing spatial relationships are more likely to require special handling and are more difficult to automatically recognize, and hence are the focus of this work. Examples (1) and (3) above demonstrate the second type of spatial relation. While Example (2) contains a spatial relation (*above*), it does not describe the relationship between the concepts of interest here and is therefore outside the scope of this paper.

In this work, we describe both manually annotated datasets and automatic NLP methods to extract disorder-anatomy relations and normalize them to their appropriate UMLS CUIs. Specifically, the contributions of this paper are:

1. A manually annotated dataset based on the Spatial Role Labeling (SpRL) schema\[1\] to extract spatial relations between disorders and anatomical locations.
3. A manually annotated dataset normalizing the extracted spatial relations to UMLS CUIs.
4. An evaluation of several existing automatic methods for normalizing text to CUIs, customized to handle the extracted spatial relations.
5. A discussion of the fundamental limitations to this task based on error analysis of the above automatic methods.

Further, both annotated datasets are being made publicly available via the National Library of Medicine website.

**Background**

While not as well studied as temporal language in medical text, spatial language—especially spatial relations—has nonetheless received considerable attention. Rindflesch et al.\[2\] describes how syntax relationships are crucial to the semantic interpretation of anatomical relationships in cardiac catheterization reports. In particular, they focus on hand-crafted rules for recognizing arterial branching relations as well as the locations of stenosis. Their method relies heavily on the structured data source University of Washington Digital Anatomist\[3\] (UWDA), part of the Foundational Model of Anatomy\[4\] (FMA). Closer to our approach are methods that utilize machine learning (ML) to relate disorders with their anatomical locations. Roberts et al.\[5\] find relations between an inflammation term and its anatomical location within radiology reports. Their method is able to recognize a single layer of relation nesting—that is, when two spatial relations combine into a single conceptual relation (e.g., “*inflammation on the wall of the gallbladder*”). Dligach et al.\[6\] similarly recognize anatomical locations for disorders. Their method is designed to operate on any type of disorder, but they do not recognize nested relations. So in the phrase “*skin tumor removed from behind his left ear*”, the anatomical location for the tumor would be the entire phrase “*behind his left ear*”. The lack of nesting can present several difficulties, however. From a practical perspective, longer phrases are more difficult to recognize automatically. From a linguistic perspective, the phrase still requires further semantic interpretation. In contrast to these two ML methods, our approach can operate on any disorder term and places no restriction on the depth of nesting, and then goes a step further by providing a semantic interpretation. Thus the method could understand a complex spatial phrase such as “*skin tumor on the side of the elbow of his left arm*”.

Also, unlike any of the previous approaches, our focus is on consumer language instead of clinical language. Consumer language has been explored in the past as a means of supporting health information seeking\[7,8,9\] and making medical terms more comprehensible\[10\] for consumers. This work fits more in the former category, where a semantic understanding of consumer language enables systems that connect consumers with health information resources. In previous work with consumer language, we have focused on co-reference\[11\] and question classification\[12,13\].

Outside of medicine, spatial relations have received more attention. Several schemas have been proposed for natural language, including SpatialML\[14\], SpRL\[1\], and ISO-Space\[15\]. Of these, ISO-Space is the most recent and likely the best developed, especially for representing highly-specified geographic descriptions. For under-specified relations, however, ISO-Space and SpRL are largely interchangeable. For our purposes here, therefore, we use SpRL due to its relative simplicity in the knowledge that our annotations could easily be transformed to ISO-Space in the future should the need arise. SpRL was utilized in two SemEval tasks, in 2012\[16\] and 2013\[17\], while a hybrid SpRL/ISO-Space representation was used in the SemEval 2014 SpaceEval task\[18\]. Successful approaches to these tasks have combined supervised ML, syntactic parsing, and integration of real-world knowledge\[19\].
Post-coordination is generally studied in the context of ontologies and medical coding. For instance, Oniki et al.\cite{20} discuss best practices for pre- and post-coordinating concepts when creating a structured knowledge source based on Clinical Element Models (CEMs). Conversely, Dhombres et al.\cite{21} employ post-coordination when utilizing a structured knowledge source, SNOMED CT, to extend its phenotype coverage. The best known NLP system to perform post-coordination is SemRep\cite{22}, which utilizes MetaMap’s\cite{23} option to identify and normalize short phrases. SemRep then identifies relations (e.g., treatment for, location of) that in many cases can be thought of as post-coordinations. However, SemRep does not, nor does any NLP application we are aware of, attempt to normalize these relations back into an ontology to determine if there is an equivalent pre-coordinated concept as described in this paper.

Instead, the most similar NLP task to the one presented in this paper is the combination of concept recognition and concept normalization.\cite{24,25} In this comparison, concept recognition would be analogous to SpRL relation extraction, while concept normalization would be analogous to relation normalization. In theory, an approach similar to concept recognition/normalization could be used here, but would likely perform poorly for two reasons: (a) concept recognizers typically use sequential classifiers, which perform poorly with long concept spans such as those in Examples (1)-(3) above, and (b) concept normalizers attempt to use all the words in the concept, but the relation structure recognizes that some of the words aren’t relevant (e.g., “my” in Example (1)). In the Discussion, we provide some insights as to how comparable our results are to the state-of-the-art in concept recognition/normalization.

Methods

We begin by describing the two sets of annotated data. Next, we describe the process of automatically extracting spatial relations from text. Finally, we describe how these relations are automatically normalized to UMLS concepts.

A. Data

In this section, we describe two different manually annotated data sets: (1) a set of spatial relations in natural language text, and (2) a set of normalizations from the extracted spatial relations to UMLS concepts. Both datasets are publicly available from the U.S. National Library of Medicine (NLM) website.\cite{26}

Spatial Relations: To gather a set of consumer-written texts likely to contain spatial relations, we started with a large set of emails and online form requests sent to the NLM customer service team. Every year, NLM receives over 40,000 such requests, several thousand of which are manually classified by NLM staff as consumer health questions pertaining to diseases, conditions, and therapies. From these, we extracted 1,976 sentences containing (1) at least one term from UMLS in the DISORDER semantic group,\cite{26} (2) at least one term from UMLS in the ANATOMY semantic group, and (3) a preposition between one UMLS term of each type. Next, two medical experts—an MD/PhD (LR) and medical librarian (SS)—double-annotated spatial relations using a simplified Spatial Role Labeling (SpRL) schema.\cite{1} SpRL defines a spatial relation between three main elements:

1. **SpatialIndicator**: The word or phrase (typically a preposition) that acts as a trigger for the spatial relation.
2. **Trajectory**: The object whose spatial position is being described.
3. **Landmark**: The location of the Trajectory.

In our case, the Landmark is almost always an anatomical location from UMLS (hereafter, an Anatomy annotation), while the Trajectory is usually a Disorder but can be an Anatomy as well. Figure 1 shows how two of the example phrases from the Introduction would be annotated in SpRL using Brat.\cite{27} In the simple example in Figure 1(a), the SpatialIndicator “in” connects the Trajectory “pain” with the Landmark “left leg”. In the more complex example in Figure 1(b), there are two connected spatial relations: (i) a Disorder-Anatomy relation connects the Trajectory “injury” to its Landmark “back”, then (ii) an Anatomy-Anatomy relation connects “back”, this time a Trajectory, to two Landmarks, “head” and “neck”. The annotators were allowed to manually add or edit Disorder or Anatomy terms. Approximately 7% of Disorders were manually created, while around 8% of Anatomies were manually created. Since the focus of this paper is relation extraction and normalization, we do not address automatic concept extraction. The UMLS and manual terms are distinguished in the publicly available data, though no distinction is made between them in the experiments below.

---

\[1\] http://lhncbc.nlm.nih.gov/project/consumer-health-question-answering
From the 1,976 sentences, a total of 1,291 SpRL relations were annotated. To assess agreement, we consider one annotator’s labels as the “gold” set and measure the other annotator’s labels against this with $F_1$-measure (if the annotators were switched, $F_1$ would be the same, while precision and recall would be reversed). Using this method, the inter-annotator agreement has an $F_1$ of 88.9 for SPATIALINDICATORS, 81.5 for TRAJECORY, 86.2 for LANDMARKS, and 72.67 for the complete relation (i.e., exact match for every argument). The annotators reported their agreement improving over time, where many of the disagreements were the result of ungrammatical and medically incorrect consumer language.

**Concept Normalization:** Instead of uninterrupted text spans, here we consider relations to refer to concepts. Any text not part of a SPATIALINDICATOR, TRAJECORY, or LANDMARK—such as the word “my” in Example (1)—is not considered part of the concept. Further, we consider the fully-nested relation of all DISORDERS and ANATOMYs connected through some SpRL relation—such as merging the DISORDER-ANATOMY and ANATOMY-ANATOMY relations in Example (3) into one nested spatial relation. The nested structure of these two examples would be:

(1) pain

   in: left leg

(3) injury

   to: back

   of: head

   of: neck

This nested structure is then used to normalize relations to an ontology. We used 514 such nested relations from the SpRL relations above and manually normalized them to UMLS concepts as follows. The same two annotators as above double-annotated both the nested relations as well as parts of the relations. Normalizing parts of a relation to UMLS enables two useful applications: (1) post-coordination of concepts when the full relation has no UMLS concept, and (2) assignment of codes to parts of a larger concept to specify its deep structure. For the two examples above, the annotated items would be:

(1) phrase: pain in left leg

   term: pain

   term: left leg

(3) phrase: injury to back of head and neck

   term: back

   phrase: back of head and neck

   term: head

   term: injury

   term: neck

Here, a “phrase” is the result of a relation, while “term” is an individual DISORDER or ANATOMY. We only distinguish for the purpose of evaluation. For each phrase/term, the UMLS Terminology Services (UTS) API\(^2\) is queried for potential concepts belonging to either the Disorder or Anatomy semantic groups. Both the words and approximate matching functions were used, since in our exploratory experiments both these had better recall than the other matching functions. The top 10 results per matching function were retrieved, de-duplicated, and sorted by CUI instead of relevance rank to reduce biasing the annotators toward choosing the top result. The annotators then chose the correct normalization or indicated that none of the concepts were proper normalizations. Table 1 shows an example of how one phrase and one term were annotated.

There were a total of 1,747 annotated phrases and terms. Around 66% of the annotations had a concept normalization (i.e., a pre-coordinated concept in UMLS). Phrases (relations) were far more likely to not have a valid normalization. 74% of the phrases had no normalization, and thus require post-coordination of their component terms to be properly interpreted. By comparison, only 15% of the individual DISORDER and ANATOMY terms have no normalization. About half of the terms without a normalization are the result of manually creating DISORDER and ANATOMY terms that were not in UMLS. The rest are the result of none of the candidate normalizations being judged valid by the annotators. Inter-annotator agreement was fairly good at 84.8%.

\(^2\)https://uts.nlm.nih.gov/home.html#apidocumentation
B. Spatial Role Extraction

Figure 2 presents the architecture of our ML-based SpRL relation extractor. We utilize a pipeline method where Disorders and Anatomys (from their respective UMLS semantic groups) are pre-annotated. Next, SpatialIndicators are extracted. Then, for each SpatialIndicator, Trajectors and Landmarks are identified. These steps are described in detail below except for the pre-annotation, which is described in the Data section.

For candidate SpatialIndicators, we consider all prepositions, adverbs, and participles. Some light verbs (such as have and get) can be indicators, but not sufficiently often to merit their inclusion here. We use Stanford CoreNLP\cite{28} to perform part-of-speech tagging. The primary goal in candidate selection is recall: incorrect indicators can still be filtered out by the classifier, but missing indicators cannot be recovered. This recall-based technique achieves 98% recall with a precision of 14%. This precision is sufficiently high to ensure the training data is not overly imbalanced, thus giving the machine learning classifier below the opportunity to filter out most of the incorrect candidates. A binary support vector machine (SVM) then classifies candidates as positive or negative. The primary consideration in deciding whether a word is actually a SpatialIndicator is its context, especially its relationship with nearby Disorder and Anatomy terms. With that in mind, the features used by this SVM are shown in Table 2(a).

Since SpatialIndicators are the central element of an SpRL relation, candidate Trajectors and Landmarks are defined in terms of the Disorder/Anatomy concept and the SpatialIndicator (e.g., in Example (3), “head” is a valid Landmark for “of” but not for “to”). For a given SpatialIndicator, all Disorder and Anatomy terms within its sentence are considered as candidate Trajectors and Landmarks (a Disorder is rarely a Landmark, but this is possible). Then, two binary SVMs (one Trajector, one Landmark) classify candidates as positive or negative. The primary consideration for a positive Trajector/Landmark is its relationship with its SpatialIndicator, especially its syntactic relationship (using syntactic dependencies obtained from CoreNLP). With this in mind, the Trajector features are shown in Table 2(b), while the Landmark features are shown in Table 2(c).

Post-processing. We then consider two post-processing modules, one for SpatialIndicators and one for both Trajectors and Landmarks. The NoArgFilter prunes any SpatialIndicators that do not have either a Trajectory or Landmark. Since most SpRL relations have all three elements, this filter is essentially a voting strategy where, if the two argument classifiers agree an indicator has no argument, then it is likely that the indicator classifier erred. Then, the AddCoords heuristic adds a new Trajectory or Landmark if an existing Trajectory or Landmark is separated by a concept of the same type (Disorder/Anatomy) by an and or an or. This helps identify errors where only one item in a coordination (e.g., “head and neck”) is marked as an argument.

C. Spatial Relation Normalization

Given a sentence containing at least one SpRL relation, the same process as described in the Data section is used to obtain the fully-nested relations as well as the sub-parts of the nested relation. For the purpose of this paper, we are not proposing any new methods for normalizing concepts. Instead, we evaluate baseline and existing methods for concept normalization, and customize these methods for the spatial relation structure. Since existing concept normalization methods expect a word sequence instead of a relation, we use all the words in any element of the relation just as for generating concept candidates from UTS. We also filter out any concepts that do not belong to the Disorder or Anatomy semantic groups.

We evaluated the following methods:

1. tfidf pref: (Baseline) Ranks the candidates (returned by the UTS method described in the Data section) using TF-IDF scored cosine similarity between the relation and the concept’s preferred name. Document frequencies are derived from a recent version of PubMed Central (PMC).
2. tfidf all: (Baseline) The same as tfidf pref, but uses every concept name instead of just the preferred name.
3. UTS[exact]: The top result for the UTS exact matching function.
4. UTS[approximate]: Same except for the UTS approximate function.
5. UTS[left trunc]: Same except for the UTS leftTruncation function.
6. UTS[right trunc]: Same except for the UTS rightTruncation function.
7. UTS[words]: Same except for the UTS words function.
8. UTS[norm words]: Same except for the UTS normalizedWords function.
9. UTS[norm str]: Same except for the UTS normalizedString function.
10. UTS[vote]: A combination of the above seven UTS methods using a simple voting strategy. Ties are broken by choosing the concept with the lower CUI number.

Here, the TF-IDF based methods provide simple baselines based on a standard similarity metric. They should work

Table 4: UMLS Normalization Results

well when relations have a high word overlap with the valid concept, but they do not utilize UMLS in any way. Instead, the UTS API utilizes the structure of UMLS to return candidate normalizations, performing its own internal ranking (though we are not aware of any way in which the internal scores are exposed through the API). In contrast to the systems evaluated in the ShARe/CLEF 2013 task\cite{24}, UTS is not limited simply to DISORDER concepts, and is thus more appropriate for our evaluation, which includes many ANATOMY concepts.

Results

The SpRL method is evaluated using 10-fold cross validation. The results are shown in Table 3. The best SPATIALINDICATOR performance (including the NoArgFilter) has an F₁ of 91.0, while the best TRAJECTOR classifier (without the AddCoord heuristic) has an F₁ of 84.9, and the best LANDMARK classifier (with the AddCoord heuristic) has an F₁ of 86.0. The post-processing NoArgFilter produced a significant gain in precision, from 87.3 to 96.8, for almost no cost to recall. The AddCoord heuristic, however, had only a small effect. In many cases, the classifiers were able to find coordinated TRAJEC'TORS and LANDMARKS without the AddCoord heuristic, which makes sense as the syntactic dependency features should be identical for both sides of the coordination. Overall, these results are quite good, even a bit high compared to similar relation extraction tasks.

The results of the concept normalization methods are shown in Table 4. The baseline methods (tfidf_pref and tfidf_all) performed poorly compared to the best UTS methods. Given that the UTS methods have a better understanding of the UMLS structure and can utilize it for retrieval (e.g., understanding synonymy), they perform quite a bit better and should form the baseline for any future work. However, the individual UTS methods varied significantly, both by method and by the type of concept they were normalizing. UTS[exact] had the best F₁ on individual terms (79.0), but performed quite poorly with the relation phrases (35.3). UTS[approximate] performed decently, but well below the best methods for each concept type. This confirmed our pre-existing observations when experimenting with the methods, as the UTS[approximate] method does a good job of retrieving the correct candidate in the top 10, but a poor job of ranking the correct candidate first. It is therefore good for annotation, but not ideal as a run-time system. The other method used in annotation, UTS[words], performed better, but was still outperformed by other methods. UTS[left_trunc] and UTS[right_trunc] where quite poor in general, followed by UTS[norm_words]. UTS[norm_str] was the most consistent method, and also the best performing method for phrases (73.8). As might be expected when forming an ensemble method from highly noisy constituent methods, UTS[vote] was unable to outperform the best individual methods. For future work, methods should be compared either to UTS[norm_str], or to the use of UTS[exact] for individual terms and UTS[norm_str] for phrases.
Discussion

Using the system described above, many of the detailed concepts found within consumer text can be mapped into an ontology containing either pre-coordinated terms or that allows for spatial post-coordination. Given the informal language often utilized in consumer text, such a method is often necessary to gain a more complete semantic understanding. We now discuss the general types of errors made by the system, how some of these errors illustrate limitations to our approach, and how they motivate future work on this task.

As is typical with consumer-authored text, many of the system’s errors were the result of ungrammatical and error-prone language. This includes misspellings (e.g., “fection” instead of infection, “boh legs” instead of both legs), missing punctuation (e.g., “pain cramping, redness and swelling”), and incorrect tense (e.g., “fingers are stick together by her skin”). These errors are compounded by the fact that many of the consumer information requests were submitted by non-native English speakers, resulting in text that can be difficult to understand (Spatia1Indicators in bold):

(4) i had got sunburn effect before 3 year on my both hands.
(5) i have pain on ma left side under the ribis n difficult on urinating seeming as if threz something blocking is it connected to the kidneys

Other errors were the result of using UMLS directly as a lexicon. While this removes the need to run a noisy concept recognition system, and while the UMLS terms should be far easier to normalize, using UMLS directly introduces noise as well. As stated above, between 7-8% of the Disorder and Anatomy terms needed to be manually created (thus indicating recall issues), but precision issues are an effect as well. For instance, mrs (in the phrase “mrs. p gupta”) and mm (in the phrase “1.3 mm”) are both marked as Disorders, and could easily result in mistaken Trajectors. In many cases, the resulting errors were relatively innocuous, as in the following:

(6) ...she developed water behind her eye balls...

Here, UMLS does not contain the full phrase “eye balls” (though it does contain “eye ball”, but we performed no stemming for relation extraction). Instead, “eye” is selected as the Landmark. Also see Example (8) below.

As with many relation extraction approaches, long distance relations often prove problematic. Consider the example:

(7) The cancer cells are in the fluid, around the lung, and in the trachea lymph nodes...

Here, “cancer cells” is the Trajector for all three Spatia1Indicators, but the classifier fails to identify it as the Trajector for the second and third indicators. The dependency parser should attach all three prepositions to the verb “are”, but instead it attaches “around” and the second “in” to the noun “fluid”. Thus, the dependency paths are atypical for Trajectors, and the classifier misses this argument. Prepositional phrase attachment is a very common source of syntax parsing errors, and the choice of attaching the preposition to the nearer word is typical.

Another common problem is Spatia1Indicators missing either a Trajector or a Landmark. For instance:

(8) Is matastatic non small cell lung cancer able to spread to the spine and brain in as little as 1 month?

Here, the Spatia1Indicator “to” should have a Trajector (“non small cell lung cancer”) and two Landmarks (“spine” and “brain”). While the classifier found both Landmarks, it missed the Trajector. With very few exceptions, all Spatia1Indicators should have a Trajector. But doing this through a post-processing heuristic by simply forcing the nearest concept to be the Trajector hurts performance. In this case, for example, the nearest concept is actually “able”, which is a Finding in UMLS. Instead, in future work, we plan to integrate more intelligent post-processing to enforce constraints such as “Every Spatia1Indicator should have at least 1 Trajector” directly on top of the output of each classifier.

Since the normalization methods evaluated here are either baseline (TF-IDF) or existing (UTS) methods, we omit a detailed error discussion and instead provide some insights on what may enable future methods to improve on normalization performance. The fundamental issue with the evaluated methods is that they consider the concept as a phrase, not as a relation, and thus miss out on potentially useful information. When normalizing a relation, a very similar process to that of post-coordination can be used to identify potentially pre-coordinated concepts. That is, identify the individual argument terms (which almost all of the UTS methods do with higher performance than the
full phrases), then identify valid pre-coordinations. For instance, the phrase “fracture on his thigh bone” results in the Trajector fracture with Landmark thigh bone. The UTSA [words] method identified the concept C0840234 (Fracture of bone in neoplastic disease; pelvic region and thigh), which is overly specific because it indicates the cause of the fracture (a bone tumor). Through relations in UMLS, it can be determined that C0840234 is a pathological fracture and thus too specific, avoiding this incorrect normalization. This type of method would clearly require a significant understanding of the UMLS relation structure and is beyond the scope of this work, but this work does provide the required NLP methods to enable such ontological methods by extracting and structuring spatially related concepts from text. A second, but also fundamental limitation of the normalization approaches used here is the lack of context employed. The context surrounding a relation likely provides valuable clues as to its proper interpretation.

As addressed in the Background section, this normalization process is largely analogous to the types of concept normalization performed in the CLEF task [24], though that task is limited to Disorders. While evaluating an automatic system in that task (e.g., DNorm [23]) would be an unfair comparison based on the type of data, some discussion on the results of the CLEF task and that of this work might provide some useful insights. The CLEF task evaluated systems in two different ways. First, an end-to-end evaluation (“strict”) that required systems to correctly recognize disorder concepts and then normalize the disorders to their UMLS CUIs. Since errors could occur at either the recognition or normalization stage, the results of this evaluation essentially form a lower bound to normalization performance. A second evaluation (“relaxed”) then measured performance of normalization on only those disorders that were correctly recognized. Since the correctly recognized disorders were likely to be shorter terms resembling those in the training data, the relaxed evaluation essentially forms an upper bound to normalization performance. The best system on the strict measure, DNorm, achieved a strict accuracy of 58.9% and a relaxed accuracy of 89.5%. By comparison, in our data the UTSEXACT method has an accuracy of 79.4%. This suggests that the UTS method, though far simpler than DNorm, is not likely to be substantially worse, but would likely nonetheless be outperformed by DNorm if that system were to be tailored to our spatial relations. Due to the complexity of such a project, we leave this idea to future work.

Conclusion

This paper described a method for extracting and normalizing spatial relations between disorders and anatomical structures. While the method might still generalize to physician and other clinical notes, our focus was on consumer language. We have described two new annotated corpora for these tasks: (1) a corpus of spatial relations from consumer health requests, and (2) a set of annotated concept normalizations for many of the relations from the first corpus. A machine learning-based method is used to automatically perform spatial relation extraction on the first corpus. Then, a set of baseline and existing methods are used to automatically perform concept normalization on the second corpus. Both achieve good performance, though we have identified several areas of future work to improve upon these results.

Automatic Classification of Structured Product Labels for Pregnancy Risk Drug Categories, a Machine Learning Approach

Laritza M. Rodriguez, MD, PhD, Dina Denner Fushman, MD, PhD
Lister Hill National Center for Biomedical Communications, National Library of Medicine,
National Institutes of Health, Bethesda, MD

Abstract

With regular expressions and manual review, 18,342 FDA-approved drug product labels were processed to determine if the five standard pregnancy drug risk categories were mentioned in the label. After excluding 81 drugs with multiple-risk categories, 83% of the labels had a risk category within the text and 17% labels did not. We trained a Sequential Minimal Optimization algorithm on the labels containing pregnancy risk information segmented into standard document sections. For the evaluation of the classifier on the testing set, we used the Micromedex drug risk categories. The precautions section had the best performance for assigning drug risk categories, achieving Accuracy 0.79, Precision 0.66, Recall 0.64 and F1 measure 0.65. Missing pregnancy risk categories could be suggested using machine learning algorithms trained on the existing publicly available pregnancy risk information.

Keywords: machine learning, pregnancy, drug risk, data-mining, knowledge extraction, document classification

Background and Justification

The use of drugs and other substances during pregnancy and lactation can be damaging for the developing embryo and fetus, and is in general discouraged, unless there is a strong medical reason. At any given time over 10 million women are pregnant or lactating in the United States; these women often need to use drugs and other substances while under care of medical providers, likely other than obstetricians. Drug effects on the fetus and embryo vary during different stages of development; the hemodynamic changes in the pregnant women cause changes on the absorption rates, and pharmacologic action of medications and substances. The obstetrical and pharmacological literature information on the effects of drugs on the embryo and the fetus is extensive, however, the information is static, difficult to maintain and not readily available at the point of care. Ideally, this information should be provided in the FDA-approved standard product labels (SPL) made available to the public by the National Library of Medicine (NLM). The SPL for each drug is created by the pharmaceutical manufacturer; it is a requirement of the FDA to provide complete information on use, dose, content, contraindications, side effects and warnings of drugs and chemical products for human and animal consumption. The drug information is stored in a structured standardized format with document sections defined by the LOINC document standard. The LOINC codes and descriptions for the SPL document sections are described in (Table 1).

The Code of Federal Regulations (CFR) Title 21 from the Federal Drug Administration (FDA) describes the specific requirements on content and format of labeling for human prescription drug and biological products. It includes specific guidelines for a section on specific populations describing the effects on pregnancy and lactation. The CFR indicates: “the section may be omitted only if the drug is not absorbed systemically and the drug is not known to have a potential for indirect harm to the fetus”. However, the pregnancy section is missing from some of the labels even for those drugs where the information is provided for the same ingredients in other brand names labels. This information is available in proprietary collections, such as Micromedex® Solutions. Micromedex Solutions is an evidenced based clinical resource curated by experienced professionals in the healthcare field. The resource includes the Micromedex Pharmacological Knowledge with a monograph for pharmaceutical products in brand and ingredient forms. The pregnancy risk categories in the Micromedex monographs include curated classes from the FDA classification, the Australian categorization system for prescribing medicines in pregnancy (ACPM), and a simplified classification defined by Micromedex. However, not all documents have categories from all three classification systems: some have only FDA categories and some only the simplified Micromedex categories. For the purposes of this study we considered Micromedex Fetal risk is minimal equivalent to FDA categories A and B, Micromedex Fetal risk cannot be ruled out equivalent to FDA category C, and Micromedex Fetal risk has been demonstrated equivalent to FDA categories D and X. Table 2 summarizes the FDA drug pregnancy drug categories, and the Micromedex classification.

