The application requires a username and a password for healthcare providers and patients. We design two interfaces for types of users: 1) patients (Figure 1) and 2) healthcare providers (Figure 2).

![Figure 1. Interface for patient.](image1)

![Figure 2. Interface for doctor.](image2)

Records

Patients have records to store patient’s weight and height over time. A record is evaluated as underweight, overweight, obese, healthy states based on BMI z-score that depends on age (taken from WHO standard).

Growth Chart

Growth chart is generated from the values of patient records and bmi-for-age z-scores taken from the WHO website.
Blood Tests
Blood test menu is designed to display recent test results.

Recommendations
Recommendation from doctors is a part of doctor-patient interaction. A doctor should give a recommendation to a patient after evaluating patient’s information if necessary. Getting a recommendation from doctor encourages parents and patients to continue updating the growth record and aware that their doctor is regularly monitoring the patient’s progress.

Contact Requests
Contact requests menu is important for doctor-patient interaction. A patient/parent can send a contact request by choosing a topic when contact is needed, thus doctors can be notified and contact during available time. A patient/parent can send only one contact request till doctors mark that request as contacted. This prevents doctor from getting too many requests from one patient.

Obesity Risk At Birth
Calculating obesity risk at birth is an approach to predict child obesity at birth. This probability is calculated by Parents BMI, Number of household members, Mother’s profession category, gestational smoking and weight at birth.

For the outcomes, OTA is expected to provide a virtual space for healthcare providers and patients with evidence-based guidelines and self-explanatory visualization to promote an important positive impact on optimal theranostic strategies in precision medicine setting.

Implementation and Dissemination
The first prototype of OTA has been implemented and completed using .NET framework within Laboratory of Translational Bioinformatics at University of Missouri. This pilot program will be tested with pediatricians and selected children with obesity condition or their family. The program requires a username and a password to access and establish communications between healthcare providers and patients. Visualizations and interface designs will be improved based on feedbacks users from the pilot testing. For a large-scale dissemination, the application will be available for download for android and apple devices. Online tutorial for the application will be presented to the medical community.

Solutions Comparisons
The OTA mobile application is useful to keep records of growth and generate growth chart for children and adolescents from 0 to 19 years of age. WHO Anthro is specifically designed for healthcare specialists. The results require time to comprehend while the OTA application provides more self-explanatory visualizations for patients

Figure 7. Visualization of Growth Chart from WHO Anthro.
Conclusion

This application can be used as an effective tool to motivate parents to accept child’s situation and decide to make changes on child’s lifestyle. If their parents use this mobile application and monitor child’s growth and situation statistically, they can be more confident to make changes for their children. This application also makes parents and children feel taken care of because their doctors regularly monitor their progress and situation.

SocialVue: Making Social Determinants of Health Visible in the EHR

Steven R. Chamberlin, ND, MAC, Ian T. Stavros, BS, Dana Womack, MS, RN
Oregon Health and Science University, Portland, Oregon

Introduction

Every patient has a distinctive physiological make up, and every patient has a unique life story. In precision medicine, clinicians strive to tailor care to unique patient characteristics. While the term precision medicine (PM) is often used synonymously with genetics-informed treatment, social determinants of health (SDoH) are social and behavioral characteristics that also affect a patient’s quality and longevity of life. Inclusion of SDoH in the electronic health record (EHR) can provide vital information to inform and improve clinical care for individuals, public health of populations, and SDoH research(1).

Although there is a growing body of evidence regarding the effects of social and behavioral characteristics on the onset and progression of disease, clinical care is not yet routinely targeted to patients’ individual SDoH characteristics. Contributing factors include a lack of SDoH documentation in the electronic health record and the absence of tools to support meaningful discussions about SDoH between providers and patients. In this student design challenge, we propose creation of an EHR-compatible application that provides at-a-glance awareness of patient SDoH issues and facilitates delivery of care that is targeted to a patient’s social and behavioral circumstances. A prototype of the application can be accessed at http://tinyurl.com/SDoH-2016.

The World Health Organization defines SDoH as the “conditions in which people are born, grow, live, work, and age, and the wider set of forces and systems shaping the conditions of daily life (2)”. In 2014, the Institute of Medicine (IOM) recommended eleven social and behavioral domains and twelve associated measures for inclusion in EHRs, but did not specify how data should be captured, presented, or incorporated into tools to support patient-provider engagement (1). The IOM report focuses primarily on patient reported SDoH data, but the literature also suggests inclusion of geography based publicly available data in the EHR, often referred to as “community vital signs” (3, 4). Informatics issues include data capture, standardization, storage, privacy, interpretation and reuse(5). There is currently a paucity of literature regarding how to present SDoH data within the EHR, and how to make this actionable at the point of care.

We iteratively collaborated with clinicians to addresses the following opportunities:

1) Integration of clinical, community, and patient-specific SDoH data in the context of the EHR
2) Increased clinician awareness of patient’s unique social and behavioral characteristics
3) Improved engagement between clinicians and patients re: unique SDoH characteristics in a manner that leads to targeted care

Design Process

We began our design process with the goal of facilitating the delivery of precision medicine by tailoring care to patients’ SDoH characteristics, but we did not have a preconceived notion of what the solution might entail. We relied heavily on representative end users to inform our resulting design solution.

Problem addressed. During an early design session at a federally-qualified health center, a social worker noted that making the SDoH data she routinely collects from patients visible to providers and other team members in the medical home is a pressing challenge. She shared that she has tried multiple locations in the EHR to help clinicians “start seeing” SDoH, including a care coordination note at the top of the problem list, a dedicated clinical note, patient history form, and the “barriers” section of the chart. She reported that none of these locations has been successful and suggested that a novel approach for making clinicians aware of unique SDoH patient characteristics is needed. We selected this as our target problem as this challenge was echoed by multiple clinicians we interviewed.

Target end users: Our target end users are clinical members of multidisciplinary teams in the medical home setting (e.g. providers, social workers, nurses, medical assistants, others). We selected this user group because multidisciplinary teams are well suited to address social determinants and deliver precision medicine in the context of the medical home.
**Design objective.** The objective of our design is to provide medical home team members with at-a-glance awareness of patients’ SDoH characteristics, facilitate engagement between providers and patients regarding SDoH characteristics, and support care that is targeted to a patient’s social, economic and environmental circumstances.

**Target clinical condition:** Our resulting solution could be applicable to multiple clinical conditions, but we selected Type II Diabetes as our target clinical condition. Our rationale is that diabetes is highly influenced by patient’s social and behavioral characteristics. Limiting the focus to a single condition scopes this project to a manageable size, and demonstrating feasibility and value in the context of a single condition would be helpful before expanding the design concept to support multiple clinical conditions.

**Design approach.** We employed Agile & User Centered Design Integration (AUCDI) as our design approach, as AUCDI incorporates the principles of user-centered design within the context of an agile development process (6-8). In user-centered design, representative end users actively participate in the design process to guide the development of functional requirements and to participate in design and usability testing of a product through all states of development. Agile development is an iterative development process in which a product is built across multiple time-boxed windows, called sprints, with the goal of developing a minimally viable product as quickly as possible. We selected AUCDI as a method that blends user centered design and agile development because it supports evolutionary requirements elicitation and incremental design via a short and iterative feedback loop between the design team and target end users.

**Requirements elicitation, prototype design, and initial evaluation.** Recognizing that effective design begins with a clearly understood problem and active engagement with end users, we executed multiple interactive design sessions with representative stakeholders across three 2-week agile design sprints, following our selected AUCDI design methodology. We conducted design sessions with at least 5 representative end users during each sprint, for a total of 16 interactive sessions with these users. We are grateful for substantial end user input, and have included the names, organizations and roles of design participants in Supplementary Materials Exhibit 2.

- **Sprint 1:** In our first design sprint, we developed a low-fidelity prototype as a launching point for design sessions as it can be easier for users to react to a loose idea than to “blue sky” new capabilities. Our interactive discussions focused on clarifying our design goals and identifying what SDoH information is most supportive of SDoH-targeted care. Key learnings from this sprint included the need to prioritize collection and display of patient-specific SDoH data (e.g. patient experiencing food insecurity), over community-level data (e.g. percent of neighborhood under 200% poverty level). Representative end users found community data to be interesting, but it is patient-specific SDoH characteristics that they value most. Users reported that patient-specific SDoH data is typically collected by a social workers or medical assistant for subsequent use by all team members in a medical home. Users emphasized the need to make SDoH highlights available to providers at a glance in the EHR, allowing them to enter a patient room with awareness of a patient’s SDoH characteristics.

- **Sprint 2:** In sprint two, we developed a higher-fidelity prototype that included the concept of a “hover” icon that hovers of selected EHR screens and when moused over, expands to provide immediate access to patient-specific SDoH highlights. We also introduced an interactive map of a 1-mile radius around a patient’s residence that highlights community features of interest to diabetes including parks, grocery stores, fast food restaurants, and pharmacies. During interactive design sessions, users validated that the hover icon was helpful and provided input on what it should look like, and the content it should display. Users appreciated that SDoH highlights were not hidden behind “yet another tab” in the EHR, and provided considerable input regarding how to organize SDoH under relevant headers. Users also identified a small subset of publicly available community vital signs that would be useful when tailoring care to patient’s SDoH characteristics. We revised our evolving prototype frequently throughout the entire process, but in this sprint in particular, it was revised on nearly a daily basis.

- **Sprint 3:** Our third design sprint focused on preliminary validation of the prototype design and elicitation of feedback regarding usability. By this time, we had migrated from a low-fidelity prototype to a functioning web-based prototype that users could interact with. Users provided feedback on the functionality of the prototype and the proposed workflow which resulted in additional refinements, such as the ability to expand the map and trended clinical data to a “Patient View” mode. This could facilitate selection of a pharmacy that is on a patient’s bus route or open during a time of day that the patient is off work, setting exercise goals that incorporate a specific park or other landmark, or discussion of the relative benefit of different food choices that exist in a patient’s immediate neighborhood. By the end of this sprint, end users became increasingly enthusiastic about the design and started asking the team when it may become available for use in practice.
Discussion of Alternative Solutions Considered

This design team considered multiple design alternatives (Table 1), including designing additional functionality within the framework of an existing EHR, development of a stand-alone app, and an EHR-compatible app that can work in conjunction with any EHR as overlay functionality. Of the alternatives considered, the EHR overlay app is the most generalizable solution in that it could operate across multiple EHR systems.

Table 1. Alternative Solutions Considered.

<table>
<thead>
<tr>
<th>Alternative Considered</th>
<th>Strengths</th>
<th>Weaknesses</th>
<th>Decision</th>
</tr>
</thead>
<tbody>
<tr>
<td>Design an additional data capture screen in an existing EHR</td>
<td>Could be made available to clinicians in a relatively short time frame</td>
<td>Limited to a single EHR solution; not reusable across vendors. Design is limited to existing EHR functionality</td>
<td>We rejected this option because users value a community map, which exceeds the capabilities of EHRs today.</td>
</tr>
<tr>
<td>Design a stand-alone app to display community vital signs</td>
<td>Standalone applications are faster to develop than applications integrated with an EHR.</td>
<td>Necessitates a separate workflow as a standalone system. Lacks integration with clinical EHR data.</td>
<td>We rejected this option because users value patient-specific SDoH data over community vital signs data.</td>
</tr>
<tr>
<td>Design an EHR-compatible app that provides novel visualization, patient-specific SDoH data, selected community data, and clinical data</td>
<td>Tells a more complete patient story, integrates clinical, pt-specific and community-level SDoH data. Provides maximum flexibility and widest distribution across EHRs.</td>
<td>Longer development time than building additional screens in an EHR. Clinic IT departments will need to approve and maintain use of an EHR-compatible app.</td>
<td>We selected this option because it includes integration of patient-specific, community-level and clinical data, and because an EHR-compatible app can be distributed across multiple EHR systems.</td>
</tr>
</tbody>
</table>

Proposed Solution

The proposed solution, SocialVue, is an EHR overlay app that will help providers quickly digest SDoH data and tailor care to patients’ unique characteristics. We describe key functionality through the lens of a patient story, using italics to highlight examples of enhanced engagement and SDOH-targeted care.

Patient story: Natalia is a 56 year old Latina female with type II diabetes. She arrives for a same-day appointment, because she is concerned about a scratch on her leg that may be infected. Her primary care provider is out of the office, so she is seen by Dr. Smith. Not familiar with Natalia’s case, Dr. Smith opens her chart to review her medical history upon entering the patient room. During a previous visit, Natalia spoke with the medical home’s social worker who utilized SocialVue to note Natalia’s specific SDoH characteristics.

- **SDoH hover icon.** When Dr. Smith opens Natalia’s record, he immediately notices an SDoH icon hovering over the home screen, alerting him that Natalia has SDoH characteristics that may affect her clinical care (Figure 1). He knows that this icon only appears when known issues have been identified, typically during past patient visits with the medical home’s social worker. As a result, Dr. Smith has come to trust that the icon’s presence means that useful information is available.

  ![Figure 1. SDoH hover icon, generated using Piktochart software, and displayed over a generic EHR screen, publicly available at http://technologyadvice.com/blog/healthcare/3-hospital-ehr-solutions/](http://technologyadvice.com/blog/healthcare/3-hospital-ehr-solutions/)

- **SDoH highlights at-a-glance.** When Dr. Smith hovers over the icon, it expands to provide immediate access Natalia’s SDoH highlights (Figure 2), populated during a previous visit via an SDoH intake form, shown in Supplemental Material Exhibit 4. He notes that Natalia is looking for work, has food insecurity, and has recently moved in with a friend. In the time it takes to hover over an icon, Dr. Smith has gone from knowing nothing about Natalia, to understanding her key SDoH challenges and her personal goal related to managing her diabetes. This provides a framework for the visit and allows Dr. Smith to tailor care and incorporate SDoH information into the clinical encounter.

  ![Figure 2. Expanded SDoH hover icon](http://technologyadvice.com/blog/healthcare/3-hospital-ehr-solutions/)

1705
Natalia explains that she was scratched by some thorny bushes when she visited an unfamiliar park. Dr. Smith acknowledges that he understands she moved recently, and commends her on maintaining her goal of walking around a park three times/week at her new location, as he begins to examine her leg. He determines that her leg is indeed infected and recognizes that he will need to order an antibiotic.

- **Diabetes 360 screen**, with integrated clinical, SDoH, and community data. Dr. Smith also wants to check on Natalia’s diabetes, so he clicks the SDoH icon to bring up a Diabetes 360 screen that displays an integrated view of Natalia’s clinical context, more detailed SDoH information, and her community context (Figure 3). Visual cues alert him to the fact that her blood pressure is elevated, so he emphasizes the value of continued exercise to manage both her blood pressure and diabetes. Together, they look at the map to **identify additional parks in her neighborhood that Natalia could explore also identify healthy and affordable food sources in her neighborhood**.

Having awareness of Natalia’s unique SDoH characteristics, Dr. Smith recognizes that it will be important to patient compliance to select a pharmacy near Natalia’s new residence, so he clicks “Patient View” to enlarge the map that covers a 1-mile radius around her address (Supplementary Materials Exhibit 1). Together Dr. Smith and Natalia **identify a pharmacy in her neighborhood that is convenient to public transportation**. By hovering over the pharmacy icon, they are able to identify that the pharmacy is ¼ mile from Natalia’s residence, and that it is open until 9 pm daily.

![Figure 3. Diabetes 360 screen, incorporating clinical, patient-specific SDoH data, and community-level vital signs](image)

- **SDoH input screen**. Natalia’s SDoH information on the Diabetes 360 screen (Figure 3) is populated via an SDoH intake form (Supplementary Materials Exhibit 2). The envisioned workflow, developed in collaboration with our clinical end users, is that the intake form would be initially filled out, and updated by medical assistants during the rooming procedure, or during patient interactions with a social worker.

- **Integration with the EHR**. While the data in our current prototype is simulated data, the envisioned solution will exist as an overlay app that is integrated with an EHR system, such that the clinical data on the Diabetes 360 screen is populated directly from the EHR. Next steps include a due diligence investigation to assess to what extent the SMART Health IT platform and Fast Healthcare Interoperability Resource (FHIR) data models(9) support the data elements required by the proposed solution. Additional future work includes formal usability testing of the interactive prototype, development into a fully developed application, and inclusion of additional community resources (e.g. food pantries) on the map.
Implementation, Dissemination and Evaluation Plan

The design team has discussed implementation and dissemination of SocialVue with OCHIN(10), a nonprofit organization in Oregon that provides EHR functionality to over 500 clinics that serve underserved patient populations in 18 US states. The SocialVue app is synergistic with OCHIN’s desire to incorporate SDoH data into its EHR in ways that support targeted care. OCHIN has expressed a sincere interest in taking prototype developed through this project, and developing it into a deployable app that sits on top of the EHR that OCHIN provides to its clinic clients. OCHIN may include SocialVue in a multi-arm study designed to evaluate the relative effectiveness of different ways of presenting SDoH data to end users in the EHR and evaluate impact on clinical outcomes.

Prior to deployment to selected OCHIN clinics, SocialVue will undergo rigorous usability testing, beyond the interactive sessions executed by the student design team during the initial development of the design concept. During usability testing, representative clinical end users will be observed as they attempt to execute defined tasks using the app. Users will be encouraged to talk aloud as they execute these tasks, so that designers can understand both what users are thinking, and what aspects of the design or user interface are causing challenges. Usability testing will lead to system enhancements that will be made prior to rollout to actual end users.

Clinical outcome evaluation related to use of the SocialVue app will be assessed as part of a planned future OCHIN study. A selected number of clinics will be randomized to use either SocialVue or one of two additional competing designs, to be developed by OCHIN. OCHIN plans to assess clinician satisfaction regarding use of SDoH tools through a survey and clinical outcomes will be compared across sites. If SocialVue is shown to improve targeted care and clinical outcomes, there is potential for it to be deployed to all clinics that utilize the OCHIN EHR.

Summary

In this submission, we present a novel approach for targeting care to patient- community-level SDoH data in the context of the EHR. Use of a combined agile & user centered design approach allowed representative users to provide substantial input across 16 interactive design sessions. Our functioning prototype demonstrates how an EHR overlay app can call attention to SDoH characteristics via an icon that expands to provide immediate access to SDoH highlights. Together, the icon and interactive “Diabetes 360 screen” create an SDoH framework for the visit in the context of an existing EHR workflow that facilitates patient engagement and results in SDoH-targeted care.

Content and Quality of Free-Text Occupation Documentation in the Electronic Health Record

Ranyah Aldekhyyel, MS1,5, Elizabeth S. Chen, PhD2, Sripriya Rajamani, MBBS, PhD, MPH1,3, Yan Wang, PhD1, Genevieve B. Melton, MD, PhD1,4

1Institute for Health Informatics, 3Public Health Informatics Program, and 4Department of Surgery, University of Minnesota, Minneapolis, MN; 5Medical Education Department, College of Medicine, King Saud University, Riyadh, SA

Abstract

Recent recommendations for capturing social and behavioral information in electronic health record (EHR) systems for downstream applications, including research, highlight the need to better represent patient occupation. The objectives of this study were to characterize the content and quality of EHR social history module free-text occupation documentation. After developing categorization schemas, occupation entries with frequencies >5 (n=2,336) and a random sample of those with frequencies ≤5 (n=381) were analyzed. The information contained in the 2,336 entries fell into five groups: occupation (84.7%), occupation details (20.6%), employment status (2.5%), not in labor force (21.6%), and other (2.5%). Quality issues included use of acronyms/abbreviations (9.1%) and misspellings (1.6%). In comparison, quality issues with the 381 entries were: other (29.1%), acronyms/abbreviations (19.0%), and misspellings (9.0%). These findings suggest the need for EHR user training, system enhancements, and content standardization to support use of occupational information for clinical care and research.

Introduction

With the increasing use of Electronic Health Record (EHR) systems driven by various healthcare reform initiatives and the EHR Incentive Program1, there is an opportunity for enhanced capture of occupation data electronically at the point of care. The importance of documenting social and behavioral factors influencing health status and outcomes has been recognized and supported by recommendations from respected advisory bodies and organizations, such as the National Academy of Medicine (NAM; formerly Institute of Medicine) and the National Institute for Occupational Safety and Health (NIOSH). For instance, in 2011 the NAM published a report entitled “Incorporating Occupational Information in Electronic Health Records,”2 which highlighted the need for representing occupational information in EHRs through emphasizing the potential benefits to the individual patient as well as the population as a whole, and included recommendations for next steps. The report also illustrated several examples suggesting that the presence of the patient’s type of work in the EHR could enable more accurate diagnosis and treatment of specific medical problems, which could lead to improved quality and efficiency of care. NIOSH supported incorporating occupation in the EHR through publishing demonstration projects, which focused on the representation of occupation related information. These include the Occupational Data for Health (ODH) data model3 (work in progress, currently not available in the public domain), HL7 Clinical Document Architecture (CDA) standard template for “Occupation Data for Health”4, and various pilot projects to understand and promote the capture of occupation data5. All these resources point to occupation as a complex concept with inter-related elements (e.g., occupation, industry, employer, and employment status).

In 2014, follow-up recommendations for capturing social and behavioral information in EHRs were issued in two reports published by the NAM5,6. Occupation/Employment was considered under the socio-demographics domain in the first report (“Capturing Social and Behavioral Domains in Electronic Health Records: Phase 1”) and employment was identified as a candidate domain in the second report (“Capturing Social and Behavioral Domains and Measures in Electronic Health Records: Phase 2”). The report also indicated an instrument to standardize the collection of employment information, which was the Multi-Ethnic Study of Atherosclerosis (MESA) question and categories5 for employment status.