The FDA pregnancy risk category is assigned according to scientific evidence of effects of drugs on the developing embryo and fetus based on animal and human studies. Clinical obstetrical pharmacological studies on the effect of drugs focus on limited numbers of drugs, require expert review and are often limited to a small number of drug classes. In recent years there has been an effort by the Advisory Committee of Prescription Medicines (ACPM) in Australia, and the FDA to change the pregnancy risk category classification, and to base the risk classification on human studies and population registries that gather accurate information on the effect of drugs on humans. These efforts will take time and extensive data analysis. For now, the most complete and widely accepted classification remains the FDA risk category. As mentioned above, the information in the SPLs is incomplete and does not include all available drugs. We sought to augment the existing information and assign missing pregnancy risk drug categories to SPLs. To that end, we applied machine learning algorithms to extract knowledge from the free text and leverage the existing categories assigned to some of the documents. Automatic SPL classification has the potential to aid expert groups when studying the effects of drugs belonging to drug classes and subclasses, and could ultimately be applied to aid prescribers at the point of care.

**Materials and Methods**

---

**Figure 1: Example of a SPL header and Warnings Section**

---

1095
We used the following regular expression in Perl to identify and extract the standard pregnancy risk categories from the labels: `/pregnan.{3,50}category[^a-z0-9]+([abcdnx])(?:[^a-z0-9]|$)/i`

We manually checked the pregnancy risk class assigned by regular expressions. Manual checking allowed us to find cases missed by the regular expressions, for example, SPLs in which “pregnancy” is misspelled; the words “pregnancy” and “category” are separated by other text or the category is set off by punctuation.

In the process, we identified two sets of documents: those that had risk categories and those with no mention of pregnancy risk category in the text. We used the standard FDA categories (A, B, C, D, X) and N when no category was mentioned in the text and assigned a risk category class to each document. Some drugs include more than one pregnancy drug category (a drug that is safe in the second trimester of pregnancy might be contraindicated in the third trimester e.g. NSAID), drugs of this type will have mention of two categories in the label. However, the overall total of documents with two categories was only 81; these labels were removed from our data set, since these sparse classes were insufficient to train the classifier. This left us with 15,221 labels in the training set and 3,039 in the testing set with an overall total of 18,260 documents. The class distribution of the labels is summarized in Table 3.

We segmented the documents using the XML section tags and then converted the sections to plain text for the machine learning approach. Each section preserved the original document unique identifier and the pregnancy risk class label. In the testing set, the unknown class label field was replaced with a “?” to comply with WEKA format requirements for unclassified documents.

Machine Learning

Support vector machines are extensively used in biomedical text processing and are known to produce good classification results. Marafino and colleagues demonstrated similar successful results in a different clinical domain using N-grams SVM. Other authors have compared the use of applying different machine learning algorithms Naive Bayes, and Stacking, Boosting and Feature Selection for document classification. We experimented with Naive Bayes and SMO with and without feature selection. SMO had the best cross-validation results, therefore, we used the Sequential Minimal Optimization (SMO) implementation of the method described by Platt, and available in WEKA for our final experiments.

To generate the support vectors we applied the unsupervised 'StringToWordVector' filter to both training and testing sets for all the document sections with the following parameters: lower case and normalization, string delimiters, word counts, N-grams restricted to 3 words per string, no stemmers, no stop word list, preserving 400 most frequent strings per document section. We applied the SMO algorithm classifier to each of the training document sections with 10 fold cross validation to decide which document section had the highest predictive value for the classification task. We used the value of Receiver Operating Curve (ROC) weighted average obtained from the cross validation to select the best performer. The SPL precautions sections had the best performance for document classification for pregnancy risk categories. We applied the resulting classification model trained on the precautions section to the precaution sections of the testing set. We then evaluated the performance on the testing set as described in the next section.

Machine Learning Model Evaluation

To evaluate the performance of the classifier we limited the set to single ingredient drugs using the SPL document mapping to RxNorm drug terminology standard. To do this we used the RxMix tool providing RxCUIs for Standard Clinical Drugs (SCD) as input and limiting the output term type to ingredients (IN). We extracted the ingredients for both the training and the testing sets separately. From the Micromedex Pharmaceutical Knowledgebase monographs we manually extracted the pregnancy risk category for these ingredients.

As previously described, the Micromedex monographs include the FDA pregnancy risk category and/or the simplified Micromedex Fetal Risk Classification. For evaluation purposes we normalized the risk categories of all three sets to the three Micromedex® categories: Micromedex Fetal risk is minimal equivalent to FDA categories A and B, Micromedex Fetal risk cannot be ruled out equivalent to FDA category C, and Micromedex Fetal risk has been demonstrated equivalent to FDA categories D and X.

We calculated accuracy, precision, recall and F1 measure to compare how well the known risk categories in the training set of the FDA-approved SPL documents agree with Micromedex manually curated expert knowledgebase.
To evaluate the performance of the classifier on the test set, we calculated the same measures, using Micromedex as reference standard. We also established a baseline classifier by assigning the majority class label (Fetal risk cannot be ruled out) to the testing set. We tested the statistical significance of the differences in performance measures between the model and the baseline taking into account sample size and the number of classes according to the description by Combrissona 16.

Error Analysis

To analyze the errors of the model we analyzed the differences in classification between the Micromedex set and the testing set for the most extreme case of disagreement, for which Micromedex categorizes the drug as demonstrated fetal risk, and the testing set as minimal fetal risk.

Results

The prescription collection of product labels included 18,341 documents. We excluded 81 labels with a multiple risk category mentions. The distribution of the risk categories for the training set was Class A 1%, Class B 24%, Class C 59%, Class D 11%, and Class X 4%; the training set accounts for 83% of the documents, and the testing set for 17% (Table 3). The distribution for the class labels assigned to the testing set by the classifier was: Class A 2.11%, Class B 15.10, Class C 54.98%, Class D 19.64%, and Class X 8.17% (Table 3)

As mentioned above, we selected the sections most likely to contain information about pregnancy risk using ROC. The highest ROC weighted average for the cross validation of the SMO on the training set was for the “Precautions section” (0.99), values for the ROC weighted average for the other document sections are in Table 4.

The 15,221 labels in the training set mapped to 685 distinct single ingredients (IN). The 3,039 labels in testing set mapped to 286 single IN. In the training set, we found 37 single ingredients with more than one risk category. Unlike the 81 documents we initially identified as having two risk categories in the text and removed, these 37 ingredients had different categories assigned in different documents, indicating inconsistency in the content labeling across different manufactures. We analyzed the content of two of the 37 ingredients for which we encountered more than one pregnancy risk category in the training set (Table 5).

We manually reviewed the Micromedex knowledgebase monographs for 685 ingredients in the training set and 286 ingredients in the testing set.

The SPL training set and the Micromedex reviewed ingredients set had 200 ingredient-class pairs in common, and the Micromedex and the testing set had 238 ingredient-class pairs in common.

The performance measures between the SPL training set and the Micromedex set resulted in: Accuracy 0.94, Precision 0.90, Recall 0.88 and F1 measure of 0.89. The performance of the classifier tested against the Micromedex knowledge base were Accuracy 0.79, Precision 0.66, Recall 0.64 and F measure 0.65. Measures for assigning the most frequent class were Accuracy 0.58, Precision 0.58, Recall 1, and F measure 0.74. The statistical significance for a sample size of 200 and 3 classes exceeds p<0.001.

Error Analysis
We found four drugs in extreme disagreement between the testing set and Micromedex where the drug is clearly contraindicated in Micromedex and the classifier assigned minimal fetal risk. Diazepam: The SPL warning for this drug is in the Warnings Section, and not in the Precautions section used to train the classifier. Both the SPL and Micromedex clearly classify it as contraindicated. Estradiol: The pregnancy section for this drug in SPL refers to no apparent increased risk of birth defects in women who have used the drug in low dose form as contraceptive during early pregnancy, there is no further statement for use of the drug in other stages of pregnancy or at higher doses. Levonorgestrel: The SPL for this drug has no mention of use during pregnancy. In Micromedex there is a clear statement of fetal risks, which affirms that the drug is contraindicated in women who are or may become pregnant. Meprobamate: Both the SPL and Micromedex affirm there is positive evidence of fetal risk but it may be used if the drug is needed in life-threatening situations for the pregnant woman, and there is no other drug that can be effective.

Discussion and Conclusions
We demonstrated that it is possible to automatically classify drug documents into pregnancy risk categories using standard document classification machine learning algorithms, and thus extracting valuable information from free text documents. Several authors have used the FDA SPL documents to extract valuable clinical information using different approaches. Fung and colleagues demonstrated the feasibility of extracting drug indication information from FDA SPL using publicly available natural language processing tools. Futhermore, Khare describes a method to extract structured and normalized indications from FDA drug labels. Culbertson and colleagues used semantic natural language processing (SemRep) to extract Adverse Drug Event Information from Black Box Warnings. Deleger et al. used a hybrid Natural Language processing method to extract indications, contraindications, overdosage, and adverse reactions from FDA SPL documents. To the best of our knowledge, our work is the first to attempt automatic drug document classification based on pregnancy risk categories.

Our work also demonstrates that the automatic classification method provides better precision and accuracy than assuming the most frequent medium-level risk for all drugs with unknown pregnancy risks.

The performance of the classifier was somewhat affected by inconsistencies in the content of the labels for the same ingredients across different manufactures, and by inconsistencies of the document section in which the pregnancy warning statement is included. Inconsistencies in the information in the SPL documents were demonstrated by Duke and colleagues who reported 68% discrepancy in the labeling across manufactures in the Warnings section of bioequivalent medications (identical active ingredient). Duke et al. also report discrepancies in the reported adverse events, post-marketing reports, and even indications differences.

It is not surprising that there are disagreements in the pregnancy risk categorization among similar drugs in the same source. In (Table 5) we included all the ingredients for which more than one risk category is mentioned for the same

We concluded that it is possible to automatically classify drug documents into pregnancy risk categories using standard document classification machine learning algorithms, and thus extracting valuable information from free text documents.
ingredient in different documents, and analyzed in detail two of those drugs. For RxCUI: 6585 RxNormName: Magnesium Sulfate the ingredient is in 15 SPL documents, all of which indicate that the substance is safe for use during pregnancy and is a drug of choice in the treatment of Pregnancy Induced Hypertension, and prevention of seizures in these patients. Only 6 documents, however, label it as category A, 2 documents label it as category C, warning that the use of the drug for more than 7 days can cause bone anomalies in the fetus, and if used 2 hours before delivery the fetus may suffer from severe hypocalcemia. Further, 7 documents label the same substance as category D based on the animal studies showing that the prolonged use of the drug can cause bone alterations and alter reproductive capacity of the fetus. Another example of multiple drug categories for the same ingredient is RxCUI: 4450 RxNormName: Fluconazole, for this drug tablets for vaginal application have a risk category A, while tablets for oral treatment have a risk category C. The drug is not expected to be absorbed systemically when used in topical or vaginal applications, therefore it is not expected to cause the teratogenic effects demonstrated in animals with oral treatment, but there is no conclusive knowledge on the amount of drug absorbed systemically with vaginal application.

Other examples of disagreements in the reference standards are the assignments of a single risk category to the drugs with different risks to the developing fetus depending on the gestational age. We excluded from our study documents that included more than one category, but some manufacturers label the drug with only the highest risk category as we demonstrated with the analysis of the text for the 15 labels containing Magnesium Sulfate. This analysis indicated that in the future, gestational age needs to be taken into consideration, when automatically assigning pregnancy risk categories to drugs.

Federal Register Content and Format of Labeling for Human Prescription Drug and Biological Products; Requirements for Pregnancy and Lactation Labeling 22 issued on December 4, 2014 removes the pregnancy risk category labeling from the Standard Product Labels and implements the requirement to include patient registry information when available. However, the FDA and its equivalent Australian organization have attempted this change for several years. Progress is slow and not likely to happen without the aid of automatic methods. Patient registries on prescription medication use are slowly growing; the information obtained from these data sources will require curation before it is applicable to clinical documentation. Patient registries will also benefit from automatic classification systems similar to the one tested by us. Moreover, patient registries are focused on drug classes and the information is not yet available to the public.

Our study demonstrates that it is possible to extract useful clinical information from free text using automatic machine learning algorithms, although more work is needed, as indicated by the 89% F1 score when comparing the known SPL category assignments and Micromedex, which could be considered an achievable agreement for machine learning methods. Additional experiments are needed to test if the accuracy, precision and recall can be improved by deeper understanding of the context, such as the gestational age, and through additional syntactic and semantic features of the SPL precautions sections. Automatic classification of drug labels lacking pregnancy risk category information can aid clinicians and patients who are attempting to identify the effects of drugs similar to those for which the information is available in text format. Our approach could also be of general interest for extraction of other information that might be incomplete in some drug labels, such as contraindications or side-effects, e.g. secondary effects of Tricyclic antidepressants (TCAs) depend on pharmacological action on histamine or serotonin receptors, an automatic system that could automatically classify these drugs could be of great benefit at the point of care. Information on drugs changes every day, continued research both in the pharmaceutical industry and in clinical practice unveil previously unknown information, the FDA is continuously releasing drug safety communications 23. It is important to provide a mechanism by which identical drugs can be automatically classified utilizing the existing knowledge.

Limitations
Our work is limited to prescription drugs, however, over the counter drugs and homeopathic medications have potential to cause harm on the developing fetus as well and need to be explored in the future.

Electronic Health Records (EHRs) have increased the utility and portability of health information by storing it in structured formats. However, EHRs separate this structured data from the rich, free-text descriptions of clinical notes. The ultimate objective of our research is to develop an interactive progress note that unifies entry, access, and retrieval of structured and unstructured health information. In this study we present the design and subsequent testing with eight clinicians of a core element of this envisioned note: free-text order entry. Clinicians saw this new order-entry paradigm as a way to save time and preserve data quality by reducing double-documentation. However, they wanted the prototype to recognize more diverse types of shorthand and apply default values to fields that remain fairly constant across orders, such as number of refills and pickup location. Future work will test more complex orders, such as cascading orders, with a broader range of clinicians.

Introduction

Electronic Health Records (EHRs) have greatly increased the utility and portability of health information by storing it in structured formats. There are numerous benefits to having patient records in these computer-readable formats including being able to perform targeted searches, exchange data between institutions, and provide real-time clinical decision support. However, current EHRs rely on an aging paradigm of windows, tables, and menus to collect and display this information. Since these elements take significant time and attention to use, providers spend precious moments navigating EHRs when they could be engaging with patients or documenting visits.

Moreover, as health records have moved from paper to computers, the progress note has lost centrality as an instrument of care. Patient information is now scattered across numerous parts of the EHR, strongly divided into structured and unstructured sections. This fragmentation imposes a range of new constraints on physicians’ documentation and is a key cause of errors. It can also lead to duplicate work, for instance when an order placed via a drop-down menu must later be manually documented in a note.

The ultimate goal of our work is to develop a novel EHR paradigm around interactive notes that unify entry, access, and retrieval of structured and unstructured health information. This study tests one feature of this note-centric vision: free-text order entry. The particular research questions we sought to answer with this study were: (i) what types of shorthand do clinicians use when placing free-text medication orders? (ii) what types of functionality do they expect from computerized free-text order entry? and (iii) do they see free-text order entry as a useful addition to their note?

Background

Moving medical records into a computational medium has conferred numerous benefits on the medical community including remote access to patient records and real-time clinical decision support. EHR use has also been associated with higher quality of care. However, there has long been recognition that by separating information into discrete categories displayed on separate pages, EHRs hinder clinicians from making inferences across categories, such as when referencing lab results to determine why an order was placed.

Despite this fragmentation, clinical notes remain a central component of EHRs. They unify the record by describing a patient’s history, interpreting test results, and justifying care plans. They are also where clinicians spend much of their time. Our prior research on outpatient visits across several Veterans Affairs hospitals found that clinicians spent the majority (58%) of their EHR time in notes. Despite being central to clinical care, notes are increasingly
difficult to write as they need to include large amounts of structured data, already documented elsewhere in the record, to meet regulatory and billing requirements and defend against lawsuits\(^6\).

Researchers in biomedical informatics and human-computer interaction have sought to reduce this duplicate work by making it easier to carry information across notes\(^7\) or copy structured information into a note\(^8\). Moreover, some EHR vendors have started to provide means for quickly importing information such as vital signs using in-note commands, such as Epic’s Smart Phrases\(^9\). This prior work has focused on pulling structured information into the progress note, but little attention has been given to the reverse conversion of creating structured data in real-time from note text. This concept is intimately connected to previous work on information retrieval, so much so that after testing the in-note information retrieval system in\(^8\), one participant remarked that they would “like to place orders for medications and tests” from within the note. The Regenstrief Institute has begun to explore this direction with Medical Gopher, an EHR that recognizes medication keywords written in a note and suggests placing related orders\(^10\). However the Medical Gopher does not recognize order details such as dosage or schedule and clicking on the suggested order takes users to a separate screen with menus to specify these details.

One of our objectives in creating an interactive progress note is to let clinicians take actions, such as placing an order, as they are creating their note. Towards that objective, we developed and tested a prototype note editor to observe how clinicians would expect to place medication orders using free-text. This research follows iterative prototyping methods common in human-computer interaction in which early prototypes are tested with potential end users to identify usability issues and validate that the design addresses the identified need\(^11\).

**ActiveNotes Prototype**

To test clinicians’ methods of free-text order entry, we developed ActiveNotes (Figure 1). At its core, ActiveNotes is a note editor that lets clinicians create and edit notes. Like many EHR note editors, there are no facilities for rich-text formatting such as bolding or changing font size.

![Figure 1. The ActiveNotes Prototype in use. The center white area is the note editor. When a user types “#med”, a medication ordering dialog appears, allowing free-text orders to be placed. Text typed in this dialog is automatically mapped to structured information as indicated by the highlighted components above the medication order (i.e., ‘Med’, ‘Strength’, ‘Schedule’, ‘Days’, and ‘Refills’ in the example). The patient information to the left of the note is static and does not reflect note content.](image-url)
ActiveNotes’ core strength is in its ability to parse semi-structured text into full medication orders. To start an order, users type the tag “#med” which opens a small order specification dialog on top of the note (Figure 2). This window provides a search bar where clinicians can type their order. ActiveNotes expects the medication and dose information to be entered first and provides auto-completion for these fields based on an underlying medication database built around RxNorm and NDF\textsuperscript{12}. As text is entered in the search field, it also appears in the note wherever the #med tag was invoked. After entering the medication and dose fields, the order is complete enough for checkout and clinicians can hit their “Enter” key to finish the order. Alternatively, they can specify other aspects of the order such as form, route, schedule, refills, etc. As each part of the order is recognized, the dialog highlights the components’ corresponding label in blue in the popover window. Users can also access a standard order specification drop-down menu by clicking the triangle to the right of the search box, though they are not encouraged to use this feature.

![Figure 2. Inline order-entry. (a) Autocompletion of a medication name (b) When ActiveNotes recognizes a field, it highlights a corresponding label above the search box in blue (c) drop-down ordering](image)

After a medication is ordered through the dialog, it can be edited or deleted through an action menu that appears when users right-click or hover over the order text (Figure 3). Anticipating future uses of ActiveNotes, we have developed order specific tasks including refill, reorder, and discontinue that can all be accomplished in a single click. These features were not tested in this study.

![Figure 3. Orders can be modified by hovering over or right-clicking on the order text](image)
Once finished with their note, users can go to the “Order Checkout” page to review and sign any orders they placed (Figure 4). Here, ActiveNotes asks for any additional information needed to fully specify the order, but it also fills in default values for some fields that were not specified in the note, such as pickup location or number of refills. ActiveNotes currently supports only basic medication orders but we plan to expand it in the future to support more complex medication orders, such as weight-based orders, as well as orders for lab tests, radiology, and consultations.

Figure 4. ActiveNotes’ Checkout screen where orders can be reviewed and edited before being signed. The red box highlights missing information. Users can either enter it here, or go back to the note to complete the order.

ActiveNotes is build on top of standard web technology stack and medical ontologies (Figure 5). The user interface was developed in HTML5/CSS/JavaScript and exploits open source libraries to enable more complex interactions and UI elements. The middle layer exploits standard servers and frameworks such as SQL, REST and PHP to recognize the order fields and provide autocomplete suggestions in real-time.

Figure 5. ActiveNotes is build on standard web technologies and medical ontologies.
Evaluation

We tested ActiveNotes through a formative usability test with eight clinicians from San Diego’s Veterans Affairs hospital and UC San Diego Medical Center. The clinicians’ specializations included internal medicine (3), infectious diseases (4), and surgery (1). Our participant pool included both inpatient and outpatient practitioners, with two fellows and six senior clinicians. Each test lasted 30 minutes or less. Clinicians were first shown a short video explaining ActiveNotes’ features. Following the task scenario method of usability testing, they were then given two short descriptions of canonical outpatient visits and asked to create a progress note for each visit in ActiveNotes. Each scenario gave basic demographic and assessment information and asked the clinicians to place four new medication orders from within their note. The orders were largely phrased without standard shorthand (e.g. PO, BID) so we could observe the shorthand clinicians naturally used. After completing both progress notes, the clinicians were asked to comment on their experience with ActiveNotes. We tracked how long it took clinicians to successfully place each order, the shorthand they used while placing each order, any unsupported uses of the system they attempted, and their comments on desired features and overall usefulness of ActiveNotes.

Results

Time to Order

Clinicians took, on average, 59 seconds to place each order, though this time varied greatly between clinicians and orders. For example, P3 averaged just 30 seconds to place each order whereas P8 averaged 1 minute 56 seconds. Also, it took clinicians an average of 39 seconds to place an order for “Simvastatin 20mg PO at bedtime daily. 30 tablets to be dispensed with 3 refills” whereas it took 1 minute 17 seconds to place one for “Aspirin 81mg once daily. 100 tablets to be dispensed with 3 refills”. The Aspirin order took longer because ActiveNotes did not recognize the “asa” as shorthand for “Asprin”, which delayed several clinicians.

Broadly, time to order depended on whether the clinician initially used shorthand that ActiveNotes did not recognize as pertaining to a particular field. For example, whereas ActiveNotes could parse “#30” as quantity information, it could not parse “Dispense: 30”. The orders that took the longest to complete were those in which clinicians tried to use several different shorthands that ActiveNotes did not recognize and then resorted to using its fall-back dropdown menu (accessible by clicking the triangle to the right of the search box). Since one of our main objectives was to identify the shorthand clinicians naturally use, we did not instruct them on what type of shorthand ActiveNotes was programmed to recognize and let them decide when they wanted to fall-back on the dropdown menu.

Shorthand

Clinicians used a variety of shorthand when placing free-text orders. Representative variants are shown in Table 1. Whereas the medication, dose, form, route and days fields saw little variation, schedule, quantity, refills, and pickup information was entered in a number of different ways.

Table 1: Shorthand used when placing orders

Functionality

As is common with prototypes, our participants wanted ActiveNotes to do more. We particularly value feedback in this context since the expected functionality can guide and inform future development. We uncovered six recurring function requests; the first three regarded time saving assistance, the last three address broader integration with the EHR. The clinicians volunteered these comments and were not asked about them specifically.

Default Values - Five clinicians wanted ActiveNotes to have default values for fields like schedule, refills, and pickup. While ActiveNotes’ refill value defaulted to “3 refills” and pickup value to “Window”, it did not have a default value for schedule (such as AM). Furthermore, there is no way to see when placing an order in the note that ActiveNotes will fill in these default values on the Checkout screen unless otherwise specified.

Auto-populated Values - Four clinicians wanted ActiveNotes to automatically populate form and quantity information whenever possible. For example, ActiveNotes should automatically mark ‘Tab’ if the specified medication and dose can only come in a tablet form. Also, after entering a schedule and duration of “BID for 30 days”, ActiveNotes should assign a quantity of 60.

Order Entry Invocation - Four clinicians wanted a simpler way to invoke the order entry window than the “#med” syntax. Clinicians either wanted to type out the full order and then hit a hotkey to tell ActiveNotes to parse the preceding text, or only wanted to invoke the “#med” once per note and fill out multiple orders in a row.

Information Retrieval - Two clinicians wanted ActiveNotes to support rich information retrieval such as “retrieve most recent colonoscopy”.

Additional Orders - Three clinicians expected ActiveNotes to handle additional order types including radiology, labs, and consults.

Additional Parsing - One clinician wanted ActiveNotes to be able to parse other note text, such as active problems, and save it to the appropriate part of the EHR.

Usefulness

Clinicians saw the current implementation of ActiveNotes as useful in two distinct ways. First, they thought it was useful to not have to switch between sections of the EHR to document and place orders. As one clinician remarked:

“I love not having to go out of the screen [to place orders]” - P1

Secondly, clinicians saw directly linking orders to documentation as a way to avoid overlooking orders:

“The thing that I really like about this is... having the order directly tied to the documentation of that order in the note. The issue I run into sometimes is that I write my note and I'm waiting to do my orders and then I have to… make sure... all the things I said I was going to do in the note I actually order.” - P3

More broadly clinicians saw value in using interactive notes to populate the EHR with structured information:

“If this had the ability to take everything in the note and just automatically download it... if you just did like #activeproblems from the note it would just put it all into that section... that would dramatically improve efficiency because there's a lot of that duplication that we're currently doing.” - P7

This is opposed to the current model of importing structured information into the note:
As it currently stands, it's the opposite. You have to first put in everything in the active problem list or medication list, and then you can populate it into the note by using smart keystrokes, but it would be nice when you're initially seeing someone to not have to write the whole note and then repeat everything” - P7

Discussion

Our first research question asked what types of shorthand clinicians use while placing free-text medication orders. Whereas the shorthand for some fields was standardized (e.g. ‘asa’ for aspirin, ‘mg’ for milligrams) fields such as schedule and number of refills were specified in a number of different ways. From this observation, we realize that it will be important for interactive notes to embrace a rich set of terminology that goes beyond current ontologies, such as RxNorm, to include terms for schedule, refills, and pickup. As a first step, we propose iteratively testing ActiveNotes through large-scale online deployments to capture a broad range of shorthands.

Our second research question asked what types of functionality clinicians expect from a computerized free-text order entry system. The six recurring functionality requests fell into two categories: time saving assistance and broader integration with the EHR. Along the lines of time saving assistance, clinicians wanted to specify their order with as little typing as possible. This principle can be seen in their desire to invoke the ‘#med’ dialog only once and place multiple orders in a row. It can also be seen in their desire for ActiveNotes to recognize when a particular dose of a drug only comes in one form, or to automatically calculate quantity given a prescription’s schedule and duration. It is worth noting that those fields that clinicians wanted the most assistance with were also those that exhibited the most varied shorthand. Clinicians also wanted ActiveNotes to be more broadly integrated with the EHR. This included both extending the types of orders it recognized to include labs, imaging, and consults and extending ActiveNotes’ parsing to cover other types of structured information such as active problems and family history.