Prior work has focused on reviewing the capture of social and behavioral factors in the EHR, involved characterizing social history information in clinical notes and identifying the eight most common statement types, one of which was occupation which represented 10-15% of statements across three different sources of clinical notes7. Subsequently, social and behavioral information was also examined in three public health surveys: Behavioral Risk Factor Surveillance System (BRFSS), National Health and Nutrition Examination Survey (NHANES), and National Health Interview Survey (NHIS)8. Occupation was a common survey item with 22 questions and corresponding responses across the three surveys.
Building upon findings from prior work and national recommendations for capture of occupational information in the EHR, the main objective of this research is to understand the practice of documentation of occupation in an institutional EHR by analyzing contents of free-text occupation entries assessing the type of information captured and evaluating the quality of data stored. This study uses similar methodologies for analysis as developed and applied in previous studies that focused on representation of various aspects of social history documentation in the EHR, including tobacco use, alcohol use, drug use and living conditions. Specifically, the aim of this study is to determine issues associated with current representation of occupation in an EHR system with potential implications for enhancing system design for discrete data collection, user training, and standardization of data as well as informing the development of natural language processing (NLP) tools to enhance access to and use of structured data for research, clinical care, and population health purposes.

Methods

Study Design

This study involved a retrospective analysis of data collected in the free-text occupation field within the Epic EHR implemented at University of Minnesota (UMN)-affiliated Fairview Health Services accessible through the UMN Clinical Data Repository (CDR). Occupation and related information is collected in the socio-economic section in the social history module of the EHR and is comprised of one structured field (Employer) and two free-text fields (Occupation and Comments) (Table 1). The current study focused on the “occupation” field and was conducted in two phases for: (1) data extraction, preparation and transformation (Figure 1A) and (2) categorization schema development and application (Figure 1B).

Figure 1: Study Methodology with Two Phases for Extracting, Preparing and Transforming Data (A) and Developing and Applying Categorization Schema (B).
Phase 1: Data Extraction, Preparation and Transformation (Figure 1A)

Occupation data from the UMN CDR collected from May 2000 through February 2015 were extracted resulting in 3,572,036 entries and imported into a relational database (MySQL). Removal of duplicate patient encounters (n=3,271,909) resulted overall in 300,127 entries. Many empty entries were found in the occupation field, which were then removed along with “0” values, as these entries were considered missing data. All entries were then converted to lowercase in order to select the “unique” entries stored in the free-text occupation field. A “unique” entry is an entry with no exact match within the dataset, taking into account space between words and punctuation marks (e.g., “homemaker” is considered a different entry than “home-maker”). The resulting dataset included 53,424 unique occupation entries representing 185,891 overall entries. The data were then divided based on the frequencies of unique occupation entries. A frequency of “5” was chosen as the cutoff for the two datasets representing about 90% of overall entries (25% of unique entries) excluding those with a frequency of “1”. The first dataset “freq. > 5” was comprised of unique entries with frequencies of more than 5 (n=2,336) representing about 87% of the overall dataset (n=123,789). A random sample of the second dataset was extracted from the remaining dataset (5 or less) of 51,088 total unique occupation entries. The second dataset “freq. ≤ 5” included 381 unique occupation entries and was based on the total number of unique occupation entries with frequencies of 5 or less to provide a precision of 5% at the 95% confidence level.

Phase 2: Categorization Schema Development and Application (Figure 1B)

Schema Development

Categorization schemas were iteratively developed to manually categorize the “contents” of the unique occupation entries and identify any “data quality” issues with the entries. The “contents” schema was developed for identifying the unique contents of the free-text occupation entries. The “data quality” schema was developed to determine any data quality issues with the “contents” in the free-text occupation entries. Both of the developed schemas allowed for entries to be placed under several categories. The process of developing these schemas was based on an approach used in a prior study focused on analyzing free-text tobacco use documentation in the EHR. The general method for developing these guidelines consisted of two phases. The first phase focused on developing initial categorization schemas based on analysis of 50 unique occupation entries and enhancing the schemas through weekly meetings and discussions involving four subject matter experts in the field of informatics with experience and expertise in clinical care, public health, and standards (GMM, ESC, RA, and SR). The second phase involved calculating inter-rater reliability using the kappa statistic to ensure consistency in categorizing entries between two reviewers (RA and SR) using the final versions of each categorization schema for 250 unique occupation entries from the “freq. > 5” dataset (n=2,336).

Earlier versions of the “contents” schema consisted of three main groups with twelve different categories. A notable topic of discussion among the group was focused on identifying the most applicable category for student-related entries. After review of six different sources of information (Standard Occupational Classification [SOC] System from the Bureau of Labor Statistics in the United States (U.S.) Department of Labor, Systematized Nomenclature of Medicine-Clinical Terms [SNOMED-CT], North American Industry Classification System (NAICS) from the U.S. Census Bureau, MESA, NIOSH and MetaMap) and then categorizing 50 entries from the “freq. > 5” dataset, the main groups “not in labor force” and “employment status” were created with associated categories and subcategories. The final version included five main groups,十二 categories, and four subcategories (Table 2). Categories and subcategories were created to provide further detail about the content being documented in the occupation entries. Subcategories are directly linked with a specific category (e.g., the subcategory “Type of Occupation” is directly linked to the “Name of Occupation” category and the subcategories “Student Related –Status”, “Student Related –Type”, and “Student Related –Other” are directly linked to the “Not in Labor Force –Student” category). This means that no entries can be placed under a specific subcategory without having part of the entry categorized under the related category. An example that explains the relationship between categories and subcategories is “Travel Consultant” where the entry was divided into two words: “Consultant” was categorized as “Name of Occupation” and “Travel” was categorized as “Type of Occupation”. Another example is “Law Student” where “Student” was categorized as “Not in Labor Force-Student” and “Law” was categorized as “Student Related-Type”.

The “data quality” schema underwent less revision since the categories were more distinct and captured common issues that are found in free-text data. The final version consisted of five main issues: (1) Misspelling, (2) Acronym/Abbreviation, (3) Ambiguous, (4) Multiple Terms, and (5) Other (Table 3). Two reviewers analyzed a set of 250 entries using the final versions of the categorization schemas. Inter-rater reliability was calculated using Cohen’s Kappa, achieving κ of 0.94 for contents and 0.86 for data quality issues (percentage agreement of 0.99 and 0.98 respectively). All differences in categorization, between the two reviewers, were revised and resolved prior to applying the schema on the datasets.

**Schema Application**

Coders manually categorized unique occupation entries using the two developed categorization schemas. The remaining 2,036 set of occupation entries, from the “freq. > 5” dataset (n=2,336), in addition to the “freq. ≤ 5” dataset (n=381) were divided in half between the same two reviewers who previously categorized the 250 unique occupations, to apply the developed schemas.

“PHY ED TEACHER” is an example of an entry from the “freq. > 5” dataset. This entry was categorized as “name of occupation” and “type of occupation” for “contents” and the “data quality” issues identified were “acronym/abbreviation” and “other-uppercase letters”. Other examples of entries include “unemp” that was categorized as “unemployment status” with one identified quality issue of “acronym/abbreviation” and “Student-4th Grade” that was categorized as “not in labor force-student” and “student related-other”.

Examples from the “freq. ≤ 5” dataset include “snowplow driver, road maintenance” and “legal assistant, retired 2012”. Both entries were placed under several categories. The first entry was categorized as “name of
occupation”, “type of occupation” and “industry” with quality issues of “misspelling” and “other-punctuation mark”. The second entry was categorized as “name of occupation”, “type of occupation”, “not in labor force-other” and “miscellaneous-date” with quality issue of “other-punctuation mark”.

After completing the manual categorization of unique occupation entries in both datasets (n=2,717), counts and percentages for both the “unique” and “overall” entries were calculated for the frequencies of “unique” occupation entries occurring within the dataset. “Overall” entries within a specific frequency group represent the overall number of times the corresponding “unique” entry occurred in the dataset.

Results

Table 4 depicts the frequency distribution of unique and overall entries, and illustrates the selection of a frequency of “5” as the cutoff for the two datasets for performing data analysis. The table provides a summary of the “unique” occupation entries (n=53,424), which includes the overall and unique counts and percentages of occupation entries grouped into the frequency of the occurrence of a specific “unique” entry within the dataset. “Frequency” represents the number of times a specific “unique” entry occurred in the dataset. “Unique” occupation entries that occurred more than 10 times within the dataset have been grouped into the “>10” frequency”.

Figure 2 compares the “overall” percentages of the “contents” of the unique occupation field distributed among the five main content groups between the two datasets. Noticeably, around 22% of the overall data being analyzed (in both datasets) were indicated as “not in labor force”. The top five “overall” entries categorized as “not in labor force”, regardless of identified data quality issues, were student (n=10,555), homemaker (n=4,693), “housewife” (n=958), retired (n=679) and stay at home (n=541). Results of the “overall” counts of the three
subcategories associated with the category “not in labor force - student” were: “student related – status” (n=31), “student related – type” (n=590) and “student related – other” (n=716).

Figure 2: Distribution of the “Overall” Percent of Entries across Main Categorization Groups for “Contents”

Applying the categorization schemas to identify the contents and data quality issues of the two datasets being analyzed are summarized in Tables 5 and 6. The results are presented to show the count and percentages of both the “unique” and “overall” occupation entries between the two datasets. Percent of “unique” entries categorized as “name of occupation” (64.9%) was higher in the “freq. > 5” dataset. As anticipated, the percent of “unique” entries categorized as “miscellaneous” was much higher in the “freq. ≤ 5” dataset (23.9%). Examples of “miscellaneous” entries included “odd jobs”, “infant”, “data” and “grocery”. The “freq. ≤ 5” dataset was also identified as having a higher percentage of quality issues indicated as “other” such as punctuation marks in the entry or the entire entry in uppercase letters.

</tbody>
</table>
Significant quality issues were found in both of the study datasets. When looking at the number of quality issues identified within a single “unique” entry, it was found that in the “freq. ≤ 5” dataset, there were about 21% “unique” occupation entries that had one quality issue identified, 18% with two quality issues, 11% with three quality issues and 1% with four identified quality issues. Comparing these findings with the quality issues identified in the “freq. > 5” dataset, it was found that 9% had one quality issue, 12% with two quality issues, 1% with three quality issues and 1% with four identified quality issues.

**Discussion**

The overall goal of this study was to understand current documentation practices for occupation in the EHR for informing efforts to structure and standardize this information for subsequent use. Although, when developing the categorization schema, federal laws related to occupation were not considered (e.g., Fair Labor Standards Act), our analysis demonstrates that data being documented in the free-text occupation field under the socioeconomic section of the EHR being studied partially reflect current standards and recommended formats from reports that have been published. As per the proposed NIOSH representation as well as other national reports and recommendations, occupation and occupation details can be captured in the following categories: (1) occupation, (2) industry, (3) employment status, (4) employer, (5) work schedule, (6) occupational injury, (7) occupational exposures and (8) work relatedness. Preliminary findings from a related study focused on evaluating the adequacy of the ODH Model developed by NIOSH supported the robustness of the ODH Model for representation of occupational information. Designing the EHR to capture occupational information for a patient in a free-text field resulted primarily in concepts related to occupation, status, industry, and employer. Having the data stored in a free-text field also creates a chance for errors during the data entry process, which could, in turn, result in lower quality of occupation data for secondary applications like research and population health interventions.

Four main observations resulted from our analysis. Within the study dataset, 38% (n=114,236) of the entries had the number “0” entered in the occupation field or had no entry at all. These were considered missing values and thus were not included in the primary analysis. Another observation was that 14% (n=44,435) had an entry that only occurred once in the entire dataset. This was mostly due to user-created terms, errors or descriptive statements being entered in the field. Examples of such descriptive sentences are “homemaker, former rn, 13 kids, 2 biologic” and “fishing guide in Ontario during summers, retired science teacher”. Reasons for this issue could be due to the fact that the occupation field is a free-text field, lack of awareness or training on the part of users on entering this information, or the absence of appropriate fields designed for structured documentation of associated occupational information. The third observation was related to the frequencies of the unique occupation entries. As the frequencies of the entries decreased, the relative number of identified quality issues increased. Therefore, the decision to split the data into two separate datasets based on the frequencies of the unique occupations was made for better overall management and analysis. The fourth observation was related to entries that described individuals not in the workforce or student-related entries such as “retired”, “on disability”, “stay at home mom”, “housewife” and “4th grade student”. Subject matter experts were faced with finding the most appropriate category to represent this group within the coding schema, as there were not any available standards that clearly addressed this group in a consistent manner. A recommendation from this is that there should be a separate field or set of fields in the EHR that represent these types of individuals and associated information. Also essential is the need to develop standards and measures that would address this specific issue and design the EHR to capture information for these individuals whom are not in the labor force.

The results of this study also highlighted significant data quality issues associated with this data field and the relative low utility of this data for secondary purposes such as research, policy and population initiatives. Due to the fact that the study only analyzed one free-text field (Occupation) and represented data from a single EHR in one healthcare system (Epic EHR at Fairview Health Services), these findings may not be generalizable or represent the quality of occupation documentation in other EHR systems or other clinical settings. Since Fairview Health Services includes six different hospitals (four are metropolitan based and two are rural), an
academic practice with quaternary care, and a community practice with a specialized children’s hospital, the
initial findings potentially represent a breadth of documentation practices for occupational information. In
addition, the methods for characterizing the contents and quality of this information could be adapted and
applied at other healthcare systems. Future studies will incorporate federal laws related to occupation, normalize
the “occupation” field entries, group and aggregate synonym entries, and analyze the occupation field in relation
to other associated fields in the social history module (i.e., Employer and Comments as shown in Table 1), as
well as other parts of the EHR that may include occupational information (e.g., clinical notes). More formal data
quality assessments, such as those described by Weiskopf and Weng17, will also be needed.

Examining a single EHR that reflects a standard input mechanism by a particular vendor may result in innate
limitations in how occupational data are currently being captured. Broader implications of this work include
informing improved EHR interfaces for capturing occupational data and how to codify free-text occupation
information stored in the EHR. This study also helps set additional foundation for efforts in the area of NLP to
analyze free-text stored in the EHR related to the occupational history of patients. NLP techniques can be used
to extract, structure, and encode relevant information from free-text data for subsequent use. Knowing what the
target is, in this case occupational information, and the type of model used to extract from text will set the
foundation for mapping to standardized terminologies such as SOC13, NAICS15, and SNOMED-CT14 that
include codes for occupation and industry. For example, the social context hierarchy in SNOMED-CT14 is
designed to cover social conditions and circumstances significant to healthcare that includes a sub-hierarchy for
occupation, which could be used to standardize different values found from this study. Future work could
involve developing and evaluating NLP techniques for the different categories of content in the occupation field
as identified in this study.

Conclusion

With the increased adoption of EHR systems and the growing recognition of social factors in impacting health
outcomes, there is a need to understand the current status of the information being stored and captured in EHRs
to increase the value of information that can be obtained. This study involved performing a content analysis of
data from a free-text occupation field of an EHR over a selected time period by categorizing the contents of
information being captured and identifying associated data quality issues, using developed categorization
schemas. The findings of this study have implications in terms of system design, user training, and
implementation of relevant standards, including vocabulary related to occupation and industry.

SMASH: A Data-driven Informatics Method to Assist Experts in Characterizing Semantic Heterogeneity among Data Elements

William Brown III, DrPH, MPhil, MA1,2, Chunhua Weng, PhD1, David K. Vawdrey, PhD1,3, Alex Carballo-Diéguez, PhD2, Suzanne Bakken, PhD, RN1,4

1Department of Biomedical Informatics, Columbia University, New York, NY; 2HIV Center for Clinical and Behavioral Studies, NY State Psychiatric Institute & Columbia University, New York, NY; 3New York-Presbyterian Hospital Value Institute, New York, NY; 4School of Nursing, Columbia University, New York, NY

Abstract

Semantic heterogeneity (SH) is detrimental to data interoperability and integration in healthcare. Assessing SH is difficult, yet fundamental to addressing the problem. Using expert-based and data-driven methods we assessed SH among HIV-associated data elements (DEs). Using Clinicaltrials.gov, we identified and obtained eight data dictionaries, and created a DE inventory. We vectorized DEs by study, and developed a new method, String Metric-assisted Assessment of Semantic Heterogeneity (SMASH), to find DEs: similar in A and Bn, unique to An, and unique to Bn. An HIV expert assessed pairs for semantic equivalence. Heterogeneous DEs were either semantically-equivalent/syntactically-different (HIV-positive/HIV+/Seropositive), or syntactically-equivalent/semantically-different (“Partner”[sexual]/“Partner”[relationship]). Context of usage was considered. SMASH aided identification of SH. Of 1,175 DE from pairs, 1,048 (87%) were semantically heterogeneous and 127 (13%) were homogeneous. Most heterogeneous pairs (97%) were semantically-equivalent/syntactically-different. Expert-based and data-driven methods are complementary for assessing SH, especially among semantically-equivalent/syntactically-different DE. Similar expert-based/data-driven solutions are recommended for resolving SH.

Introduction

Interoperability of health information systems is critical to the effective provision of health care. Interoperability involves the exchange and interchange of diagnostic, treatment, prescription, and billing-related data. For these information types to be exchanged accurately and effectively, healthcare providers working with these data must understand the true meaning, or semantics, of the data and their relationship to each other1–3. Moreover, integration of diverse domain-associated datasets provides new opportunity for analysis, the development of new knowledge, improved disease discovery, diagnoses, treatment, and intervention4. It also provides an opportunity to resolve common data analytic problems, such as small sample size, need for subgroup analysis, need for comparative analyses between populations, and low statistical power2,4. For these reasons, integration of health-related data becomes critical to health care. Semantics play an instrumental role in the integration process, assuring that researchers who use the integrated datasets are analyzing what they truly mean to analyze4,5.

The difference in meaning and interpretation of data elements (DEs) is known as semantic heterogeneity (SH)6,7. It can occur when database schemas or datasets for the same domain are developed independently6,8. Because of the critical relationship of semantics to health-related data, SH is a major source of challenges for data integration, lack of interoperability among health information systems, and barriers to the provision of accurate and effective health care, and knowledge generation9–11. For this reason, resolving SH, also known as semantic harmonization, is key to achieving both interoperability among healthcare systems and integration of diverse domain-associated datasets11.

SH results from independent development of database schema or datasets for the same domain, forming differences in meaning and interpretation of DEs and data values6,9. Decomposing the various sources of SH provides a basis for understanding how to map and transform data to overcome these differences. Unfortunately, the nature or extent of SH in a given domain is rarely known or quantified. Most researchers try to get around the issue of SH quickly by immediately identifying semantically homogeneous DEs12,13. Consequently, the optimal solution may be missed, the issue of SH remains, and to what extent and why is left unknown. If SH is to be addressed in a meaningful and long-lasting way, we must characterize the SH. Thus, assessing how much SH exists among domain-associated DEs is an important, yet challenging informatics task.

Data-driven methods such as approximate string matching are relatively high-throughput methods, but only work at the syntactic level and are weak at dealing with semantics. Expert-based methods support consensus semantic
reasoning between expert raters and across multidisciplinary domain-similar groups; however, these methods are often time-consuming and expensive\textsuperscript{6,13,14}. In this research, we used both expert-based and data-driven informatics methods to assess SH among empirically generated DEs in HIV-associated data dictionaries. Specifically, we present a new method, String Metric-assisted Assessment of Semantic Heterogeneity (SMASH), to find similar DEs and assist experts in assessing DE pairs for semantic equivalence.

**Background**

SH is one of the more important and challenging sources of differences in heterogeneous datasets\textsuperscript{11}. Moreover, SH is compounded by the flexibility of semi-structured data and various coding methods applied to unstructured data, such as narrative documents\textsuperscript{13,15}. Such is the case within the HIV research domain.

Since the early years of the epidemic, National Institutes of Health (NIH) Institutes and Centers, as well as other funding agencies, have supported numerous studies that have collected longitudinal data on HIV-associated variables and HIV-disease specific measures (e.g., viral load and CD4 counts)\textsuperscript{16}. Most of these studies research comparable populations and include patients with similar demographic characteristics. However, assessment approaches, instruments, and protocols are often created independently\textsuperscript{13,16}. Given the complexity and multitude of possibly interrelated factors that influence HIV outcomes, larger, integrated datasets could contribute significantly to advanced analysis.

Because HIV research is often conducted independently by a variety of clinical trials networks and investigators, schematic and syntactic differences are generated that contribute to SH. What’s more, few efforts have been made to combine data across studies\textsuperscript{13,16,17}. However, such harmonization would significantly increase the value of the collected data to address HIV-related questions for those living with, or at risk of acquiring, HIV. For these reasons, we focused our efforts on characterizing the SH of the datasets in the HIV research domain.

**Methods**

**Empirically Generated Data Sources**

We set out to characterize SH among empirically generated HIV-associated research DE. In this study, empirically generated data sources were defined as those DE that derived from the practice of HIV clinical or behavioral research. To this end, HIV-associated research data dictionaries were collected. This study was reviewed by the institutional review board and declared to be exempt.