Our final question asked if clinicians saw free-text order entry as a useful addition to their note editor. They saw free-text order entry as being useful in a number of ways including being a potential time saver, less distracting than form-based input, and requiring less navigation compared to current EHRs. Furthermore, they thought it could save them from needing to enter information twice, once in a structured format, and then in an unstructured format. Textual entry may also require less attention than form-based or drop-down based entry, letting providers focus more on their patients if they choose to document during the patient encounter.

There are also potential technical benefits to letting clinicians tag note content as structured data compared with post-hoc Natural Language Processing (NLP). First, it enables the parser, whether it is looking for orders or a problem list, to use a more targeted ontology for recognizing terms. Second, it adds structure to the note itself by marking which parts of the note refer to medication, conditions, and so on. Such tagging could assist with later NLP or the development of richer note interactions related to targeted search, filtering, and highlighting. Thirdly, order entry dialogs could be expanded to include real-time clinical-decision support, potentially catching errors and drug-drug interactions while notes are being written on rounds, not while orders are being placed later.

Looking towards future designs, we observed that free-text entry of structured information is not a familiar interaction paradigm as compared to menu and drop-down driven user interfaces. While our subjects were not constrained in what they typed, some had difficulty understanding the full functionality of the system. One participant did not grasp that ActiveNotes would let him document and place orders at the same time. Instead, he wrote each order in the note twice, first with fairly standard shorthand (e.g. po, #30) while “documenting” and then with less standard shorthand when “ordering” (e.g. Dispense: 30 ). Beyond developing a robust interactive note, it will take time and experience before some clinicians are comfortable with this new note-creation paradigm.

Pilot tests before this study also revealed that for free-text entry to work, careful thought has to be given to its exact mechanics. For example, which keys users press to complete an order, how they select an auto-completed phrase, and how the system shows that it recognizes part of the order all need to fit clinicians’ expectations.

Conclusion

This study takes a step towards our ultimate objective of developing an interactive progress note. We tested one critical feature of such a note, free-text order entry, and found that (i) clinicians use a variety of shorthand when placing free-text orders, particularly when specifying schedule, pickup location, and number of refills, (ii) clinicians
want to specify a minimum number of fields and rely on default or auto-populated values to fill in routine information, and (iii) clinicians see free-text order entry as a useful addition to their progress notes with the potential to save time and ensure orders are not overlooked.

In the future, we plan to test ActiveNotes with a broader range of clinicians across locations and disciplines, letting us observe a wide range of shorthands so we can develop a more robust order parser. Since ActiveNotes is built on web technology, we can easily deploy it on a larger scale and track visitors’ interactions with the site. Secondly, we plan to extend ActiveNotes’ ordering capabilities to include more complex medication orders, such as weight-based orders and cascading orders, as well as consults, labs, and imaging. Finally, we plan to test ActiveNotes on mobile platforms, exploring the usage of dictation for text input.

We posited that introducing a new interaction technique based on within-note free-text data entry could help solve a variety of problems that EHR users face. To investigate this claim, we designed and tested a novel note-centric approach to medication order entry and found that while work remains before being deployed in a live EHR, our in-line free-text approach was validated by representative end-users. By considering the note as the central element of the EHR and incorporating interactions and operations that typically span multiple parts of EHRs, we have an opportunity to transform documentation from being a complicated and time-consuming clerical task to a more natural interaction with the EHR that is closer to both the clinician and the patient, supporting increased efficiency, fewer errors, and ultimately, better health outcomes.

Improving Continuity of Care via the Discharge Summary

Farrant H. Sakaguchi, MD, MS1, Leslie A. Lenert, MS, MD2
1Intermountain Healthcare, Salt Lake City, UT; 2Medical University of South Carolina, Charleston, SC

Abstract

Discharge summaries (DCS) frequently fail to improve the continuity of care. A chart review of 188 DCS was performed to identify specific components that could be improved through health information technology. Medication reconciliations were analyzed for completeness and for medical reasoning. Documentation of pending results and follow-up details were analyzed. Patient preferences, patient goals, and the handover tone were noted. Patients were discharged on an average of 9.8 medications, only 3% of medication reconciliations were complete and medical reasoning was frequently absent. There were 358 pending results in 188 hospital discharges though only 14% were mentioned in the DCS. Documentation of clear, timely follow-up was present for less than 50% of patients. Patient preferences, patient goals, and lessons learned were rarely included. A handover tone was in only 17% of the DCS. Evaluating the DCS as a clinical handover is novel but information for safe handovers is frequently missing.

Introduction

Discharge summaries (DCS) can decrease readmissions and adverse events. When a DCS was available at follow-up after hospital discharge, van Walraven et al. found a trend for decreased readmissions (relative risk 0.74), and when it was unavailable, Li et al. found a statistically significant 79% increase in the readmission rate within 7 days.1,2 The incidence and severity of adverse events (AEs) after hospital discharge were found to be preventable or ameliorable with better communication from the hospital to community providers by Forster et al.3,4

However, DCS frequently fail to reach their potential to improve the continuity of care. A complete list of medications and discharge diagnoses are among the most important components of the DCS.5–9 Yet discharge medication discrepancies are common, even when a pharmacist was involved.10 Inaccuracies in discharge medication lists, medication changes, and reason for medication changes were found in only 36%, 30%, and 38% of DCSs by Legault et al.11

The exclusion of tests pending at the time of discharge is another weakness of DCSs. Were et al. found only 13% of DCS reported all pending tests and that only 16% of all pending results were reported.12 Roy et al. found results returning after discharge for 41% of patients, 43% of which were abnormal, two-thirds of which were potentially actionable.13

Moore et al. found the diagnostic and follow-up plans in the inpatient medical record were not completed by the outpatient physicians 41% of the time.14 However, the recommended workups were documented in only 46% of the DCS.15

van Walraven et al. also found that DCSs were not reaching follow-up physicians at 85% of the follow-up visits.16 Two thirds of those cases were because the DCS was simply never sent to the outpatient physician. In only 59% of cases studied by Were et al. was there sufficient information to ensure delivery of the DCS and results.12 Though there is no clear standard in the literature, the timeliness of the delivery of the DCS is frequently related to its quality.5,6,17–19

As the lack of timely postdischarge follow-up has been associated with hospital readmissions and emergency department visits, the Society for Hospital Medicine has endorsed the scheduling of follow-up appointments and including the details in the DCS.9,20

Multiple metrics have been developed to measure the quality of the DCS. van Walraven and Rokosh surveyed 100 physicians who identified admission and discharge diagnoses, discharge medications, follow-up plan, pending labs,
1-2 pages total length, receipt within four days, active medical problems, and outstanding social issues as being components of a high quality DCS. Horwitz et al. scored the timeliness of completion separately from the transmission of the DCS. Rao et al. focused on the quality of the communication (the clarity of the DCS, exclusion of irrelevant material, and consistency of the documentation). Stetson et al. developed the nine-question physician documentation quality instrument (PDQI), but still felt unable to describe an ideal DCS.

However, a comprehensive framework for DCS that emphasizes clear communication to support continuity of care is missing from the literature. Kripalani et al. specifically identifies communication deficits between inpatient and outpatient physicians as being common and with the potential to adversely affect care. Easily coded data such as accurate medication lists and tests pending at discharge are essential. Yet a comprehensive data dump should not obscure the context about patients; the medical reasoning behind the selection or duration of a treatment regimen or recommended next steps for the workup are also critical. Prior metrics have been useful to recognize specific information components, but without putting them in the context of a handover; in a handover both the responsibility and the information needs to be passed from the inpatient provider to the outpatient provider. Patient handovers involve 1) the sharing of information, 2) exchanging responsibility for a patient, and 3) transferring an understanding of the medical decision-making. As Moore et al. found, the outpatient provider is unable to complete recommended workups if those plans are not communicated; continuity of care is more feasible when there are effective handovers.

With the growing use of EHRs, it is important to consider how to leverage health information technology to ensure efficient communication between clinicians. Administrative and encoded clinical data should be automatically inserted into documentation to ensure the consistency of useful documentation. But such boilerplates should not come at the cost of clear clinical communication or by excessively long documents. Thoughtful summarization may emphasize the gist of the hospitalization and follow-up needs efficiently and effectively in a concise, cohesive narrative. Since DCS may be the only communication between the hospitalist and the primary care provider, they should be treated as handovers.

The aim of this study is to characterize the data in DCS through a retrospective chart review for its availability and its effectiveness of facilitating continuity of care. We focused on the medication list in the DCS, pending results, coordination of follow-up, and evidence of a clinical handover.

Methods

Setting: Data for this study come from an urban tertiary academic referral center in the intermountain west. Most patients are English-speakers. Patients admitted to the general medicine services were treated by four teaching or one attending hospitalist services. Each of the four teaching teams consisted of an attending, a senior resident, two interns, and two medical students. The attending service consisted of an attending and a senior resident. The housestaff generally dictated the DCS though typing was allowed.

Participants and Data Sources: To stratify the experience-level of the housestaff, three convenience samples were defined. The first 122 consecutive patient discharges were from the general medicine teaching service starting August 1, 2010, the next 33 consecutive discharges started May 1, 2011 from the same service, and the next 33 consecutive discharges starting May 1, 2011 from the attending service; i.e. the DCSs were created by new interns, experienced interns, and senior residents, respectively.

Discharge summaries, computerized-provider-order-entry (CPOE) orders, lab results along with date-timestamps of the order and the availability of the result, patient demographic information, length of hospital stay, and diagnostic codes used for the billing record were collected from the enterprise data warehouse (EDW). An adapted Charlson Comorbidity Index (CCI) was calculated from diagnoses and comorbidities in the billing record for the date of discharge.

Chart Abstraction and Data Analysis: Each DCS was abstracted into four main categories: a) the medication list, b) labs pending at the time of discharge, c) posthospitalization follow-up, and d) the clinical handover for continuity of care. The data abstraction was performed by one author (FS), a biomedical informatics postdoctoral fellow and practicing family physician.
The medication list was evaluated for its completeness, and each medication was evaluated for its status and for the presence of any relevant medical reasoning. A “Complete” medication list should indicate the status of each medication being “Continued,” “New,” “Changed,” or “Discontinued.” If the status of a given medication was “Unclear,” it was categorized as such and the medication reconciliation was considered “Incomplete.” The presence of medical reasoning regarding the indication, selection, or duration for each medication was noted. The number of medications per DCS, the proportion of “Complete” medication lists, and the proportions of the status and the presence of medical reasoning for each of the medications are reported.

Labs pending at the time of discharge were measured by treating the DCS and the EDW record of CPOE orders as separate sources. From the DCS, every mention of a pending result (e.g. a pending blood culture) and recommended follow-up test (e.g. follow-up INR or scheduled sleep study) was recorded. From the EDW, every laboratory order with pending results at the time of discharge was identified. The two lists were compared for each patient, item by item. For each pending result, there was one possible condition: a) reported in both the DCS and the EDW, b) reported in the DCS but not the EDW, or c) reported in the EDW but not the DCS.

Hospital follow-up was measured by the identification of a follow-up provider and the appointment. e.g. “Dr. Smith” was considered “General” whereas “Dr. George Smith in Clinic 2” was considered “Specific.” Follow-up appointments were categorized as a) within 14 days, b) beyond 14 days, c) not scheduled but recommended within a specific timeframe, d) not mentioned, or e) deferred due to patient transfer.

We developed a framework to assess “continuity of care” and “handover tone” as these qualitative concepts are missing from other metrics. To assess for a “continuity of care,” we looked for the presence of Patient Values, Preferences, Goals, and “Lessons Learned” in the DCSs. e.g. “a patient values independence more than safety,” “a patient preferred nursing home A due to proximity to family,” “the patient’s goal is to return to her own home before the holidays,” or “the key lesson from this hospitalization is...,” respectively. We drew from Weir’s adaptation of Hollnagel and Wood’s contextual control model (COCOM) to describe components of an effective handover. “Handover Tone” was operationalized as when there were three of the following: a) a cohesive story, b) predictions and guidance for the patient’s clinical trajectory, c) an explicit plan moving forward, d) key parameters to monitor, e) clear medical reasoning, or f) a holistic perspective about the patient. The frequencies of Patient Values, Preferences, Goals, “Lessons Learned,” and a “Handover Tone” in the DCSs are reported.

Statistical analysis was performed to evaluate differences between the cohorts. A 75% probability was estimated that a given categorical measure, such as whether the primary care provider was identified, would be present in the DCS. The minimal sample size to detect a difference between categorical variables is calculated by $N = 4z^2p(1-p)/\Delta^2$. For $z_{0.05} = 1.96$, probability $= 0.75$, and precision $= 0.2$, the necessary sample size to detect a difference between would be 51. The chi-squared test evaluated for statistical difference between the three cohorts for categorical variables (gender distribution, whether the primary care provider was identified, and whether the patient was discharged to home, the length of the DCS, and the time from discharge to dictation of the DCS. An ANOVA was used to evaluate for gross differences between the cohorts regarding patient age, length of stay, and the Charlson Comorbidity Index.

The data were summarized in a fishbone diagram to illustrate quality gaps and informatics opportunities to improve the DCS. Each “bone” of the diagram represents a component of the DCS, that when missing or incomplete, contributes to creating discontinuity of care; the modes of failure do not occur in a simple linear process.

Results

Using ANOVA (for continuous variables) and chi-squared tests (for categorical variables), we found no statistical differences for the age, length of stay, comorbidity index, DCS length in words, time from discharge order to dictation, gender-ratio, identification of PCP, or discharge to home between the three cohorts, as summarized in Table 1. Grouping all discharges together, 95 or 51% of the patients were female, with an average age of 58 (SD 18) years, length of stay of 4 (SD 5.2) days, and a modified Charlson Comorbidity Index of 3.2 (SD 2.5). The mean length and time until dictation of all the discharge summaries were 762 (SD 336) words and 2 (SD 3.9) day, respectively.

Table 2 summarizes the number of medications, their status, and the availability of the related medical reasoning. 188 patients were discharged on an average of 9.8 (SD 5.7) medications. Only five out of 188 discharge summaries
were “Complete,” explicitly reporting the status of every medication. In the 61 discharge summaries when it was explicit, an average of 2.1 medications were discontinued. Seven discharge summaries failed to name any specific medications by either omitting the medication list or indicating “all medications were continued.” An analysis of the differences between the discharge summary and the pharmacist-performed medication reconciliation at discharge is reported elsewhere and is currently under review.

In the 188 discharges, 358 lab results (an average of two results per patient), were pending at the time of discharge from the hospital. 31 (9%) of the pending results were identified in both the discharge summary and by the EDW, 17 (5%) were identified by the discharge summary but not by the EDW, and the remainder, 310 (86%), were identified in the EDW but not in the DCS.

Not only are pending lab results commonly omitted from the DCS, those reported correlate poorly to those identified in the EDW, shown in Table 3. Of the 188 patients, only two (1%) cases had an exact match between the dictated discharge summary and the electronic record. In one of those cases, there were pending results and in the other case, the summary stated correctly there were no pending results.

Another 61 (32%) of cases implicitly matched where no pending results were mentioned in the DCS and none were found in the EDW. In the remaining 125 (66%) of cases, there was some discrepancy between the pending results noted by the discharge summary and reported by the EDW.

31 (16%) patients were discharged on warfarin. In only one third of those discharge summaries (10 patients) was there mention of a follow-up INR or how anticoagulation was to be managed as an outpatient.

A primary care provider (PCP) was identified specifically, generally, or not at all in 34%, 27%, and 39% of DCS, respectively. Since some DCS mention a PCP and specialist, 45% of all DCS identified at least one specific follow-up provider.

The DCS contained scheduled follow-up appointments for 88 (47%) and 11 (6%) of patients within 14 days and beyond 14 days, respectively. For 48 (26%) patients, some follow-up was recommended while no follow-up was mentioned for 29 (15%).

There were references in zero (0% of discharges), 11 (6% of discharges), 2 (1% of cases), and 5 (3% of cases) to patient values, patient preferences, patient goals, and lessons learned, respectively. An example statements of patient preferences was, “It was a good talk with Palliative Care; and the patient is to remain DNR/DNI, but would still like interventions other than that to help keep her healthy.” An example of a patient goal was, “He was transferred to [skilled nursing] for ongoing PT and OT therapy in hopes to regain his strength and eventually return home.” An example of a lesson learned was, “It also should be noted that the patient was only taking three medications at home once daily and it was unclear which medications he was taking and therefore we restarted the above medications and set the patient up with home health for assistance with medication administration.”

Handover tone was also uncommon. While a cohesive story and clear medical reasoning of the hospitalization was available in 151 and 156 cases, respectively, predictions and guidance for the patient’s clinical trajectory, an explicit plan with key parameters to monitor or a clear process to follow, or a holistic perspective of the patient was present in only nine, 22, and 20 of the cases, respectively. A handover tone was achieved in only 32 (17%) cases.

Figure 1 summarizes the modes of failure to provide continuity of care in discharge summaries in the topic areas of Medications, Follow-up, Pending Results, and Clinical Handover. These points were chosen as based on the data available in our study as well as the potential to improve these areas through health information technology. It helps to illustrate that improving discharge summaries will require a socio-technical solution.24

Strengths and Limitations
The key strength of these findings is framing the analysis of the DCS primarily as a handover. Also, the mixed analysis method of performing a chart review and comparing relevant findings to results from an EDW query is relatively unique.
One of the greatest limitations to these findings is the use of a single data abstractor. It was felt that a physician or possibly a nurse was necessary in order to be familiar with the clinical context. Unfortunately, other clinical resources were unavailable for the data abstraction.

Another potential limitation was the attempt to stratify the experience levels of the physicians. Some might argue that a random sampling may be more representative. However, we found no differences between the three cohorts in terms of patient demographics, case complexity, or general analysis of the DCSs themselves.

Some might express concern about the generalizability of the results from a single academic institution or the use of a specific EHR. However, the hospital uses a common, widely implemented EHR and has CPOE fully implemented. Future work may reproduce this analysis at other sites.

Discussion

We found several quality gaps in the DCS at our institution, consistent with the literature. The context for these opportunities to improve are the DCSs created at an institution recognized by the U.S. News & World Report’s Best Hospitals and the University Health System Consortium as among the best in quality. It is also noteworthy that the institution’s readmission rate is below the national average.

Based on the DCS, we conclude that continuity of care was not a consideration at discharge; a specific follow-up provider was identified only 45% of the time, lower than the 67% observed by Were et al. Without identifying a specific follow-up provider, it becomes impractical and a legal liability to forward important information regarding the hospitalization contained in the discharge summary. These conclusions are inline with the low continuity scores observed by Van Walraven et al. Were et al. found 16% of pending tests reported in the discharge summary and Roy et al. found that 41% of patients discharged had pending labs where we found 67%. Were et al. found that discharge summaries reported only 48 (14%) of all pending results but that 17 (5%) were not identified by the EHR. Our conclusions were consistent with those of Walz et al.; the majority of pending test results were microbiology tests with the majority of those specifically being pending cultures.

Despite consensus that anticoagulation at transitions of care should be carefully coordinated, there was little evidence of this in our data with 68% of warfarin patients lacking mention of a follow-up INR.

Several prior efforts to improve discharge summaries have focused on the content of the discharge summaries such as through the use of checklists. A related approach that has shown improvement in the rated quality of discharge summaries is through formal teaching interventions. O’Leary was successful in creating a draft electronic discharge summary template that would automatically insert specific data elements and found an overall improvement in the quality and timeliness of discharge summaries.

A focus on conveying medical reasoning in the discharge summary has been essentially missing altogether from the literature. Several studies seem to recognize this problem, but fail to identify the need to explicitly communicate medical decision-making. The paucity of medical reasoning became evident in our chart review. However there is no “best” place to document the medical reasoning. Such information is not universally applicable; there is no data whether medical decision making fits best as a comment with each individual therapy within individual modules such as CPOE, the medication list, or even the problem list, versus combined sections of a history and physical, progress note, or discharge summary. Even the Moore et al. documentation of failure to communicate loose ends and intended diagnostic plans did not address the concepts of “lessons learned” or the clinical trajectory of a patient, patient preferences, or patient goals. The absence of this global perspective for the patient once he or she left the hospital was evident in our study.

The discharge summary may be the only clinician-to-clinician communication when the patient leaves the hospital and thus appears to be the most practical form for a handover. Our findings suggest that not only are DCSs imperfect as information containers, they are poorly suited as clinical handovers. While the data could be more complete by leveraging the EHR alone, handover tone will likely require a paradigm shift. The real failing of the discharge
summary is not the mere absence of data, but rather the failure to recognize the need for a handover. In a separate paper, we discuss that potential of using the DCS as a handover instrument.

A new paradigm for discharge summaries may be needed. This new paradigm for discharge summaries would include not only data, but would focus on clear communication. We envision the EHR being able to generate a dynamic, prepopulated discharge summary that includes data already stored within the EHR. The discharge summary would then be completed by clinicians adding brief narratives that clarify the medical decision making of the case and that provide guidance and a useful handover to the next provider. We are investigating automatic generation of portions of the DCS and teaching the DCS as a handover in our institution. Further research may be necessary to clarify the most valuable elements of medical reasoning, how to record patient preferences, and how to most efficiently gather and present this knowledge.

*In 13 (7%) of Discharge Summaries, there were mixed discrepancies so that some pending results were missing from the EDW while other pending results were missing from the DCS. The DCS with an explicit match stated, “there are no pending results,” which matched the EDW query. The DCSs with an implicit match did not mention the presence or absence of pending results, though none were found in the EDW.

Determinants of Consumer eHealth Information Seeking Behavior

Abstract

Patients are increasingly using the Internet and other technologies to engage in their own healthcare, but little research has focused on the determinants of consumer eHealth behaviors related to Internet use. This study uses data from 115,089 respondents to four years of the National Health Interview Series to identify the associations between one consumer eHealth behavior (information seeking) and demographics, health measures, and Personal Health Information Management (PHIM) (messaging, scheduling, refills, and chat). Individuals who use PHIM are 7.5 times more likely to search the internet for health related information. Just as health has social determinants, the results of this study indicate there are potential social determinants of consumer eHealth behaviors including personal demographics, health status, and healthcare access.

Introduction

Engaging consumers in managing their health as a key to solving the core problems of healthcare access, quality, safety, efficiency, and effectiveness is an assertion boldly outlined by a plethora of landmark publications, including Institute of Medicine (IOM) reports.1,6 The import of these problems is exacerbated by out-of-control spending in health care that is expected to reach $4.6 trillion or 19.8% of the nation’s gross domestic product by 2020.7 Moreover, the already strained health care system will face an influx of patients as 30 million additional Americans obtain health insurance.8 Chronic health conditions are the leading cause of death and consume 75% of health care dollars in the U.S.9 Individuals with chronic conditions are more likely to be older, experience medical emergencies, and have higher healthcare expenses than other adults.10 The socioeconomic differences in health outcomes have been defined as the "social determinants of health."11

Multiple federal health policies and financial programs require or substantiate the need for consumers to engage electronically with their health care providers through the use of health information technologies (IT). The Centers for Medicare and Medicaid Services’ (CMS) Incentive Program for Meaningful Use of Electronic Health Record (EHR) requires health care providers to give consumers access to their health information and in future stages must allow submission of patient-generated information into EHRs.12,13 Emerging programs focused on care coordination and cost reduction also emphasize the use of patient portals and/or personal health records (PHRs), including the Accountable Care Organization (ACO) and the Patient Centered Medical Home (PCMH) programs.14

Recent research indicates that consumers and their families who use personal health information management (PHIM) applications such as PHRs have increased control over their personal health information and their use is associated with better health management, improved patient satisfaction, improved health care quality and safety, and more effective communication and collaboration between patients, doctors, caregivers and other stakeholders.15-19 Approximately 86% of US adults rate electronic access to PHRs and online health information as important.20 The use of PHRs is beneficial for patients and their providers in managing chronic diseases such as diabetes, hypertension, congestive heart failure, and depression.21-25 PHRs are also known to be beneficial for medication management,26-28 prevention screening,29, 30 clinical trial recruitment,31 patient education,32 and information exchange.33 There is a significant association between use of secure messaging with providers and lower Hemoglobin A1c values (i.e., glycemic control).34, 35 A greater frequency of secure email communication was associated with significant improvements in outcomes related to HbA1c screening and control, retinopathy screening, nephropathy screening, and blood pressure control; providers had an increased likelihood of improved performance on four diabetes measures.36

Patients are increasingly using the Internet as a source for obtaining health-related information. According to a study conducted by the Pew Research Center, 62.6% of Americans looked for health information online within the past year.20 An estimated 4.5% of all Internet searches are health related.37 Research has shown that there is variation in the quality of the information obtained from the Internet38 and the impact of the information obtained from Internet
searches on daily life is low. While a large number of Americans are using the Internet to search for health-related information, significantly fewer are adopting technologies such as PHRs to collect and store their personal health information and engage with healthcare providers.

There is, however, a mismatch between the perceived importance of access to PHIM tools versus their actual use. According to one estimate, only 7% to 9% of American adults used the Internet for tracking information in their personal health records. Use varies based on a variety of factors. PHR use is predominantly associated with people between the ages of 45 to 70. Racial disparity has been associated with patient portal use with higher use among Caucasians. Inconsistencies in Hispanic use of PHIM exist with the implication that further studies of culturally-diverse populations are needed. Females are reported to use PHRs more frequently than males. In a systematic review of PHR studies, Archer identified higher PHR use rates among individuals with chronic health conditions, those with frequent visits to health care providers, and families caring for older adults. Low income and low education levels are two additional factors that influence lower use of patient portals or other health IT for PHIM. Because PHIM is known to play an important role for those with chronic conditions, it is fundamentally important to identify the actual need and perceived value of PHIM among diverse users.

The use of the Internet for conducting health-related searches has been examined in terms of the socioeconomic factors, and research has shown that using the Internet for health-related searches is a more common among Americans than other PHIM activities. This is likely due to relatively few barriers, such as interdependencies with organizations, username and password issues, privacy and security concerns, and technology usability limitations. There has been limited research regarding the use of PHIM tools such as a PHR and its relationship to eHealth behaviors such as searching the Internet for health related information. The purpose of this study is to examine the association between those health-related Internet searches and use of at least one PHIM tool, including emailing healthcare providers, scheduling appointments online, refilling prescriptions using the Internet, and participating in health-related chat groups as well as other sociodemographic and health-related concerns.

**Methods**

This study used U.S. National Health Interview Series (NHIS) data that was collected by the Integrated Health Interview Series (IHIS). The Centers for Disease Control and Prevention conducts the NHIS annually “to secure accurate and current statistical information on the amount, distribution, and effects of illness and disability in the United States and the services rendered for or because of such conditions.” The NHIS randomly samples approximately 35,000 households and 87,500 persons annually, and the average response rate for the survey is near 90% of eligible households in the sample. Samples are drawn from each U.S. State and the District of Columbia and it is representative of the U.S. population. The NHIS has been conducted annually since 1957 and details about the NHIS have been published elsewhere. Data were extracted from the IHIS as a SAS text file, and the SAS text file was read into R and converted to a data set for all analyses.