**Data-driven Methods**

We systematically searched Clinicaltrials.gov for relevant HIV-associated studies. We used fifteen NIH criteria outlined in RFA-MH-14-200 “Integration and Analysis of Diverse HIV-Associated Data (R03)”. Criteria for DEs included: HIV+, HIV-, Male, Female, Transgender, men who have sex with men (MSM), Adult, Youth, Children, Neuro-psychological, Psychosocial, Behavioral, Biological/Biomarkers, Longitudinal, accessible data. After identifying eligible research studies with datasets that included several criteria, we approached principal investigators (PIs) of the research studies via email using a participation recruitment letter. The letter summarized the nature of the study, outlined the use of the data, and described the approvals needed for the use of the data dictionaries.

Once we obtained data dictionaries, we extracted DEs (both variables and metadata) from the data dictionaries. We used Excel to create an inventory of DEs, organized by study. Data elements for each study were vectorized using R which requires that vectors must be of the same data type (e.g. character, logical, numeric, integer). Thus, all non-character string DEs were converted (“coerced”) to character strings so that they could be compared (see Figure 1).
Next, to begin the DE comparative analysis, we used R approximate (Fuzzy) string matching to compare the DE vectors\textsuperscript{18,19}. We did this by computing distance metrics (in this case, the syntactic difference) between DE pairs. We compared DE vectors in the following ways (Figure 2) and asked the following questions of the data:

- What are the similar DEs in study $A_{n,s}$ and study $B_{n,s}$?
- What are the unique DEs in study $A_{n,s}$, but not in study $B_{n,s}$?
- What are the unique DEs in study $B_{n,s}$, but not in study $A_{n,s}$?

To find similar DEs and assist experts in assessing DE pairs for semantic equivalence we devised SMASH, a string metric-assisted assessment of semantic heterogeneity. SMASH assumes a possible relationship between syntactic and semantic similarity, and uses one or more string metrics to compare syntactic similarity of DEs to find DEs that may also be semantically similar. String comparison, similarity and distance, metrics used for SMASH were provided by the \textit{stringdist} package (R library(stringdist)) in the R statistical programming environment\textsuperscript{18,19}. We used the \textit{stringsim} command to compute pairwise string similarities between elements of character string vectors in vector $A_n$ and $B_n$, where the vector with fewer elements is recycled. This involved first calculating the distance using \textit{stringdist}, set to Levenshtein distance (LD) (method='lv'). The \textit{stringsim} command then divides the distance by the maximum achievable distance and subtracts the value from 1. For \textit{stringsim} we set the method to Jaro-Winker distance (JWD) (method='jw'). This produces a score between 0 – 1 (1 = complete similarity [distance 0] or 0 = complete dissimilarity)\textsuperscript{18}. The function then returns a vector with similarity scores (see Figure 3). Recursion was used to iterate through all of the possible pairs between vectors. These methods are case sensitive; thus, all character strings were changed to lowercase before the analysis.
Expert-based Methods

To continue the DE comparative analysis, an HIV expert assessed all vector pairs according to DE distance and similarity scores. DEs were first organized in their comparison category: (A, B), (A, not B), and (B, not A). Pairs that were similar in A∞ and B∞ were assessed first, followed by data elements that were unique to A∞, and unique to B∞. Among (A, B) pairs, the expert first assessed those pairs with a distance of less than 13, since these commonly included simpler strings that could be assessed quickly; however, all (A, B) pairs were eventually assessed. All groups of pairs were organized from highest similarity score to lowest similarity score. Context of usage was also factored into judgment of SH. The expert also confirmed that unique DEs were truly unique (i.e., having no semantic or syntactic equivalence to a DE in the vector to which it was compared).

To identify semantically heterogeneous DEs, two types of DE pairs were assessed, either semantically-equivalent/syntactically-different DEs (e.g., HIV-positive/HIV+/Seropositive), or syntactically-equivalent/semantically-different DEs (e.g., “Partner”[sexual] vs “Partner”[relationship]). Although unique DEs contribute to heterogeneity in general, they may not directly contribute to the SH heterogeneity between two domain-associated datasets. To find the percent of data elements that specifically contributed to SH, we subtracted the number of unique DE—((A, not B) and (B, not A))—from the total number of DE. This left only those DEs with semantic similarity, syntactic similarity, or both. To complete our analysis, we divided the number of semantically heterogeneous DEs over all non-unique DEs. This can be represented by (A||B, SH)/(A, B) – ((A, not B) + (B, not A).

Results

Clinicaltrials.gov Search

Our search from Clinicaltrials.gov returned 453 studies. Principal Investigators (PIs) with an existing relationship with either this study’s PI, institution, or internal review board (IRB) were contacted. This was done to help facilitate not only the procurement of data dictionaries, but also the acquisition of related datasets for use in subsequent aims of this research, which will include use of actual participant data. We sent invitations to the PIs of 20 studies and received responses from ten PIs, and of the ten PIs we were able to confirm that 18 datasets were available for use in our study. The total number of participants represented by the 18 datasets was >4,300. Currently, of the 18 that were indicated as possible to use in our study, we have procured and analyzed eight (see Tables 1-3), six are still being procured, and four could no longer be offered for analysis. The total number of DE among the eight studies we have analyzed was 1,142. Examples of DE from those eight studies are provided in Table 4 and the number of DE per study is indicated in Table 5.

The eight data dictionaries procured met from 63% to 100% of the population inclusion criteria outlined in RFA-MH-14-200 “Integration and Analysis of Diverse HIV-Associated Data (R03)”, and all included data involving youth (18-25) and adults (ages 26-55). None included children (ages 12-17), which was one of the originally desired criteria in RFA-MH-14-200, but ultimately dropped in our study for IRB associated reasons. Six included HIV-positive participants, six included HIV-negative participants, and four included a combination of both. All eight also included male participants, most of which were MSM except for one study. Six studies included female participants, and three studies included transgender participants (see Table 2).

SMASH and Comparative Similarity Analysis

Tables 4 and 5 below show the results from the data-driven, expert-based similarity analysis. Table 4 shows the results from SMASH, the data-driven string metrics described in the “Data-driven Methods” section, and Table 5 shows the results from the expert-based assessment of the pairs found by using SMASH (described in the “Expert-based Methods” section). There were a total of 1,175 pairs of semantic similarity DEs. We found a total of 1,048 (87%) cases of SH similarity between study vectors A_n and study B_n. Most heterogeneous pairs (97%) were semantically-equivalent/syntactically-different. Of the 1,048 >50% were repeated matches with two or more studies. Conversely, 127 (13%) pairs were semantically homogeneous. Semantically homogeneous pairs most often consisted of demographic DEs (e.g. race, age, gender, sex) and administrative DEs (data, time, consent, testing). Studies with a smaller number of DEs that were being compared to studies with a larger number of DEs had the most similarity overlap of their DEs. That is, smaller studies’ DEs most often matched to at least one of the DEs of a larger study.

Study abbreviations are listed in Table 1. Number of DE per study are in parenthesis.

We identified a total of 498 SH DEs without overlap between studies. Heterogeneous DEs were either semantically-equivalent/syntactically-different (ex. HIV positive = HIV+ = Seropositive), or syntactically-equivalent/semantically-different (e.g., “Partner” [sexual] vs. “Partner” [relationship]). Context of usage was considered. Semantically-equivalent/syntactically-different were the most common pairs identified (Additional examples can be found in Table 5). Finally, we calculated the percent of heterogeneous pairs over all pairs from each vector comparison. Word distance varied (min=0, max=23, avg=7). We were able to calculate that the average amount of SH between vector pairs was 87% from the results in Table 6. The fact that most heterogeneous pairs (97%) were semantically-equivalent/syntactically-different did not change in this part of the analysis.

Discussion

In this study we used a combination of data-driven (e.g., SMASH) and expert-based informatics methods to characterize SH. By using SMASH to analyze DE from data dictionaries from empirically generated sources, we gained a better understanding of the nature and extent of SH in the HIV research domain. Our use of empirically developed data is unique in that we are not responding to an internal need to address SH in our own system, but rather to understand the problem within a domain of research. Most often, attempts to address SH have been in reaction to a need for an institution to integrate its data with various internal systems or with the data of other institutions. As a
result, they attempt to harmonize the data without characterizing the extent of the problem. We started with first assessing the problem and used diverse empirically generated sources of data. This gave us the advantage of understanding different relationships between the nature (e.g., semantically-equivalent/syntactically-different) of the data and the extent of SH.

For instance, we found that although all of the data dictionaries collected had more than 60% of overlapping populations and data types, they still had a very high level of SH among their DEs. However, we also found that the crossover between research teams also had an impact on the amount of SH between different studies. For instance, though HT2, GEL, SI, and Top Mic had different PIs, they all had overlapping research staff. As a result, their percent of SH was notably lower than the other studies. Also, though GEL and Top Mic were conducted at different institutions, they had at least one PI (or Co-PI) in common. In contrast, Pathways was conducted at the same institution as GEL and HT2, and had no staff in common. In this case, there was still a high amount of SH between Pathways and the other two studies (GEL and HT2).

The use of Clinicaltrials.gov was instrumental to the dataset identification process. Furthermore, using both our data-driven SMASH method and expert-based methods in our similarity analysis had distinct benefits over using one method alone. The SMASH method for the discovery of syntactically similar DEs helped to identify DEs that potentially were semantically similar. This sped up the process of discovery. Also critical was leveraging both the distance score and the similarity score in the organizational process. We found that by leveraging both, those DEs that had a low distance score and a high similarity score often had a notably close relationship. This method is not only helpful for identification of SH but also may facilitate the identification of common DEs. However, we also found that data-driven methods alone were insufficient.

The expert-based methods we used (see Figures 1-3) were instrumental in identifying those DE that were semantically similar, but completely syntactically different (i.e. had a high distance score and a similarity score of 0). For example, HIV+ and seropositive, have a direct 1:1 semantic relationship; however, they have a distance of 10 and a similarity score of 0 based on SMASH (see Table 4). The HIV expert was able to find this relationship, but the data-driven methods alone may have missed it. Though semantic learning may have done a better job, computational methods require additional data to learn how syntactically different relationships are semantically similar. This level of data is not often present in most data dictionaries. Similarly, HIV status and sero-discordant have a close semantic relationship, but these also had a high distance (14) and a similarity score of 0. Lastly, one of the fundamental characteristics about the heterogeneity that we found was the type of SH. We found that most heterogeneous pairs were semantically-equivalent/syntactically-different. This has strong implications for how, or on what, to focus attempts to resolve SH.

**Future Work**

Future development of methods to resolve SH, particularly those in the HIV research domain, should focus on variables that are semantically-equivalent/syntactically-different, which we found most likely to reflect SH. Variable types that we found to be commonly homogeneous, such as demographics, should have lower priority. Also, Clinicaltrials.gov should be leveraged for identifying empirically generated data sources for future SH discovery in other research domains. Future work should also include data dictionaries on children and transgender individuals. It should also focus on data dictionaries from international research. Moreover, looking at data dictionaries alone may limit the data-driven approach. Future work should also look at actual values for each DE to see if any additional information about the DE can be gained from the data it elicits. This could make for a stronger data driven approach. Methods to identify SH and achieve semantic harmonization should be developed in a way that more seamlessly integrates both data-driven and expert-based informatics methods for identifying SH. SMASH should also be systematically evaluated against other computational methods and assessed for sensitivity and specificity. Lastly, future work should also aim to analyze a larger number DEs from basic science research (e.g., genomics).

**Limitations**

The relatively small number of empirically derived DE sources is a limitation. Moreover, the search parameters used in Clinicaltrials.gov did not account for the full breadth of topics in the HIV research domain (e.g., genomics, proteomics, virological research). Also, DEs that address specific variables related to some sub-populations were lacking in the data dictionaries (i.e., children, transgender individuals).
Conclusion

SH is detrimental to interoperability between healthcare systems and data integration among domain-associated DEs in health research. For multiple data sources to interoperate with one another, it is essential to reconcile these semantic differences. Moreover, SH has the potential to negatively impact the interpretation of NIH funded study results, and health policy implications that are drawn from the analyses of data from various studies. As a result, SH may also have an effect on FDA medical product approvals and the comparability of results across trials. Thus, it is imperative that health policy makers encourage methods to minimize semantic heterogeneity, starting with characterizing its extent in a given data source. We identified the various sources of SH and found that characterizing SH provides a basis for understanding how to map and transform data to overcome these differences. Most of the DE in the HIV research domain were semantically heterogeneous, and most of the SH derived from semantically-equivalent/syntactically-different DEs. Expert-based solutions alone may be impractical, and data-driven methods may miss critical semantic relationships. We found that our data-driven method, SMASH, and expert-based methods are mutually beneficial for assessing SH among health-associated data, especially among semantically-equivalent/syntactically-different DEs. We recommend that health policy makers encourage the characterization of semantic heterogeneity in health related data, and we encourage the continued development of high-throughput expert-based and data-driven solutions, working in concert, that can address semantically-equivalent/syntactically-different DEs.

Contributions

William Brown III played a major role in all aspects of the research, conducted the analysis, devised the SMASH method, and was the primary author of the manuscript. Suzanne Bakken (PhD thesis sponsor) and Alex Carballo-Diéguez contributed to data dictionary identification, recruitment, acquisition and provision. Suzanne Bakken, David Vawdrey, and Chunhua Weng contributed to conceptualization and design of the overall research. Suzanne Bakken wrote the overall grant and secured funding for the project. All authors significantly contributed to the substantive review of the manuscript.

Affirming Proposed Variable Relationship Patterns in a Conceptual Nursing Model by Converting Qualitative Data to Causal Loop Diagrams

Jennifer A. Browne, Ph.D., RN-BC, CCRN

1University of Texas Health Science Center San Antonio, Texas

Abstract

Even with decades of use, there is minimal understanding about the impact that the use of Health Information Technology has on nursing work and workarounds. Reliance on quantitative methods has to some degree constrained our understanding by viewing phenomena from only one perspective. This multimethods research used qualitative data to develop causal loop diagrams and inform a Health Information Technology Workaround model. This approach can play an important role in generating an improved understanding of nursing clinical workflow and workarounds. This research strategy has not been identified in nursing literature to date, but perhaps will encourage future exploration and paradigm crossing. Investigating the use of causal loop diagrams and systems modelling in nursing can create an opportunity to enrich our insights and encourage scientific dialogue about the complexity of clinical workflow and the integration of Health Information Technology.

Introduction

The purpose of this paper is to describe a multimethod approach to model development and workflow diagramming. In informatics research there is a tendency to use a quantitative approach to investigations under the assumption that this is the way to reach significant conclusions. A flaw in this perspective is that it relies on linear, structured relationships to build knowledge about clinical care, a phenomenon that does not operate according to straight path algorithms. The study of complex adaptive systems (CAS) however is framed by dynamic interactions and complexity. It often addresses multiple levels and units of analysis; using multimethods to tell a story about how and why phenomenon evolved. Unfortunately, as a newer science, there are not many examples of CAS analysis in nursing.1

This paper describes the transformation of qualitative data into causal loop diagrams (CLD’s) in order to map the proposed variable relationships in a Health Information Technology Workaround (HITW) Model (See Figure 1) depicting health information technology (HIT) workarounds. This work was part of a larger dissertation study exploring HIT workarounds being used by nurses in intensive care. This study generated a multi-level conceptual framework through the specification of relevant variables and relationships essential for understanding what is actually happening with the use of HIT at the bedside. One aspect of analysis was the creation of causal loop diagrams (CLDs) in order to integrate feedback loops with the proposed HITW Model. This paper describes the development of these diagrams. The CLD’s are models that portray the behavior of variables in a system, presented as causal relationships and feedback loops.2 The premise of this work is that the feedback loops of a system should be understood in order to understand the system.3
The proposed HITW model is presented in Figure 1. This is a three level model with the micro level representing the patient, mezzo representing the nurse and macro the organization. This model is based on Arthur Stinchcombe’s constructing social theories work for functional theoretical explanations. The dependent variable in this work is the homeostatic variable (H). The variables (causes) that disrupt homeostasis are tensions (T) and the variable that tries to compensate for this and return the system to homeostasis is structure (S). Stinchcombe’s work allows the review of functional theory as an easily understood pattern of relationships between variables.

**Systems Thinking**

The complexities of healthcare can be overwhelming, yet in order to simplify workflow models we may be missing the real-world experiences of clinicians and the true complexity of care. For example, cosigning high risk medication should result in better patient safety, however as one nurse described, there may be unintended consequences such as altered or missing documentation: “I will not list all my IV medication titration changes that I made just to keep from having to beg someone to put in their password several times for each change”.

Quantitative approaches tend to break processes down, focusing on small numbers of linear relationships. Conversely, systems thinking looks at interactions and relationships between variables and expands our view of the ever-changing landscape of the phenomena. Systems are active, dynamic processes with multiple, variable interactions that will vary with time and environment. For instance, the same variable can act as an independent and dependent variable simultaneously in a systems thinking approach. Negative and positive feedback loops are a fundamental point of focus and can significantly influence systems behavior.

There is a formal process for systems thinking, systems dynamics, that blends modeling and simulation research with qualitative methods. This multimethod research is generally broken down into five parts. The first step is to identify variables from the qualitative data and secondly to develop a causal loop diagram (CLD) using those identified variables. From the CLD, stock and flow diagrams are constructed. The fourth stage is the development of the mathematical equations formulating the problem as designed in the stock and flow diagram. Finally, model simulation is performed using the predefined formulas. The scope of this work led only as far as to consider the presence and general implications of feedback loops with interactions between safe patient care, turbulence, workload, barriers, workarounds and HIT protocols. In order to explore relationships between variables, the methodology for the development of causal loop diagrams (steps one and two) from the coding of qualitative data was followed.
Methods

This study was conducted in collaboration with The American Association of Critical Care Nurses and approved by The University of Texas Health Science Center IRB. A sample of 307 Registered Nurses voluntary responded to an email survey consisting of two qualitative open ended questions followed by quantitative items measuring nurse characteristics, elements of nursing work, HIT problems, and patient safety. Multiple sources of data were used to compare, refine, and elaborate findings from both methods. The qualitative/ modeling techniques have been described in systems dynamics research over the last decade, yet they are still poorly specified. In this case the procedures described by Kapmeier and Yearworth and White were followed. As a strategy to help ensure rigor, the research outline offered by Kapmeier was followed. To enhance the validity of the multimethod research, legitimation process and checks guided each stage of the research.

The initial HITW model was designed using literature and personal experience. An internet survey was selected to collect data from the critical care nurses. The survey asked the nurse to describe, in their own words, the problem they experienced with HIT and the workaround used. Quantitative variables alone (from the literature) would have limited the data collected, and variables we knew to be important (such as workarounds) had no associated measures. It was clear that qualitative inquiry would be essential in modeling this complex system. The ability to follow up with participants was considered and rejected because assuring complete confidentiality was imperative to gaining truthful responses.

We were cautious in determining the a priori sample size because of concern over the amount of narrative transcripts we would receive. Nunally recommends sampling at least 10 times as many subjects as variables, and so the sample size was determined from quantitative methods and set at 290. Unlike true grounded theory, the qualitative analysis was conducted after the literature work, but before the quantitative analysis. Using a qualitative data analysis software, new behaviors or problems were identified and quantified. Themes and concepts were explored across texts to identify relationships. After reducing the volume of data during the coding process, categories were generated that could be linked to the concepts presented in the literature.

The work was divided into six exercises:

1. Qualitative data was coded from the survey transcripts. Specific qualitative variables (i.e., types of workarounds and frequency measures) were quantified and imported to IBM Corp. SPSS.
2. Reliability procedures were performed with each scale and exploratory factor analysis performed on the scales for turbulence and HIT problems. Inter-rater reliability was performed by different groups of experts to determine the internal validity of qualitative items, and to confirm agreement between quantitative items and qualitative descriptions. To confirm the agreement of preliminary workaround definitions, inter-rater reliability analysis was conducted by a panel of critical care nurses.
3. Quantitative correlation analysis of variable relationships and identification of relational patterns.
4. Qualitative code relations browsers were utilized to produce variable relationship matrices using MAXQDA software. The strength and direction of the relationships were informed by the narratives and quantitative analysis.
5. Development of multilevel causal loop diagrams representing the micro/ mezzo level and the mezzo/ macro level.

Results

The respondents were 87% female and 13% male. Fifty-eight percent of the nurses were 45 years old or greater. Almost 50% of the nurses had a bachelor’s degree in nursing. 20.6% an associate degree and 19.9% had a master’s degree. Nurse experience was midway between a proficient and expert. Intensive care specialties included adult, pediatric and neonatal. Patient acuity was reported as: 61.8% critical, 28.7% guarded and 9.2% stable. Workload of the nurse was reported as heavy (40%) and moderate (58%). There was a wide range of software represented including: KBMA (Allscripts), Carefusion, Cerner, Epic, Meditech, McKesson, Soarian, eICU, EndoTool and GlucoStabilizer.

Key variable definitions were confirmed using quantitative approaches; factor structures were identified and the reliability of new scales assessed. The key variables and associated survey items were: workload, turbulence, patient safety hazard, and HIT barriers/ problems. In previous work on the HITW model, the variable workload did not fully describe the amount and type of work nurses were performing. The variable turbulence was created to measure additional, unanticipated work that nurses perform. Examples of turbulence attributes include distractions,
interruptions, missing equipment and loss of information. The alpha coefficient for the 15 items was .751, suggesting acceptable internal consistency. Turbulence is connoted as the delta symbol in the HITW model. Four workaround variables developed during a previous pilot were confirmed and their specific attributes identified. These workarounds variables are: problem solving and intuitive workaround, and informal and formal communication.19 All proposed variable definitions and attributes were supported.