The NHIS includes questions on a variety of health outcomes, demographic variables, and individual characteristics. The measure of information seeking as an eHealth behavior was the questionnaire item “During the past 12 months, have you ever used computers to look up health information on the Internet.” Responses were categorized into “Yes,” “No,” “Refused,” “Not Ascertained” or “Don’t Know.” For the purpose of the analysis, “No” was coded as 0 and “Yes” was coded as 1. The following variables were also included in the analyses: sex, gender, race, ethnicity, age, education level, health status, income, geographic region, care access, and hypertension prevalence. Hypertension was included in the analysis as a measure of a chronic condition for two reasons: there has been limited research examining PHIM among patients diagnosed with hypertension and hypertension is the most frequently reported chronic condition on the NHIS (47% of respondents reported hypertension). Education level was recoded into five categories (less than high school, high school or GED, some college or two year degree, bachelors degree, and graduate degree). Income was recoded into five categories (<35k$, $35-49.9k, $50-74.9k, $75-99.9k, and $100k+). The variable PHIM was created by combining together responses to questionnaire items related to the use of online health-related chat groups, email with healthcare providers, scheduling healthcare appointments online, and refilling prescriptions online. Responses were categorized into “Yes,” “No,” “Refused,” “Not Ascertained” or “Don’t Know,” and a response of “Yes” to any of these four questions resulted in a positive PHIM response. For the purpose of the analysis, “No” was coded as 0 and “Yes” was coded as 1. Any response of “Refused,” “Don’t Know,” or “Not Ascertained” were treated as missing values in the analysis.
For the purposes of this study, survey data regarding adults 18 years old or greater from 2009, 2011, 2012, and 2013 were combined. The 2010 survey was excluded since it did not address use of the Internet for seeking health information. Between 2009-2013, 492,948 individuals were interviewed across 191,395 households. The data used in this study was limited to adults responding “Yes” or “No” to the question regarding eHealth behavior, and was further limited to only individuals with complete data for the variables included in the logistic regression, resulting in a study sample size of 115,089 individuals. The University of Minnesota IRB deemed analysis of the NHIS data exempt from review.

In order to understand the characteristics of adults who engage in the eHealth behavior of information seeking, proportions and a Multivariable logistic regression were computed using the R version 3.1.0. Proportions were used to calculate the use of the Internet to search for health information across multiple variables. Multivariable logistic regression models were estimated to determine which variables were related to this eHealth behavior. Demographics, health and PHIM measures were included as independent variables in the logistic model. While PHIM activities are reported less frequently than using the Internet for health information seeking, the PHIM factor is included in this analysis to test the association between eHealth behavior and PHIM. The answer to the question about the use of the Internet to search for health information was the dependent variable. The results of the logistic regression are presented as odds ratios (OR) with the corresponding standard errors, 95% confidence intervals, coefficients, and Wald Statistic.

Results

Descriptive statistics are presented in Table 1. Overall, 45% of respondents reported using the Internet to search for health-related information but this ranged from 49.8% in 2009 to a low of 41.5% in 2012. Females were much more likely to search for health information than males (49.7% versus 39.8%, respectively). Adults were also more likely to search for health information if they were younger, white, highly educated, employed, and had higher incomes. Over 72.3% of adults reporting a graduate level education used the Internet to search for health-related information; 13.3% of adults with less than a high school degree reported conducting health-related searches. There were slight differences in geographic variation in health-related searching—the West and the Midwest had the highest rates (47.5% and 47.3%, respectively), while the Northeast and the South had the lowest (45.2% and 42.2%, respectively). Those individuals who have been diagnosed with hypertension reported searching for health information at a lower rate than those without hypertension (37.4% and 48.8%, respectively), as are those individuals who reported being in poor health compared to excellent health (24.9% and 51.7%, respectively). Adults who reported not having a usual place for medical care also reported searching for health information at lower levels (37.9%, and 46.6%, respectively).

Individuals who reported using the Internet for health-related searches also reported higher rates of PHIM activity. The overall rate of PHIM use is low—14.2% of respondents reported using at least one mode of PHIM such as use of online chats (3.6%), email with provider (5.9%), scheduling healthcare appointments online (4.7%), and refilling prescriptions online (6.7%). Individuals who reported using PHIM reported higher levels of using the Internet to search for health-related information than those who did not use PHIM (87.1% versus 37.9%).

Table 2 summarizes the output from the logistic regression on the eHealth behavior of using the Internet for health related searches. All the following results for each independent variable take into account adjustments for all of the other independent variables. Adults using PHIM were significantly more likely to use the Internet to search for health information (OR 7.50). Having a usual place for medical care was positively associated with using the Internet for health-related searches (OR 1.20). Adults reporting a diagnosis of hypertension are significantly more likely to conduct health-related searches (OR 1.08), and individuals who report being in Fair or Good Health were significantly more likely to conduct health-related searches (OR 1.22) than those reported being in poor health.

Adults who were younger, non-Hispanic, white, female, and had higher incomes were significantly more likely to conduct health-related searches. Adults who reported being in poverty were less likely to conduct health-related searches, but employment status was not significantly associated with conducting searches. These results are similar to previous research. Education level was positively associated with health-related searches. Adults with a graduate level education were over 9 times more likely to report a health-related searching than those with less than a high school degree.

Discussion

After examining the impact of social determinants of health, our findings show that individuals who report engaging in consumer eHealth applications by using online chat groups to learn about health topics, communicating with healthcare providers using email, scheduling an appointment with a healthcare provider using the Internet, and refilling prescriptions on the Internet are nearly 7.5 times more likely to search for health-related information online. This finding suggests that there is an association between PHIM and general engagement in healthcare information seeking. Given that consumer eHealth is negatively impacted by a variety of social determinants of health, the promotion and use of a single consumer eHealth modality (searching the Internet for health information) may promote wider adoption of consumer eHealth (PHIM). Considering the strong relationship between consumer eHealth engagement and the use of the Internet for conducting health related searches, healthcare providers should be encouraging their patients to use the Internet as this may be an entry point for patients into using PHIM.54 Individuals who email healthcare providers, schedule appointments online, and request prescription refills online are significantly more likely to search for health-related information online, and individuals who are more engaged with consumer eHealth report better health outcomes, patient satisfaction, and other measures of healthcare quality.19,30 This finding validates previous research demonstrating patient health status, experience, and knowledge of the Internet has a significant impact on seeking information online.55

Overall, our findings indicate that engaging in the eHealth behavior of using the Internet for health-related searches is much lower than has been previously reported (45% versus 63%),56 and that rate has been lower than 50% from 2009 to 2013. Previous estimates by the Pew Internet Research Project18 were based on a telephone survey with a much lower response rate than the NHIS survey 38 (18.1% and 75.5%, respectively), which potentially resulted in non-response bias. Our findings indicate that up through 2013 the level of adoption of these consumer eHealth practices has been generally low (14.2%).

Our research demonstrates a relationship between what have been labeled by the World Health Organization as the “social determinants of health” and using the Internet to conduct health-related searches.11 Individuals with a lower socio-economic status, lower levels of education, and non-White race or Hispanic ethnicity are less likely to engage in the eHealth behavior of using the Internet to search for health information, which confirms previous research.23,30,45,46,47

Our findings do indicate that individuals with hypertension (a chronic condition) are slightly more likely to conduct health-related Internet searches than individuals without hypertension, thus validating previous research.40,47 Individuals reporting a “Good” health status were also slightly more likely to conduct health-related searches. These findings suggest that those populations in poor health are somewhat less likely to engage in conducting health-related Internet searches. Indeed, this study provided additional evidence for a digital divide in consumer eHealth, implying that programs aimed at engaging patients through technology will struggle to reach underserved populations.

Our results also show that individuals who do not have a usual place for medical care are somewhat less likely to conduct a health-related Internet search. This demonstrates that access to medical care—a social determinant of health—is also a possible determinant of consumer eHealth behavior. The use of consumer eHealth applications, including patient-provider email, has been promoted as a tool for improving understanding and therefore decision making between patients and providers and increasing the level of patient and family engagement generally in healthcare.

Our results also suggest that patients who have a healthcare “home,” a place where they routinely obtain healthcare, are somewhat more likely to engage in searching the Internet for health information. This result supports recent initiatives aimed at promoting consumer eHealth, including the meaningful use requirement that 5% of unique patients have communicated with a healthcare provider through an online portal.13

There are several limitations with this study. First, the data was limited to self-reported responses regarding using the Internet to search for health information and use consumer eHealth applications. There are no additional details regarding the types of information searched or the frequency of searching by individual respondents, nor do we have details about frequency of emailing providers, scheduling appointments, refilling prescriptions, or participating in online chat groups.
Additional research is needed to evaluate the factors that drive adoption of consumer eHealth by individuals least likely to use the Internet for conducting health-related searches, and research is also needed to assess trends in consumer eHealth adoption by specific groups, including more detailed analysis of PHIM use by individuals who report chronic conditions. Research is also needed regarding the means by which individuals are conducting these searches and accessing eHealth technologies, including the use of mobile devices and mobile applications. This research could be useful for identifying best practices for engaging patients in personal health information management, and developing tools to assist healthcare organizations and individual healthcare professionals meet patient needs.

**Conclusion**

This study has demonstrated that there is significant relationship between the use of the Internet for conducting health-related searches and the use PHIM. This engagement is, however, impacted by a variety of demographic and health-related factors—“determinants of consumer eHealth.” Overall, the adoption of PHIM remains low, and to be successful, consumer health information technology must be designed to address the needs of people of varying ages, socio-economic status and geographic location. While many consumers are ready and willing to access their health information online, much less is known about consumer motivations related to personal health information management. The perspectives of a variety of consumers from diverse population groups are requisite to gaining an improved understanding of their personal health information management needs so that technologies that effectively capture and sustain their interest in managing their own health can be effectively designed and deployed.

Abstract

Objective: To create a relevant and clinically informative visualization of passively collected patient mobility data from smartphones of rheumatoid arthritis (RA) patients for rheumatologists.

Methods: (1) Pilot analysis of smartphone mobility data in RA; (2) Assessment of rheumatologists’ needs for patient data through semi-structured interviews; and (3) Evaluation of the visual format of the RA data using scenario-based usability methods.

Results: We created a color-scale mobility index superimposed on a calendar to summarize the passive mobility measures from the smartphone that the rheumatologists confirmed would be clinically relevant.

Conclusion: This assessment of clinician data needs and preferences demonstrates the potential value of passively collected smartphone data to resolve an important data question in RA. Efforts such as these are necessary to ensure that any smartphone data that patients share with their doctors will not exacerbate clinician information overload, but actually facilitate clinical decisions.

I. Introduction

Informatics problem

Sixty-four percent of American adults owned a smartphone as of October 2014¹, which has significant implications in healthcare. Smartphones are intimately associated with so many daily activities that, if the data could be captured and analyzed, they could provide detailed information about an individual’s behavior as it relates to health. The smartphone itself passively tracks daily movements but it also allows for ease of data input into symptom or medication logs. There are accessories that can measure blood pressure, heart rate, oxygen saturation, expiratory flow velocity, cardiac electrical activity, and even brain electrical activity². A measure of how pervasive the belief is that these data sources could change healthcare delivery and research is the activity of several tech giants in this space, as exemplified by Google Inc.’s “Fit” and Apple Inc.’s HealthKit and recently announced ResearchKit technologies³.

Smartphone data gathered from patients with certain medical conditions, if processed and presented to their physicians effectively, could improve physician decision-making⁴. Unfortunately, physicians are already on the brink of information overload⁵. The average primary care physician might receive 1000 test results per week⁶ and is expected not only to be aware of the results, but also to analyze them and take the appropriate management actions. Data from patient smartphone applications, however potentially useful, is likely to be met by resistance from physicians if the clinical relevance is not immediately apparent. A significant amount of time and research must be spent on which measurements are truly useful and determining the best way to present the smartphone data in a clinically relevant and actionable manner.

Building on these ideas, our research group is studying methods for combining passive mobility monitoring and active questionnaires to create clinically informative measures for patients with rheumatoid arthritis (RA). As part of this larger effort, we sought to determine how to process and present smartphone data in a cognitively manageable, clinically relevant format for rheumatologists caring for patients with RA.
Rheumatoid arthritis management challenges

To place this work in context, it is helpful to recognize that RA management is fraught with many challenges related to assessing rapidly changing patient status and making appropriate decisions on the basis of this data. Managing an RA patient can be conceptualized as operating a complex feedback control system where the input variable is the RA medication and the output variable is the RA disease activity. Rheumatologists choose the dosing and frequency of non-steroidal anti-inflammatory drugs (NSAIDs) and disease-modifying antirheumatic drugs (DMARDs) such as methotrexate and steroids based on observing the RA disease activity. RA disease activity is characterized by painful, stiff joints in the hands and/or feet accompanied by fatigue and morning stiffness that takes at least an hour to resolve with activity. RA disease activity is unpredictable with flares that last a couple of days to several weeks. Clinical practice guidelines were designed based on available research to help rheumatologists improve their efforts at preventing long-term joint destruction and disability. The guidelines emphasize that rheumatologists frequently monitor patient disease activity and adjust medications and doses in order to achieve “tight control” of disease activity, which means maintaining remission or low disease activity at all times.

The guidelines encourage the use of composite disease activity indexes, which simplify and standardize the measurement of disease activity by assigning a single numerical score to patients for classification into one of four states: remission, low disease activity, moderate disease activity, or high disease activity. The composite disease activity indexes are well validated but have significant drawbacks. The composite disease activity indexes were created to capture the heterogeneity of RA into a standard measure, but it is possible for two patients with the exact same score to have vastly different signs and symptoms and actually be in two very different disease states. There is evidence suggesting a disconnect between the composite disease activity indexes and patient satisfaction with their treatment, which rheumatologists must overcome with their patients in order to make the best shared treatment decisions. It is also thought that most U.S. rheumatologists do not routinely use composite disease activity indexes in clinical practice because they are not practical to assess given the limited amount of time they have available during their patient encounter. These challenges of RA management call for more patient-driven data and a supplement to the composite disease activity index.

Objectives

The objective of this study is to create a relevant and useful visualization of patient generated smartphone mobility data and to elicit rheumatologist perspectives on 4 questions: (1) Is smartphone mobility data a relevant measure of RA disease activity? (2) Does this data answer clinician data needs in RA management? (3) Does it ease challenges of RA management? and (4) How would rheumatologists use it in the office setting?

2. Methods

This study had three steps: (1) Pilot analysis of smartphone mobility data in RA; (2) Patient data needs assessment through semi-structured interviews with rheumatologists; and (3) Evaluation of the visual format of the RA data using scenario-based usability methods.

Collecting sample mobility data from an RA patient

To obtain realistic data for the study, we recruited an RA patient to participate in data collection. The subject met the following inclusion criteria: 25 years old or older; worked full-time outside the home; and routinely carried a smartphone whenever leaving the house. The subject downloaded a commercially available motion/activity tracking software application onto an iOS smartphone, and was instructed how to link the application to the sensing technology platform used in this study. The subject provided information about which days were workdays versus non-workdays and notified the researcher by email when an RA flare occurred.

The smartphone recorded mobility measurements over time, leveraging the built-in accelerometer and GPS/Wi-Fi locator. We processed the raw data into multiple dependent variables for each day. They included: (1) time spent walking/running; (2) gait speed for walking/running; (3) distance travelled walking/running; (4) time spent using transportation and distance travelled; (5) maximum gait speed in miles per hour when walking for more than five minutes; (6) number of hours away from the house; (7) time of day that the subject left the house; and (8) geodiameter (furthest distance travelled from home). The rheumatologists reviewed these variables and gave
opinions about the usefulness of each of these and which ones might deserve a higher priority. The pilot data with the dependent variables measured by the smartphone were separated into workday and non-workday groups. Deciles for each dependent variable were calculated using Stata (version 13.1, StataCorp, College Station, TX). The decile values were used as a basis for creating a scoring scale from 0 to 9 unique for each variable.

Assessing clinical data needs of clinicians treating RA

Physicians with experience treating RA were recruited from a nationally known orthopedic hospital in New York, NY. Two of the physician subjects were co-investigators of a study related to this project. A snowball sampling approach was utilized in which these two co-investigators suggested the names of other rheumatologists for the interview.

A series of semi-structured interviews were conducted with these clinicians. The interview questions were developed based on literature review and designed with the following objectives: (1) to understand how rheumatologists assess an RA patient’s symptoms and functional disabilities; (2) to understand how they cognitively process this information to make medical management decisions; and (3) to identify gaps in data needs that might be addressed by patient-generated mobility data.

The interviews were audio-recorded and transcribed. Analysis was done in an iterative manner guided by a grounded theory approach. The insight and feedback gained from the interviews was used to alter the questions, patient scenarios, and format for summarizing the smartphone mobility data before the next subject was interviewed.

Evaluating the clinical utility of RA patient mobility data

During the physician interviews, a scenario-based design approach was used to evaluate the clinical utility of patient-generated mobility data. The approach involved presenting multiple RA patient scenarios to the physician subjects and asking them to think out loud while they decided how to manage the patients. Such “think-aloud protocols” or “verbal protocols” are useful in tracing problem-solving and decision-making steps. The scenarios were presented in two parts. After reading the first part the physicians were asked to describe how they would manage the patient. Then, they were given the second part of the scenario, which involved the same patient with some new or different information involving a presentation of the data. The physicians were asked to describe how they would manage the patient again, given this new information. The purpose of this method was to determine what effect, if any, the mobility index had on management. The presentation of the mobility index was revised after each interview, and the most current iteration was used in the scenarios. Physician subjects were also asked to critique the mobility index. This approach helped guide a discussion about the best way to present patient-generated mobility data so that it would integrate smoothly into the rheumatologist’s typical process for evaluating and managing RA patients.

Ethical approval

The Weill Cornell Medical College institutional review board approved the study. All physicians gave oral informed consent, and the patient subject granted written informed consent.

3. Results

Five board-certified rheumatologists participated who all reported <50% but >10% of their patients have a diagnosis of RA.

Physician clinical data needs when treating patients with RA

Five general themes about data needs when managing RA surfaced during the semi-structured interviews.

Theme 1: An accurate and detailed history is essential for helping rheumatologists recognize the patterns that help them properly identify RA flares

Flares present in various ways, even for the same patient. Some flares present suddenly while others have a more
gradual onset. Some cause obviously swollen joints but no joint tenderness while others cause no swollen joints but exquisite joint tenderness. “For some patients it is mostly pain, for some it is stiffness, and then there can be fatigue overriding the whole thing.” [Physician 1] Even laboratory tests can be unreliable. There are frequently patients with swollen, tender joints from RA with no elevation of the erythrocyte sedimentation rate or C-reactive protein (sensitive serologic markers for RA).

It is not always obvious that a patient is experiencing a flare. Back pain, a common symptom for all adults, is a good example. Rheumatologists must have enough historical information to rule out muscle strain, joint trauma, fibromyalgia, gout, herniated discs, neuropathic pain, and even depression as a cause of the back pain.

A detailed history can help rheumatologists evaluate a patient more accurately. It can help them detect the subtle patterns that define an RA flare so that they can more quickly and confidently prescribe the appropriate treatment.

**Theme 2: An accurate and detailed history is essential for fine-tuning dosing to maintain the delicate balance between RA symptoms and side effects from RA medications.**

Managing each individual RA patient’s treatment “is a delicate, fine balance because a small increase in DMARD dosage can improve symptoms, but that same small increase can also cause serious side effects.” [Physician 4] This effort is further challenged by the fact that rheumatologists are not always aware of which doses a patient is actually taking. Many patients are allowed to self-dose their prednisone and do not necessarily keep an accurate account of what they took or when. Also, medication adherence is a common challenge because patients are often more concerned about the side effects of DMARDs than they are of their RA. Once a reliable medication history is established, then subtle changes in symptoms and mobility can be associated with changes in dosing so that the optimum doses for the individual patient can be established.

**Theme 3: Ambivalence about validated disease activity indexes in RA management**

The composite disease activity indexes are well-validated measures of disease activity and are the basis for most of the RA management algorithms published in the clinical practice guidelines. However, two of the physicians had problems with the indexes. One physician felt that the indexes did not correlate with disease activity enough to be worth the time it takes to do them. “I’m not sure how helpful I find it. This may or may not be right but I like to treat the patient more than the number of things.” Another physician was very confident in the part of the index based on physical exam findings, but not in the single self-report question for the patient - “How much pain and stiffness have you had in the past week on a scale of one to ten?” This question appeared too subjective to be valuable because some people tolerate pain more than others, which makes the score inaccurate. The question also did not differentiate RA pain from something like degenerative joint disease pain, which is common among RA patients. The participant described a common scenario:

> “Sometimes the patient will look very comfortable but answers 8/10 where 10 is the worst. I’ll have to ask them if they mean a constant 8/10 or is that the worst score but most of the time they are a 3/10. I’ll end up having to ask them to try to pick whatever number pops into their head or a type of average, which is obviously extremely subjective. It also only asks about the last week. If I saw them three months ago, or even a month ago, then I really want to know about more than just the past week.”

The four physicians who used the indexes (whole or in part) felt that they generally correlated well with their subjective and physical assessments. However, these four physicians made the point that the composite disease activity index was only a part of their total assessment and did not replace any other part of their assessment. It was perceived as especially good at providing a way to consistently compare how a patient is doing relative to how they were doing at their previous appointment.

**Theme 4: Self-reporting of symptoms during the clinical encounter often gives an incomplete picture**

Rheumatologists rely heavily on a patient’s self-report to determine the true level of disease activity especially since there is no gold standard for measuring disease activity in RA and there is such wide variability in presentation. Unfortunately, patient self-report can lead to misrepresentations of the truth in many instances. “It is common to
have a patient complain about their swollen finger but say nothing about their knee that is swollen the size of a grapefruit.” The swollen finger may attract attention because it is new, whereas the knee has been symptomatic for months.

Self-report can also be inaccurate when patients understate the severity of their symptoms. One participant stated that it is common for “patients to say that they are doing much better, their joints feels good, and they are feeling good. Then I examine them and they have really swollen joints and are really tender.” Some patients accept more pain than they should. One explanation is the so-called “adaptation effect” in many chronic pain patients, in which pain appears normal to the patient because it has been present for so long. Only increases in pain are noted. Some patients who improve on a new treatment regimen will say, “Wow, I realize that I really wasn’t doing great now that I know how I am supposed to feel.” Other patients understate the severity of their symptoms simply because they are stoic and are not comfortable complaining. While other patients may be doing so much better on their new regimen that they understate their residual symptoms out of the fear of being asked to change to a new medicine.

Conversely, some patients overstate their symptoms. They could be more sensitive or vocal about lower levels of pain than the average patient, or the behavior could be drug seeking. Another possibility for a disproportionately high level of perceived pain is fibromyalgia. “Fibromyalgia is a condition that I believe acts as an amplifier. Pain begets pain in this situation and any pain they experience seems to cause them to complain more than other patients with similar physical findings.”

Theme 5: Self-report data generated between visits may help RA management, but presents new challenges

All the physicians agreed that more information about the time between office visits would be helpful in managing RA.

“The reality is that there is so much we don’t know about RA. We aren’t even sure exactly what causes flares. As a result, each flare is a learning experience that is lost. If somehow we could record what happened to the patient leading up to the flare and how they responded to the doses of prednisone or NSAIDS that they took, then it would provide valuable knowledge on how to prevent another flare and how to manage the next one.”

This type of knowledge could help rheumatologists achieve “tight control” more rapidly with the benefit of preventing the long-term damage that keeps occurring as long as their disease activity is elevated.

Two of the five interviewed physicians asked some of their patients to keep a symptom diary. The three physicians who did not stated that they would not have time to read a diary. “If I asked every patient to do a diary, 90% wouldn’t do it and then 10% would make it their life.”

One physician subject thought the journal information would be valuable for helping her manage her patients’ conditions, yet she was concerned that tracking symptoms at home would be tedious and boring and that patients would tire of it. She also expressed concern that forcing patients to document their symptoms might make them overly aware of them.

Creation of Passive Mobility Measures

The physicians all agreed that an index modeled after the composite disease activity index would be an effective way to represent a summary of the passive mobility measures and we decided to call it a “mobility index”. When asked about the individual mobility measures, the majority felt that time spent walking, time away from the house, and gait were the most useful in defining the level of RA disease activity. Four of the rheumatologists agreed that gait would be one of the more sensitive measures of increased disease activity, so we decided to apply more weight to gait in the mobility index weighted gait. Less weight was attributed to the time away from the house because two rheumatologists raised concerns that it was not as meaningful as the other measures.

The resulting formula for a summary estimate of the degree of mobility for the day was:
Another formula needed to be created to give a weekly summary of a patient’s mobility level. It could not be calculated as a simple average because rheumatologists want the weekly score to be defined by the worst days. Flares can often resolve in 48 hours, so its effect on a workweek mobility index could be washed out by a simple average. As a solution to this problem, the following formula was designed to enhance the signal of a low peak in the daily score where $d$ equals the number of days in the workweek.

$$
\text{Mobility index}_{\text{workweek}} = \frac{\sum_{n=1}^{d} \text{workday score}_n + 2(\text{lowest workday score})}{d + 2}
$$

For the purposes of the current study, we included only workday data and excluded weekend data because there was a large number of scores of “0” resulting in scores that were not interpretable.

**Clinically meaningful visualization of the Mobility Index**

The physician subjects were asked specific questions about how they would like this type of data presented to them. All of the physicians wanted to be able to review this smartphone data at the beginning of their office visit with the patient. They all wanted the smartphone data to be in the form of a simple single-paged report. The physicians wanted the smartphone data to help them understand symptom and side-effect trends over appropriate time intervals.

For a patient who was experiencing a flare, they expected to see daily changes. For a patient who was initiating a new medication, they would expect to see weekly changes. For a stable patient, they wanted to see an even broader view with a month-to-month summary.

In order to accomplish these goals, the daily and workweek mobility indexes were assigned a color shade according to its numeric value and the corresponding color shade was superimposed on a calendar view. Originally we used the colors red, orange, yellow, and green to represent different levels of mobility, but we determined that it was easier to convey the concept that these expressed ordinal categories of the same variable if we used different saturation levels of one color. That is, it was difficult to understand that green was a different level from red but easy to understand that dark purple is a different level from light purple. We used the color scheme in Figure 1. The darkest, most saturated level of purple was used to draw attention to the most impaired mobility. Figure 2 demonstrates the mobility index for the pilot patient with the color shades superimposed on the calendar for a daily score. Figure 3 demonstrates the weekly score.

![Figure 1](image.png)

**Figure 1.** Mobility index. The most impaired mobility is represented by the lowest mobility index values and the darkest shade of purple.
The physicians were generally enthusiastic about the potential benefits that mobility information on a calendar could bring to understanding RA after using it in the patient scenarios. “I think this type of information will be great. It will give me a better feel for the reality of what’s going on in their life,” one said. Another called it “a springboard for obtaining more insight into a person’s life than we get from the typical appointment interview.”