Once qualitative coding was completed, binary code matrices were produced (Table 1). These matrices allowed identification of relationship patterns and represented a starting point for investigation of mutual causality and feedback. This approach helped identify co-occurring concepts within and across groups. Table 1 identifies, for example, no relationships between patient safety risks, workarounds, and the lack of a unit secretary. There is also no relationship between the workload attributes of admissions, transfers and discharges and patient safety risk. The matrix did however identify relationships between turbulence (technology response time), patient safety risk and workarounds. Some interesting relationships were suggested. For instance, technology response time and ethical/moral conflict were the only two items associated with workarounds creating a patient safety hazard. On the other hand, the creation of a patient safety hazard caused by the primary problem was associated with 9 turbulence items such as loss of information, equipment issues and information overload.

Turning to the quantitative items, correlations examined between workaround variables and demographic data (i.e., nurse characteristics) demonstrated no significant relationships. Quantitative variable analysis revealed that direct relationships exist between nursing workload, turbulence, the HIT barrier (problem) and patient safety hazards. For example, there were significant positive relationships between the HIT barrier (problem) and workload ($r = .32, N = 293, p = .000$) and HIT barrier and turbulence ($r = .33, N = 293, p = .000$). Turbulence was positively correlated with safety hazards ($r = .41, N = 293, p = .000$) and workload ($r = .48, N = 293, p = .000$). The weakest association was between workload and safety hazards ($r = .16, N = 29, p = .005$). There was overall agreement between the quantitative correlation findings and the qualitative binary matrix.

The correlational analysis supported a number of positive loops. An example of four positive reinforcing loops suggested by the data is presented in Figure 2. Positive reinforcing feedback loops are labeled as R in a CLD.7 As the number of HIT problems increase, so does workload. As turbulence increases, workload increases and as HIT problems increase, turbulence increases. Finally, as turbulence increases, risks of a patient safety hazard increases.

The analysis also supported a number of negative loops. Examples of four negative balancing loops are presented in Figure 2. These negative balancing feedback loops are labeled as B in a CLD.7 In these examples, as intuitive and informal communication workarounds increase, stress decreases. As workarounds increase, inefficiency decreases and as informal communication workarounds increase, complexity decreases. The correlation results provided direct and inverse relationship data to derive proposed feedback loops, however for
quantitative data to be useful and accurate a large amount of data is required. The qualitative data resulted in more representative and detailed matrices.

**Figure 2.** Positive (reinforcing) and negative (balancing) feedback loops

To begin modeling of the CLDs, qualitative matrices were produced for the micro and mezzo variables. Since the relationships can be in either direction, the nature of the relationships (direction) is determined by the researcher, but assessment of the strength of the category relationships can be determined by the number of times two categories are linked. In many cases, the quantitative correlational data supported the findings and suggested the direction of the relationship (direct or inverse). The more frequently the category is linked in the matrix result, then the more evidence there is that the two categories are related. The qualitative matrix example in Table 2 suggests, for example, that as the stress associated with HIT problems increase so does the patient safety risk (n=17). The strongest relationship in this table showed that as efficiency improved with the use of workarounds patient safety improved (n=38).

A CLD of the micro and mezzo interfaces was developed based on the preliminary data produced from the qualitative matrix report and supported by the quantitative analysis (Figure 3). This CLD provides evidence that
protocols are interacting with barriers, workload and turbulence creating positive and negative feedback loops that also interact with safe patient care. This is by no means complete, but does give a sense of the complexity of the balancing and reinforcing loops and some of the primary relationships that were identified.

Figure 3. Causal loop diagram micro and mezzo levels

Some of the primary relationships identified in the micro/ mezzo causal loop diagram included:
1. Balancing loop 1 (B1): As turbulence increases, workarounds increase and problems decrease.
2. Balancing loop 2 (B2): As patient safety risks increases, workarounds increase. When workarounds increase, stress and inefficiency decrease and so safety risks decrease.
3. Balancing loop 3 (B3): As problems increase, workarounds increase. Workarounds act to improve the performance of HIT, decreasing process steps. Decreased process steps result in decreased problems.
4. Reinforcing Loop 1 (R1): As patient safety risks increase turbulence increases. Increased turbulence results in increased workload and that increases the patient safety risks.
5. Reinforcing Loop 2 (R2): As problems increase, turbulence increases. As turbulence increases so does workload. Increased turbulence and workload is associated with increases patient safety risk; increased risks contribute to an increase in problems.

Some of the primary relationships identified in the mezzo/ macro casual loop diagram (Fig.4) included:
1. Balancing loop 1(B1): As formal communication increases, process steps increase. As added steps increase there is a reduction in adherence to the protocols which forces an increase in formal communication.
2. Balancing loop 2 (B2): As protocol adherence increases so do the work process mismatches. These mismatches cause an increase in delays, increasing workarounds, and a reduction in adherence to protocols.
3. Balancing loop 3 (B3): As adherence to hospital protocols decrease, hospital reimbursement also decreases. When reimbursement decreases so does job security/ salary. As job security decreases, workarounds increase and are used not necessarily to increase accurate protocol use but to increase the perception that protocols are being followed.
4. Balancing loop 4 (B4): As care delivery delay increases, lost time increases. With an increase in lost time, there is an increase in workarounds. As workarounds increase the care delivery delays decrease.
5. Reinforcing loop 1 (R1): As workarounds increase, meeting the intent of the protocol increases. As compliance with protocols increase (or at least the appearance of compliance) then job security increases.
6. Reinforcing loop 2 (R2): As formal communication workarounds increase, added process steps also increase. As the steps increase so do the delays. When delays increase, the workarounds increase and this increases the use of formal communication workarounds.
7. Reinforcing loop 3 (R3): As workload increases, turbulence increases. An increase in turbulence causes an increased safety risk which then causes an increased errors. Increased errors cause an increase in workload.
Discussion

The use of qualitative modeling can provide an opportunity to consider situations that might not have been considered before. In quantitative inquiry the variables explored are pre-determined while causal loop diagramming allows for consideration of new behaviors during the study. For example, a number of nurses described that their year-end evaluations were directly tied to a compliance audit of scanning percentages and documentation. As this was explored, it was realized that nurses who could not perform the behavior were using workarounds to give the appearance that the protocol had been met.

The qualitative data supported the idea that nurses try to use HIT and the associated protocols to deliver safe patient care. It was also evident that nurses were attempting to comply with the HIT protocols even when the technology, added steps and work process mismatches made it difficult or impossible. When attempting to utilize Structure variables to achieve Homeostasis, nurses often encountered problems and turbulence which disrupted care delivery. In turn, nurses used workarounds as solutions for efficiency, complexity and time problems in an attempt to achieve Homeostatic outcomes.

Increased workload and reduced staffing were confirmed to add additional complexity, time pressure and inefficiencies further threatening safety and efficiency. Workarounds acted to mediate the relationships between turbulence, workload and patient safety. This was substantiated by balancing feedback loops between turbulence and workarounds and the time saved by use of a workaround in the absence of a problem. Current thinking is that patient safety risk increases when workarounds are utilized, but this analysis suggests that the opposite may also be true; workarounds are being used when a nurse recognizes a patient safety threat. It was also determined that workarounds were being used to comply with protocols. For example, it was reported that one protocol required that barcodes on all blood products be scanned prior to administration as part of the safety checks. When the blood bank had to split the blood product between 2 bags, there was no barcode on the second bag. The nurse entered another order for the same blood product in order to generate a barcode, and then canceled the order. Using this workaround, the nurse could follow the policy and scan the barcodes on both bags.

The CLD’s helped identify additional processes that the primary relationships might contribute to. For instance, formal communication workarounds are defined as written or oral communication that occurs through designated channels of the organization to address HIT systems barriers and disseminate protocol variations. Correlation analysis and CLD’s identified positive relationships between formal communication, extra process steps and care delivery delay. The CLD also identified that the administrative sanctioned workarounds (formal communication) indirectly reduced a nurses’ adherence to protocols. (Fig.4) This had not been apparent from the qualitative analysis alone. Finally, the development of CLD’s from code matrices also permitted us to see quite
rapidly where relationships did not exist. For instance, in nursing it is often assumed that inadequate HIT training is somehow associated with increased patient safety risk and workarounds. In fact, it is not uncommon to find mandatory education sessions following safety events. The code matrix (Table 1) did not identify a relationship between these variables.

Figure 5 presents an overlay of the CLD’s with the micro-mezzo HITW model. The feedback loops confirmed and clarified the relationships in the HITW model. The relationship between workload and adherence to HIT protocols was confirmed as bi-directional. Problems with S are filtering directly back to T (i.e., HIT performance, additional steps, staffing) further increasing workload and Tension. Turbulence interaction with model variables was apparent at the anticipated interfaces. The CLD’s supported the HITW model proposal that barriers (problems) and turbulence interfere with a nurses’ ability to utilize HIT to protect the patient from safety risk.

Figure 5. Causal loop diagrams and HITW model at the micro-mezzo level

One criticism of qualitative system dynamic modeling is the concern that wrong inferences might be attained. Causal loop structures can quickly become overly large and complex, masking the primary model behavior with excessive detail. It is recommended that a system archetypal model be maintained summarizing the essence of the model. In this case, the HITW model summarizes the relationships between HIT protocols, patient safety and workload and denotes the primary feedback loops derived from the quantitative and qualitative findings (Figure 5).

Implications

Qualitative inquiry allows identification and incorporation of variables that were perhaps never even considered at the onset of study. For example, documentation audits and the influence of nurses’ job evaluations on the use of workarounds was unexpected and not considered at the start of the study when quantitative variables were being designed. The qualitative analysis allowed the identification of this relationship during coding, inclusion in the matrix evaluations and timely integration of this interaction into the study.

Feedback loops occur when the output of a process becomes the input of another. Resulting behaviors, such as unintended consequences can be very hard to predict. The development of CLD’s assists in developing a view of the intertwining of problems and solutions and helps to anticipate the possible consequences of system or process use and changes. At the very least, interdisciplinary CLD development sparks a planning dialogue.

The CLD’s, although valuable, are only a first step. The next consideration must be the integration of time and time delay into the models. Integrating time into the analysis allows for understanding how much of a delay one variable can cause for the entire system. Matrices can be developed for time, and will assist in determining which variables are appropriate for intervention. This would be a most valuable asset for nursing and informatics planners.

Arising from the qualitative CLD development that displays links between cause and effect, are the stock and flow diagrams. The diagrams are more detailed and precise, relying on mathematical functions.
development of stock and flow diagrams. From stock and flow diagrams evolves the ability to run systems dynamic simulation and many simulation software products are evolving for precisely this type of use.

Although CLD’s are used as a stepping stone to more advanced analysis, there are some underlying truths and patterns that can be identified and utilized. CLD’s can be used to better predict consequences of change resulting from feedback loops. For example, CLD’s with a majority of negative feedback loops are more likely to display systemic resistance to changes or disturbances. Alternately, a system predominated by positive feedback loops can be highly unstable. Change should be approached cautiously and monitored for the emergence of new feedback loops. Different approaches to change management are recommended in each situation. Finally, as big-data and data analytics become more common place, the integration of system dynamics with data mining can more rapidly expand the knowledge discovery in databases.

Conclusions

Critical care nursing and healthcare in general is in a significant transformation. Rapid adoption of cutting edge technologies, new reimbursement systems and changes in the characteristics of nursing and physician jobs can stress an already complex healthcare system. The complexity of healthcare creates barriers to care delivery and, along with rapid change and poor workflow design, can inhibit a nurses’ ability to comply with the desired protocols envisioned by policymakers. When integrating HIT into clinical care and nursing workflow, a lack of theoretical underpinnings and a reliance on linear models has limited the ability to anticipate unintended consequences and consider the possible adaptations that nurses might make when using HIT.

This research offered one approach to integration of qualitative data into workflow analysis in order to explore variable relationships in a HITW model by creating causal loop diagrams. The foundational assumption in this work is that the nursing environments we are studying are dynamic complex adaptive systems that are constantly changing. The approach presented here offers one alternative to the structured linear methodology of nursing research by combining different methods in an attempt to better describe and understand the complexity of HIT use in critical care. The causal loop diagrams developed here, although elementary, do provide insights into nurses HIT workarounds in critical care. The research approach described in this paper is just the first step to more advanced analysis and the development of simulation models. Continuing to view our acute care environments as the complex adaptive systems that they are will require new approaches to research design and methods. This paper was one attempt to offer alternative ideas to the utilization of qualitative inquiry and discovery in nursing informatics research.

Multi-Trajectory Models of Chronic Kidney Disease Progression

Philipp Burckhardt, MSc, Daniel S. Nagin, PhD, Rema Padman, PhD
Carnegie Mellon University, Pittsburgh, PA

Abstract

An ever increasing number of people are affected by chronic kidney disease (CKD). A better understanding of the progression of CKD and its complications is needed to address what is becoming a major burden for health-care systems worldwide. Utilizing a rich data set consisting of the Electronic Health Records (EHRs) of more than 33,000 patients from a leading community nephrology practice in Western Pennsylvania, we applied group-based trajectory modeling (GBTM) in order to detect patient risk groups and uncover typical progressions of CKD and related comorbidities and complications. We have found distinct risk groups with differing trajectories and are able to classify new patients into these groups with high accuracy (up to $\approx 90\%$). Our results suggest that multitrajectory modeling via GBTM can shed light on the developmental course of CKD and the interactions between related complications.

1 Introduction

Chronic Kidney Disease (CKD) is a growing burden for the national health-care sector. Today, it is estimated that more than 11% of the US adult population have some degree of CKD, and projections indicate that more than 50% of those aged 30 to 64 years will develop CKD. With costs amounting to $49.2 billion in the United States in the year 2011 for the treatment of End Stage Renal Disease (ESRD), the final stage of CKD, it is paramount to gain deeper insights into the progression of the disease in order to facilitate the development of new preventive care approaches.

The increasing adoption of Electronic Health Record Systems (EHRs) in recent years, fueled by the promise of cost savings, increased efficiency and better communication between the various healthcare providers, has resulted in the accumulation of a massive amount of structured data on patients and their disease progressions. It has been argued that the identification and the quality of care of CKD patients could be improved by an effective utilization of EHRs.

Using a rich data set consisting of the EHRs for more than 33,000 patients from a leading community nephrology practice in Western Pennsylvania, this is the first study that applies group-based trajectory modeling (GBTM) in order to uncover typical progressions of CKD and related comorbidities and detect patient risk groups. By modeling biomarkers not only for CKD, but also complications typically linked to it, we aim to obtain a fuller, multi-dimensional picture of its progression. Specifically, we use the estimated glomerular filtration rate (eGFR) as a biomarker for CKD and other appropriate laboratory-based biomarkers for its complications.

Historically, CKD progression was assessed via patient's serum creatinine levels. However, serum creatinine is not a good measure of kidney function, so laboratories nowadays report eGFR in addition. eGFR can be calculated from the level of serum creatinine and patient characteristics such as age, gender and race. This change in reporting was associated with an increase in first nephrologist visits, but eGFR by itself is not sufficient for guiding decision-making on the care of kidney patients.

A multi-dimensional approach is required since CKD patients tend to have numerous comorbidities. In fact, a large fraction of patients suffering from CKD do not progress to the later stages of the disease but die prematurely due to these comorbidities and complications. Thus, any treatment should take into account the contemporaneous progression of CKD and its varying complications at differing levels of severity that patients experience. This poses a major challenge, though, since care coordination amongst various medical professionals is involved. Discerning disease patterns via interpretable and accessible statistical models has the potential to alleviate the communication challenges between these stakeholders. To facilitate this, we develop and test a statistical model which can be used to track not only the progression of CKD but also the development of several complications. This can be accomplished by monitoring the levels of biomarkers for the considered complications.

In clinical research, group-based trajectory models (GBTM) are increasingly used to model the development of a clinically important indicator over time, with the goal of identifying groups of individuals sharing a common trajectory.

1737
Originally devised by Nagin and colleagues as a criminological tool for classifying criminal careers, this approach lends itself towards usage in a wide range of disciplines, including clinical research.\textsuperscript{8} At their core, GBTMs are an example of a class of statistical models called finite mixture models. More precisely, GBTMs are mixtures of regression models applied to longitudinal data, where the likelihood of a time series for an individual is assumed to be a mixture of linear models that include both an explicit time variable as well as other covariates. This way of analyzing biomarker trajectories is different from other approaches such as latent growth curve modeling, which rests upon the assumption of a common functional form for the trajectories for all individuals, with its parameters varying randomly. Growth curve models, which can be formulated either as structural equation models or as multilevel models, effectively assume all individuals to belong to a single class. In contrast, GBTM have a finite number of classes, each of which is characterized by its own parametric trajectory. Given that our interest lies not in the study of the variability between subjects, but in discovering the typical marker trajectories that we suspect to exist, GBTMs are more appropriate for our needs.

The data set spans four years of patient data and includes diagnoses, lab results and patient characteristics. After restricting the data set to all patients who were diagnosed with CKD Stage III during the covered time span, we removed all transplant patients as their trajectories differ significantly from the rest of the patients. The final cohort consists of 1,944 individuals.

We fit a single, joint multi-group trajectory-model for five biomarker time series, and use an appropriate model selection procedure to identify a parsimonious and interpretable model. Covariates such as patient characteristics (age, weight, gender, race, etc.) and binary indicators on whether the patient suffers from the comorbidities of diabetes and hypertension are included in addition to the biomarker time series. By fitting a joint model for all markers, we build upon earlier work on single and dual trajectories, whose results hinted at the usefulness of GBTMs for risk stratification of CKD patient populations, even though only one or two markers were used at a time.\textsuperscript{9} The constructed trajectory model is necessarily a simplification of the real world, but ideally one which captures the main distinctive trajectories of disease progression one would typically encounter in patients. Its use could enable better screening of patient populations for high-risk individuals and lead to insights about the interplay between the various complications that are suffered by CKD patients.

\section{Data}

We are working with a rich clinical data set of patients from a leading nephrology practice in southwestern Pennsylvania. The total number of unique patient records is 33,882. The data set contains information about patient characteristics (age, gender, weight and height) as well as all of their lab measurements with associated dates.

The lab results span a total of 18 quarters, ranging from the years 2009 to 2013. The patient population is split almost evenly among female and male patients. Most patients are retirees, with median age of 70 years. 94\% of the patients are white. About half the patients have a diagnosis of CKD Stage III while the remaining are in more advanced stages of CKD.

For our analysis, patients diagnosed with CKD Stage III between January 1, 2009 and November 19, 2012 were selected on the grounds that this diagnosis usually marks the point when patients start showing first disease symptoms and are referred to a nephrologist. Patients in CKD Stages I and II show almost normal kidney function, and are therefore rarely diagnosed. A doctor will only make these diagnoses by linking additional evidence like proteinuria or haematuria, which are not sufficient indicators of CKD.

Patients who received a kidney transplant on or after January 1, 2009 were removed from the analysis since their level of kidney function differs sharply from those who did not receive a transplant and keeping them will likely distort the identified disease progressions.

Historically, serum creatinine levels have been used as a marker for CKD: As kidney function deteriorates, blood levels of creatinine typically rise. Tracking the estimated Glomerular Filtration Rate (eGFR) has replaced the creatinine test as a more reliable means to detect early kidney damage and is a method suggested by the National Kidney Foundation (NKF). eGFR can be derived from the creatinine level and additional variables such as age, sex and race and possibly height and weight. For this study, eGFR was calculated from serum creatinine levels using the CKD-EPI equation.
The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) developed and validated this equation, which is more accurate than the previously used Modification of Diet in Renal Disease (MDRD) Study equation, although it is not clear whether it improves risk prediction.11

Creatinine values larger than 10 mg/dl were removed because these values were likely entered incorrectly. We only keep measurements collected on or after the date the patient was diagnosed with CKD Stage III. Typical complications of CKD include Anemia,12 Secondary Hyperparathyroidism,13 Hyperphosphatemia14 and Metabolic Acidosis.15 Our data set allows us to track each of these via corresponding lab measurements. The respective lab measurements of Hemoglobin (HGB), parathyroid hormone (PTH), phosphate (PO4) and carbon dioxide (CO2) can be used as markers for the considered complications. In the cohort, 1,367 patients develop Anemia, while 1,476 of them are diagnosed with Secondary Hyperparathyroidism. 438 patients have Acidosis, but only a hundred suffer from Hyperphosphatemia. Table 1: Averages for the five considered biomarkers across time periods (quarterly). Standard deviations are displayed in parentheses. The overall data availability is displayed in the second row.

All outcome variables were averaged by quarter to deal with the relative data scarcity and infrequency of the lab measurements. In addition, this procedure yields measurements on a discrete time scale as required by the group-based trajectory model. For each biomarker, Table 1 displays the average value across time periods and its standard deviation.

Patients who do not have at least four observations in the considered time range were removed. Even for the remaining patients, observations are scarce: On average, for each patient we have only measurements for 34 quarters whenever there was a missing quarter between them. Doing so increased the percentage of available data from 42% to 62.42%.

After data cleaning and processing, 1944 of the patients diagnosed with CKD Stage III on or after January 1, 2009 were used for model fitting.

3 Methods

Single Trajectory Model

Let \( Y_j \) define the multivariate response variable for the \( j \)-th marker, for example eGFR. Then, \( Y_j = (Y_{j,1}, \ldots, Y_{j,18})^T \) is a vector of length 18, which holds the quarterly lab results for the marker in question. For a single response, the group-based trajectory model posited by Nagin16 assumes the following density for a sequence of longitudinal measurements \( y_j = (y_{j,1}, \ldots, y_{j,18}) \):\[
f(y_j) = \sum_{k=1}^{K} p_k f_{Y_j}(y_j | C = k), \tag{1}
\]
where \( K \) denotes the total number of groups, \( p_k \) the probability of belonging to group \( k \) and \( f_{Y_j}(y_i | C = k) \) the conditional density of the observed data given class \( k \).