The physicians agreed that tracking a patient’s mobility would be most helpful in situations where the patients are understating their symptoms. In one of the scenarios where the smartphone data indicated that the patient was less mobile than they had admitted, one physician described how she could use this information as a way to point out that a patient may be accepting more disability than necessary and that there are changes in management that could help. “This information that is derived from objective measurements could also make it easier for patients to overcome their barriers of shame and embarrassment to reveal the truth about their symptoms,” another said.

The smartphone data did not have any effect on how the rheumatologists would treat a patient complaining of pain. The physicians agreed that they treat any patient who is in pain with maximal medical therapy. “Pain trumps everything,” one said. The physicians treat patients in pain based upon their self-report above all else, whether the smartphone data was in agreement or not with what the patient was saying. The mobility information also did not
affect treatment decisions for patients when it was consistent with the patient’s self-report and physical exam but it did offer an extra degree of confidence that they were doing the right thing. “I would use this mobility information as much as what was said and what I examined.”

Finally, the feedback from the clinician participants indicated that the mobility index in the calendar format could enhance the cataloging of RA signs and symptoms over time in the context of different environmental factors and medical interventions. “I ask patients to use a calendar to log symptoms and medications for me all of the time, but they don’t.” [Physician 3] Discussions with our clinician subjects suggested that successful adoption of an application like this by patients could help obtain generalizable knowledge about the behavior of RA. For example, if the mobility index and self-report are presented effectively for all of a rheumatologist’s RA patients, then after a while it could improve their understanding of the RA disease process enough to give them added knowledge to help them manage all of their patients. “If I have seen 10 people get 25% better in two weeks on a certain drug, then that is something I could share with a patient to give them an idea of what kind of benefits to expect from this new drug.”

4. Discussion

A key goal in creating mobile health-based tools for physicians is to assist them in making better patient management decisions. It is essential to have a thorough understanding of physicians’ data needs in order to create a tool that is relevant to clinical care. This also helps avoid the trap of developing a mobile health tool that is technologically sophisticated but does not have any real impact on the efficiency or quality of care delivered.

This study addressed those concerns by interviewing rheumatologists and describing the actual clinical problems and real world needs of rheumatologists. It also contributed information about the best format for presenting the smartphone data so that physicians would understand it and willingly adopt it into their patient management workflow.

The semi-structured interviews demonstrated that all of the rheumatologists were consistent in the opinion that more real-world data (generated outside of the clinical environment) about how RA affects an individual patient’s functionality would help them with management. Rheumatologists indicated that smartphone applications that track a patient’s movements throughout the day could be an indirect but valid measure of RA disease activity. Most importantly, all of the rheumatologists that were interviewed expressed a willingness to regularly spend a small amount of appointment time with their RA patients to review this type of data, as long as it was easy to understand, concise, and visual.

The patient scenarios demonstrated that visualizations of passive mobility were overall clinically useful to the rheumatologists. All of the five physicians understood the particular design that they were shown with little explanation. The calendar format added an improved understanding of the patient’s fluctuation of symptoms with time and helped physicians draw conclusions about trends. Allowing the calendar to change in granularity from daily to weekly to monthly helped the physicians adapt the data appropriately to the specific clinical situation. It also prompted rheumatologists to ask the theoretical patients more probing questions so that they would discover important details that the patient might have left out or forgotten. They felt that the addition of the visualizations would be better than performing a history and physical exam alone. It helped give them a more accurate picture of the patient’s true functionality, which even led to subtle changes in their choice of medical management.

There are numerous efforts ongoing to do this type of work in other domains. For Parkinson’s disease, researchers are using smartphones to transmit home motion-sensor data in a 3D animated form to clinicians for help with dose-finding16. For elderly patients, researchers are presenting physicians with a visualization of home motion sensor data and physiologic data to give them a better sense of patient overall health status17. There are also efforts to transform smartphone habit data with the Health Mashups System into a visual format that clinicians can evaluate and use to assist patients in promoting behavior change18. All of these projects aim to harness valuable information that the smartphone can collect and present it to physicians to aid in clinical decision-making.
Limitations

There are several limitations to this study. A single researcher performed data collection and analysis, although the iterative nature of the study meant that later physicians validated the interpretation of the analysis of the earlier interviews. The sample size was small, and the physician subjects were colleagues at a single medical center. The interviews revealed significant variability in preferences and disease management practices, but nevertheless, the results may not capture the diversity of opinion in other populations, such as rheumatologists in private practice or in different geographical areas. Given that many patients with RA will be cared for by a multidisciplinary team (physical and occupational therapists, nurses, etc.), another limitation of the study was that the clinicians interviewed were all physicians. Future work will include participation from other allied health professionals involved in the treatment of RA.

The pilot data collection was conducted with a single patient and may not reflect the full diversity of experiences of the RA population. An additional limitation is that we were unable to arrive at a stable score for non-workday readings and therefore excluded them from the current study. Additional data collection with more patients on non-workdays will help determine best how to calculate the meaningful score from non-workday data, as non-workdays may be even more informative about the severity of disease than workdays since most non-workday activities are voluntary. The current paper also does not address user testing, which is ongoing.

5. Conclusions

This assessment of clinician data needs and preferences demonstrates the potential value of passively collected smartphone data to resolve an important data question in RA, which is the daily activity level of the RA patient. This project also proposes a visualization solution identified by practicing rheumatologists as potentially valuable.

Concurrently with this data needs assessment, the mobile health development project is continuing. In addition to the passive data collection, we are developing a feature for patient self-report to allow patients to explain their schedule and report presence or absence of symptoms. Once all of this information can be captured simultaneously, then data analysis and data modeling will be able to improve and validate the choice of mobility measures, the formula for the mobility index, and the appropriate levels of severity to apply to the range of scores.

Patients are increasingly interested in capturing their health related data with their smartphones and wearable devices, and clinicians are going to be challenged in the future with interpreting these data. This study serves as an example of how to focus on a particular clinical problem, identify data needs, and design a data visualization technique that serves a clinical purpose. We think that this approach is necessary to ensure that the data patients generate and share with their doctors will not overwhelm them with information overload, but actually enhance their ability to provide the best possible care.

Vessel Delineation in Retinal Images using Leung-Malik filters and Two Levels Hierarchical Learning

Abstract
Blood vessel segmentation is important for the analysis of ocular fundus images for diseases affecting vessel caliber, occlusion, leakage, inflammation, and proliferation. We introduce a novel supervised method to evaluate performance of Leung-Malik filters in delineating vessels. First, feature vectors are extracted for every pixel with respect to the response of Leung-Malik filters on green channel retinal images in different orientations and scales. A two level hierarchical learning framework is proposed to segment vessels in retinal images with confounding disease abnormalities. In the first level, three expert classifiers are trained to delineate 1) vessels, 2) background, and 3) retinal pathologies including abnormal pathologies such as lesions and anatomical structures such as optic disc. In the second level, a new classifier is trained to detect vessels and non-vessel pixels based on results of the expert classifiers. Qualitative evaluation shows the effectiveness of the proposed expert classifiers in modeling retinal pathologies. Quantitative results on two standard datasets STARE (AUC = 0.971, Acc = 0.927) and DRIVE (AUC = 0.955, Acc = 0.903) are comparable with other state-of-the-art vessel segmentation methods.

Introduction
Color photography of the ocular fundus is a widely used imaging modality that permits the non-invasive analysis of the retinal microvasculature. Color images allow ophthalmologists and trained medical professionals to diagnose and monitor progression of retinal diseases, including age-related macular degeneration [1] and diabetic retinopathy [2]. Diabetic retinopathy as the primary cause of blindness can be prevented with treatment at an early stage, therefore WHO suggest yearly retina screening of patients. The reliable vessel segmentation can facilitate screening and improve vascular analysis that leads to improve Diabetic retinopathy detection [2, 3].

The manual analysis of ocular fundus images is time-consuming, expensive, and sometimes inaccurate. Computer aided ocular fundus image analysis permits the quantification of the extent of retinal abnormalities in vascular diseases and is fast and inexpensive and allows batch mode processing [3] [4]. Blood vessel segmentation is an important early step for the analysis of ocular fundus images. This can be a challenging task if the images are low quality and noisy vary in brightness, or have lesions underlying or adjacent to blood vessels [5]. Some automatic vessel segmentation methods extract feature vectors for pixels and use a set of manually segmented vessels (by experts) to train their classifiers, while the others are mainly developed based on filter response thresholding or other rule based techniques.

The matched filter technique [6] [7] is one of the earliest blood vessel segmentation methods that uses the maximum response of 12 different templates (2D kernel with Gaussian cross sections), in different orientations, to detect blood vessels. The filter parameters are then changed to increase the matched filter response to blood vessel detection by Al-Rawi [8]. The tracking approaches [9] [10] [11] build vessel trees by propagating vessel labels from manually or automatically selected pixels to unknown pixels, based on underlying correlations among pixels or tracking vessel center lines. The mathematical morphology is combined with cross-curvature evaluation and linear filtering by [12] [13] [14] to segment vessel-like patterns from background. The most recent filtering-based method is called B-COSFIRE [15], which uses a combination of shifted filter responses to extract vessels. B-COSFIRE is a trainable
filter approach in which the selectivity of a filter is determined automatically based on user prototype patterns such as straight vessels, bifurcations or a crossover points.

In learning based approaches, the proposed method by Ricci [16] uses a line detector on the inverted green channel of a retinal image. The average gray level on line passing through the pixels is computed in different orientations and the line with maximum value is selected. The line strength is computed as a difference between the selected line and the average of contrasts in the square neighborhood of the pixel. The line strength is high for vessel pixels and low for non-vessel pixels that allows unsupervised pixel classification by thresholding. Furthermore, an orthogonal line is defined based on a line of three pixels, centered on the midpoint of the main line and orthogonal to it. Then, its strength is obtained again by subtracting the average intensity on the orthogonal line from average intensity of the square neighboring of the pixel. The orthogonal line strength, line strength and intensity of pixels are combined to build a three-dimensional feature vector for every pixel. Later a SVM classifier is used to improve the supervised vessel classification result.

The proposed method by Fraz and et al [17] builds feature vectors based on orientation analysis of the gradient vector field, line strength measure, Gabor filter responses and morphological transformation for every pixel. Then, supervised methods, based on an ensemble of bagged and boosted decision trees, are used to classify pixels as vessels and non-vessels. The line elements are approximated based on grouped image ridges in the method developed by Staal [18]. The properties of line elements and their associate patch are used to build feature vectors for every pixel while the proposed method by Niemeijer [19] uses a response of a multiscale Gaussian filter to build feature vectors. Then, the k-Nearest Neighbor (kNN) classifier is used to classify pixels in both methods. Soares et al. [20] use a two-dimensional Gabor wavelet filter response, in multiple scales, to build feature vectors for every pixel. Then, a Bayesian classifier with class-conditional probability density functions (likelihoods) described as Gaussian mixtures is used to classify pixels as vessel and non-vessels. Most of the supervising method are designed to classify vessels and non-vessel regions regardless of the presence of abnormal pathologies such as lesions or exudates. Their performance is high when dealing with normal retinal images while it degrades drastically when dealing with abnormal retinal images.

The main goal of this paper is to develop a vessel segmentation method based on Leung-Malik filters [21] that seeks to minimize false positives and negatives in the face of retinal pathologies such as lesions, exudates and optic nerve abnormalities in diseased retinas. The proposed method uses a response of Leung-Malik filters in different scale and orientations to build set of feature vectors for every pixel. Then, a two level hierarchical learning framework is employed to segment vessels in abnormal retinal images. In the first levels, three classifier is trained to detect vessels, background and abnormalities then in the second level, a new classifier is trained to combine results of first level classification to delineate vessel and non-vessels. The performance of the proposed method on standard databases including STARE [7] and Drive [18] is comparable to the state of the art vessel segmentation methods.

The rest of the paper is organized as follows: in Section 2 we explain the proposed method and show how the LM filters responses can be used to detect blood vessels. In Section 3 we discuss and evaluate our method followed by discussions and finally we draw conclusions in Section 4.
The proposed method delineates vessels in 2D fundus images by classifying vessel or non-vessel pixels. The response of multi-scale, multi orientation Leung-Malik filter bank [21] is used to extract features for every pixel. The Leung-Malik filter bank consists of 60 filters, including first and second derivatives of Gaussians at 8 orientations and 3 scales (making a total of 48 filters); 8 Laplacian of Gaussian (LOG) filters; and 4 Gaussian filters. In our experiments the first and second derivative filters occur at the scale $\sigma = \{1, \sqrt{2}, 2\}$ with an elongation factor of 3 ($\sigma_x = \sigma, \sigma_y = 3\sigma_x$). The Gaussians occur at the four basic scales $\sigma = \{1, \sqrt{2}, 2, 2\sqrt{2}\}$ while the 8 LOG filters occur at scale $\sigma = \{1, \sqrt{2}, 2, 2\sqrt{2}, 3, 3\sqrt{2}, 6, 6\sqrt{2}\}$. The examples of the LM filter bank is shown in Fig1.b. The standard configuration for scales and number of orientations is used [21]. The maximum response of LM filters on the green channel image for different orientations, standard deviation of maximum responses on different scales and intensity value and its standard deviation in neighborhood of 5x5 of pixels are used to build a 14 dimensional feature vector for pixels as shown in Fig1.c. The LM filter bank extracts both textural, shape and intensity based features. The first and second derivatives of Gaussian in different orientation and scales have high response for elongated and vessel like objects and moreover the LOG and Gaussian filters have high responses for blob objects like exudate and hemorrhages. The extracted features in Fig1.c show how effectively the vessel like objects are highlighted in different orientation and scales using LM filters. Once feature vectors are extracted for every pixel then a Two Level Hierarchical Classification is applied to detect vessel and non-vessel pixels in abnormal retinal images as shown in Fig.2.
Fig 2. Two level Hierarchical classification framework. 

a) Expert classifiers to detect vessels, abnormalities and background pixels. 
b) Binary classification results and probability maps generated by expert classifiers. 
c) Local means and standard deviation of probability map as an input features for the classifier in the next level. 
d) Classifier in the level 2 and its outcome.
In the case of multi-class classification problem, the hierarchical classification framework takes advantages of simple expert classifiers in the first level to discriminate one class against all others. The expert classifiers are ensembles of n decision trees and they are trained to discriminate pixels in vessels, background and abnormal regions. Abnormalities in our experiments are considered as lesions, exudate, optic disk and regions with different textural pattern from normal retinal image. The expert classifiers are shown in Fig2.a.

The decision tree generates class label however the probability of samples originating from the class can be computed as the fraction of observations of the class in a tree leaf. The final probability map for expert classifiers is computed by averaging probability maps generated by all decision trees. The binary classification and probability maps of expert classifiers are shown in the Fig2.b.

The local mean and standard deviation in 3x3 square neighborhood in probability maps of three expert classifiers are used to build 6 dimensional feature vectors for every pixel. The 6 dimensional feature vectors are shown in Fig.2.c and it is used as an input for the classifier in the second level. In the second level, a new classifier based on ensembles of n decision trees is trained on 6 dimensional feature vectors (results of expert classifiers in the level one) to classify pixels as vessel or non-vessel. The classifier in the second level and its results are shown in Fig2.d. Different classifiers such as K nearest neighbor, Gaussian mixture models and ensembles of decision trees are used in the first and second levels but ensembles of 60 decision trees outperforms other classifiers. Therefore in our experiments the ensembles of 60 decision trees are used in the first and second level.

![Fig3. Illustration of Vessel segmentations. a) Green channel of retinal images from STARE and DRIVE datasets. b) Result of three expert classifiers in detecting background, abnormalities and vessels, c) segmented vessels by proposed method, d) Groundtruth vessel segmentations](image)

The performance of the proposed method is evaluated on standard STARE [7] and DRIVE [18] data sets. The STARE data set, collected at the Shiley Eye Center of UC San Diego, is used as a training set for the classifier. The STARE consists of 20 color retinal images (10 normal and 10 with pathology) captured by a Topcon TRV-50 fundus camera at 35 deg FOV. Two observers (an expert ophthalmologist, MHG) manually segmented images in which 10.4% and 14.9% of pixels are segmented as vessels by first and second observers respectively. In our experiment, segmentation by the first observer is used as gr ound truth as it is commonly used by other methods. In dealing with STARE data set a Cross-validation is used to train and test the classifiers on 75% and 25% images,
respectively. This process is repeated 4 times to test all images. The DRIVE data set consists of 40 images (20 for train and 20 for test) captured by a Canon CR5 nonmydriatic 3CCD camera at 45 field of view (FOV). The training and test sets are manually segmented one and two times respectively by observers trained by an ophthalmologist. In test set, 12.3% and 12.79% of pixels are segmented as vessels by first and second observers respectively and first observer is used as ground truth.

**Results and Discussions**

In qualitative evaluation, the performance of the proposed method in dealing with retinal images with abnormalities is evaluated. The green channel retinal images with and without abnormalities from STARE and DRIVE databases are shown in the Fig.3.a. The results of the three expert classifiers in detecting the image background, image abnormalities, and vessels are encoded with red, green and blue colors as shown in the Fig.3.b. The segmented vessels by the proposed method and the ground truth images are shown in the Fig.3.c, d.

The abnormalities close to the macula in the first STARE image are successfully detected by expert classifiers, but some part of their boundaries are wrongly considered as vessels, as highlighted with green and blue respectively in Fig.3.b. The expert classifiers successfully detect scattered and intensive pathologies in STARE images two and three, as shown in Fig.3.b. The proposed method takes advantage of expert classifiers and is able to segment vessels that are surrounded by confounding abnormalities, as shown for STARE images in the Fig.3.c. Fewer of the DRIVE images abnormalities, and result of vessel segmentation is comparable to ground truth labeling, (Fig.3.c, d). The regional post processing based on the shape and morphological characteristics of vessel or connecting disconnected vessels can improve the results, but in order to have fair comparison with other methods we do not use any post processing in our experiments.

The evaluation metrics of area under the curve (AUC) and accuracy (Acc) are used to quantitatively compare performance of the proposed method with state-of-the-art vessel segmentation methods on STARE and DRIVE databases, as shown in the Table.1. The accuracy of segmentation is computed as $Acc = \frac{TP+TN}{N}$, in which $TP$, $TN$ and $N$ are true positive, true negative and number of pixels respectively. To avoid having to select a single threshold for classification, one may scan through all possible thresholds, and observe the effect on the true positive rate and the false positive rate. The Area under the graphed curve is a reliable measure to compare performance of different methods. In our experiment the internal function (percurve) of Matlab software is used to estimate the AUC.

The proposed method achieves AUC of 0.971 on the STARE database, which is comparable with methods developed by Fraz [17], Marin [22] and Ricci [16] [22], with AUC of 0.977, 0.977 and 0.968 respectively. The performance of the proposed method is better on the STARE database than on the DRIVE database, because the STARE database has more retinal images with abnormalities.

**Conclusion**

In this paper we have proposed a novel method to segment vessels in retinal images that have confounding abnormalities. The proposed method takes advantages of multiorientational Leung-Malik filters in different scales.
and makes use of a two-level hierarchical learning framework to detect vessels in diseased retinal images. The retinal abnormalities, vessels, and background are modeled by expert classifiers in the first level. The outcomes of the expert classifiers are combined to detect vessels in the second level. The qualitative evaluation shows that retinal abnormalities are successfully delineated from vessels and background by the expert classifiers. Moreover, the quantitative evaluation on two standard data sets, STARE (AUC = 0.971, Acc=0.927), DRIVE (AUC = 0.955, Acc =0.903), are comparable with state-of-the-art vessel segmentation methods.

Application of a Consumer Health Information Needs Taxonomy to Questions in Maternal-Fetal Care

Jared A. Shenson, B.S., Ebone Ingram, B.A., Nadja Colon, M.D., and Gretchen Purcell Jackson, M.D., Ph.D.
Vanderbilt University Medical Center, Nashville, Tennessee

Abstract

Pregnancy is a time when expectant mothers may have numerous questions about their unborn children, especially when congenital anomalies are diagnosed prenatally. We sought to characterize information needs of pregnant women seen in the Vanderbilt Children’s Hospital Fetal Center. Participants recorded questions from diagnosis through delivery. Questions were categorized by two researchers using a hierarchical taxonomy describing consumer health information needs. Consensus category assignments were made, and inter-rater reliability was measured with Cohen’s Kappa. Sixteen participants reported 398 questions in 39 subcategories, of which the most common topics were prognosis (53 questions; 13.3%) and indications for intervention (31 questions; 7.8%). Inter-rater reliability of assignments showed moderate (κ=0.57) to substantial (κ=0.75) agreement for subcategories and primary categories, respectively. Pregnant women with prenatal diagnoses have diverse unmet information needs; a taxonomy of consumer health information needs may improve the ability to meet such needs through content and system design.

Introduction

Pregnancy is a common health condition that generates a diverse set of consumer health information needs, not only for the mother, but also for all individuals who are involved in the care of the mother and child. In the United States, there are approximately 6.5 million pregnancies each year, resulting in over 4 million live births. Although the duration of pregnancy is limited, it is nonetheless a 40-week health condition with a variable and changing course that can be viewed within an illness trajectory framework. Pregnant women must adopt new health practices to support their developing baby, manage existing medical conditions in the context of pregnancy, and address maternal or fetal complications. For the numerous American women each year who are pregnant in addition to having one or more existing chronic illnesses, the concurrent management of these conditions can be quite challenging. Even women with relatively “normal” pregnancies may have widely varied experiences influenced by their individual symptoms, degree of physical limitations, and effects of their lives.

Annually in the United States, approximately 875,000 women experience one or more complications of pregnancy, and approximately 120,000 children are born with birth defects. When disruptions in the pregnancy trajectory, such as a maternal complication or fetal anomaly, are identified, the conceptualization and management of the pregnancy changes drastically, especially as more information is discovered and measures to affect maternal or fetal outcomes are initiated. Parents may be faced with difficult decisions about high-risk testing or treatments, pregnancy termination, or the withdrawal of support after the birth of a child with a poor prognosis. Maternal or fetal complications can result in newborns with chronic illnesses that will require lifelong management. During this time, the mother and her support network have increased interaction with the healthcare system and may experience significant physiological, psychosocial, and financial changes.

Obtaining information is the most basic and perhaps most important action one can take to manage a health condition and make informed decisions. Consumer health information needs have been studied across a number of patient populations, but little is known about the needs of pregnant women. Among those referred for genetic counseling, the most commonly expressed concerns were the risks of certain diseases and interpretation of genetic tests. Most questions in this population were prompted by uncertainty and the need for reassurance. Studies of prenatal consultations for congenital anomalies identified diverse information needs about the nature of the anomaly, treatment options, and prognosis. They also highlighted the value of these consultations in reducing anxiety, preparing the families, and maintaining hope. Parental and caregiver information needs and information-seeking behaviors are notably dynamic over the course of a disease and as a result of interventions performed, such as surgery.
Adequately addressing the information needs of parents and caregivers can improve prenatal care as well as maternal and fetal outcomes. It is well known that appropriate prenatal education and care reduces the risk of preterm birth, pregnancy complications, and congenital anomalies. Several long term studies of nurse home visits to educate pregnant women before and after delivery have shown dramatic improvements in a wide variety of social, economic, developmental, and other health-related outcomes for the mother, family, and child.

Patients and families are increasingly turning to the Internet and other health information technologies (e.g., patient portals and mobile applications) to manage health-related information and answer questions. Complex social, economic, and cognitive factors are likely to contribute to the willingness to use such technologies and individuals’ success in finding appropriate answers. Knowledge about information needs, information-seeking behaviors, and resource preferences are needed to guide the design and support the adoption of health information technologies with the goal of improving prenatal care and outcomes. In this study, we characterized the information needs of pregnant women seen in an advanced maternal-fetal care clinic using a taxonomy of consumer health information needs developed by our research team. We also evaluated the reliability of this taxonomy in describing consumer health information needs.

**Methods**

*Population and data collection*

We examined the quantity and nature of information needs of pregnant women evaluated for a pregnancy complication or congenital disorder at the Fetal Center of the Monroe Carell Jr. Children’s Hospital at Vanderbilt University Medical Center. Patients who were 18 years of age or older were approached to take part in this study, and those women providing informed consent were enrolled. Data were collected between November 2007 and January 2009. The research protocol was approved by the Vanderbilt University Institutional Review Board.

Participants were given notebooks and asked to record questions that arose regarding the medical problems of their unborn children from the time of diagnosis through the end of their pregnancies. Questions were collected from the notebooks at the time of follow up clinic visits and at the end of the study.

*Data analysis*

Participants’ journal questions were transcribed into text files with all identifiable information removed. Multi-part questions were separated into individual question segments for coding analysis. We categorized questions using a taxonomy we developed to represent consumer health information needs (Table 1). Model development started with a representation of Clinical Information needs, which are questions requiring clinical knowledge; this model of clinical information needs has been used to organize and facilitate search in online medical information resources. This model divides clinical knowledge into four primary categories: Problems, ranging from non-specific findings such as fever to well-defined diseases such as stage 4 melanoma; Management, the general framework for addressing a clinical problem; Tests, encompassing any diagnostic modality; and Interventions, including any therapeutic modality from education to medications or surgical procedures. Subcategories, such as indications or contraindications for tests and interventions capture more detailed types of information.

A research team comprised of clinicians, medical students, and human factors experts expanded the taxonomy after analyzing a variety of consumer health communications, including journal entries, patient-provider messages exchanged via a patient portal, and patient and family interviews about informational needs. After independent and consensus review of these sources, three additional primary categories were added to the taxonomy: Medical needs, addressing desire for or delivery of medical care; Logistical needs, pertaining to the pragmatic and supporting aspects of care delivery; and Social communication, expressions of social interaction or an interpersonal relationship that is not directly related to care delivery. Subcategories were then enumerated to describe the specific question types identified in these primary categories. Our final taxonomy contains seven primary categories, 59 subcategories, and one category (Other) for content that cannot be categorized due to being incomplete or incomprehensible.

Two raters with clinical experience were trained to use the taxonomy on the first 200 questions collected. The remaining questions were independently coded by the two raters, with their responses used to calculate measures of inter-rater reliability. Cohen’s kappa was used for this purpose as it estimates the beyond-chance agreement of two raters coding with mutually exclusive categories. A gold standard consensus for all messages in the corpus was developed through discussion between the two raters and the lead taxonomy author (GPJ).

Participants and journal questions

Sixty pregnant women were enrolled in this study. The age of the participants ranged from 18 to 38 years with a median age of 24.4 years. Fifty-five participants were Caucasian, two were black, and three declined to provide their race. The average gestational age at enrollment was 26 5/7 weeks with a median of 27 weeks and range of 14 to 37 5/7 weeks. The average time from enrollment to delivery was 67.1 days for all study subjects. There were 67 prenatal diagnoses in the fetuses of the 60 women who participated in the study. The most common anomalies were gastroschisis (n = 13), spina bifida (7), ventriculomegaly (7), and congenital diaphragmatic hernia (7). Other diagnoses included holoprosencephaly, Dandy Walker malformation, hydrocephalus, cleft lip or palate, hypoplastic left heart, hypoplastic right heart, transposition of the great vessels, congenital cystic adenomatoid malformation, pulmonary sequestration, multicystic or polycystic kidney, polyhydramnios, hydronephrosis, skeletal dysplasia, talipes, absent radius, anemia, thrombocytopenia, heterotaxy, trisomy, and conjoined twins.