The probabilities \( p_k \) of this mixture model are not estimated directly, but related via the softmax function to a \( K \)-
dimensional vector $\theta$ of class coefficients and time-stable covariates $x$ with associated weight vectors $w_k$:

$$p_j = \frac{e^{\theta_j + x^Tw_j}}{\sum_{k=1}^{K} e^{\theta_k + x^Tw_k}}.$$  

(2)

The response vector for each outcome is modelled as a multivariate normal random variable

$$Y_j | C = k \sim \mathcal{N} \left( \mu_{jk}, \sigma_j^2 I \right),$$  

(3)

where the elements of the mean vector are related to the period $t$ (= time in quarters since diagnosis of CKD Stage III) of the individual patient as follows:

$$\mu_{jkt} = \beta_{jk0} + \beta_{jk1} t + \beta_{jk2} t^2 + \beta_{jk3} t^3.$$  

(4)

As can be seen, the group-based trajectory model is based on the assumption that the trajectories in each group have a simple polynomial form. From our experience, a polynomial order above three is rarely necessary, which is why we have constrained the model to have cubic terms at most.

### Multi-Trajectory Model

This is one of the first works in which the group-based trajectory model devised by Nagin\textsuperscript{16} is used not to model just a single time series, but jointly the trajectories of multiple outcomes.\textsuperscript{17} In this model extension, the density for $J$ outcomes becomes

$$f(y) = f(y_{j=1},...,J) = \sum_{k=1}^{K} p_k \prod_{j=1}^{J} f_{Y_j}(y_j | C = k).$$  

(5)

Model fitting and inference is carried out via the `traj` procedure from the Stata package of the same name,\textsuperscript{18} which implements a Newton-Raphson optimization algorithm for maximum likelihood estimation. For $N$ observations $y^{(1)}, \ldots, y^{(N)}$ of all outcomes, the maximum-likelihood optimization problem is

$$\max_{\theta, \beta, \sigma, \omega} \mathcal{L} = \max_{\theta, \beta, \sigma, \omega} \prod_{i=1}^{N} f_{y^{(i)}}(y^{(i)}; \theta, \beta, \sigma, \omega).$$  

(6)

Following the suggestion given by Jones et al., the Bayesian information criterion (BIC) is used to perform model selection and to determine the number of groups $K$.\textsuperscript{18}

### Model Predictions

The aforementioned procedure yields a multi-response model, which fits trajectories for all five biomarkers and incorporates time-stable covariates, namely demographic variables and indicators for the existence of diabetes and hypertension. New patients can be classified using the posterior probabilities of group membership, which can be computed by using Bayes’ rule as

$$\Pr \left( C = l \mid \{Y_j \mid j=1,\ldots,J \} \right) = \frac{p_l \prod_{j=1}^{J} f_{Y_j}(y_j \mid C = l)}{\sum_{k=1}^{K} p_k \prod_{j=1}^{J} f_{Y_j}(y_j \mid C = k)},$$  

(7)

where the number of outcomes $J$ is equal to five in our case. For the conditional densities, it follows from Equation (3) that

$$f_{Y_j}(y_j \mid C = k) = \prod_{t=1}^{T} \phi \left( \frac{y_{jt} - \mu_{jkt}}{\sigma_j} \right),$$  

(8)

in which $\phi$ is the density function of the standard normal distribution. For the data used for model fitting, $T = 18$. However, in order to form predictions, we cannot calculate the group membership conditional on $Y_i$ for all time
periods as they might not be available yet. By conditioning only on measurements up to the observed time, we can calculate posterior probabilities that take all currently available information into account.

Similarly, if for any outcome the time series $Y_t$ contains missing values or starts at a later time, the product will only be taken over the observed data. This allows us to generate predictions for new data points for which we have not yet observed the trajectories for 18 time periods, which is important given the goal of detecting high-risk patients early on and not when it may already be too late.

4 Results

![Trajectories for eGFR](image)

The estimated trajectories for eGFR from the multi-trajectory model are displayed in Figure 1. While all patients in our cohort have been diagnosed with CKD Stage III and thus suffer from kidney damage, it becomes clear that some patients belong to groups characterized by trajectories that show almost no change in eGFR values (groups 5-8), whereas the kidney function of patients in other groups deteriorates significantly after they were first diagnosed (groups 1-4).

The number of groups was determined using Bayesian information criterion (BIC) as the model selection criterion, as was the order of the polynomial terms and the inclusion of time-stable covariates. Using BIC in the model search is supposed to help build a sparse but at the same time sufficiently large model to accurately reflect the data at hand. Starting from a full model with cubic polynomials and all available covariates, variables were removed from the model if they were statistically insignificant and their exclusion improved the BIC score. Eight groups were selected in total, and of the available time-stable covariates, gender, BMI, age, and indicators for being black, being diagnosed with hypertension and having diabetes all ended up in the model. First-order interaction terms between the indicators were not significant and hence we dropped them from the model.

Table 2: Displayed are the group sizes as a proportion of the entire population in the second column of the table, as well as the averages of the included time-stable covariates inside of each group in columns three to eight.

Table 2 shows that the groups are roughly equal in size, but differ with respect to some demographic variables. The
differences are most pronounced for the racial makeup, with Blacks being over-represented in groups one and seven. Even though the differences might be more nuanced for some of the other variables, the null hypothesis that there are no differences among the groups is rejected for each variable at a significance level of 5% when conducting an ANOVA. As one can also see from Table 2, patients with diabetes are more likely to belong to the high-risk groups compared to groups such as seven and eight, which are characterized by stable and better eGFR values.

![Fitted Trajectories of the Eight-Group Multi-Trajectory Model](image)

**Figure 2:** Fitted trajectories of the eight-group multi-trajectory model for the five considered biomarkers

Since patient characteristics seem to tell only part of the story, inspecting the estimated trajectories for the biomarkers might reveal deeper insights into the risk factors associated with CKD. All estimated trajectories are displayed together in Figure 2. Background shading indicates a ranking of the group trajectories in terms of whether marker values are better or worse than those for the other groups. As emphasized by the color coding, groups one to four have worse values compared to the rest for most markers, with group one being uniformly worse and the other three each having one or more markers for which values are better, indicating that patients might not (yet) be afflicted by the corresponding complication.

For example, groups one, two and four are all characterized by patients suffering from Anemia, as evidenced by their low hemoglobin values. It has been argued that there are “potentially severe consequences of anemia in CKD”. Indeed, these three groups develop worse in terms of eGFR than the rest, except for group three. Yet, the remaining markers also show signs for the complications, which furthermore illustrates that patients suffer not only from CKD, but often a variety of other chronic conditions.

The complications are associated with how fast CKD itself progresses: For example, high-risk group one shows the worst trajectories for all considered markers, and a majority of its members do progress to at least CKD Stage IV, if not ESRD, as can be glanced from Table 3.

As expected, groups with worse trajectories for the considered markers (such as groups one to four) have a larger percentage of patients ending up in a more serious disease stage.

For each diagnosis displayed in Table 3, a chi-squared test rejects the null hypothesis of independence between the variable in question and group membership ($p < 0.001$). Knowing the risk group a patient most likely belongs to is therefore inextricably tied to observable outcomes and diagnoses.
Table 3: Contingency table for group membership and the final CKD diagnosis of the patient. A patient can experience either no progression of his CKD status or advance to either Stage IV or Stage V, which is also called End-Stage Renal Disease (ESRD).

One promising use of trajectory models for health outcomes is to detect sub-populations of patients who are particularly at risk and might benefit from early interventions. In Figure 3, the changes in misclassification rate are displayed when not all time periods of the data are used, but only those up to a chosen period. As expected, the misclassification error for the full training data approaches zero when all periods of data are used, which is tautological because the group memberships are determined by assigning each patient to the group with the highest posterior probability. However, when we use fewer and fewer data points, the misclassification rate goes up since the patients cannot be placed definitely in one of the groups yet. The negative slopes of the two plotted lines are large in magnitude, though, indicating that the model does dramatically better as more data becomes available. To demonstrate that this pattern occurs also on previously unseen data, we set aside 20% of the observations as a test set and refit the model on the remaining 80% of the data. The misclassification rate on the test set is displayed as the solid line in the plot. It shows the same curvature, with the main difference being that the error does not approach zero but instead converges to 10% after all periods are taken into account. The group memberships deemed as ground truth are obtained from fitting a multi-trajectory model on the entire data set. These results are encouraging evidence that the model has useful predictive power.

Figure 3: Model performance of the multi-group trajectory model as a function of the number of time periods.

Given our interest in obtaining predictions for individual patients, it is convenient that the laws of probability lead
naturally to individualized posterior probabilities of group membership for a patient given his or her lab measurements and demographic variables, which we can track over time. In Figure 4, posterior probabilities are displayed for an average patient with the values for the biomarkers set to the overalls means of the entire cohort. The average patient has an age of 71.45 years and a BMI of 31.26. All other covariates are set to their baseline levels, i.e. the patient is male, has neither diabetes nor hypertension and is white. Starting with the second quarter, the posterior probability of belonging to group three exceeds all others. The final group label emerges as the top choice after only two time periods, suggesting that the trajectory model quickly converges to assign a patient to one of the groups as new data comes in. This is an encouraging observation, as it shows that trajectory modeling might be useful not only in analyzing outcomes ex post, but also beforehand.

Figure 4: Posterior probabilities as a function of the number of time periods for the average patient in our patient population.

Profiling the average patient might not be of much interest in itself, but is illustrative of the potential uses of the model in predicting group membership for individual patients and sub-populations that are of special concern.

5 Conclusion

Using group-based trajectory modeling (GBTM) to detect patient risk groups for CKD sharing comparable trajectories for the estimated glomerular filtration rate (eGFR) and markers for four complications of CKD, we have identified eight groups in a multi-trajectory model for the five outcomes. The results are consistent with the previous study by Padman et al., but build on those findings with the application of the multi-trajectory to the five jointly considered outcome variables, thus offering a more detailed perspective. The eight groups are characterized by distinct trajectories and patient demographics. For the high-risk groups 1-4, diabetes is prevalent, whereas it occurs less often for patients in the lower-risk groups 5-8. Interestingly, the proportion of black patients is largest in the two most extreme groups, one and eight, which are characterized by both the best and the worst development of the tracked biomarkers.

It is a well known fact that Blacks are more prone to develop CKD than non-Blacks. Yet, at the same time it has been observed that Blacks have a survival advantage in the ESRD population, the reasons of which are not entirely clear. Against this background, one might have expected the larger proportion of Blacks in the high-risk group, but not necessarily in group seven.

In an analysis of the progression of renal failure, Hannedouche et al. found gender to be correlated with disease progression, with male patients progressing significantly faster. We did find some large differences in the gender makeup of the eight groups, with group eight standing out in particular: Only 18% of patients assigned to this group were females. While patients in this group are younger than in the others, in line with the finding that males develop CKD faster, their eGFR rate is surprisingly stable and only few of its members progress to stage 4 or stage 5 of the disease. This is a somewhat unexpected finding, which could be explained by the fact that groups seven and eight might be separated just because of the difference in hemoglobin levels between the sexes.

It is known that CKD prevalence increases drastically with age and it has been speculated that elderly people might be more susceptible to CKD. Yet, Hallan et al. found low eGFR to be “independently associated with mortality and
ESRD regardless of age across a wide range of populations” in patient cohorts selected for CKD.\textsuperscript{21} This is consistent with our results, which do not enable us to use age to discriminate between the high-risk and low-risk groups.

All in all, it seems that the value of demographic variables for risk stratification is not high, and that more emphasis should be placed on the trajectories of the different biomarkers. At the same time, given the complex nature of CKD, additional biomarkers such as Urine-Albumin Creatinine Ratio (UACR) may need to be included in future studies.

We have shown that patients can be classified into the detected groups with an accuracy of more than 50\% after a year of data. Collapsing the groups into the high-risk and low-risk communities of groups 1-4 and 5-8, this number increases to approximately 82\%. For previously unseen patients, accuracy increased to 90\% after using all time periods as evaluated against a gold standard data set obtained by fitting the GBTM on all observations. These are encouraging signs, which indicate that GBTM could help with population risk stratification as well as to assess individual patient’s risk. For example, our model could be used for predicting stage progression (see the work by Perotte et al.\textsuperscript{22}) or another outcome like the need for a transplant. To avoid distorting the results, this latter case would require the inclusion of transplant patients into the cohort, which could be achieved by incorporating all their lab values until the day of their transplant. Here a strength of GBTMs is rendered visible: The ability to handle missing data.

One limitation of this study is a lack of mortality data for the patient population, which might have caused a bias in our results. Also, results might not generalize to other populations, given that the patients in our data set are fairly homogeneous in terms of demographic variables such as race and age. To establish that the identified patterns are externally valid, analyses based on samples with different demographics should be conducted. In this study, we had to deal with several data quality issues of the EHR such as erroneous patient identifiers and wrongly encoded lab values. Since it is not possible to rule out that some issues might have persisted, further analyses on similar data sets should be undertaken to replicate the results.

GBTMs could be extended in several ways, too. Assuming a polynomial trajectory is may not reflect reality well, but is a convenient assumption since it makes model fitting tractable and improves interpretability of the model. Alternatively, one could consider a non-parametric approach, at the expense of interpretability. In addition, the model assumes that conditional on group membership, the elements of $Y_j$ are uncorrelated with each other. Weakening this assumption and permitting the off-diagonal elements of covariance matrix $\sigma_j^2 I$ to be non-zero might yield a more realistic picture of the true underlying data generating process. Yet, the assumption is not as restrictive as it might appear on first glance: Outcomes are not modelled to be conditionally independent at the population level. The model merely assumes that conditional on the latent group membership, the Gaussian noise added to the trend line stays constant over time.

The analysis could also be enhanced by exploiting the rich data available inside the EHRs of each patient, most of which is unstructured. For example, clinical narratives written after each patient’s visit might reveal insights which the biomarkers themselves would not give away. Alternatively, one could investigate whether medications are associated with a decline or increase in one of the trajectories. This was not done in the present study because of significant difficulties posed by the high-dimensionality of the problem, which would require dimensionality reduction by mapping individual drug names to drug classes. This is the subject of a follow-up study conducted at the Heinz College at CMU.

While group-based trajectory modeling (GBTM) has seen increasing adoption in clinical research, to the best of our knowledge, this study is the first to jointly model multiple outcomes, thereby providing a fuller picture on patient’s disease progression. Given our results, we believe that multi-trajectory models provide a simple but powerful tool for risk stratification of patients as they allow identification of a finite number of groups with distinct trajectories for the developmental course of a disease and relevant predictors of group membership. Hence, GBTMs provide interpretable summaries of typical disease progressions and might help in the development of targeted, proactive interventions for patients in all risk groups.

Abstract

In this paper we proposed a framework: PRivacy-preserving EstiMation of Individual admixtiture (PREMIX) using Intel software guard extensions (SGX). SGX is a suite of software and hardware architectures to enable efficient and secure computation over confidential data. PREMIX enables multiple sites to securely collaborate on estimating individual admixture within a secure enclave inside Intel SGX. We implemented a feature selection module to identify most discriminative Single Nucleotide Polymorphism (SNP) based on informativeness and an Expectation Maximization (EM)-based Maximum Likelihood estimator to identify the individual admixture. Experimental results based on both simulation and 1000 genome data demonstrated the efficiency and accuracy of the proposed framework. PREMIX ensures a high level of security as all operations on sensitive genomic data are conducted within a secure enclave using SGX.

Introduction

Identifying the demographic histories of patients is an important problem arising in biomedical research. For example, given the accurate ethnicity information, researchers can better understand whether certain populations are more susceptible to particular disease or most likely to benefit from certain therapeutic interventions1. Understanding the individual admixture from different ancestries is also important for researchers who conduct case-control association studies2. Electronic medical records (EMRs) can provide clinicians and biomedical researchers a new perspective in studying associations with the symptom or medication use. However, research studies based on the races/ethnicity from EMRs often faces problem with missing or inaccurate self-described information1. Hispanics, for example, represent an admixed group between Native American, Caucasian and African. In addition, African-Americans represent another large admixed group. Researchers have shown that the individuals within the Hispanics or African-Americans groups did not form a distinct subgroup, but clustered variously within the other groups4. As a result, the self-report ethnicity information in EMRs may not provide the most accurate characterization of patients.

Genome-wide association studies (GWAS) provide a powerful tool for identifying genetic biomarkers which reflects an individual’s ethnicity by applying admixture models on allele frequencies of SNPs5–2. A basic assumption for ethnicity testing is that any current individual genome or population is a mixture of ancestries from past populations7. Population methods developed according to the amount of loci that can be traced back to a certain ancestry population is largely used. Companies such as 23andMe8 or Ancestry DNA9 have been the major autosomal DNA tests existed to reveal the ancestry of an individual. However, it is usually infeasible for researchers to scan for every patient’s ethnicity through these expensive tests. Rapid advances in sequencing technologies enable the meaningful use of human genomic data in a wide range of healthcare and biomedicine applications. Reuse existing genomic data of patients to identify patient ethnicity or improve the accuracy of self-report information can significantly improve the data quality in research study that requires population stratification.

The research team of 23andMe published 22 population-specific common SNPs that can reflect demographic histories5. The study was done from the self-reporting, participant-driven data gathered on the Web, and associations were discovered for the hair color, eye color, and freckling (in the genes OCA2, HERC2, SLC45A2, SLC24A4, IRF4, TYR, TYRP1, ASIP, and MC1R)5. Similar researches with SNPs associations are done by Yaeger et al.10 and Kosoy et al.11, which found 107 and 128 SNP race/ethnicity-related biomarkers, respectively. For example, Yaeger et al.10 investigated with 50 African Americans and 40 Nigerians as their subjects. Ancestry informative markers (AIMs) used in their study were based on bi-allelic SNPs that were selected from the Affymetrix 100K SNP chip based on “informativeness” of ancestry’s genotype data. Informativeness12 between multiple population groups

∗ Both authors share the first authorship
was determined using mutual information. Furthermore, Kosoy et al.\textsuperscript{11} worked on providing continental ancestry and characterized a set of 128 AIMs. The markers were chosen for informativeness, genome-wide distribution, and genotype reproducibility from 825 individuals. There are several ancestry estimation software that quantify genetic variation of admixture between populations using high-throughput sequencing data, such as the models used in the programs STRUCTURE\textsuperscript{11}, FRAPPE\textsuperscript{14}, TESS\textsuperscript{15}, and Admixture\textsuperscript{16}.

However, many existing studies on race/ethnicity identification are restricted by sample size or biased by sample selection. For example, the evaluations for Eriksson et al.\textsuperscript{17} were done only on the European population in America. Yaeger et al.\textsuperscript{10} specifically focused on African Americans born in the United States and in Africa. A total of 825 individuals were examined by Kosoy et al.\textsuperscript{11} covering a wider range of individuals, but the sample size is still limited. Aggregating data from multiple sources could significantly improve the power of the study in race/ethnicity identification. However, direct sharing of labeled patients’ genetic information for data mining would violate the policies concerning patient privacy\textsuperscript{18}. Besides the privacy concerns in data mining phase, the same issues are also associated with the testing phase, where a researcher needs to identify the ethnicity through individual’s genomic data, but without compromising the patient’s privacy.

Regarding the privacy concern, human genomic data must be handled carefully to avoid disclosure of sensitive patient information to unauthorized parties. Previous studies\textsuperscript{19–23} have demonstrated several privacy risks regarding to human genomic data. For example, Homer et al.\textsuperscript{24} discovered that the presence of an individual in a case group can be reliably determined (known as a re-identification attack) from the allele frequencies using an individual’s DNA profile, which can be acquired, for example, from a single hair or a drop of blood. The biomedical community has recognized the importance of privacy and data protection for genomic projects\textsuperscript{25}. Many privacy and security technologies, e.g., differential privacy (DP)\textsuperscript{26}, homomorphic encryption (HME)\textsuperscript{27–30} and secure multiparty computation (SMC)\textsuperscript{31,32} have advanced in protecting biomedical data\textsuperscript{33–39}. Among them, DP solutions will alter data to make it difficult to identify information to a particular individual, and DP might also render outputs useless\textsuperscript{25}. HME and SMC (e.g. based on garbled circuits and secret sharing) hold the promise of secure general-purpose computing in the cloud but existing solutions are too computationally cumbersome to be used for complex big-data analysis. In addition, efficient SMC solutions exist (e.g. based on secret sharing and arithmetic circuit) but are domain-specific, thus inappropriate for exploratory analyses that need constant tuning. Distinct from some of the existed tools, our pipeline will not only allow users to perform ethnicity detection of a patient, but also provide secure protection of the subject’s information (Figure 1). We chose to use Intel\textsuperscript{20} Software Guard Extensions (Intel\textsuperscript{20} SGX)\textsuperscript{40}, which is a set of new CPU instructions that can be used by applications to set aside private regions of code and data. Intel\textsuperscript{20} SGX allows application to protect sensitive data from unauthorized access or modification and enables application to preserve the confidentiality without disrupting the software system. Both the labeled data and the unlabeled data from different sources will be protected during the process (Figure 1). Clients can only obtain the encrypted results (e.g., estimation of individual admixture) but cannot access the training data deposited by other institutions.