Nineteen women returned notebooks for question analysis, and 16 of these participants submitted at least one question during the study period. The average age of patients returning notebooks was 24.6 years with a median age of 23 years. All patients returning notebooks were Caucasian. The average gestational age at enrollment for participants returning notebooks was 28 3/7 weeks with a median of 28 6/7 weeks. For the patients who submitted at least one question, the average time from enrollment to delivery was 58.3 (range of 1–130) days. Participants returning notebooks each reported up to three congenital anomalies associated with their pregnancies, including gastroschisis, ventriculomegaly, hydrocephalus, holoprosencephaly, microcephaly, heterotaxy, congenital adenomatoid malformation, congenital diaphragmatic hernia, trisomy 6, choroid plexus cyst, mosaicism, lemon sign (a fetal skull ultrasound finding), and hypoplastic left heart syndrome. The participants reported a total of 398 questions with an average of 21 questions per participant who returned a notebook.

Health information needs

The great majority (86.3%; Table 1) of questions submitted by participants concerned clinical information needs, with most related to Problems (36.7%), Interventions (25.4%), or Management (18.6%). Clinical information needs about Tests accounted for just 5.8% of all questions. The remainder of participants’ questions addressed Medical Needs (5.0%) or Logistical Needs (8.3%). One question could not be categorized as it did not contain a question or expressed need (Other, 0.3%). No questions were identified as Social Communication.

Participants’ questions most commonly addressed specific concerns about the prognosis of their fetus (13.3%), the indications or contraindications for performing particular interventions (7.8%), policies of the medical facility where the participant and their fetus was receiving care (6.3%), the clinical presentation of the problems affecting their fetus (5.8%), and the risk factors for the problem (5.8%). Sixty-six percent (39/59) of all subcategories in the taxonomy had at least one question meeting their criteria for coding.

Within primary categories, the most commonly identified subcategories were: fetal prognosis (36.3% of all Problem questions); recommended or available interventions and the sequence/timing of management plans (each 28.4% of all Management questions); indications or contraindications for particular interventions (30.7% of all Interventions questions); interpretation of test results (60.9% of all Test questions); requests for administration of interventions (50.0% of all Medical Needs questions); and facility policies (75.8% of all Logistical Needs questions).

Taxonomy reliability

Two raters independently assigned codes to a random sample of 198 questions that were distinct from those used to train the raters in the use of the taxonomy. The raters achieved 60.1% agreement with $\kappa = 0.57$ when using the subcategories only. This represents moderate agreement beyond chance, according to the widely used criteria proposed by Landis and Koch. When the raters’ subcategory codes were mapped to their respective primary categories, percent agreement improved to 82.3% with $\kappa = 0.75$, representing substantial agreement beyond chance.

Discussion

Health information needs of pregnant women

Through the application of a novel taxonomy of consumer health information needs, we have identified and categorized diverse needs expressed by women carrying high-risk pregnancies. The journaling process by which
participants generated and recorded their questions enabled participants to reflect and focus on the many clinical information concerns that arose as a result of their fetus’s prenatal diagnosis, and greater than 85% of questions addressed such clinical information needs. Many women wished to understand the implications of the diagnosis, including the prognosis of their fetus, the clinical features of the congenital anomaly or syndrome, and the natural history of the problem. There was also significant concern about the frequency of and reasons why the problem arose and the likelihood that it would affect future pregnancies (i.e., epidemiology, risk factors and etiology).

With many of the fetuses likely to require interventions including surgery and/or medications, women wanted to know more about available management strategies and timing as well as specific details of the interventions that might be required. Among questions oriented to a specific intervention, most dealt with indications, contraindications, adverse effects, care for the infant after the intervention, and the technique by which the intervention is administered. These findings reinforce the key informational elements that should be included in both verbal discussions between clinicians and patients as well as electronic resources (e.g., patient portals, knowledge websites) developed to support this patient population. Despite the importance of testing in evaluation and management of most prenatal diagnoses, few questions addressed such information needs and most focused on the interpretation of test results that the participants had already received. This observation suggests that clinicians and genetic counselors providing support to this population may need to give additional attention to explaining the results of testing performed and the implications for problem management.

Most non-clinical information needs were logistical in nature, focused on either facility policies (e.g., restrictions on visitors to the neonatal intensive care unit) or the availability of services or equipment at a particular medical facility. These unanswered questions are an easily addressed category of unmet information needs, and providing such information may help decrease anxiety in a stressful time for the expectant mother. Few active medical needs were expressed, but these frequently included the need for maternal interventions, such as scheduling a Cesarean section, treating swollen joints, or enrolling in special birthing classes.

As the questions in our study were collected throughout a participant’s pregnancy, we observed changing health information needs as the participants progressed toward delivery. This trend was demonstrated by Participant 32, who initially asked questions about future management of her fetus once an infant (e.g., “Should I make sure any kids he will be around aren’t sick?”), but later asked questions about the impending surgery for her fetus once born (e.g., “After his surgery how long before he can have a bath?”). Such changes reflect a woman’s evolving priorities and need for answers as more information is discovered and measures to affect maternal or fetal outcomes are planned or initiated. Our ongoing research projects are evaluating patterns of information needs over time and expanding the illness trajectory framework for pregnancy.

**Taxonomy development, reliability, and implications**

In addition to describing consumer health information needs among women with complicated pregnancies, our study reports the preliminary evaluation of a novel taxonomy for their organization. Notably, our evaluation demonstrates our taxonomy’s ability to comprehensively categorize a large number of questions with moderate to substantial reproducibility. Our study reports the distribution of self-reported information needs in pregnant women experiencing a problem with their pregnancies or unborn children. The types of questions identified in other patient populations and sources of consumer health information needs (e.g., patient portal messages) may differ significantly. While we did not identify questions for all categories in our proposed taxonomy in the current study, additional work by our group evaluating other sources of consumer information needs has shown a broad range of questions across the proposed categories and sufficient coverage to justify their inclusion. Additional validation on other sources of consumer health questions and an analysis of categories with high rates of disagreement between our raters will enable refinement of our taxonomy for future use.

Other researchers have proposed taxonomies for clinical questions asked by physicians, but these are complex and contain potentially overlapping categories. Consumers’ health information needs are more varied than physicians’ and extend beyond the clinical information domain. Classifying consumer health information has been a research priority, and some studies have examined patient and caregiver needs in specific diseases. However, comprehensive taxonomies to characterize broadly the semantic types of consumer information needs independent of domain or disease have not been proposed.

As clinicians, informaticists, and systems developers collaborate to build resources to support healthcare consumers, a comprehensive taxonomy of consumer health information needs may have several important applications. First, our taxonomy could be used to characterize the information needs of populations, as we have demonstrated here for
women carrying high-risk pregnancies. Such research may identify gaps in current sources of knowledge for consumers and guide content authors in producing resources that best address information needs. Our taxonomy could also be used to triage questions or map to appropriate information resources to provide answers. The broad classification of information needs into clinical information, medical, and logistical needs may guide selection of an appropriate resource type, and the specific subcategories in our taxonomy can provide filtering of content to meet the consumer’s particular need. For example, clinical information needs might be answered by medical textbooks or corresponding consumer health knowledge resources, while logistical needs could be directed to appropriate pages on the healthcare institution’s website. Medical needs might require urgent intervention by a healthcare provider, but social communications could be addressed during normal business hours.

Limitations

Our study was conducted in an advanced maternal-fetal care setting, and the information needs observed may not generalize to women with normal pregnancies. We did not collect information about whether the participants had been pregnant previously, and the median age of our participants of 23 years was slightly younger than the average age of first-time pregnancy in the United States of 26 years. Participants’ age and parity are likely to have affected the types of questions reported. We had a relatively low response rate, as dedicated research personnel were not available to collect notebooks at all clinic visits. The questions collected likely reflect the needs of patients with more complicated pregnancies, as healthy mothers may not have returned to the Fetal Center or our tertiary care center for delivery. Although only 16 participants provided questions, we obtained 398 questions for analysis, which exceeds the quantity studied in other populations and provided coverage of two-thirds of our taxonomy.

The distribution across types of questions reported is likely biased by our method of collection and the prompts provided to participants. Our instructions most likely elicited greater numbers of clinical information needs, and pregnant women have many additional medical and logistical needs that were not captured in our study. Given the time-dependent nature of the latter types of needs, participants may have addressed them through telephone or online messaging communications rather than recording them in their journal for review at a later date. Participants were advised that questions were being collected only for research purposes. They were encouraged to use their notebooks to remind them of questions for their physicians, but explicitly instructed that their physicians would not review their questions unless asked to by the participant. The limited racial diversity of the participants providing questions in our study may also limit the generalizability of our content distribution to populations with greater racial heterogeneity.

We achieved only moderate inter-rater reliability of the taxonomy when using the subcategory codes. As compared to other studies categorizing medical content, our coding reliability is stronger, especially considering the limited training our raters received. For example, in a study of primary care doctors evaluating clinical questions from other primary care and family doctors, they achieved 55% overall agreement with $\kappa = 0.53^{35}$. Further, our substantial agreement using only primary categories suggests that these categories are well-defined and mutually exclusive. We expect that with additional training and experience using our taxonomy, inter-rater agreement will increase substantially.

Conclusions

In this study, we have proposed and evaluated one of the first comprehensive taxonomies of consumer health information needs and applied it to describe the information needs of women carrying high-risk pregnancies. Pregnant women with prenatally-diagnosed congenital anomalies or pregnancy complications have significant and diverse information needs, and the observed needs could all be categorized using our simple but comprehensive taxonomy. The unmet needs identified in this population were largely related to clinical knowledge about the prognosis, diagnosis, management, and intervention plans for the fetus. Additional easily addressed logistical needs about healthcare facility policies were identified. We achieved moderate to substantial coding reliability with our proposed taxonomy. By modeling the spectrum of consumer health information needs, our taxonomy may guide content development for healthcare consumer information resources and improve automated systems to intelligently process and answer consumers’ questions.
Acknowledgments

This research project was funded by a grant from the Vanderbilt Children’s Hospital Children’s Development Fund. We acknowledge Mary Dabrowiak, Mariann Rimer, and staff at the Fetal Center at Vanderbilt for assistance with recruitment of research subjects for this study. We are indebted to the pregnant women who participated in this study.

Adaptation of a Published Risk Model to Point-of-care Clinical Decision Support Tailored to Local Workflow

Jeffrey L. Sobel, MD1, Craig C. Baker, BSN2, David Levy, MD1, Carol H. Cain, PhD2
1The Permanente Medical Group, Oakland, CA; 2Kaiser Permanente Care Management Institute, Oakland, CA

Abstract
Electronic clinical decision support can bring newly published knowledge to the point of care. However, local organizational buy-in, support for team workflows, IT system ease of use and other sociotechnical factors are needed to promote adoption. We successfully implemented a multi-variate cardiac risk stratification model from another institution into ours. We recreated the model and integrated it into our workflow, accessing it from our EHR with patient-specific data and facilitating clinical documentation if the user accepts the model results. Our clinical leaders championed the change and led educational dissemination efforts. We describe the ad-hoc social and technical collaboration needed to build and deploy the tool. The tool complements a clinical initiative within a community of practice, and is correlated with appropriate use of nuclear imaging.

Introduction
Electronic clinical decision support (CDS) shows promise for hastening the use of the latest evidence in clinical practice, but factors in addition to the clinical content influence adoption, including integration with workflow, presentation, and ease of use1,2. The challenge of localization means that CDS built at one institution is often not directly transferable to another. Furthermore, the adoption of a tool depends on local champions, support, and change management, components of the sociotechnical approach to information systems1,3.

We report on the successful adaptation of a published multi-variate cardiac risk model, the Cleveland Clinic treadmill mortality risk calculator4 to multiple medical centers in Kaiser Permanente (KP) Northern California. KP Northern California is an integrated healthcare delivery system providing comprehensive inpatient and outpatient care for more than 3.6 million members. KP physicians practice as part of a Permanente Medical Group, with peer-to-peer collaboration through Chiefs Groups. Each KP medical center has Chiefs of various areas, who have responsibility for oversight and improvement of clinical practice within their area. Most areas are clinical specialties, though there are Chiefs Groups for areas like Technology as well.

The Chiefs of Cardiology identified the need to better assess cardiac risk in patients during treadmill testing so that nuclear imaging tests, with their balance of harms and benefits, could be used more appropriately. They reached agreement about the best evidence-based clinical model, collaborated with KP’s Technology Chiefs and KP’s Clinical Library (CL) to create CDS that fit into daily workflow, and led integration and use by clinicians. We describe the sociotechnical steps we took to assure implementation, and report on use and associated outcomes.

Methods
Clinical need and clinical content. KP Chiefs Groups meet together regularly several times a year, led by a designated Chair. These peer groups act as change agents for general KP-wide initiatives, and also elevate specialty-specific concerns in order to draw upon KP-wide resources. The approximately 150 cardiologists in KP Northern California are represented through the Cardiology Chiefs. The Cardiology Chiefs reviewed region-wide utilization and determined that there was unwarranted variation in referrals to nuclear imaging after treadmill testing, that a common evaluation algorithm (the Duke TM score5) categorized low-risk patients as intermediate risk, and that nuclear imaging test results were not always needed to make the treatment decision. Nuclear imaging tests carry a risk of patient harm through unnecessary exposure to radiation. In addition, mis-categorizing patients at low risk of coronary artery disease can lead to further invasive evaluations or unwarranted medical therapy, where the risks outweigh the benefits. High-risk patients do often benefit from invasive procedures (e.g., cardiac catheterization), but low-risk patients can and should be effectively treated through medical management.
With the 2007 publication of a novel treadmill risk model, the Chair of the Cardiology Chiefs identified an opportunity to improve and align KP’s evaluation algorithm so that more low risk patients could be appropriately identified without need for nuclear imaging. The algorithm gives mortality prognosis to patient and providers, taking into account functional capacity and other proven parameters including heart rate recovery. The algorithm is appropriate for patients with a normal baseline ECG, no known coronary disease, cardiac or renal transplantation, pacemaker or defibrillator placement, or end-stage renal disease. This algorithm had improved prognostic accuracy, allowing for appropriate conservative management. The algorithm could be encapsulated into a CDS model with the data available at the time of the treadmill test. Furthermore, it had been tested and validated in a population that included KP patients. Before implementation, the algorithm was further evaluated on a historical sample of KP patients. The algorithm is not meant to be a replacement for clinical judgment, and predicts mortality but not coronary artery disease.

**Technology infrastructure.** KP uses an electronic health record (EHR) by Epic Systems with integrated CDS. We also have robust CDS that interfaces with the EHR but lives outside it, allowing us greater flexibility in programming logic and maintenance. Clinical calculators comprise one such category of CDS, hosted through KP’s web-based Clinical Library. We extracted patient-specific data from the EHR and replicated the calculations reported in the literature using Javascript. In testing, we found that our initial results did not match those reported in the literature. Subsequently, we contacted the original researchers at Cleveland Clinic. They assisted us in translating among programming languages and more accurately matching our model parameters to their model; limitations of paper journal publication prevented reporting of the entire model. Additional testing was performed to confirm model accuracy. The cardiac risk calculator is available to all KP clinicians through the intranet at KP facilities, individual log-on to CL, or a KP-specific Toolbar on the top of every EHR screen. The Toolbar view is specific to the user’s clinical role (in this case, the Treadmill department) and integrates calculator access into EHR workflow.

**Collaboration and Implementation.** An ad-hoc group of clinicians and technologists collaborated to build the calculator. The Cardiology Chiefs directed the clinical algorithm selection and the target users, as well as the form of the CDS. They elected to implement it as a consultation tool to complement clinical judgment rather than, for example, a required step of the workflow. These decisions led to conversations with different technology groups about CDS possibilities, including KP’s EHR development team, KP’s Toolbar team, and KP’s CL team. The calculator was tested with Cardiologists for ease of use, and functionality was built to show clinical definitions upon hovering over terms, and to generate a model report in a format that meets clinical documentation needs. The documentation was designed so the user could enter it into the patient chart with one click. The CDS calculator was developed over approximately 6 months. The algorithm endorsed by the Cardiology Chiefs and the calculator were publicized through regular meetings of the Chiefs Group and in-person conferences. The Cardiology Chiefs and other subject matter experts then carried the message to their own medical centers through verbal and written communication and specific in-person tutorials. The Cardiology Chiefs regularly review data on imaging use. Model use is tracked using Webtrends.

**Results**

The risk calculator became available to all KP users through Clinical Library in early 2010 (Figure 1), and is featured on the KP-specific Toolbar within the EHR for clinicians in the Treadmill department. It takes as input patient characteristics of age, sex, history of angina, diabetes, hypertension, smoking, treadmill test results of total METs, and ECG results. The age and sex can be pre-populated from the EHR, and the other fields are entered by the physician or clinician during the patient’s treadmill test. The model calculates 3, 5 and 10-year survival. The calculator generates a summary report which is shared with the patient and easily copied to their electronic chart as well. The workflow efficiency of an automatically generated report makes clinical documentation faster, more efficient, and more complete in contrast to manual transcription methods.
From 2010 to 2014, the calculator was accessed approximately 42,800 times, over 500 times a month (Figure 2). We count a visit as complete after 15 minutes of inactivity; if the page was accessed multiple times within 15 minutes, it is counted as one visit. We did not rigorously count the total number of eligible patients for the calculator, in part because, like all decision support, we would not necessarily expect it to be consulted for all eligible patients. A rough sense of the eligible population is the total number of outpatient treadmill referrals per month, approximately 3500 referrals; this referral volume includes patients who would be excluded from the algorithm, and does not include inpatient referrals. The Cardiology Chiefs’ communication, even before go-live, and the ease of access contributed to a large volume of views, achieving 500 views per month after the first three months. The calculator complements improvement initiatives to deliver patient-specific precision medicine, reduce unnecessary and potentially harmful testing, and spread best practices throughout KP. From 2006 to 2011, use of nuclear myocardial perfusion imaging declined by 51%8, after which imaging use remained flat. Over that same interval, KP maintained nation-leading outcomes in cardiac health9. The Cardiology Chiefs continue to receive and monitor imaging use data as a component of their quarterly dashboards.

An Externally Validated Model for Predicting Long-Term Survival Exercise Stress Treadmill Testing in Patients with Suspected Coronary Artery Disease and a Normal Electrocardiogram. *Annals of Internal Medicine* 2007;147:821-829.

This calculator was developed with the permission and the generous assistance of the Cleveland Clinic.
Discussion

Electronic clinical decision support can be effective at bringing knowledge to the point of care, but several factors influence its success, including whether the CDS supports a broader change initiative. Our sociotechnical experience of bringing a published model into our institution reveals several lessons.

People. Identifying, building, and deploying a model of care required ad-hoc collaboration among many groups, even in an organization that has many established structures for collaboration. This effort included collaboration...
between multiple clinical and technology teams. KP’s Cardiology Chiefs were a critical driving force in leading this effort. The Chair of Chiefs provided the intellectual and clinical case for change. Indeed, the momentum for alignment around one algorithm preceded and fueled the creation of an electronic tool, especially as the discussions around tool creation took many months. The tool was a solution to the desire to make it easy for practicing clinicians to align with the recommended algorithm; the algorithm, while considered better than alternatives, primarily served to ensure consistency of care and reduce harm. The Cardiology Chiefs determined that the most effective target audience was cardiologists rather than primary care physicians, due to the volume of candidate patients each specialty was likely to see. They directed how the model would fit into clinical workflow, how users were likely to access the system, and the simplicity required in the user interface to the model. They also directed how the interface should yield further information about the model details in order to increase confidence in the model. Most importantly, they had the trust of their peers and understood their roles as champions of change. The tool became available in the midst of a campaign for change, and joined the arsenal of methods to create and sustain recommended referral criteria.

Replicating a published model was not completely straightforward. In re-building their model, we contacted the original researchers for their model parameters as well as technical mathematical implementation details that differed between programming languages. We sincerely thank the researchers for their generosity in sharing their model and their time.

Technology. We chose to replicate the model despite the researchers providing a publicly accessible web-based version. Before our tool was ready, the Cardiology Chiefs provided the external URL in their presentations to align care for nuclear imaging. We have found that externally hosted models are not reliably accessible, and indeed the original URL of the published model is no longer valid. A replicated model also allows us to create tighter data interfaces to our EHR. The technical replication of a model is not entirely straightforward. Our EHR does not have an easy interface to build, modify, customize or maintain an algorithmic calculator, so we decided to build it in CL, which hosts several KP-built calculators. Interoperability between the EHR and external CDS is a challenge. We initially built screen scraping functionality to extract patient age and sex from the EHR; of late we have been able to use Epic Systems’ ClinKB function to extract patient-specific data to our new calculators. We find that some data elements cannot be pulled discretely from the patient record, and had to provide the ability for users to enter the data quickly and easily into our calculator. By building CDS outside the EHR, we were able to add functionality that improved clinical adoption, including explanations of rationale and tailored clinical documentation.

Process. The collaborative designers of the tool followed principles associated with good clinical decision support, including ease of use, workflow integration, meeting a user need, and getting feedback. User-entered data is not written back into the EHR from the calculator. We automatically copy calculator results in summary form to the computer desktop clipboard, which users can then paste into a patient note. We believe this dramatically increased adoption because the function was easy to use and made it quicker to document the encounter, overcoming the inherent inertia associated with a change (Figure 4). We find that performing calculations outside of the EHR has several benefits. We have seen the calculator used as a simulation and patient education tool, where users enter hypothetical parameters to see the results. For example, the calculator can show patients the effect of quitting smoking on their mortality risk, an often powerful addition to a smoking cessation conversation. Having the calculator outside the EHR also allows clinicians to exercise clinical judgment about when the model applies.

The Chiefs Group endorsed and created awareness of the tool, in concert with the changes associated with appropriate imaging use. This involved duplicative communication: presentation at regular bi-monthly meetings, presentation at KP’s annual cardiology conference, and local peer-to-peer teaching. It also relied on clinicians’ pre-existing knowledge of where such tools are found: KP’s Clinical Library and the KP-developed toolbar within our EHR. The Chiefs Group regularly reviews quality outcomes including the appropriate use of potentially harmful imaging modalities. This pre-existing organizational structure and process allowed us to achieve steady-state use within months, made organizational deployment relatively easy, and is reusable for CDS addressing other topics. Intangible, but critical, is a physician leadership culture that supports patient-centered decisions, continuous improvement, reduction in unnecessary interventions, quality, and safety.
Limitations. The deployment of our calculator was designed to complement a broader clinical initiative, so it is difficult to isolate the effect of the tool itself on the observed outcomes. Nuclear imaging use has been on the decline throughout KP since 2006, and the calculator is one of several tools to support clinical judgment. This aligns with published evidence that multi-modal interventions are more effective than CDS alone at changing clinical practice10. The literature supports our hypothesis that peer-based communication is effective in changing practice, but we did not measure outcomes, such as intent-to-change self-assessments, associated with these communications.

Conclusion

KP is a large integrated delivery system with robust communities of medical sub-specialties, and established channels for delivering CDS. The replication and uptake of a new calculator was markedly easier because we did not have to create sociotechnical mechanisms specifically for one CDS tool. We find the adage, “If you build it, they will come” is true with qualifications. Building a tool, even a published one, is not entirely straightforward. Vigorous communication through peer communities, support of workflow, and ease of use are critical ensuring that CDS affects patient outcomes.

Data-driven Temporal Prediction of Surgical Site Infection

Abstract

Analysis of data from Electronic Health Records (EHR) presents unique challenges, in particular regarding non-uniform temporal resolution of longitudinal variables. A considerable amount of patient information is available in the EHR - including blood tests that are performed routinely during inpatient follow-up. These data are useful for the design of advanced machine learning-based methods and prediction models. Using a matched cohort of patients undergoing gastrointestinal surgery (101 cases and 904 controls), we built a prediction model for post-operative surgical site infections (SSIs) using Gaussian process (GP) regression, time warping and imputation methods to manage the sparsity of the data source, and support vector machines for classification. For most blood tests, wider confidence intervals after imputation were obtained in patients with SSI. Predictive performance with individual blood tests was maintained or improved by joint model prediction, and non-linear classifiers performed consistently better than linear models.

Introduction

When using observational data from secondary sources such as the Electronic Health Record (EHR) one needs to take into account that the information is rarely recorded in a systematic way. Indeed, the data are often sparse, and gathered at a clinician’s discretion. For example, blood tests are taken at a mixture of predefined stages in a patient pathway and clinically driven sampling. Thus, if predictive analytics relies on regularly sampled data, imputation methods need to be employed such that regular sampling is simulated. However, in the case of very irregular sampling a classical imputation approach may not be sufficient. In this paper we study prediction models for real time evaluation of patients admitted for gastrointestinal surgery with respect to surgical site infections (SSI) post-operatively.

SSIs are among the most common hospital-acquired infections. In fact, they represent up to 30% of all hospital acquired infections. 1,2 SSIs are associated with considerable morbidity and mortality. A mortality rate of 3%, prolonged stay up to 10 days and a significant decrease in quality of life, are reported. Similarly, readmissions related to SSIs are associated with a considerable increase in healthcare cost, up to 27,000 USD per readmission. 3 This persistent in-hospital morbidity is particularly associated with surgery for colorectal cancer. 4,6

The American College of Surgeons Surgical Quality Improvement Program (ACS-NSQIP) and The Centers for Disease Control and Prevention divide SSI into three subtypes based on the anatomical location of the infection, i.e. superficial, deep incisional and organ space. 4 Superficial infections can usually be cured with oral antibiotics and surgical debridement. In contrast, deep and organ space SSI require intravenous antibiotics, percutaneous drainage and laparotomies.

The patient specific risk factors for SSI are well documented and reported. A recent study by Lawson et al.4 identified open surgery, ulcerative colitis, older age, overweight, smoking, disseminated cancer and prolonged operation time as factors contributing to an increased risk of SSI. However, they found that different risk factors were associated with

1164
superficial and deep SSI. High Body Mass Index (BMI) and revision of an osteomy were associated with superficial SSI, whereas prolonged operation time and perioperative transfusions were associated with organ space SSI.\textsuperscript{4,6}

Using blood test results as predictive features in a data-driven decision support system is useful since these are performed relatively often with little burden to the patient. Therefore it is possible to estimate the expected information content of a blood test at stages in a patient trajectory.\textsuperscript{7} However, combining different tests performed at different stages in the trajectory, a necessity when observational data are used, presents challenges that we address here. The information from tests may be further combined with other data such as textual features that are predictive of complications.\textsuperscript{8}

For the purpose of this manuscript we denote the sparsity of the clinical data as missing data. Missing data percentages are even larger for some studies such as clinical laboratory measurements or biomarkers. Despite of the efforts made to develop statistical methods for handling missing data, there is no global best approach because they inevitably depend on stated assumptions.

In this work we present methods for predictive modeling in a context of features that have strongly irregular sampling patterns. We analyze different smoothing and interpolation/imputation techniques and different input spaces to predict SSI using blood tests. Finally we look at linear and non-linear classifiers to do the predictive modeling. Figure 1 shows an overview of the data-driven decision support system used in this work for SSI prediction.

\textbf{Methods}

We extracted a cohort of patients based on relevant International Classification of Diseases (ICD10) or NOMESCO Classification of Surgical Procedures (NCSP) codes related to severe post-operative complications, and in particular to surgical site infections, from the EHR of the Department of Gastrointestinal Surgery at the University Hospital of North Norway. The selection of codes was guided by input from clinicians at the hospital. The cohort identified as control was matched with patients that did not have any of these codes but were otherwise similar in terms of which blood tests were performed. Additionally, a text search was performed to ensure that the controls did not have the word “infection” in any of their post-operative text documents. This resulted in a cohort of 101 cases and 904 matched controls. Patients with codes indicating superficial infections were excluded. A set of 10 different types of blood tests were defined as clinically relevant and extracted for all patients from their EHRs. All tests were not available every day, which results in a high percentage of missing values when analyzing data on that scale, yielding to a non-uniform time sampling description for each patient (Fig. 2). The data matrix is hence sparse over lab tests and time, therefore constituting a challenging data set to work on. A method denoted bootstrap nonparametric resampling\textsuperscript{9,10} was designed to statistically describe the influence of imputation. Thus, the population mean and corresponding 95\%

Figure 2: Available laboratory test measurements for one control (a) and another infected (b) patient. The $y$-axis shows the available tests for a patient, with no specific order, as each patient can have different number of tests. The $x$-axis represents the day when each test was recorded, being $t = 0$ the day when the first test was recorded. Vertical black line indicates the surgery day, whereas red line indicates the infection day.

CI was computed on a daily basis for each test, obtaining an averaged trend.

The data represent a diverse group of patients undergoing gastrointestinal surgery such that results can generalize across this group. The basic demographics of the cohort are given in Table 1.

**Feature extraction for sparse clinical data.** Working with complete datasets is the standard scenario for most statistical and machine learning methods. In the literature, there are works that simply omit patients with any missing data. However, discarding patients with missing data may lead to incorrect assessments or prognostics. To avoid this situation, different methods have been proposed to deal with observations at non regular sampling. These methods can be categorized into: (1) smoothing or interpolation techniques; (2) spectral analysis tools such as wavelets or Lomb-Sargle Periodogram; and (3) kernel methods.

Regarding interpolation methods, the well-known Last Observation Carried Forward (LOCF) scheme imputes the last non-missing value for the following missing values. Some works support that LOCF should not be considered as the primary approach to the treatment of missing data. Alternatively, Lasko et al. suggest using Gaussian Process (GP) followed by a warped function, and we follow this approach in this paper. The warped function is intended to adjust for the fact that rapid changes in temporal variables in connection with active treatment is often followed by long periods of apparent stability leading to highly nonstationary processes. The time warping function can be constructed as

$$d' = d^{1/\alpha} + \beta$$  

where $d$ is the original distance between two adjacent observations, and $\alpha$ and $\beta$ are free parameters to be tuned. This function converts non-stationary clinical data into a stationary process which allows the use of a GP to deal with sparsity.

A random process $f(t)$ is a Gaussian process if, for any finite set of values of $t_1, t_2, \ldots, t_k$, the variables of the corresponding random vector $\mathbf{f} = f(t_1), f(t_2), \ldots, f(t_k)$ are jointly normal (Gaussian). Element $K_{ij}$ of the covariance
matrix $K$ of $f$ is $k[f(t_i), f(t_j)]$ where $k[·, ·]$ is a covariance (kernel) function, such as the radial basis function, or the squared exponential function. Using Bayes theorem, the posterior density function for an (unseen) random variable $f_* = f(t_*)$ conditioned on the observed $f$ becomes
\[
P(f_*|f) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left[ -\frac{(f_* - \hat{f})^2}{2\sigma^2} \right],
\]
where the posterior mean value is given by $\hat{f} = k^T K^{-1} f$; and the posterior variance is $\hat{\sigma}^2 = \kappa - k^T K^{-1} k$. In this expression, element $i$ of the vector $k$ is $k[f(t_i), f(t_i)]$, $i = 1, \ldots, k$, and $\kappa = k[f(t_i), f(t_i)]$. In Gaussian process regression, $\hat{f}$ is used as the estimate, or prediction, of $f_*$, while $\hat{\sigma}^2$ provides the level of confidence in the prediction. Thus, we use this approach in this manuscript to deal with sparse data.

**Prediction Analytics.** The SSI prediction is performed from a data-driven approach based on machine learning techniques. These techniques learn the underlying predictive model from a set of $d$-dimensional examples known as training set, where $d$ corresponds to the number of features which are supposed to be relevant to the predictive task. The generalization of the model is estimated using an independent set of examples known as test set. Among the plethora of machine learning techniques proposed in the literature, Support Vector Machines (SVM) have shown to provide good generalization capabilities, and they have been considered in this work. We next briefly describe linear and non-linear SVM classifiers as well as the feature selection (FS) methods used in this work.

**Linear and non-linear SVM.** The data model for a linear classifier is given by $y = \langle x, w \rangle + b$, where $x$ is the feature vector, $w$ is the weight vector of the linear model, $b$ is the bias term, $y$ is the classification output and $\langle ·, · \rangle$ denotes the inner product. We focus on the Support Vector Machine (SVM) classifier, with a regularization term such that model complexity is controlled, and the upper bound of the generalization error is minimized. These theoretical properties make the SVM an attractive approach for predictive modeling.

Denote $D = \{x_i, y_i\}_{i=1}^n$ as a binary labeled training set, where $x_i \in \mathbb{R}^d$ and $y_i \in \{-1, +1\}$. The SVM classifier seeks the separating hyperplane with the largest margin between the two classes. The hyperplane optimally separating data is defined from a subset of training data named support vectors (SV), and it is obtained by minimizing $\|w\|^2$, as well as the classification losses in terms of a set of slack variables $\{\xi_i\}_{i=1}^n$. Considering the $\nu$-SVM introduced by Schölkopf et al. and a potential non-linear mapping $\phi(·)$, the $\nu$-SVM classifier solves
\[
\min_{w, (\xi_i), \nu, \rho} \left\{ \frac{1}{2} \|w\|^2 + \nu \rho + \frac{1}{n} \sum_{i=1}^n \xi_i \right\}
\]
subject to:
\[
y_i(\langle \phi(x_i), w \rangle + b) \geq \rho - \xi_i, \quad \rho \geq 0, \quad \xi_i \geq 0 \quad \forall i = 1, \ldots, n.
\]
The variable $\rho$ adds another degree of freedom to the margin, and the margin size linearly increases with $\rho$. The parameter $\nu \in [0, 1]$ acts as an upper bound on the fraction of margin errors, and it is also a lower bound on the fraction of SVs. An appropriate choice of non-linear mapping $\phi$ guarantees that the transformed input vectors are more likely to be linearly separable in the (higher dimensional) feature space.

The primal problem in Eq. (3) can be solved using its dual formulation, yielding $w = \sum_{i=1}^n y_i \alpha_i \phi(x_i)$, where $\alpha_i$ are Lagrange multipliers corresponding to constraints in Eqs. (3–4). Thus, the decision function for any test vector $x_*$ is given by
\[
f(x_*) = \sum_{i=1}^n y_i \alpha_i K(x_i, x_*) + b
\]
In order to predict the label of $x_*$, the sign of $f(x_*)$ is used. The so-called SV are those training samples $x_i$ with corresponding Lagrange multipliers $\alpha_i \neq 0$. The bias term $b$ is calculated by using the unbounded Lagrange multipliers as $b = 1/k \sum_{i=1}^k (y_i - \langle \phi(x_i), w \rangle)$, where $k$ is the number of non-null and unbounded Lagrange multipliers.
The use of Mercer kernels allows to handle the non-linear algorithm implementations as $K(x_i, x_j) = \langle \phi(x_i), \phi(x_j) \rangle$. In this work, we use two well-known Mercer kernels: the linear kernel $K(x, z) = \langle x, z \rangle$, and the Radial Basis Function (RBF) kernel $K(x, z) = \exp\left(-\frac{\|x-z\|^2}{2\sigma^2}\right)$, where $\sigma$ is the width parameter, to be tuned together with $\nu$ free parameter.

**SVM Feature Selection.** Feature Selection (FS) strategies have been widely studied in the machine learning literature. The purpose of FS is to choose a subset of features that are relevant for classification or regression tasks, while at the same time maintain or improve the performance of the learning method in comparison of using the whole set of available features. Regarding FS for SVM linear classifiers, the Recursive Feature Elimination (RFE) method has been shown to compare very favorably to many of the classical FS methods. Improved versions of SVM FS methods that included non-linear kernel functions have been described.

**Results**

In this section, we evaluate the capabilities of different ways to deal with sparse data and show the effects on performance results. Furthermore, linear and non-linear classifiers are benchmarked to predict SSI when using data from different laboratory tests obtained from the EHR. Firstly, each laboratory test was used separately to predict SSI using linear and non-linear classifiers after dealing with sparse data. Secondly, we analyzed the use of multiple blood tests to check the impact of combining them as well as the temporal-feature relative importance.

Our database was imbalanced, with 101 and 904 cases in the positive and negative classes, respectively. This is a common situation for clinical databases, where different number of patients are assigned to each class. Though previous studies have demonstrated that balanced classes in the training set often improve the overall classification performance, we used an undersampling strategy (discarding samples from the majority class), such that the training set was built by enforcing balanced classes. In order to represent correctly the population, we selected a different number $S$ of subsets of the negative class with 101 samples in each, and computed classification performances in terms of the mean and the standard deviation of the results for each subset.

We used a cross-validation strategy to ensure the generalizability of the prediction analytics. First, we balanced the classes and then we split the data into training and tests subsets (80%-20%). A leave-one-out (LOO) cross-validation was carried out on the training subset of the balanced set for selecting the classifier free parameters. Thus, the SVM classifier was retrained $R$ times, where $R$ is the number of cases per class for balanced classes ($R = 101$ in this work). In this work, accuracy was considered as performance measurement for free parameter tuning.

**Effect of the imputation methods on performance.** Two different strategies, namely, LOCF and warped-GP, were considered to deal with the extreme sparsity present in the input space as given by different tests measured in a patient at different days.

*Last observation carried forward (LOCF).* The last observed non-missing value was used to fill in the missing values into a regular time sampling grid with a daily time basis, i.e., if we have a missing value, we consider instead the previous value if it exists. A nonparametric resampling method to represent the averaged trend was applied to statistically describe the influence of imputation. See two examples in Fig. 3 (a) for C-Reactive Protein (CRP) and Fig. 3 (b) Potassium tests. It is well known that CRP is a good predictor for complications after colorectal surgery. We note that our pattern of CRP levels following surgery is consistent with that observed by Singh et al.

For most blood tests, wider confidence interval (CI) after LOCF imputation were obtained for patients with SSI. Specifically, the data recorded at the day of surgery are highly noisy, as it can be seen in Fig. 3. For this reason, we excluded these values from our analysis, and we focused only on pre-operative and post-operative periods.

*Warped function and GP.* Using the time warped function Eq. (1), for each test we selected values of $\alpha$ and $\beta$ parameters which maximize the accuracy of the predictive system. For this purpose, we used a grid search over values $\alpha \in [1, 10]$ and $\beta \in [0, 100]$. A LOO strategy was considered to ensure generalizability. The use of GP regression allows us to transform a set of finite measurements contained in the EHR from each blood tests into a continuous longitudinal function. In this way, missing values are inferred, allowing pre-operative and post-operative feature extraction.
Prediction of SSI. Table 2 shows the pre-operative and post-operative classification performance in terms of accuracy (mean and 95% CI) for each blood test individually when considering a LOCF strategy and warped function with GP methodology. Pre-operative stage was defined as four days before surgery, and four days immediately after surgery were considered in the post-operative stage (i.e., $d = 4$). We considered linear and non-linear SVM classifiers for the prediction of SSI, and we benchmarked results with a simpler logistic regression classifier. Results suggest the presence of strong non-linear relationship among input features for the analyzed tests, as given by consistently achieving the best performances when a non-linear SVM was considered. Note also that the post-operative predictive power is in general higher than pre-operative, which is to be expected.

Table 2 also shows that performance depend on the method used to deal with sparsity. In general, the combination of warped function and GP improved results, however, it can be seen that for some tests LOCF is better.

Feature selection. The results in Table 2 suggest that a non-linear classifier provides a better prediction of SSI. Taking that into account, we obtained the accuracy using a non-linear SVM classifier both for pre-operative and post-operative stages. First, we considered all blood tests together, i.e., $d = 40$ (first row in Table 4) and then we applied the FS method denoted as RBF RFE (second row in Table 3). Table 3 shows the mean and 95% CI accuracy when using both schemes. Comparison of Table 2 and Table 3 shows that the model built with all tests provide higher accuracy. Note also that a similar or tending to higher accuracy is obtained with the FS method, so it is appropriate for addressing the interpretation of the relevance and meaning of the input space.

Figure 4 summarizes the results of FS with non-linear SVM (with RBF kernel) in terms of relevance of blood tests. Towards that end, we calculated how many times every feature is selected (frequency of relevance), separately for the pre-operative and post-operative stages. From these values, a relevance index for each blood test is obtained as the normalization of the cumulative frequency of relevance by number of features per day ($d = 4$) times the number of subsets ($S = 5$). Note that a comparison with baseline level is remarkable for all tests (excepts sodium), indicating the relevance of the intra-patient pre-operative levels on each test. In general terms, thrombocytes reached the highest prediction information, together with ALP, CRP, albumin, creatinine and leukocytes, most of them being consistent with previous results. Although less relevant in the pre-operative state, the other tests (potassium, ALAT, and hemoglobin) also included highly relevant information in the post-operative state.
Table 2: Pre-operative and post-operative prediction results in terms of accuracy (mean and 95% CI) for each test individually and different classifiers: Logistic regression (first row), linear SVM (second row), and non-linear SVM (third row). The best accuracy values for pre-operative and post-operative are shown in bold.

CRP: C-Reactive Protein; ALAT: Alanine aminotransferase; ALP: Alkaline phosphatase

Discussion

The results clearly demonstrate the utility of blood tests for predicting SSIs both pre- and post-operatively. These results will potentially be useful as part of a data-driven online clinical decision support system that can enable clinicians to improve post-surgical recovery rates. With proper warning necessary actions such as closer follow up and risk stratification can be performed.

We chose to generate the cohort in a way that may open the problem to being in a sense “too easy”. Since our emphasis was on methodology development, we chose to generate a cohort where the testing patterns were similar in the negative and positive classes. This aids the algorithmic development, but opens the possibility that the problem does not entirely reflect the clinical scenario since many in the negative class would not be suspected of having SSIs. Nevertheless, this does not invalidate the methodology development or the results. Indeed, if the envisioned decision support system is thought of as a warning system flagging patients at risk, the cohort reflects well the actual clinical setting.

Figure 4: Pre-operative and post-operative relevance index for each blood test using LOCF (a) and Warped-GP (b).

Testing is often done at the discretion of the clinician, and often not driven by formulaic rules. This is part of the reason for the irregular sampling in the data, leading to the problem formulation in this paper. Thus, the testing pattern for patients in inpatient care itself may be an informative feature of post-operative complications independent of the test results. By generating the cohort by matching testing patterns, this information is largely lost and only the test results remain as the informative features.

In retrospective EHR studies there is inevitably the chance of a censoring effect where a test result informs the clinician of a possible complication and the clinician takes appropriate and successful action to avoid the complication. Then the pattern for complication will be present, but not the complication itself, which leads to effectively mislabeled data, known as confounding medical interventions. In our case this is unlikely to be a large issue since there is little information to act on to avoid a SSI such that most cases are likely to be correctly coded.

Using ICD10 and NCSP codes to phenotype a cohort there is a significant chance of miscoding leading to labeling errors. However, there is a far greater chance of false negatives (i.e., missing coding) than false positives. In this case, the positive class will be correct while the negative class may contain erroneous labels. When generating the cohort by matching we alleviate this since a minority of patients get SSIs, and additionally we check for the Norwegian equivalent of the word “infection” in the post-operative notes, which would almost surely appear if the patient actually got an SSI.

In the literature several approaches for reducing SSI have recently been described. Wick et al, used a multidisciplinary approach to reduce SSI and showed that formation of small groups of front line providers to address SSIs reduced SSIs by 33%. One of the most popular existing risk models for SSI is the National Nosocomial Infection Surveillance (NNIS) Basic SSI Risk Index. Also, recently, a logistic regression model for predicting SSIs was developed by van Walraven et al. A more data driven approach has been used by Gbegon et al. predicting SSIs in real time within 30 days of the operation. However, these studies rely on clinical data, demographic and other information but do not take blood tests into account. There exists validated risk assessment tools for post-operative complications, including the Surgical AGPAR Score and the POSSUM score. Both of them assess the immediate post-operative risk based...
on a number of variables. The American College of Surgeons’ NSQIP risk calculator was developed as a preoperative risk stratification tool.\textsuperscript{33}

In this context our work presents a path forward to combine clinical variables along with demographic and other data with test results that can be updated in real-time and provide a live assessment of a patient’s progression.

**Conclusion**

We have shown that our model has a potential for real time prediction and identification of patients at risk for developing SSI. This can give decision support to clinicians, and treatment plans can be adjusted taking into account the identified increased risk.

Appropriately adjusting the temporal structure of blood tests can dramatically improve the system accuracy. This can provide the basis for a future on-line system that alerts clinicians to patients at risk for complications, such that appropriate action can be taken. With early identification of these patients, improved clinical outcomes, reduced readmissions and cost savings are likely.

Abstract

Ginkgo biloba is a widely used herbal product that could potentially have a severe interaction with warfarin, which is the most frequently prescribed anticoagulant agent in North America. Literature, however, provides conflicting evidence on the presence and severity of the interaction. In this study, we developed text processing methods to extract the ginkgo usage and combined it with prescription data on warfarin from a very large clinical data repository. Our statistical analysis suggests that taking concurrently with warfarin, ginkgo does significantly increase patients’ risk of a bleeding adverse event (hazard ratio = 1.38, 95%CI: 1.20 to 1.58, p<.001). This study also is the first attempt of using a large medical record database to confirm a suspected herb-drug interaction.

Introduction

The National Center for Complementary and Alternative Medicine (NCCAM) is an agency in the U.S. Department of Health and Human Services dedicated to defining the usefulness and safety of complementary therapies through rigorous scientific research. Complementary and alternative medicine (CAM) is a term used to describe two different treatments. NCCAM defines “complementary therapies” as “non-mainstream” approaches used in combination with allopathic medicine, whereas “alternative therapies” are those that replace conventional medicine with non-mainstream approaches (1). Although CAM was previously divided into different categories, NCCAM states there are two basic subgroups – natural products, and mind and body practices. Natural products consist of botanicals (including herbs), vitamins and minerals, and probiotics. These natural products are commonly found in dietary supplements.

According to the National Health and Nutrition Examination Study (NHANES 2003-2006), approximately half of all Americans use supplements and spend $15 billion annually (2,3). Ginkgo biloba is one of the most purchased dietary supplements used in the United States, and is used to treat a variety of conditions such as memory deficits or dementia, intermittent claudication, tinnitus, and many other health concerns. One of the main concerns with ginkgo use is increased bleeding risk. Ginkgo may decrease platelet aggregation and many case reports have suggested increased bleeding risk, as verified by a systematic review (4). The increased bleeding risk posed by ginkgo may therefore be of great concern in persons taking anticoagulants such as warfarin.

Warfarin is one of the most frequently prescribed anticoagulant agents in North America. Warfarin works by blocking the effects of vitamin K, inhibiting the synthesis of clotting factors and preventing thromboembolic events. Despite its widespread use, warfarin therapy is associated with increased risk of hemorrhage and interacts with various medications, dietary supplements, and some foods. Patients taking warfarin are monitored closely for abnormal or increased bleeding and receive frequent blood testing for the prothrombin time international normalized ratio (INR) to ensure the warfarin dose is adequate yet safe. A high, out-of-range INR is often associated with warfarin drug-drug or drug-herb interactions and indicates increased risk of bleeding.

The interaction between ginkgo and warfarin has not been adequately studied in patients taking both products in combination. Since ginkgo combined with warfarin is a potentially severe interaction that may result in bleeding, we chose it as the first test case in a research study that evaluated the possibility of this occurrence in patients identified as being on both products. In this study, we mined a large national clinical data repository called VINCI to
investigate the ginkgo-warfarin interaction. With over 20 million unique patients and extensive medical records, we were able to identify thousands of patients who were using ginkgo and warfarin concurrently.

**Methods**

**Data Source**

We used existing electronic medical record data from the Veterans Administration (VA) Informatics and Computing Infrastructure (VINCI) database. Available to VA researchers, this database includes over 20 million unique patient electronic medical records from all VA hospitals and clinics in the United States, which are compiled using uniform coding of data elements. VINCI also includes a suite of research tools to facilitate analysis, such as natural language processing.

To identify concurrent usage of ginkgo and warfarin, we queried both structured and free text data in the VINCI database. We queried the clinical documents table for information containing the terms “ginkgo” and variants “ginkgo” and “ginko.” Of the matching documents approximately 50% used the terms ginkgo, 25% gingko, and 25% ginko. We also queried the filled prescriptions table for the term “warfarin” and its alternate brand names (Jantoven, Coumadin, Marevan, Lawarin, Waran, and Warfant). There were no occurrences of the alternate brand names, since they are not on the VA formulary, so future queries only used warfarin.

**Natural Language Processing (NLP)**

An NLP module was developed to further process the notes retrieved by the ginkgo query. We prioritized the NLP of ginkgo cases because little structured data are available for herbal supplement usage (Table 1).

For NLP development, we randomly selected 100 patients with notes containing any mention of ginkgo or one of its spelling variants (n=441) to create an annotated data set. Two reviewers developed a guideline to establish true positive cases and conducted chart review. The inter-reviewer agreement was calculated (Cohen’s kappa = 0.82).

Based on the manual review, we first crafted a set of processing rules to classify highly prevalent document templates (n=41). These processing rules identified positive occurrences of ginkgo in patient supplement lists recorded within the documents as well as negative occurrences of ginkgo in standard documents instructing the patient not to take ginkgo prior to an upcoming surgery. Then using the annotated documents that do not contain templates, we trained a support vector machine (SVM) model to classify the remaining notes not covered by the template rules. The SVM developed was conducted using the Waikato Environment for Knowledge Analysis (WIKAI) sequential minimal optimization (SMO) algorithm with the default parameters and bag-of-word features. The final NLP module first applies the template rules and then applies the SVM model.

To test the NLP module, we further annotated another 200 randomly selected notes retrieved by the ginkgo query and calculated the sensitivity and specificity of the NLP module. On the 200 randomly selected ginkgo notes, the NLP model reached a sensitivity of 97%, specificity of 87%, and F measure of 93%. Applying this NLP model to all ginkgo related notes (n=836,506), 600,107 documents and 132,061 patients were identified as positive.

The documentation of ginkgo usage often does not specify the start date or duration. The warfarin exposure was calculated using the VINCI pharmacy fill record. Co-administration was established when patients were exposed to both ginkgo and warfarin. Combining the NLP results with medical fill records, we found 54,139 combined use events in 9,862 distinct patients (Table 2).

**Sample Size**

The study sample consisted of all patients in the VINCI database that had at least one warfarin order during the study period (years 2008 to 2014), which provided a sample size of n=807,399 patients. Of these, n=11,003 also used ginkgo at least once concurrently with warfarin, and so composed the warfarin + ginkgo group (gingko group). The remaining n=796,396 formed the warfarin only group (non-gingko group).
Bleeding Events

Bleeding is the most frequent complication of warfarin therapy (5). A large body of evidence evaluating the safety of warfarin therapy is available. In clinical trials, bleeding events are classified as fatal, major, life-threatening, clinically significant, overt, or minor. ‘Major bleeding’ is the most common safety outcome cited in clinical trials but the definition varies across trials. According to the International Society on Thrombosis and Hemostasis, the definition of major bleeding should be based on objective criteria and only include events which are life-threatening, utilize major health-care resources, or result in death (5). A list of ICD-9 codes (Table 2) for bleeding events based on the above criteria have been identified and used in a number of clinical trials and analyses evaluating warfarin safety (5-8). We used this list to identify bleeding events in our patient population (Table 3).

Statistical Analysis of Ginkgo-Warfarin Interaction

The comparison of bleeding events between the warfarin only and the warfarin plus Ginkgo groups was made using Cox regression. The cumulative bleeding risk is displayed graphically with Kaplan-Meier plots. Multivariable Cox regression models were also fitted, controlling in a fixed covariate fashion for several binary comorbidities: age 75 or older, history (Hx) of heart failure, Hx of high blood pressure, Hx of vascular disease, Hx of stroke, Hx of diabetes, Hx of hypertension, Hx of renal disease, Hx of liver disease, and Hx of alcohol use. These comorbidities were identified using ICD codes.

Results

At least one bleeding event was noted in 143,360 of the n=796,396 non-ginkgo, warfarin only, patients (18.0%) and in 2,484 of the n=11,003 warfarin patients who at some point while on warfarin were also noted to be using ginkgo (22.6%). It was discovered, however, that the first bleeding event was most frequently noted on the first day that
warfarin was noted in the EMR (24.4% of non-ginkgo patient with bleeding event, and 16.4% of ginkgo patients with bleeding event). The bleeding events after day 1 were relatively uniform across the follow-up period. (Table 4)

It is not likely the bleeding would occur so frequently on the first day of warfarin use, since warfarin does not have that rapid of an anticoagulant effect. Apparently, many patients that were already on warfarin went to a Veterans Administration (VA) hospital to seek care for a bleeding event. These could have been patients who already had an EMR encounter at the hospital, or a patient who sought care there for the first time. Either way, the bleeding event would give the providers cause to inquire about warfarin use and to note its use in the EMR. So on that day, many of these patients had warfarin use noted in their EMR for the first time. To reduce this measurement bias, the first 30 days of warfarin use (first 30 days of follow-up) were next eliminated from the dataset, which reduced the sample size somewhat. This also insured that warfarin dose was stable at a level acceptable to the provider and warfarin induced anticoagulation had reached a therapeutic level. This effectively eliminated the uncharacteristic spike in bleeding events at the first day of follow-up, which was now day 31 on warfarin. (Table 4)

Next, we created a new day 1 of follow-up. For the non-ginkgo group, this was day 31, recoded to day 1. For the ginkgo group, it was the first day that ginkgo was noted in the EMR after the first 30 days of warfarin use. For some ginkgo patients, this was warfarin day 31, and for others, it was somewhat uniform across days after that. The first day was recoded to day 1 in this group, as well. The follow-up, then, represented the days on warfarin only for the non-ginkgo group, and days on warfarin + ginkgo combination for the ginkgo group. Follow-up ended with the first bleeding event, or the end of therapy of these agents in the EMR, whichever came first. This is consistent with a time to first event survival analysis (Cox regression).