**Materials and Method**

In this paper, we will focus on the secure estimation of individual admixture using genomic data. We will first introduce the methods used for selecting AIMs and identifying individual admixture followed by the details about Intel\textsuperscript{20} SGX frameworks.

*Selection of AIMs:* The selection of the most discriminative AIMs can significantly improve the efficiency of prediction for identifying individual admixture\textsuperscript{10}. In this paper, we compute and sort the mutual information\textsuperscript{12} between multiple population groups to select the most discriminative bi-allelic SNPs (used as AIMs in this study).
More specifically, the markers that are informative in one collection of source populations are generally informative in others\textsuperscript{10}. Therefore, we apply statistical methods that use multilocus genotypes and population allele frequencies to represent the average frequency of allele at a certain locus, and assign informativeness to no-admixture model based on the conditional entropy of a random population given the knowledge of the genotype. Next, the informativeness is sorted from the largest to the smallest.

**Identifying individual admixture:** Our pipeline determines an individual’s ethnicity based on the method developed by Tang et al.\textsuperscript{14}. The Estimation Maximization (EM) algorithm proposed by this model demonstrates increased robustness and comparable efficiency when compared to existing maximum likelihood (ML) model\textsuperscript{12} and Bayesian MCMC method\textsuperscript{13}. This estimation allows for uncertainty in ancestral allele frequencies, provides an advantage toward separating an admixture population at an individual level, which they referred to as “individual admixture” (IA), and could achieve extensive stimulations to produce point estimates\textsuperscript{14}. The goal is to estimate IA for the admixed individuals, $Q_i = (q_{i1}, ..., q_{ik})$ and $i = 1, ... I_0$, where $Q_i$ is the individual admixture fraction of the $i$-th individual; $I_0$ is the total number of individuals to be identified; $K$ is the number of ancestries. The allele frequencies of different ancestral markers are denoted as $P$. A likelihood function given an unobservable variable $Z_{ima} \in \{1, ..., K\}$ can be expressed as

$$l(G, Z\mid P, Q) = \sum_{i=1}^{I} \sum_{m=1}^{M} \sum_{a=1}^{2} \sum_{k=1}^{K} 1(G_{ima} = l, Z_{ima} = k) \log(p_{mik} q_{ik})$$

where $1(\cdot)$ is an indicator function; $p_{mik}$ is the frequency of allele $l$ at marker $m$ for the $k$-th ancestry; $G_{ima}$ is the allele for the $i$-th individual at the $a$-th allele of marker $m$. An EM algorithm can be implemented to efficiently estimate the parameters $P$ and $Q$. Convergence is declared when the difference in the estimates of $Q$ and $P$ fall below a small threshold\textsuperscript{14}.

**Secure computation methods:** To mitigate the privacy risk while supporting scientific discovery, security researchers have developed many theoretical frameworks. However, even the best-known methods based on HElib\textsuperscript{41} for homomorphic encryption or FlexSC\textsuperscript{42} for garbled circuit-based secure multiparty computation are not practical enough to handle large-scale genomic data analysis. These real challenges motivate the development of new solutions. Intel recently announced a new Software Guard eXtensions (SGX)\textsuperscript{40} architecture for their next generation CPUs, which shed light to novel solutions to above mentioned challenges using a hybrid software-hardware framework. Figure 2 shows some of the major conceptual functions of the SGX architecture (need to be developed on a case-by-case manner depending on the application). As a built-in feature in the Intel\textsuperscript{10} Skylake family Central Processing Units (CPUs), SGX-enabled devices can be found in most recently released computing platforms (e.g., laptops, desktops and servers). Intel\textsuperscript{10} SGX framework provides a cost-effective solution to achieve affordable secure computation in terms of both complexity and finance concerns. For example, a pioneer study of SGX-based MapReduce framework for distributed high-performance computations\textsuperscript{43} shows a negligible overhead of 8% to achieve read/write integrity using SGX. This is a significant advantage of using SGX in comparison to other secure computation scheme like homomorphic encryption or garbled circuits, which usually increase the complexity thousands of times over. Furthermore, an SGX-enabled machine only cost as low as a few hundred dollars. In SGX, a protected area in CPU, which is usually referred to as enclave, is dedicated to execute sensitive codes and compute sensitive data in a secure manner, where any interfere from software outside the enclave are prohibited by the SGX hardware. Therefore, both data confidentiality and integrity can be achieved with a proper systemic design of SGX applications. SGX is resilient to both software level attacks (e.g., malicious operating system, etc.) and hardware level attacks (e.g., for memory, hard disk, network etc.). Some preliminary studies\textsuperscript{44-45} have revealed the possibility of SGX to significantly enhance the security and privacy of many applications. However, most of them are based on simulation study and none of them has tackled genomic data security and privacy in a real SGX-enabled computing platform.
To ensure the security of the whole system, an SGX framework requires the adoption of industry-standard cryptographic primitives and systemic implementation of several key steps, as shown in Tables 1 and 2, respectively. Taking advantage of this novel architecture, we developed a PREMIX framework for privacy-preserving estimation of individual admixture in this paper.

Results

Study Subjects and Ancestral Population: We have used the phase 3 release (May 2013) of the 1000 Genomes project data to identify SNPs. Datasets from 1000 Genome project include genetic variation across diverse populations from Europe, Asia, Africa and the Americas. The present 1000 Genome data contain 2504 samples from 26 populations which can be categorized into five super-populations: East Asian (EAS), South Asian (SAS), African (AFR), European (EUR), and American (AMR). The global allele frequencies for each super-populations were calculated by counting the AC (“Total number of alternate alleles in called genotypes”) and AN (“Total number of alleles in called genotypes”) for all the individuals from a particular super population and using that to calculate the allele frequencies.

Experimental setup: We use both simulation and real data to test the performance of our algorithm. For simulation experiment, we follow the setup used by Tang et al. Assume there are two ancestral populations X and Y. The simulated data consist of 500 admixed individuals, and 250 individuals from each of two populations as the training data. Since there are two groups, the IA vector is a scalar, and we sample it from a mixture model of Gaussian and uniform distributions. We select the SNPs that the differences of its allele frequencies from two parties are bigger than a δ-value 0.3. Conditioning on the SNPs and the IA vector, we can randomly generate the 1000 individuals for simulation. From 1000 genome data, we used two populations: ACB (African Caribbeans in Barbados) and TSI (Toscani in Italia), and each of them contains 96 and 107 subjects. We extracted the first 31,000 SNPs of their 22nd chromosomes. All of these SNPs will be processed by the informativeness algorithm to choose the top SNPs for computing the IA vector of the admixed individuals.

We implemented the proposed PREMIX server and client on two machines: the server is an Intel® Xeon core E3-1275 v5 with Intel® SGX support and 64 GB memory; the client machine is Intel® Core i7-6820HQ CPU and 48GB Memory.

The experiments are designed to focus on the following three aspects: (a) computational complexity comparison between secure SGX-based C++ implementation vs insecure C++ implementation; (b) the simulation data results; (c) the real data results using different number of top informative AIMs.
**Experimental results:** Table 3 shows the key steps and total running times of PREMIX using secure SGX implementations with encrypted remote data and insecure C++ with local data. We tested four different data sizes, and all of the results in Table 3 are the averaging values over 10 trials. From the results, we can see that, there is no significant different between the two frameworks in implementing EM algorithm, but the total running times of secure SGX is a little slower than those of insecure C++. The additional overhead in the total running times of secure SGX is due to the data encryption, attestation, data transfer and analysis over encrypted data.

Table 3. Comparison of the running times of computing PREMIX between secure SGX-based C++ implementation vs. insecure C++ implementation. Here $I_0$ and $I$ are the number of admixed individuals and the total individuals, respectively. The unit of all running times is second.

Simulated data is used for evaluating the PREMIX framework. We suppose that the labeled data with ethnicity information are non-admixed and there are two populations. Each individual in the labeled data set is sampled from one of the two populations. The number of SNPs used in our simulation is 200. The iteration rounds of the EM algorithm are set to 200.

Table 4 is the results of PREMIX using simulated data. Since we know the ground truth under simulation environment. We can compute the root mean square error (RMSE) and the bias. Table 4 shows that the RMSE will less than 0.1 with no more than 0.01 bias, if the $\delta$ value of two groups is bigger than 0.3.

(b) Three populations

**Figure 3.** Estimated individual admixture using the proposed PREMIX framework.

For the real data, we split each population into two groups, where the first group is used as admixed individuals to be predicted and the second group is used as the labeled data. Specifically, the individuals from ACB and TSI
populations were included in our experiment. For both populations, the first 50 individuals are viewed as admixed individual, and the rest individuals from both populations (i.e., 46 ACB individuals and 57 TSI individuals) are used as labeled data. In addition, we suppose these labeled data were from two sources to simulate a secure collaboration scenario. The SNPs were screened based on their informativeness, where the top M SNPs will be selected for the next step in PREMIX framework. For the real data, since there is no ground true of IA vector, the admixed individual will be classified to the population based on their maximum estimated IA component. Tables 5 and 6 depict the percentage of correctly identified individuals using different number of AIMs and different labeled data sizes, respectively. In Table 5, we can see that the percentage of correct identification increases as the number of AIMs M increases. Based on our experiments, a high percentage of correct identification can be achieved with 50 or more AIMs. Moreover, Table 6 shows the framework can achieve a relative accurate identification performance with as few as 40 labeled data.

Figure 3 (a) shows the estimated IA vectors for two populations. The first 50 individuals are from the ACB population, and the second 50 individuals are from TSI population. We can see that the PREMIX can successfully identify the ethnicities of most individuals in both groups.

To further evaluate the performance of the PREXIM, we included a third population CHS (Southern Han Chinese) in our experiment. In Figure 3 (b), the first 50 individuals are from the ACB; the second 50 individuals are from CHS; and the final 50 individuals are from TSI. We see that there is some performance degradation of the proposed PREXIM framework in identifying more than two populations.

**Discussion and Limitation**

The main contribution of this paper is to introduce a new hybrid solution (i.e., Intel® SGX) using both hardware and software to enable efficient and privacy-preserving estimation of individual admixture. The proposed PREMIX framework can protect the privacy of sensitive genomic data with ancestry information, as well as the privacy of the data users, who would like to identify their individual admixture. Due to the adoption of strong security protection primitives, multiple data owners can collaborate on the study to improve the estimation performance without sacrificing individual data privacy. In the proposed framework, we provided both a secure feature selection module based on informativeness of SNPs and a secure EM based maximum likelihood estimator to achieve both computational efficiency and estimation accuracy. Our experimental results demonstrated the advantage of secure collaboration in identifying individual admixture.

There are several limitations in this study. First, even it can well protect the data privacy, the SGX hardware is vulnerable to Denial-of-service (DoS) attack; however, the data privacy will not be compromised under this attack. Second, proposed method was only evaluated through limited data sets (i.e., simulated data and 1000 genome data) in this pilot study. The use of Human Genome Diversity project (HGDP) could improve the impact of this study and provide better performance assessment. In addition, the proposed method relies on an EM-based maximum likelihood estimator, which can only support a small number of populations. Recently, many advanced ethnicity identification programs have been developed particularly for genome-wide SNP data. For example, TESS, an updated version of the spatial ancestry estimation program TESS, which combines matrix factorization and spatial statistical methods. TESS estimates ancestry coefficients with comparable accuracy and fast run-times, and can be used to perform genome scans for selection, separate adaptive from non-adaptive genetic variation using ancestral allele frequency differentiation tests. AncestryMapper assigns each individual analyzed with a genetic identifier, referred as Ancestry Mapper Id (AMid) which corresponds to its relationship to the HGDP reference population. TreeMix follows a tree-based approach with branches built by maximum likelihood lengths and migration weights. Population was identified by searching through the space of possible graphs with optimized the branch lengths and weights. FastSTRUCTURE is a recent modification of the popular model STRUCTURE which provides a faster approximate inference using a variational Bayesian framework and poses the problem of computing relevant posterior distributions as an optimization problem. The software identifies the number of populations represented in a dataset with heuristic and new hierarchical prior to detect weak population structure in the data. Among a large population, algorithm such as Eagle detects association analysis of rare variants from a large population cohorts based on genotyping arrays using long-range phasing (LRP) to rapidly phase segments of genome identical-by-descent (IBD) with closely or distantly related individuals. Eagle runs two iterations of fast approximate Viterbi decoding using a simple diploid analog of the Li-Stephens HMM to allows phasing of segments lacking IBD to ensure accurate results. The development of trustworthy computation framework to support advanced methods in race/ethnicity identification warrants the further investigation along this line. Finally, the limited secure memory (~
96 MB) in SGX restricts the algorithm to process a huge amount of data concurrently. In the next step, we will optimize the secure memory usage to improve the data processing capacity of the proposed method.

Abstract

Chronic disease affects patient quality of life through symptoms of the disease and the work of receiving treatment. While the effects of illness are well investigated, the burden of treatment is not commonly studied or monitored. We developed a method to quantify one dimension of the burden of treatment based on patient encounters with the healthcare system. We applied this method to a population of stage I-III breast cancer patients. As hypothesized and observed, stage III patients had more appointments, spent more time in clinic, and spent more time admitted to the hospital in the first 18 months after diagnosis compared to stage I and II patients. Future work will evaluate the reproducibility and generalizability of this method for quantifying burden of treatment across other clinical settings and chronic diseases. This approach could enable identification of high-risk groups that could benefit from interventions to decrease patient work and improve outcomes.

Introduction

Chronic illness is detrimental to a patient’s quality of life both because of the symptoms of the illness itself as well as the burden of treatment needed to combat the illness. The complexity of medical care today makes it difficult for healthcare providers to monitor a patient’s capacity to receive care even though treatment overburden can impact disease outcomes. A high burden of treatment can cause lower compliance in patients with chronic diseases, thus increasing other complications. Patients with high burden of treatment tend to have lower satisfaction scores. Excessive treatment can also lead to wasted resources for the medical center, and contribute to a patient’s financial toxicity. Physicians who practice minimally invasive care assess burden and tailor treatment plans that give a patient the maximum likelihood of recovery while taking into consideration the patient’s limitations. To improve the effectiveness of this paradigm, providers and healthcare systems need reliable ways to identify overburdened patients and patient populations.

Cancer patients often undergo intense, multi-modal treatments resulting in diminished quality of life. Figure 1 shows a typical two-week schedule for a breast cancer patient undergoing adjuvant chemotherapy following surgery. This schedule includes 11 appointments over 7 unique days and a total clinic time of 9.5 hours. Additional appointments needed to address complications and comorbid conditions compound the treatment burden for cancer patients. A nationwide study showed that among patients undergoing chemotherapy and radiotherapy, 28% had to schedule appointments to treat side effects, 77% had to arrange for caregivers to accompany them to their appointments, and 43% had some impact to their professional lives.

Figure 1. Example of a breast cancer patient’s schedule over a two-week period. This patient had 11 appointments over 7 unique days and a total clinic time of 9.5 hours between July 11 and August 1. MO = Medical Oncologist, NP = Nurse Practitioner.
Burden of treatment measures focus on the impact of the acts of receiving care. Previous research on the topic of treatment burden have focused on qualitative methods to describe factors contributing to patient work\textsuperscript{13}. By surveying patients, researchers identified a taxonomy of factors that contribute to the burden of treatment including healthcare tasks and situational factors that exacerbate a patient’s work\textsuperscript{14,15}. Tran et. al. also developed and validated the Treatment Burden Questionnaire (TBQ), a survey instrument designed to measure patient burden\textsuperscript{5,14}. Disease specific questionnaires have also been developed to assess the burden of treatment in specific chronic conditions such as chronic heart failure\textsuperscript{16} and end stage renal disease requiring dialysis\textsuperscript{17}. While these qualitative methods are effective in defining treatment burden, they do not enable population studies of burden or automated monitoring to identify overworked patients who may need intervention.

Figure 2. Relative completeness and structure of data elements related to factors of treatment burden that may be amenable to automated extraction and quantification from the electronic health record.

Research using electronic health record data is most effective when that data is structured and complete\textsuperscript{19}. Figure 2 displays several dimensions of treatment burden identified by Tran et. al.\textsuperscript{13} and Eton et. al\textsuperscript{14} evaluated by approximate completeness and structure of data in the electronic health record. Treatment burden elements in the top-right quadrant of Figure 2 such as financial costs and clinic visits are both highly structured and highly complete by virtue of their relation to billing. These top-right elements are more reliable measures than elements in the bottom-left that are unstructured and less available. For example, a patient’s exercise program is less likely to be captured in an EHR but may be recorded in other systems managed by the patient outside the EHR. While healthcare institutions may differ in how these factors of treatment burden are recorded, many of these data elements are available across different implementations of clinical information systems.

This study proposes a method to quantify one of the more reliable contributors to treatment burden: clinical encounters. While appointments only contribute to part of a patient’s overall treatment burden, time and effort spent coordinating, traveling for, and waiting for care were among the most commonly mentioned contributors to burden in patient surveys\textsuperscript{13}, and the factors most highly correlated with the overall TBQ score\textsuperscript{5}. Hospital admissions are also of particular interest to patients and hospital administration. Cancer related readmissions are often unexpected and the most frequent among patients with private insurance\textsuperscript{15}. Although inpatient time was typically not mentioned in previous burden of treatment literature, admissions are disruptive to patients and their caregivers. To our knowledge, no previous studies have used data from electronic health records to assess treatment burden in patient populations. By using appointment and admission data, our evaluation of treatment burden is reliable, reproducible, and scalable given accurate electronic records.

To evaluate our method, we chose to investigate patients with stage I-III breast cancer. We hypothesized that patients with stage III cancer would have a higher treatment burden than patients with stage I or stage II cancer given the more aggressive therapy they receive for higher risk disease. Additionally, we anticipated that burden of
treatment would be greatest in the first few months after the date of cancer diagnosis, and that this burden would decrease over time.

**Methods**

To study the use of these treatment burden metrics, we applied them to a population of breast cancer patients at Vanderbilt University Medical Center (VUMC). The goal of this analysis was to investigate whether there was differentiation in number of appointments, total time spent in clinic including wait time, and total inpatient length of stay between breast cancer patients with stage I, stage II and stage III disease. We also identified outliers who had abnormally high treatment burden for their stage.

**Study population**

The patient cohort for this study was chosen from the VUMC Cancer Registry since those were the patients who were diagnosed and receive all or part of their first course of treatment at our institution. We collected 18 months of encounter information from all stage I-III breast cancer patients who were diagnosed over a 17-year period between January 1, 1998 and June 1, 2014. In order to facilitate comparison between sub-populations of patients that received the majority of their care at our institution, we included only patients with at least three appointments from both a Vanderbilt medical oncologist and a Vanderbilt surgical oncologist. We determined which appointments were with a medical or surgical oncologist by mapping their national provider identification number with their specialty in the national patient identifier (NPI) data dissemination file.

Among the 8161 patients with breast cancer in the VUMC Cancer Registry, 5661 had a date of diagnosis between January 1, 1998 and June 1, 2014. Among these, 4152 patients had stage I-III disease at diagnosis. After collecting 18 months of appointments after the date of diagnosis for these patients, we found that 904 had more than three appointments with a medical oncologist and a surgical oncologist at VUMC (Figure 3).

**Data Considerations**

To get a holistic view of each patient’s treatment burden, we included all patient appointments, including appointments in non-cancer related departments, and all hospital admissions. We extracted outpatient appointment data from the Epic scheduling system that had been in use at VUMC since 1997. Hospital admission and discharge data was extracted from the Medipac admission, discharge, transfer (ADT) system with data going back to 1984. To approximate the total time spent in clinic including waiting time, if a patient had more than one appointment in a day, we calculated the time from the beginning of the first appointment to the end of the last appointment of the day. We used the schedule appointment duration as an estimate of the time the patient spent in clinic understanding that true appointment durations could vary.

**Analysis**

We compared distributions of the total time spent in clinic, the number of appointments, and the number of admissions over 18 months by stage. We used an ANOVA test to see if there was a significant difference between stages I-III for each of the means of these three metrics. We also compared the estimated time spent in clinics by month over 18 months by stage. The Vanderbilt Institutional Review Board approved this study and granted a waiver of consent since we analyzed a large population of patients in aggregate.
Results

Table 1 summarizes the clinical encounter burden by stage. Among the 904 patients in the final cohort, 419 had stage I, 337 had stage II, and 148 had stage III disease. Across all stages, the average patient in our cohort had 67 appointments on 44 unique appointment days, spent 3.6 hours in clinic per month, and was admitted for 1.9 days over the 18 months after diagnosis. On average, Stage III patients had the greatest number of appointments (92), the greatest amount of time spent in clinic per month (5.4 hours), and the greatest number of hospitalized days (3). Stage II patients had the second greatest totals in each of these parameters and stage I patients had the least. The ANOVA tests for all of the metrics were significant with p-values less than .001.

Table 1. Summary of clinical encounter burden for breast cancer patients by stage with ANOVA p-values comparing the difference between stage I, stage II, and stage III.

Figures 4A and 4B. Distribution of total number of appointments over 18 months by breast cancer stage (ANOVA p-value < .001), and total length of stay over 18 months by breast cancer stage (ANOVA p-value < .001). The dark line for each boxplot represents the median and the colored box represents the interquartile range (IQR) (25th to 75th
percentile). The “whiskers” extend to 1.5 times the IQR or to the minimum or maximum value, whichever is closer. Any data points outside the whiskers are outliers and are represented individually as circles.