To investigate if a bleeding event created an information bias, where the provider would more carefully inquire about ginkgo use if a bleeding event occurred, we created a table in a case-control fashion (Table 5). If bleeding
created an obvious information bias, giving the provider cause to inquire about ginkgo use, ginkgo would be expected to be noted in the EMR more often than in patients who never have a bleeding event. The opposite occurred. Ginkgo was noted one-fifth as often in patients with at least one bleeding event compared to patients without a bleeding event (Table 5). This reveals that a ginkgo information bias is only subtle, if it does exist.

Table 5. Probability (%) of noting Ginkgo in the EMR, conditional upon a bleeding event was also noted in the EMR.

The follow-up was limited to one year, under the assumption that if ginkgo interacts with warfarin, its effect should be seen by then. It was suspected that ginkgo might first appear in the EMR because a bleeding event had occurred, giving the provider reason to more carefully inquire about herbal use with the patient. Table 6 shows the patients with follow-up periods of days 1, 2, or 3, to determine if bleeds are occurring at the time of beginning of follow-up. This was true about one-third of the time in ginkgo group. Unfortunately, there is no way to extract from the EMR when ginkgo exposure actually first occurred, just when its use was first recorded.

Ignoring time-at-risk, a bleeding event was observed in in 331 (3.4%) patients in the warfarin plus ginkgo group and in 38,816 (5.4%) patients in the warfarin only group. After accounting for time-at-risk in a univariable Cox regression model, ginkgo was associated with a higher risk of bleeding (hazard ratio = 2.08, 95%CI: 1.87 to 2.32, p<.001). The association is shown as a Kaplan-Meier curve in Figure 1. The association was unchanged after adjusting for co-morbidities (hazard ratio = 2.08, 95%CI: 1.87 to 2.32, p<.001).
To assess if the association was just a matter of the high incidence of bleeding noted on the first day of ginkgo follow-up, the analysis was repeated after dropping subjects with one day of follow-up. This left a sample size of n=6,759 with in the warfarin plus ginkgo group, with 210 bleeding events. Ignoring time-at-risk, a bleeding event was observed in 210 (3.1%) patients in the warfarin plus ginkgo group and in 38,408 (5.4%) patients in the warfarin only group. After accounting for time-at-risk in a univariable Cox regression model, ginkgo was associated with a higher risk of bleeding (hazard ratio = 1.38, 95%CI: 1.20 to 1.58, p<.001). The association was unchanged after adjusting for co-morbidities (hazard ratio = 1.38, 95%CI: 1.20 to 1.58, p<.001).
Figure 2  Kaplan-Meier graph of risk of bleeding for one year of follow-up, after dropping patients with only one day of follow-up, which hazard ratio from a univariable Cox regression model.

**Discussion**

Although the potential bleeding risk of *Ginkgo biloba* has been much discussed in the literature, initial concerns were based on case reports. These reports described a temporal association between ginkgo use and the bleeding events (4). Some evaluations of randomized controlled trials have not found a higher bleeding risk (10). A systematic review and meta analysis of 18 randomized controlled trials looked at the impact of ginkgo on hemostasis parameters associated with bleeding risk and found a significant reduction in blood viscosity. However, there were no effects on other factors, such as ADP-induced platelet aggregation, fibrinogen concentration, activated partial thromboplastin time, and prothrombin time. Thus the authors concluded there was no higher bleeding risk. Another evaluation looked at claims data in the Taiwan National Health Insurance Research Database (11). The authors concluded there was no significant correlation to the risk of hemorrhage but did note that caution should be exercised in elderly persons and those with known bleeding risk.

Thus the existing literature does not confirm the ginkgo-anticoagulant interaction. The effects and true risks of this interaction are difficult to estimate, based on the limited quantity and quality of existing reports. Leveraging a large database, with documentation of herb use in a high number of patients with cardiovascular disease, as is the case with this project, a positive signal between warfarin and ginkgo was found. This is new information that may help to elucidate the relationship between gingko and warfarin usage and bleeding events.

One limitation we noted is that the documentation rate of herb usage in medical records is possibly low. As shown in the Table 7, the NLP extracted ginkgo use in this study is fairly consistent with those reported in the literature.
Table 7. Prevalence of Ginkgo usage derived from the NLP of VHA notes and the prevalence reported by literature.

Another limitation of study is the lack of detailed information in the EMR. The length of time of ginkgo is obviously longer than what is noted in the EMR. This could have impacted the statistical result. However, the separation of the two curves in Figure 2 occurring after day 30 of follow-up helps support the increased risk observed with the warfarin-ginkgo combination. The dosage and frequency of herbal product use is not regulated and rarely recorded. Information bias is well-known to exist in medical records, with missing information and more complete information being in sicker patients (17).

A final limitation is the possibility of confounding by other medications. That is, some patients might have received other medications that could have increased their risk of bleeding, such as aspirin or other antiplatelet agents. No attempt was made in this study to collect those data in order to control for such medications. However, to use confounding by other medications as an explanation for the direction of the observed study outcome, with higher bleeding risk for the warfarin plus ginkgo group, these other medications would have to have been prescribed more often in the warfarin plus ginkgo group, and it is not likely providers would have chosen to do that.

Despite the limitations, our analysis provides information that is previously unavailable to researchers and clinicians. Given the wide use of ginkgo in the US population, the bleeding risks associated with gingko-warfarin usage is worth noting. In the future, we plan to investigate other suspected herb-drug interactions.

ABSTRACT

Clinical concept recognition (CCR) is a fundamental task in clinical natural language processing (NLP) field. Almost all current machine learning-based CCR systems can only recognize clinical concepts of consecutive words (called consecutive clinical concepts, CCCs), but can do nothing about clinical concepts of disjoint words (called disjoint clinical concepts, DCCs), which widely exist in clinical text. In this paper, we proposed two novel types of representations for disjoint clinical concepts, and applied two state-of-the-art machine learning methods to recognizing consecutive and disjoint concepts. Experiments conducted on the 2013 ShARe/CLEF challenge corpus showed that our best system achieved a “strict” F-measure of 0.803 for CCCs, a “strict” F-measure of 0.477 for DCCs, and a “strict” F-measure of 0.783 for all clinical concepts, significantly higher than the baseline systems by 4.2% and 4.1% respectively.

INTRODUCTION

With rapid growth of medical informatics technology, a large number of electronic health records (EHRs) have been available in recent years, including a huge mass of data, such as clinical narratives. They have been being used not only to support computerized clinical systems (e.g., computerized clinical decision support systems [1][2]), but also to help the development of clinical and translational research [3]. One of the challenges to use them is that much information is embedded in clinical notes, but cannot be directly accessible for computerized clinical systems which rely on structured information. Therefore, natural language processing (NLP) technologies, which can extract structured information from narrative text, have received great attention in medical domain [4], and many clinical NLP systems have been developed for different applications [5].

Clinical concept recognition (CCR) as a fundamental task of clinical NLP has also attracted great attention, and a large number of systems have been developed to recognize clinical concepts from various types of clinical notes in last two decades. Earlier systems were based on rules or dictionaries manually built by medical experts. The representative systems included MedLEE [4], SymText/MPlus [6][7], MetaMap [8], KnowledgeMap [9], cTAKES [10], and HiTEX [11]. In the past few years, with the increasingly available annotated clinical corpora, researchers started to apply machine learning algorithms to CCR, and several clinical NLP challenges were organized to promote the research on this task. For example, the Center for Informatics for Integrating Biology & the Beside (i2b2) organized NLP
challenges on CCR in 2009 and 2010 respectively [12][13]. The ShARe/CLEF eHealth Evaluation Lab (SHEL) organized a NLP challenge in 2013 [14], which includes a subtask of disorder recognition [15], and launched a similar NLP challenge as a part of the SemEval (Semantic Evaluation) in 2014 (i.e., SemEval-2014 Task 7) using the same training set, but different test set. Rule-based, machine learning-based and hybrid methods were developed to recognize medications by over twenty participating teams in the 2009 i2b2 NLP challenge [12]. In the 2010 i2b2 NLP challenge, clinical concepts, including problems, tests and treatments, not limited to medication, were required to recognize [13]. Most systems were primarily based on machine learning algorithms in this challenge, likely due to a large available annotated corpus [14]. In both the 2013 ShARe/CLEF and SemEval-2014 challenges, machine learning-based systems achieved state-of-the-art performance on disorder concept recognition [15]. Among the four NLP challenges, the ShARe/CLEF and SemEval-2014 challenges first considered disjoint clinical concepts (DCCs), which consist of multiple non-consecutive sequences of tokens. Actually, DCCs always drew much attention because they widely exists in clinical text and are important for subsequent applications such as clinical reasoning systems. In the 2013 ShARe/CLEF challenge, CCR is a preliminary step for concept mapping, mapping concepts in clinical text to UMLS concepts. Almost no machine learning-based method was proposed for disjoint clinical concept recognition except some simple rule-based systems such as MetaMap [8] and cTAKES [10], as well as disjoint named entity recognition in other domains. The main reason may lie in that it is more difficult to annotate DCCs than CCCs. In the 2013 ShARe/CLEF challenge, the organizers annotated a corpus with both CCCs and DCCs where DCCs account for about 10%. This corpus gave us a good chance to investigate how to recognize DCCs using machine learning-based methods. Compared with CCC recognition, the main challenge of DCC recognition is how to represent them. In previous studies, clinical concepts were typically represented by “BIO” tags, where B, I and O denotes that a token is at the beginning, inside and outside of a concept respectively [16]. This representation worked very well for CCCs, but not suitable for DCCs. For DCC recognition, a few systems tried some methods in the 2013 ShARe/CLEF challenge, including rule-based [17] and machine learning-based [18][19] [20] methods. The machine learning-based methods showed much better performance than the rule-based methods. Among all machine learning-based methods, our method was the best [14], which proposed a novel representation for DCCs.

In this paper, we proposed another type of representation for DCCs based on our previous work for the 2013 ShARe/CLEF challenge, which ranked first among 20 participating teams [14][15] on the disorder recognition task. In that study, we proposed a novel type of representation for DCCs by using two additional tags (i.e., H-head entity and D-non-head entity) based on the representation for CCCs, and a two-step method to recognize them. Although this type of representation can completely separate DCCs from CCCs, it does not provide enough information about how to combine head entities and non-head entities except that head entities should be shared with more than one DCC, and non-head entities should be combined with other head/non-head entities. Therefore, Some extra rules is needed for head/non-head entity combination. In this study, we proposed another type of representation for DCCs that integrates combination information into the representation strategy. Using this representation, a separate step for combination is not required any more. Similar to our
previous work in [20], we compared Conditional Random Fields (CRF) [21] and Structured Support Vector Machines (SSVM) [22] when using the two types of representations. To prove the effectiveness of our methods, we also compared them with the CRF/SSVM-based systems ignoring DCCs. To the best of our knowledge, it is the first time to comprehensively investigate DCC recognition using machine learning-based methods, which can be used as a benchmark for further studies. Moreover, the methods proposed in this paper can also be easily applicable to recognize disjoint named entities in other domains.

METHODS

Representations for CCCs and DCCs

We adopted “BIO” tags to represent CCCs in the whole paper. For convenience, we did not repeat any more. For DCCs, two different types of representations were proposed. The first representation used “BIOHD”, where ‘H’ denotes head entities which are consecutive sequences of tokens shared by multiple disjoint concepts in a sentence, and ‘D’ denotes non-head entities which are consecutive sequences of tokens in a disjoint concept not shared by other disjoint concepts in a sentence. The second representation used “BIOHD1234”, where ‘1’, ‘2’, ‘3’ and ‘4’ denote that a non-head entity is combined with the nearest head entity at left, the nearest non-head entity at left, the nearest head entity at right and the nearest non-head entity at right respectively. Figure 1 shows some examples of DCCs represented by “BIOHD” and “BIOHD1234”, where three sentences were used to illustrate different cases of DCCs. In sentence 1, two disjoint disorders (i.e., “extremities … turned in” and “extremities … clinched together”) share a head entity (i.e., “extremities”). The head entity is represented by “extremities/HB-disorder” no matter using “BIOHD” or “BIOHD1234”. The non-head entities (i.e., “turned in” and “clinched together”) are represented by “turned/DB-disorder in/DI-disorder” and “clinched/DB-disorder together/DI-disorder” when using “BIOHD”, while are represented by “turned/D1B-disorder in/D1I-disorder” and “clinched/D1B-disorder together/D1I-disorder” when using “BIOHD1234” as both of them should be combined with the nearest head entity at left. Considering that head entities are represented by “H” in both “BIOHD” and “BIOHD1234”, and non-head entities are always represented by “D” when using “BIOHD”, we did not explain them any more in the following examples. All non-head entities mentioned in the following examples are the cases of representing DCCs using “BIOHD1234”. In sentence 2, two disjoint disorders (i.e., “ABD … distend” and “ABD … tenderness … RUQ”) share a head entity (i.e., “ABD”). The non-head entity in the first disjoint disorder (i.e., “distend”) is represented by “D1B-disorder” as it should be combined with the nearest head entity at left. The non-head entities (i.e., “tenderness” and “RUQ”) in the second disjoint disorder are represented by “D1B-disorder” and “D2B-disorder” respectively because “tenderness” should be combined with the nearest head entity at left, while “RUQ” should be combined with the nearest non-head entity at left (i.e., “tenderness”). In sentence 3, there is a disjoint disorder (i.e., “left atrium … dilated”) composed of two non-head entities (i.e., “left atrium” and “dilated”), which is represented by “D4D2…D2” (i.e., “left/D4B-disorder atrium/D4I-disorder” and “dilated/D2B-disorder”) as the first non-head entity (at left) should be combined with the second non-head entity (at right), and vice versa.
Sentence 1: “Her extremities appeared turned in and clinched together except for her right arm.”
Concepts: “extremities... turned in” and “extremities... clinched together”
BIOHD: “Her/O extremities/HB-disorder appeared/O turned/DB-disorder in/DI-disorder and/O clinched/DB-disorder together/DI-disorder except/O for/O her/O right/O arm/O /O”
BIOHDI34: “Her/O extremities/HB Disorder appeared/O turned/D1B-disorder in/D1I-disorder and/O clinched/D1B-disorder together/DI1-disorder except/O for/O her/O right/O arm/O /O”

Sentence 2: “ABD: mild distend, mild tenderness in RUQ.”
Concepts: “ABD... distend” and “ABD... tenderness... RUQ”

Sentence 3: “The left atrium is dilated.”
Concepts: “left atrium... dilated”
BIOHD: “The/O left/D2B-disorder atrium/DI-disorder is/O dilated/DB-disorder /O”

Figure 1. Examples of two different representations for disjoint clinical concepts.

When using ”BIOHD” tags to represent disjoint clinical concepts, it is required to develop another system to determine how to combine head entities and non-head entities in a sentence as mentioned in our previous work [20], where two simple rules are proposed for combination as follows:

1) For each head entity, combine it with all other non-head entities to form disjoint concepts.
2) If no head entity, combine all non-head entities together to form a disjoint concept.

When using “BIOHDI34” tags to represent DCCs, it is straightforward to combine head entities and non-head entities since the combination information has been integrated into tags. For example, in the sentence 2 in Figure 1, there are two paths from non-head entities to the head entities: 1) distend—ABD; 2) RUQ—tenderness—ABD, forming two disjoint disorders.

Machine learning-based consecutive and disjoint CCR

When CCCs and DCCs are represented by “BIOHD” or “BIOHDI34”, CCR can be recognized as a classification problem, where each token of a sentence is labeled with a tag of “BIOHD” or “BIOHDI34” as shown in Figure 1. For “BIOHD”, the tag set is {B-disorder, I-disorder, O, HB-disorder, HI-disorder, DB-disorder, DI-disorder}. For “BIOHDI34”, the tag set is {B-disorder, I-disorder, O, HB-disorder, D1B-disorder, D1I-disorder, D2B-disorder, D2I-disorder, D3B-disorder, D3I-disorder, D4B-disorder, D4I-disorder}. Moreover, the machine learning methods proposed for consecutive CCR can also be applied to consecutive and disjoint CCR, such as Support Vector Machine (SVM) [13], CRF [23], SSVM [24][25] and so on. In our study, we compared CRF and SSVM, two state-of-the-art machine learning methods for consecutive and disjoint CCR [25], and used CRFsuite (http://www.chokkan.org/software/crfsuite/) and SVMhmm (http://www.cs.cornell.edu/people/tj/svm_light/svm_hmm.html) as implementations of CRF and SSVM respectively. For sentence boundary detection and tokenization, we adopted the corresponding modules of MedEx (https://code.google.com/p/medex-uima/downloads/list), a specific tool for medical information extraction.
**Features**

We used the same features as our previous work in [20], including bag-of-word, part-of-speech (POS), note type, section information, word representations, semantic categories of words. Most of them were also used in our previous systems for medical concept recognition [23][25][24][26]. For detailed information, please refer to the references.

**Dataset**

We used the dataset of the 2013 ShARe/CLEF challenge, which is composed of 298 notes from different clinical encounters including radiology reports, discharge summaries, ECG reports and ECHO reports. For each note, only disorders, including consecutive and disjoint disorders, were annotated according to a pre-defined guideline. The dataset was divided into two parts: a training set of 199 notes used for system development, and a test set of 99 notes used for system evaluation. In the training set, 651 out of 5811 disorders were disjoint, and 439 out of 5340 disorders were disjoint in the test set. Table 1 shows the counts of disorders in the training and test sets, where the number in parenthesis is the count of disjoint disorders.

**Experiments and Evaluation**

All models were trained on the training set and evaluated on the test set, and their parameters were optimized by 10-fold cross-validation on the training set. The performance of disorder concept recognition were evaluated by precision (P), recall (R) and F-measure (F) in both “strict” and “relaxed” modes [14], calculated by an evaluation tool provided by the organizers ([https://sites.google.com/site/shareclefehealth/evaluation](https://sites.google.com/site/shareclefehealth/evaluation)). To investigate the effect of the proposed methods, we started with two types of baseline systems: one treated every head and non-head entity of disjoint clinical concepts as an individual CCC (1st); and the other one removed all DCCs (2nd), and then compared them with our systems.
RESULTS

Table 2 shows the overall performance of the machine learning-based consecutive and disjoint CCR systems on the test set, when using different types of representations for CCCs and DCCs. The systems using “BIOHD” or “BIOHD1234” showed significantly better performance than the corresponding baseline systems, indicating that the proposed representations are suitable for CCCs and DCCs. For example, when using “BIOHD”, the CRF-based system outperformed the 1st baseline system by 3.9% (0.777 vs 0.738), and the 2nd baseline system by 5.9% (0.777 vs 0.718) in “strict” F-measure respectively; The SSVM-based system outperformed the 1st and 2nd baseline systems by 4.1% (0.782 vs 0.741) and 4.0% (0.782 vs 0.742) in “strict” F-measure respectively. When using the same representations for CCCs and DCCs, the SSVM-based systems showed better performance than the CRF-based systems. For example, the “strict” F-measure of the SSVM-based system was 0.782, while that of the CRF-based system was 0.777 when using “BIOHD”. For each machine learning method, the system using “BIOHD1234” slightly outperformed the system using “BIOHD”. For example, the SSVM-based system using “BIOHD1234” achieved a “strict” F-measure of 0.783, while the SSVM-based system using “BIOHD” achieved a “strict” F-measure of 0.782.

Here, we should note that the CRF-based and SSVM-based systems using “BIOHD” in this paper achieved better performance than our previous systems submitted to the 2013 ShARe/CLEF challenge as some bugs in previous systems have been fixed in current ones.

</tbody>
</table>

Furthermore, table 3 shows the performance of machine learning-based systems in the “strict” mode for CCCs and DCCs respectively. The machine learning-based system using “BIOHD” or “BIOHD1234” not only correctly recognized a number of DCCs, but also improved the performance for CCCs. For example, the “strict” F-measure of the CRF-based system using “BIOHD” for DCCs was 0.433, and that for CCCs was 0.799, higher than the 1st and 2nd baseline systems by 2.8% (0.799 vs 0.771) and 4.4% (0.799 vs 0.753). When using the same
representations for CCCs and DCCs, the SSVM-based systems showed better performance than CRF-based systems for both CCCs and DCCs. For example, when using “BIOHD”, the SSVM-based system achieved a “strict” F-measure of 0.802 for CCCs and a “strict” F-measure of 0.487 for DCCs; while the CRF-based system achieved a “strict” F-measures of 0.799 and 0.433 for CCCs and DCCs respectively. For each machine learning method, the systems using “BIOHD1234” showed slightly better performance than the systems using “BIOHD” for CCCs, but slightly worse performance for DCCs. For each machine learning-based system, the performance for CCCs is much higher than that for DCCs.

**DISCUSSION**

It is reasonable that the proposed two types of representations improved the performance of CCR systems as expected since they can distinguish DCCs from CCCs. To evaluate their representation abilities, we calculated upper boundaries of systems using “BIO”, “BIOHD” and “BIOHD1234” on the training set respectively. Firstly, we represented notes with gold clinical concepts using one of the three types of representations, and then converted the labeled notes back to clinical concepts. Finally, the upper boundary was calculated by comparing the converted clinical concepts with the gold ones using the evaluation tool. The upper boundaries of the systems using the three types of representations are shown in Table 3. The upper boundaries of systems using our representations were much higher than the systems using “BIO” (i.e., baseline systems shown in figure 1), and the differences ranged from 6.7% to 12.9% in “strict” F-measure. Among the proposed two types of representations, the upper boundary of the systems using “BIOHD1234” is slightly higher than the systems using “BIOHD” (0.969 vs 0.965 in “strict” F-measure). It means that the representation ability of “BIOHD1234” is slightly stronger than “BIOHD”, and is much stronger than “BIO”.

Although both “BIOHD” and “BIOHD1234” have good ability to represent both CCCs and DCCs, they are not complete. When clinical concepts are represented by “BIOHD”, clinical

concepts in the following three cases might be wrongly represented: 1) more than two head entities in a sentence; 2) more than one non-head entity in DCCs; 3) more than one DCC in a sentence. Some examples of clinical concepts wrongly represented by “BIOHD” are shown in figure 2. When clinical concepts are represented by “BIOHD1234”, the clinical concepts in sentence 2 and 3 are correctly represented, but the clinical concepts in sentence 1 are wrongly represented. Therefore, designing a complete representation for CCCs and DCCs is still a valuable topic, which is one case of our future work.

Sentence 1: “There is a small amount of blood seen within the third and fourth ventricles.”
Gold: “blood … thirdventricles” and “blood … four … ventricles”
BIOHD: “There/O is/O a/O small/C amount/O of/O blood/HB-disorder seen/O within/O the/O third/D3-disorder and/O fourth/D4-disorder ventricles/HB-disorder./O”
Converted: “blood … third”, “blood … fourth”, “third … ventricles” and “fourth … ventricles”

Sentence 2: “**ABD**: mild distend, mild tenderness in RUQ.”
Gold: “**ABD** … distend” and “**ABD** … tenderness … RUQ”
BIOHD: “**ABD/HB-disorder** /O mild/O distend/D4-disorder,/O mild/O tenderness/D4-disorder in/O RUQ/D4-disorder ./O”
Converted: “**ABD** … distend”,”**ABD** … tenderness” and “**ABD** … RUQ”

Sentence 3: “The patient had blood in his mouth and on his tongue, pupils were pinpoint and reactive.”
Gold: “blood … on his tongue” and “pupils … reactive”
BIOHD: “The/O patient/O had/O blood/D4-disorder in/O his/O mouth/O and/O on/D4-disorder : his/DI-disorder tongue/DI-disorder,/O pupils/D4-disorder were/O pinpoint/O and/O reactive/D4-disorder ./O”
Converted: “blood … on his tongue … pupils … reactive”

**Figure 2.** Examples of clinical concepts wrongly represented by “BIOHD”.

Since the ratio of CCCs to DCCs in the 2103 ShARe/CLEF challenge corpus is about 9:1, which is imbalanced, it is easy to understand that the performance of machine learning-based systems for DCCs is not as good as the performance for CCCs. An interesting direction is to consider data imbalance for further improvement, which is another case of our future work.

Moreover, all methods proposed in this paper are not limited to clinical concepts, but also suitable for general named entities. Therefore, they are potentially useful in other domains.

**CONCLUSIONS**

In this study, we investigated the machine learning-based methods to recognizing CCCs and DCCs. Two novel types of representations were proposed for CCCs and DCCs, and their
effectiveness was proved on a benchmark dataset.

Challenges and Solutions in Optimizing Execution Performance of a Clinical Decision Support-Based Quality Measurement (CDS-QM) Framework

Abstract

Given the close relationship between clinical decision support (CDS) and quality measurement (QM), it has been proposed that a standards-based CDS Web service could be leveraged to enable QM. Benefits of such a CDS-QM framework include semantic consistency and implementation efficiency. However, earlier research has identified execution performance as a critical barrier when CDS-QM is applied to large populations. Here, we describe challenges encountered and solutions devised to optimize CDS-QM execution performance. Through these optimizations, the CDS-QM execution time was optimized approximately three orders of magnitude, such that approximately 370,000 patient records can now be evaluated for 22 quality measure groups in less than 5 hours (approximately 2 milliseconds per measure group per patient). Several key optimization methods were identified, with the most impact achieved through population-based retrieval of relevant data, multi-step data staging, and parallel processing. These optimizations have enabled CDS-QM to be operationally deployed at an enterprise level.

Introduction

Close relationship between clinical decision support (CDS) and quality measurement (QM). CDS and QM are closely related, in that CDS may recommend that X be done if Y is true, while QM may measure if X was done when Y was true in order to assess the quality of the care given. For example, a CDS rule may recommend that aspirin be given if a patient has suffered an acute myocardial infarction, while a QM may measure if aspirin was given when a patient had suffered an acute myocardial infarction. Another commonality between CDS and QM is the goal of improving the quality of care. It has also been reported in the literature that they also share many of the same implementation challenges.

Given the close relationship between CDS and QM, there have been increasing efforts to align these two related aspects of quality improvement. Of particular interest from an informatics perspective, the U.S. Office of the National Coordinator for Health IT (ONC) and the Centers for Medicare & Medicaid Services (CMS) are sponsoring a public-private partnership known as the Clinical Quality Framework initiative to develop a common set of harmonized interoperability standards to enable both CDS and QM.

Benefits of a CDS-based framework for QM and prototype implementation. Due to the similar nature of CDS and QM, there are at least two important benefits to using a CDS-based quality measurement (CDS-QM) framework, in which the same approach is leveraged for both CDS and QM purposes. The first important benefit is semantic consistency. Because the same technical framework and core clinical knowledge is re-used across both CDS and QM, clinicians can receive consistent assessments both when receiving CDS at the point of care and obtaining performance feedback through QM. The second important benefit to CDS-based QM is implementation efficiency. By re-using the same underlying infrastructure and content, what may otherwise have involved two separate teams and development efforts can now be completed by a single team and effort. Such de-duplication of effort is particularly important given the significant complexity and attendant resources involved in the development, validation, and maintenance of this type of knowledge resource.