The boxplot in Figure 4A further shows that the median and interquartile ranges of the number of appointments is greatest for patients with stage III disease followed by stage II and stage I. There were 5 outliers for stage I patients with an unusually high number of appointments while there were 2 outliers for stage II patients. Figure 4B shows the distribution of total length of hospitalized days in the first 18 months after diagnosis. The median patient for stage I and stage II was admitted for one day or less while the median stage III patient was admitted for about two days. Among stage I patients, 67% had no admissions, while only 49% of stage II and 41% of stage III patients had no admissions. With so many patients clustered near zero, there were many outliers for all stages.

**Figures 5A and 5B:** Distribution of total time spent in clinic over 18 months by breast cancer stage (ANOVA p-value <.001), and average total time spent in clinic per month over 18 months by breast cancer stage.

Figure 5A shows that the median time spent in clinic was greatest for stage III patients followed by stage II and stage I. There are 26 outliers for stage I patients in time spent in clinic and 2 for stage II patients. Over the course of 18 months after diagnosis, the average total time spent in clinic per patient decreased (Figure 5B). In the first month of treatment, stage I patients spent on average 8 hours in clinic while stage II and III patients spent 10 and 12 hours respectively. All three stages saw a decrease in time spent in clinic in the second month but then had an increase in the third and fourth months. In each month after diagnosis, the average time spent in clinic was greater for stage III than stage II or stage I breast cancer patients, although this difference was not statistically significant for any given month.

**Discussion**

We have developed a simple method for quantifying an important aspect of treatment burden using clinical encounter data derived from the outpatient scheduling and inpatient ADT systems. The results of the ANOVA tests from Table 1 confirm our hypothesis that there is significant separation between stages I-III breast cancer patients with respect to the number of distinct appointments, total time spent in clinic, and total number of hospitalized days. We also observed that treatment burden diminished over time in the 18-month period following diagnosis (Figure 5B). This decrease is expected since the most intense portion of treatment for early stage breast cancer is usually completed in the first 12-14 months after diagnosis. Our metric is concordant with this pattern of treatment.
This approach for assessing burden of treatment is simple and generalizable to other healthcare organizations. Since Stage 1 Meaningful Use was enacted, healthcare systems are incentivized to maintain accurate patient encounter records\textsuperscript{21}. Therefore, any healthcare organization could use scheduling data to approximate patient burden. On the other hand, some limitations impede direct comparisons between our study population and those at other institutions. Other institutions may record appointments differently than VUMC. For example, another healthcare system with the patient in Figure 1 could have just one appointment for lab, medical oncologist, and infusion. Meanwhile at VUMC, each of those encounters is recorded as a separate appointment. Comparing patient populations within that institution would still be possible but comparing populations across institutions might be challenging.

Our method of determining the amount of time spent in clinic is a gross estimation. It does not take into consideration situations where patients arrive early, appointments start late, patients leave between appointments, or appointments end earlier than the time allotted. Using data from systems such as VUMC’s outpatient whiteboard would enable detailed analysis of patient whereabouts\textsuperscript{32}. For even more granular data, healthcare systems have used real time locator systems (RTLS) to pinpoint the location of patients as they move through the medical center\textsuperscript{23}. These advanced techniques would provide precise data about patient burden during patient encounters but would be difficult to generalize to other institutions that do not have infrastructure for patient tracking.

Future work in developing quantitative measures for assessing treatment burden includes incorporating additional factors that influence patient outcomes identified in previous literature. To more accurately capture the patient experience related to appointments, we plan to incorporate commute time into their burden assessment by adding the time to drive from their home address to the clinic address before and after appointments. We will use other structured data such as medication prescriptions to determine the frequency of home medication use, and billing information to approximate other medical encounters not captured directly as appointments. There is also potential for natural language processing of notes to capture other provider recommended activities crucial to outcomes such as exercise or diet changes. Complementary to the need for an accurate assessment of a patient’s treatment burden is the determination of a patient’s capacity for treatment. With burden and capacity, we can compare outcomes for patients for whom burden exceeds capacity against those who receive care within their means.

There are multiple applications where a data driven and quantitative measurement of treatment burden could impact patient, provider, and system level decision-making. Using the electronic health record to characterize burden is much like phenotype classification, where researchers use electronic health data to group similar patients for more personalized care delivery\textsuperscript{24}. Understanding treatment burden can aid in delivering the right amount of care that is prioritized to what each individual can handle. When patients are newly diagnosed with stage I-III breast cancer, Figure 5B could help them anticipate how much time they will need to devote to coming to receive care and how much time they will need to take off from work. Likewise, Figure 4B could help them understand how much time patients like them are admitted in the hospital. Future work could further divide our cohort into patients who chose different treatment paths such as prophylactic contralateral mastectomy followed by reconstruction compared to lumpectomy with radiation therapy. Showing the treatment burden of similar patients could help educate patients about treatment options and their trade-offs.

Our analysis could also help with provider monitoring of patient burden. Our work looking at treatment burden is analogous to using electronic health records to predict risk for readmission. In readmission prediction, clinicians use social and clinical factors to identify patients who are high risk for readmission, which is costly to the medical center and harmful to the patient\textsuperscript{25}. Similarly, treatment burden factors can identify patients at risk for non-compliance and wasted resources which are also costly to the medical center and harmful to the patient. The boxplot in Figure 4A is a good example of how healthcare systems can use appointment data as a proxy for treatment burden to identify outliers. In our population, a provider would notice that there are five stage I patients who had around 150 appointments in an 18-month period. A patient care team for one of those patients could investigate whether the appointments are appropriate. If that care is necessary, the healthcare system may look into ways to help ameliorate burden such as home visits or transportation assistance. Additionally, these types of data demonstrate the potential risks in pursuing alternative payment models such as bundled payment models. Administrators and providers could use these tools to help monitor for patients at high risk for high care utilization.

Focusing on outliers in appointment burden could also identify opportunities for improved care coordination and more convenience for the patient. For stage I patients in Figure 5A, there are many more outliers for total time spent in clinic than for count of appointments in Figure 4A. Since Figures 4A and 5A visualize the same population of patients, an increase in the number of outliers means that some patients who are outliers in time spent in clinic either have longer appointments or more time between their appointments. These patients would be candidates for care.
coordination interventions such as arranging their appointments closer together on the same day, or assigning them to a medical home clinic.

There were several potentially confounding factors that we attempted to control for in our cohort selection. The first and most significant is that we had to determine which patients received their first course of treatment at VUMC. Although the cancer registry had information about which providers saw patients in the registry and what institutions they were from, the availability of that data was inconsistent. We decided on a data driven approach where we defined patients as having received their first course of treatment at VUMC if they had at least three appointments with both a medical oncologist and surgeon from VUMC in the first 18 months of treatment. This constraint cut our cohort by more than 75%, but enacting the constraint was necessary to ensure that analysis focused on patients receiving care where we had more complete data on their encounters. We limited our analysis to stage I-III patients for a similar reason. Stage 0 and incurable stage IV patients have very different patterns of care making them less comparable in the first 18 months of treatment to stage I-III patients. We chose 18 months as the interval for analysis since a typical course of treatment occurs within that time frame and there is a very low risk of disease recurrence during this time.

Another limitation of this study is that we were not able to address missing data from patients lost to follow-up during the 18-month time span, or for care patients received outside of our institution. Furthermore, during the 17-year period where we observed our patients, there were changes in the way appointments were recorded in the system. There was a gradual increase in appointments per patient due to an increase in departments using the scheduling system. The effect of this increase in appointment capture should have been minimal on the analysis since they would be equally distributed across patients in the different stages.

Conclusion

With increasing interest in care coordination and value based care, there are already many reasons to limit unnecessary treatment for chronic diseases. Evidence is mounting that appropriate care for patients with a given disease may differ depending on their capacity to handle the burden of treatment. Our study of patient encounters is the first step toward a comprehensive and automated method to assess treatment burden applicable to disease population comparisons. In comparing patients with breast cancer, we found significant differentiation in appointments and admissions for patients with stage I, II, and III disease, as well as a downward trend in amount of time spent in outpatient appointments over time after diagnosis. Future work includes incorporating more factors that influence treatment burden and comparing treatment burden across different types of chronic disease. By better understanding burden of treatment, we can begin to deliver precision medicine not only based on genetic makeup and disease phenotypes, but also on the patient’s capacity to comply with treatment plans in order to maximize the likelihood for improved outcomes.

Abstract

Over the last decade, Electronic Health Records (EHR) systems have been increasingly implemented at US hospitals. Despite their great potential, the complex and uneven nature of clinical documentation and data quality brings additional challenges for analyzing EHR data. A critical challenge is the information bias due to the measurement errors in outcome and covariates. We conducted empirical studies to quantify the impacts of the information bias on association study. Specifically, we designed our simulation studies based on the characteristics of the Electronic Medical Records and Genomics (eMERGE) Network. Through simulation studies, we quantified the loss of power due to misclassifications in case ascertainment and measurement errors in covariate status extraction, with respect to different levels of misclassification rates, disease prevalence, and covariate frequencies. These empirical findings can inform investigators for better understanding of the potential power loss due to misclassification and measurement errors under a variety of conditions in EHR based association studies.

Introduction

Along with the widely use of electronic health record (EHR) systems over the last decade, huge amounts of longitudinal patient information, including coded/structured data (e.g., the International Classification of Disease codes) and clinical narratives (e.g., as admission notes and discharge notes), have been accumulated and are available electronically. These large clinical databases are valuable data sources for clinical, epidemiologic, genomic, and translational research, where identifying patients with specific diseases is often the critical step. However, manual review of patients’ charts is extremely time-consuming and costly as the decision criteria are often complex and require review of different sources of information by domain experts. Many studies have shown that structured data such as the ICD codes are not sufficient enough to determine the patient cohorts as much of the detailed patient information was recorded in clinical narratives. Therefore, a large number of phenotyping methods have been developed to combine the clinical narratives with coded data to identify patients with certain diseases. Due to the sensitiveness of clinical data and intrinsic difference between diseases, current phenotyping studies are often performed in a disease-specific manner, where training and test corpus are developed for each disease. Many studies have focused on the prevalent diseases, such as diabetes, hypertension, and rheumatoid arthritis, or some common healthcare problems associated with significant morbidity and mortality, such as heart failure, colorectal cancer, and venous thromboembolism. Some studies also focus on observational characteristics such as smoking status, obesity. Various clinical NLP systems have been applied to extract clinical information from text to facilitate phenotype identification, e.g., MedLEE, MetaMap, KnowledgeMap and cTAKES. Some of them provide individual module to identify common phenotypes, e.g., the smoking status detection module in cTAKES. Both rule-based and machine learning based systems have been developed to determine phenotypes. Most of the rule-based methods heavily involve domain experts’ knowledge, and the machine learning based phenotype identification methods often achieve better performances by leveraging different sources of information. The performances of phenotyping methods vary greatly among different diseases, and perfect genotype identification is difficult to achieve.

Although EHR-based clinical observational studies have been successfully performed based on automated phenotyping solutions, there is no systematic study to examine the misclassification of outcome and/or measurement...
error in covariates caused by imperfect phenotyping algorithms. In epidemiologic studies designed for EHR data, researchers have already noticed that the statistical models suffered from the information bias caused by the misclassification and/or measurement errors. Many studies have demonstrated that naive analyses ignoring misclassification lead to biased results in a variety of settings. As a result, the last 15 years have seen a rise in statistical methods to accommodate misclassification of disease status and measurement error in covariates, specifically when estimating odds ratios (ORs) or relative risks (RRs) in binomial regression; unbiased estimation of these parameters is typically of interest in pharmacoepidemiologic research. Several statistical methods have been developed to correct for a misclassified outcome or to correct for a misclassified covariate, for example using matrix methods, inverse matrix methods and maximum likelihood methods. However, the loss of power due to the misclassification of outcomes and measurement error in covariates has not been fully understood.

In this study we perform a systematic analysis on the power loss of EHR-based association studies due to misclassified outcomes and measurement errors in covariates through simulation studies. We aim to discuss this problem in two general types of studies. In the settings of genetic association studies using EHR-based phenotypes, we focus on the impact of misclassified binary outcomes (i.e., misclassified phenotypes) only. In the settings of epidemiological association studies using EHR-based disease status and covariates, we investigate the further impact of measurement errors in covariates on the association test. Various settings of misclassification rates, magnitudes of measurement errors and levels of factors that would influence the power are considered. Simulation designs, parameter settings and models to be compared are introduced in the Methods section. Power curves and other simulation results are shown and discussed in the Simulation Results section. Further discussion on the power loss, type I error and effect size estimation are shown in the Discussion section. Our study highlights the issue of power loss in association test with the presence of measurement inaccuracy, which should be considered in all association studies that use data from the EHR systems.

Methods
Simulation setups
To investigate the impacts of misclassification of binary outcome (disease status) and measurement error in covariates on association studies, we start with the non-differential misclassification where the misclassification rates do not vary across covariate categories. Also, the measurement error of the covariate is assumed to be independent with the outcome. We consider two general types of studies: the genome-wide association studies (GWAS) where the outcome is EHR-based binary disease status and the covariate is the genotype at a single nucleotide polymorphism (SNP) locus, and the epidemiological studies where both the outcome and covariate are EHR-based (e.g., type II diabetes and smoking status). In this empirical study, we conduct simulations to mimic the setups of these two types of studies. We consider different scenarios by choosing different parameters of disease prevalence, covariate frequency, and misclassification rates in both outcome and covariate.

The prevalence of type II diabetes and multiple sclerosis are chosen to represent the common disease and the rare disease respectively. The prevalence for the common disease is 37.5% and for the rare disease is 3.2% according to recent literatures. To mimic the performance of some commonly used phenotyping algorithms, we choose the misclassification rates of the outcomes to be similar with the eMERGE algorithm of identifying phenotypes from EHR clinical texts. This algorithm has been used in many EHR related studies and its performance has been reported in different literatures. According to Ritchie et al (2010), in a relatively high-performance situation for phenotyping type II diabetes, the positive predicted value (PPV) of the algorithm is approximately 0.9 and the sensitivity is 0.84. The specificity is then calculated to be 0.96 as in Ritchie et al (2010). In a relatively low-performance situation, the sensitivity and specificity of the eMERGE algorithm are reported to be around 0.665 and 0.819, respectively. The misclassification rates of the phenotyping algorithm often depend on the prevalence of the disease. Phenotyping a rare disease tends to be more accurate than a common disease. For rare diseases (e.g., multiple sclerosis), the sensitivity of the eMERGE algorithm is around 0.857 and the specificity is 0.997 in a high-performance situation, and 0.707 and 0.988 in a low-performance situation. We fix the sample size at 5,000, and consider a sequence of effect sizes (in the scale of log odd ratio) in a logistic regression to evaluate the statistical power. These settings are the same for both genetic and epidemiological studies, and number of simulation is 1,000 for each setting.

In genetic association studies, the genetic information (i.e., genotypes) is often quite accurate with low genotyping errors. Therefore, we consider only the outcome misclassification in the GWAS settings. Minor allele frequency (MAF) of SNPs is set to be 0.2 for common variant scenarios and 0.03 for rare variant scenarios. In each scenario, two logistic regressions are fitted using the true outcomes and the misclassified outcomes, respectively. The reject rates are reported for each effect size, and power curves are plotted. The difference in power between using the true outcome and the misclassified outcome quantifies the impact of misclassification in each.
In almost all GWAS, a large number of SNPs are investigated. In order to understand the overall power loss for a typical genetic association study, averaged powers are obtained by sampling MAFs from a real genetic dataset (1000 Genomes Project Consortium, 2012) without replacement in each simulation to mimic the situation in a real GWAS.

In epidemiological studies, however, categorical covariates such as smoking status are often measured with different amount of measurement errors. Hence, we considered both the outcome misclassification and covariate measurement error in the epidemiological settings in order to evaluate the further impact of the measurement error in the covariate on association test. In some EHR systems, smoking status is recorded as a discrete variable with three categories (i.e. the classified smoking status): non-smoker, past-smoker, and current smoker. In this case, we use a single categorical variable which takes values 0, 1 and 2 to mimic the smoking status (non-smoker, past-smoker, and current smoker). The true status of the covariate is then generated from a multinomial distribution where the proportions of the three smoking status categories are based on the results in Liu et al (2012)\(^\text{17}\). The misclassified covariate is generated by mimicking the performance of the cTAKES smoking status detection module\(^\text{17}\). More precisely, as discussed in the paper, the algorithm first classifies subjects into non-smokers and smokers, and then classifies the smokers into past smokers and current smokers. Both classifiers involve misclassification and the misclassification rates are listed in Liu et al (2012)\(^\text{17}\). For scenarios with small amount of measurement errors (e.g., customized cTAKES module for eMERGE data), the sensitivity and specificity are approximately 0.98 and 0.97 for the first classifier and 0.94 and 0.92 for the second classifier. For scenarios with relatively large amount of measurement errors (e.g., direct use of cTAKE module without customization), the sensitivity and specificity are around 0.31 and 0.91 for the first classifier and 0.84 and 0.51 for the second classifier. In some other EHR systems, smoking status is recorded as the self-reported number of cigarettes per day (i.e. the quantified smoking status). To mimic this type of covariate data, we generate the smoking status as a variable taking non-negative integers using a zero-inflated Poisson distribution, considering a lot of patients are non-smokers. According to Kiviniemi et al (2011)\(^\text{3}\), the non-smoking proportion in the US is around 83% and the average number of cigarettes per day for one person is 15. The measurement error in smoking status is generated by randomly adding or subtracting a random error which follows a negative binomial distribution. For the situation with relatively small amount of measurement errors, we generated the random error from a negative binomial distribution with mean 0.5 and variance 0.625; and for large amount of errors, the random error are generated from a negative binomial distribution with mean 3 and variance 7.5. Figure 1 shows the scenarios what we consider and the corresponding parameter we choose in this paper.
In all scenarios, the smoking status is treated as ordinal variable assuming the effect of smoking on presence of disease is additive. Powers are calculated for different effect sizes from 0 to 1 (in the scale of log odds ratio) in the GWAS setting and the epidemiological setting with classified smoking status, and for different effect sizes from 0 to 0.05 in the epidemiological setting with quantified smoking status.

**Methods under comparison**

Under genetic settings, we compare the model using true disease status with the model using misclassified outcome. Under epidemiological settings, we compare the model using true disease status and true smoking status with the model using misclassified disease status and misclassified smoking status. The models to be compared are described below:

1. Logistic regression using true disease status and true covariate.

   Let \( Y \) denote the true disease status (e.g., type II diabetes) of a patient, and \( X \) denote the true covariate status (e.g., genotype at a SNP locus, or true smoking status), we assume a logistic regression model: 
   \[
   \text{logit} \left( \Pr(Y = 1) \right) = \beta_0 + \beta_1 X,
   \]
   where \( \Pr(Y = 1) \) is the probability of a patient having the disease.

2. Logistic regression using misclassified disease status and true covariate.

   In the genetic association studies using the EHR-based phenotypes, instead of observing the true disease status, we could only obtain the disease status of the patients with misclassification. Let \( Y^* \) denote the surrogate of the true disease (e.g., type II diabetes status extracted from EHR data), and \( X \) denote the genotype at a certain SNP. The logistic regression model using the surrogate as the true type II diabetes status could be expressed as: 
   \[
   \text{logit} \left( \Pr(Y = 1) \right) = \gamma_0 + \gamma_1 X.
   \]
   Here, the probability of having type II diabetes (\( \Pr(Y = 1) \)) is replaced by the probability of observing the patient in the disease category (\( \Pr(Y^* = 1) \)). This model is not correct since these two probabilities are not equal and: 
   \[
   \Pr(Y^* = 1|Y = 1) = \alpha_1, \quad \Pr(Y^* = 1|Y = 0) = 1 - \alpha_2,
   \]
   where \( \alpha_1 \) is known as the sensitivity and \( \alpha_2 \) is the specificity of the phenotyping algorithm.

3. Logistic regression using misclassified disease status and covariate with measurement error.

   In epidemiological studies using EHR-based phenotypes and covariate (e.g., type II diabetes and smoking status), both the outcome misclassification and covariate measurement error are considered. Let \( Y^* \) denote the surrogate of the true disease status and \( X^* \) denote the surrogate of true smoking status. The logistic model using surrogates of both disease status and smoking status could be expressed as: 
   \[
   \text{logit} \left( \Pr(Y = 1) \right) = \eta_0 + \eta_1 X^*.
   \]
   It also holds that \( \Pr(Y^* = 1|Y = 1) = \alpha_1, \quad \Pr(Y^* = 1|Y = 0) = 1 - \alpha_2 \). When the smoking status is recorded as non-smoker, past-smoker and current smoker, the misclassification of smoking status involves two classifiers and satisfies:
   \[
   \begin{align*}
   &\Pr(X^* = 1, 2|X = 1, 2) = \alpha_a, \quad \Pr(X^* = 1, 2|X = 0) = 1 - \alpha_b, \\
   &\Pr(X^* = 2|X = 2) = 1 - \alpha_c, \quad \Pr(X^* = 2|X = 1) = 1 - \alpha_d,
   \end{align*}
   \]
   where \( \alpha_a \) and \( \alpha_b \) are the sensitivity and specificity for the first classifier and \( \alpha_c \) and \( \alpha_d \) are the sensitivity and specificity for the second classifier of the smoking status detection algorithm.

In each setting, we are interested in testing for an association between the covariate (smoking status) and disease (type II diabetes) by testing the association parameter being 0, i.e., \( H_0: \beta_1 = 0, \gamma_1 = 0, \) or \( \eta_1 = 0 \) in the models.

In the simulation studies, we generate the true status of disease and covariate from model 1, and generate the surrogates using the assumed misclassification rates and error distribution. Powers are compared between the misclassified model and the true model in order to quantify the impacts of misclassifications of outcomes and measurement errors of covariates on association test.

**Simulation results**

1. Genetic settings.

   Figure 2 presented the power curves of the genetic association tests in settings with common and rare diseases. When true disease statuses were known, the power for detecting association was higher for common diseases compared to rare diseases, and higher for common variant compared to rare variant when controlling for other parameter values. Such a finding also held when true disease statuses were unknown and surrogates were used. This finding was consistent with the experiences in association studies\(^{15,16}\). To evaluate the impact of misclassifications, we compared the power of using true outcomes against using the surrogates within the same setting of disease prevalence and allele frequency. The left panel in Figure 2 suggested that for a common variant (i.e., high allele frequency), the loss of power was relatively small as long as the misclassification rates were low (the maximal loss of power is around 15%). On the other hand, if the variant was rare (i.e., low allele frequency), the loss of power due
to the misclassification was sizable (up to 20%) when misclassification rates were low. However, when misclassification rates were high, the losses of power were all larger than 50% for both common and rare variant scenarios. The right panel in Figure 2 suggested a similar finding, except the corresponding power was lower due to the fact that the disease was rarer.

Another observation from the solid and dashed curves in the left panel of Figure 2 was that when the true log odds ratio was 0.3 (i.e., odds ratio of 1.35), the association test based on the true outcome (or misclassified outcome with small misclassification rates) had a power of 100%. In other words, misclassification had no impact on loss of power, provided the effect size was moderately strong, both disease and covariate were common, and misclassification rates were relatively small. If any of these conditions failed to hold, the loss of power due to misclassification was still substantial. For example, for the same effect size, when considering the common disease and rare variant scenario, the power loss due to misclassification was 17.3% for small misclassification rates and 46.2% for high misclassification rates. These numbers were 10% and 29.6% respectively, for rare disease and common variant, and 2% and 7.2% for rare disease and rare variant. In the setting of no misclassification, the power for the rare disease and common variant scenario and the rare disease and rare variant scenario were 68.7% and 18.6%. Therefore the power loss could not be ignored.

Figure 3 presented the power for association tests at a single SNP in different settings. For a typical GWAS, millions of SNPs are tested where both rare variants and common variants are included. We are often more interested in the averaged loss of power due to misclassifications, where the loss of power in association test at each SNP is averaged over millions of SNPs. To obtain the averaged power, we sampled the allele frequencies without replacement from the data from the reference panels of The 1000 Genomes Project (here we used Utah Residents with Northern and Western European Ancestry, or CEU) (1000 Genomes Project Consortium, 2012). The empirical distribution of the minor allele frequencies was displayed in Figure 2. The SNPs with a MAF greater than 0.1 were distributed approximately evenly, and SNPs with MAF less than 0.05 were considered rare in this population.
Figure 4 showed the averaged power curves for a genetic association study based on the CEU population. Power curves in the left and right panels showed the impact of misclassified phenotypes on association testing for common and rare diseases. These power curves implied that from an overall perspective how much power was lost due to misclassified outcomes in different settings of misclassification rates. Since the minor allele frequency of most SNPs in the genetic association study was distributed from 0.1 to 0.5, the averaged power curves were similar as the common variant scenarios in Figure 3. It suggested that when misclassification rates were low, the power loss was relatively mild compared to the power loss when misclassification rates were high. For common diseases, when the testing allele had an effect size (log odds ratio) larger than 0.3 and under low misclassification rates, using the surrogates did not cause power loss greater than 1%. When misclassification rates were high, however, the log odds ratio had to be at least 0.5 to reach a power loss less than 5%. When diseases were rare, the log odds ratio had to be greater than 0.4 for the low misclassification scenario, and 0.6 for the high misclassification scenario to ensure a power loss less than 5%.

To evaluate the power loss in extreme situations, we calculated the maximal power loss when the effect size was varying from 0 to 1. When misclassification rates were low, the maximal power loss was 15% for common disease and 11% for rare disease. While when misclassification rates were high, the maximal power losses were 50% and 29% for common and rare diseases correspondingly. Therefore, when the sensitivity and specificity of the phenotyping algorithm were not high enough, the average power loss could be huge for SNPs with relatively moderate effect sizes for both rare and common diseases.

2. Epidemiological settings.

In this section, we mimicked the settings of epidemiological studies using EHR-based disease and covariate status (i.e. smoking status). Besides the misclassified binary outcomes, we evaluated the further impact of measurement errors in covariates on the power loss of association test. The misclassification settings for the disease status and smoking status could be found in Figure 1.

When the smoking status only contained three classes, Figure 5 showed the power curves in different settings of misclassification and measurement errors for common and rare diseases. The previous finding that the power for rare diseases is lower than common diseases when controlling for other settings also held in the epidemiological studies. The comparison between the solid line and the four dashed lines within each panel showed the impact of different levels of misclassification and measurement errors on the power of association testing.

Combined with Figure 3 and Figure 5, it suggested that adding the measurement error increased the power loss compared with models with only the outcome misclassification. For example, when the effect size (log odds ratio) was 0.3 for common disease, the power losses of the four scenarios in the plots (low misclassification small measurement error, high misclassification small measurement error, low misclassification large measurement error and high misclassification large measurement error) were 2.7%, 35.8%, 48.8% and 77.6%. For rare disease, the powers of the four scenarios were 15.1%, 30.6%, 45.8% and 48%, respectively. It also showed that only when both
misclassification and measurement error were small, the power loss was relatively small. When either outcome or exposure had a high misclassification rate, the power loss was severe.

Figure 5 Comparison of Power for common and rare diseases in epidemiological settings where the covariate contains three categories (non-smoker, past smoker and current smoker). Misclassified outcome* stands for high sensitivity and specificity (Sensitivity=0.84, specificity=0.96 for common diseases; sensitivity=0.857, specificity=0.997 for rare diseases). Misclassified outcome† stands for low sensitivity and specificity (Sensitivity=0.665, specificity=0.819 for common diseases; sensitivity=0.707, specificity=0.988 for rare diseases). Covariate* stands for small amount of covariate misclassification (sensitivity and specificity were chosen as 0.98 and 0.97 for the first classifier and 0.94 and 0.92 for the second classifier). Covariate† stands for large amount of covariate misclassification (the sensitivity and specificity were set to be 0.31 and 0.91 for the first classifier and 0.84 and 0.51 for the second classifier).

Figure 6 Comparison of Power for common and rare diseases in epidemiological settings where the covariate is the self-reported number of cigarettes per day. Misclassified outcome* stands for high sensitivity and specificity (Sensitivity=0.84, specificity=0.96 for common diseases; sensitivity=0.857, specificity=0.997 for rare diseases). Misclassified outcome† stands for low sensitivity and specificity (Sensitivity=0.665, specificity=0.819 for common diseases; sensitivity=0.707, specificity=0.988 for rare diseases). Covariate* stands for small amount of covariate measurement error in number of cigarettes which was generated from NB(0.5,0.625). Covariate† stands for large amount of covariate measurement error which was generated from NB (3, 7.5).

When using the number of cigarettes to code the smoking status, the power curves under different scenarios were showed in Figure 6. The major findings under this scenario were the same as the previous scenario in which the smoking status was recorded as three categories. When the outcome misclassification was low and measurement error of the covariate was small, the power loss was within 18.2% for common diseases and 12.4% for rare diseases.
However, when either the outcome misclassification or the covariate measurement error was large, the power loss was severe up to 50%.

Through this simulation study, we quantified the impact of misclassification and measurement error in association studies. It was showed that rare diseases, compared to common diseases, had lower power for testing the association controlling for the prevalence of covariate, misclassification rates and measurement error amount. The prevalence of the covariate (minor allele frequency in this study) also influenced the power in the sense that rare variant scenarios had lower power than the common variant scenarios when controlling for other settings. Therefore, in practical researches, study designs should account for these factors to adjust the sample size to achieve a proper testing power. When only outcomes were misclassified, the power loss was small when the misclassification rates were low, and it was sizable when misclassification rates were high. Moreover, when the covariate and the outcome were not measured accurately, the power loss increased compared to the models with only the outcome misclassification. In these scenarios, power loss was relatively large when either the measurement error or the outcome misclassification rates were large.

Discussion

In this empirical study, we conducted simulation studies under different values of misclassification rates and amount of measurement errors to evaluate the loss of power in both genetic and epidemiological association study settings. We concluded that factors including disease prevalence, covariate frequency, misclassification rates of the disease status as well as the amount of measurement errors all influenced the power of association test. The power loss was relatively small as long as the misclassification rates and/or measurement error were low. Otherwise, power loss could be substantial and was increased with higher misclassification rates and/or measurement error rates. From the simulation results, we also observed that the type I error of the association test that ignored misclassification and measurement errors were not inflated under all scenarios. In other words, although the outcome and covariate could be measured with errors, the naive logistic regression ignoring these errors can still control type I error well as long as the misclassification is nondifferential. This is consistent with the findings of Neuhaus (1999) and Li & Duan (1989). Therefore, the only issue of using the naive logistic regression is the power loss.

However, while the EHR data are widely used in all kinds of association studies, the problem of power loss due to inaccuracy of EHR-based phenotypes and covariate records are sometimes ignored. Our study investigated this problem in two major types of studies and showed that when observations were measured with certain amount of errors, the power loss could be quite substantial. If no adjustment is made to account for the misclassification and measurement errors, sample size should be recalculated to deal with the loss of power.

In practical studies, when sample size is fixed and misclassification exists, association tests that account for the misclassification are needed. Moreover, the estimations of the effect sizes can also be biased and need to be corrected. Neuhaus (1999) and Li & Duan (1989) pointed out that when the outcome and covariate were misclassified, the estimated effect size (log odds ratio) is biased towards the null if using naive logistic regression. One limitation of our empirical study is that we only considered two levels of disease prevalence, minor allele frequency, misclassification rates and measurement error amount. The scope of scenarios that we have discussed in this paper is still limited. For example, in real applications, the disease prevalence could be lower than 3.2% as we considered here, and misclassification rates could vary from a wider range. However, the results of this study are useful to inform and guide investigators on the magnitude of loss of power in certain scenarios. And the conclusions about the relationships between powers and each factor could help the investigators obtain a rough estimation of potential loss of power in their studies.

In this study, we considered a relatively simple situation where the misclassification of the outcome is independent of the covariate, as well as the measurement error of the covariates. This assumption might not hold in some practical situations since the error probabilities might differ across different covariate levels. Moreover, the amount of measurement error of the covariate might be correlated with the disease misclassification rates. Empirical evaluation of power loss in these more complicated situations will be reported in the near future.

Furthermore, as we concluded that the power of the association test is influenced by various factors such as the disease prevalence, frequency of the covariate, as well as the misclassification rates, it is of interest to investigate how the power loss is attributable to these factors individually and jointly. Our future work also includes the extension from simple univariate logistic regression to multivariate regression to better understand the impact of misclassification on the power loss of association test in the presence of confounders.

Conclusion

Over the last decade, EHR systems have been increasingly implemented at US hospitals. Substantial amounts of
detailed patient information, including lab tests, medications, disease status, and treatment outcome, have been accumulated and are available electronically. These large clinical databases are valuable sources for clinical and translational research. Despite their great potential, the complex and uneven nature of clinical documentation and data quality brings additional challenges for analyzing EHR data. A critical challenge is the information bias due to the measurement errors in outcome and/or covariates. We conducted empirical studies to quantify the impacts of measurement errors on EHR based associated study. More specifically, we designed our simulation studies based on the disease prevalence, covariate frequencies and misclassification rates using data from the Electronic Medical Records and Genomics (eMERGE) Network. Through simulation studies, we quantified the loss of power due to misclassifications in case ascertainment with respect to different levels of misclassification rates (e.g., an algorithm with high precision and recall vs one with low precision and recall), disease prevalence (e.g., common disease vs rare disease), and covariate frequencies (e.g., common allele frequency vs rare allele frequency). We also evaluated the further loss of power if the covariate conditions were subjected to measurement errors, such as smoking status extracted from medical records by a certain algorithm. These empirical findings can help to inform investigators for better understanding the potential power loss due to different types of measurement errors under a variety of conditions in EHR based association studies.

Supporting Common Ground Development in the Operation Room through Information Display Systems

Yuanyuan Feng, MS, and Helena M. Mentis, MS PHD
1University of Maryland Baltimore County, Baltimore, MD, USA

Abstract

Effective information sharing is crucial for clinical team coordination. Most information display systems have been designed to replace verbal communication. However, information may not be available for capture before a communication event and information needs often become clear and evident through an evolving discourse. Thus, to build tools to support clinical team in situ information sharing, we need a better understanding of how evolving information needs are identified and satisfied. In this study, we used sequential analysis techniques to explore the ways communication and information sharing events between an attending surgeon and a resident change throughout a laparoscopic surgery. We demonstrate how common ground is developed and maintained, and how information needs change through the efforts of grounding. From our findings, we suggest that the design for information display systems could encourage communication and support the articulation work that is necessary to accomplish the information sharing.

Introduction

Timely and accurate information sharing is crucial for the coordination of clinical team members in dynamic and information-rich clinical environment1. Failures in communication have been shown to be a major contributor to medical errors and adverse events in healthcare2. Because of these collaborative challenges, there has been extensive effort in designing systems to replace verbal communications, such as hand-off tools, by retrieving, integrating and visualizing information to the team3-6. For instance, in the study of team communication in the cardiac operating room, Parush et al. proposed an augmented display to increase the team situation awareness of patient information, vital signs, and critical events5. However, the underlying assumptions in this paper and others like it has been that (1) the information is already stored somewhere in the system, and (2) health care professionals are aware of their information needs. These assumptions are in contrast to studies that highlight how communication contains a high volume of information that may not be collected before a communication event and, through an evolving discourse, information needs become clear and evident.

For instance, Coiera highlights how communication and information tasks take place on a continuing basis where informal tasks are accomplished with discourse-embedded information7. This practice is manifest in the survey conducted by McKnight et al., which showed that clinicians preferred informal communication instead of the time-consuming explicit information seeking process8. Furthermore, in the study of collaborative information behavior in the clinical settings, Reddy et al. had shown that communication not only allows team members to identify and share information, but also ties together different pieces of information to make sense of the context9. Moreover, information needs have been found to be highly complex, which requires team members to clarify individual information seeking tasks and to integrate their tasks together to generate knowledge10.

The concept of common ground can further elucidate how effective information sharing between team members is embedded in a context and requires ongoing effort16. A lack of previous collaborative activity leads to a large hurdle for the team to quickly and effectively share the relevant content and coordinate the work process; not least in part due to the team members’ different levels of expertise17. This increases the need for team members to quickly build enough shared knowledge. In particular, they must establish that they both engender the same knowledge of how to perform the task as well as, throughout the collaboration, maintain that they both have a shared knowledge of the task domain18. Common ground entails an ongoing process of checking, clarifying, and sharing further knowledge in order to maintain this shared understanding19. This process of maintaining common ground actually enables greater efficiency or minimal effort for communication over time for the team20. Studies of teamwork in critical settings, such as flight crews, have shown that more efficient communication among team members results in better coordination and performance. This is especially relevant for supporting teams of experts with diverse skillsets collaborating on critical problems with time constraints21.
To build tools that support clinical team collaboration, we need a better understanding of the mechanisms through which common ground is developed and maintained. Although previous research has demonstrated that common ground increases through joint experience on a task over time, scrutinizing the grounding process of a clinical team in an information-rich environment leads us to ask a series of questions regarding information needs. For example, how does the information need change over the course of team collaboration? How is the information need identified and satisfied? The answers to these questions are essential for designing systems to display information and support collaborative activities. By identifying the grounding process, we can make informed decisions on when and how to provide appropriate tools.

One information-rich medical environment that has garnered recent attention in the design of information collection and display systems is surgery. With the increasing rise of minimally invasive surgery, surgeons are required to coordinate around highly specialized medical images such as fluoroscopic x-rays and laparoscopic video throughout a surgery. In most cases, surgeons rely on efficient and effective communication practices to successfully coordinate with each other. This is all the more complex when, as in teaching hospitals, one of the coordinating surgeons has a reduced level of knowledge as in the case of a resident. Many residents practice their surgical skills and learn the process of surgical procedures through assisting in surgeries. Although a resident may have performed a particular surgery before, they are certainly not yet proficient. Oftentimes, the resident and attending surgeon have not worked together before or, if they have, it is not the specific surgery they are about to perform. Thus, not only do they have to coordinate their actions, but the attending surgeon also has to assess the resident’s level of knowledge of the case and determine how much direction they need to perform the procedure.

In this paper, we present a conversation analysis study of in situ laparoscopic surgical training to show the considerable information generated and knowledge gained throughout the discourse. We used sequential analysis techniques to explore the ways communication is conducted and demonstrate how common ground is developed and maintained over the course of a laparoscopic surgery. Examining the communication patterns exposes not only how attending surgeons pass on their knowledge and skills to residents through verbal communication, but also how information needs change through the efforts of grounding. From our findings, we address the importance of communication patterns in information acquisition and sharing, as well as question the predominant direction for information display systems in the operating room.

**Study Design and Data Collection**

The study was based on videos recorded during fieldwork in the operating rooms of the Cambridge Hospital. Human Subject’s approval was granted through the Cambridge Health Alliance IRB.

A total of ten laparoscopic cholecystectomy cases were video recorded. The cases included three different surgeons and three different PGY4 residents in different combinations of the two groups (Table 1). In each case, the surgery was performed primarily by a senior resident with assistance from an attending surgeon. The videos were transformed into picture-in-picture format, including the external video showing the interaction between attending surgeons and residents, along with the internal video captured by the laparoscopic video recorder. The communication was recorded with a wireless microphone worn by the attending surgeon.

**Coding Scheme and Procedure**

In our cases, the surgeons were collocated and verbally communicated over the laparoscopic video, which displayed the operative field. In our analysis, we focused on the utterances made by the surgeons. The communication content was coded manually based on a dialogue act scheme, which was developed to
understand the development of common ground among interdependent team members in emergency management tasks to provide implications for the design of collaborative systems24 (Table 2). This method emphasizes the use of communicative intentions to interpret the development of common ground. It includes two types of common ground – content and process. Content common ground is defined in the coding scheme as “the shared understanding on the subject and focus of work”, while process common ground is defined as “the shared understanding of the rules, procedures, timing and manner in which the interaction will be conducted”25.

We used this coding scheme to understand the processes of knowledge sharing and common ground building in OR-based training for laparoscopic surgery. Specifically, dialogue acts provided us insights into the ways that information was gained, the kinds of information that were transferred, and the collaboration between attending surgeons and residents.

All utterances between attending surgeons and residents were coded using the dialogue act coding scheme by two coders. For better reliability, the coders viewed the videos and coded the transcripts independently. After the first independent coding session, the inter-rater reliability for the coders was found be to Kappa = 0.64. The two coders negotiated for any conflicting codes with one of the researchers who developed the coding scheme (last author of this paper). After this discussion, the two coders independently coded again and achieved an agreement of Kappa = 0.87. This was deemed high agreement26 and so the remainder of the cases were coded. The inter-rater reliability was analyzed using the Kappa statistic for each case. For any case with Kappa less than 0.7, the two coders negotiated the difference to achieve higher agreement. In the end, the average Kappa score is 0.78, ranging from 0.71 to 0.87.

Phase Identification

A well-established hierarchical task analysis of laparoscopic cholecystectomy identified five high-level surgical steps27. For our study, we used these surgical steps to define the five main phases of our laparoscopic cholecystectomy: patient preparation, gallbladder isolation, gallbladder removal, and cleanup. By using the hierarchical task analysis, we identified the start and end times of each phase in each surgery. The communicative events were then associated with a phase of the surgery by matching the communication occurrences to the phase time stamps.
Data Analysis

The focus of data analysis in our study was to identify the significant patterns of communication between an attending surgeon and a resident across phases in a laparoscopic cholecystectomy. We used lag-sequential analysis with log linear modeling to identify the sequential nature in the data. Since the lag sequential analysis emphasizes the consecutive nature of the data, it allows us to understand the immediate reactions to a given utterance, and further to identify the information needs for developing common ground. The non-parametric Friedman test was used to compare frequencies of significant communication patterns across phases. The data analysis was conducted in SPSS v 22.0 (Chicago, IL). A value of $P < 0.05$ was considered to indicate statistical significance.

Results

Of the ten laparoscopic cholecystectomy cases in this study, 657 minutes of operative time were assessed. During that time, a total of 4287 utterances were observed, among which 3221 utterances were between attending surgeons (87.6%) and residents (12.4%) with a median of 227.5 and a range from 126 to 910.

Lag-sequential Analysis

In order to identify the speakers of utterances, we labeled each utterance with the speaker as well – attending surgeon (att) or resident (res). Since we were interested in how the information was gained, we included repeated codes in our analysis. Thus, in total, we received 3161 two-chain communication events across 21 dialogue codes. Table 3 shows the average time spent and the frequency of communication events in each phase.

We first constructed an initial three-dimensional matrix of Lag0 Dialogue Act (21) × Lag1 Dialogue Act (21) × Phase (4) to represent the sequential frequencies between dialogue acts across phases. Lag0 represents the initial utterance provided by either attending surgeons or residents. Lag1 presents the feedback provided by any surgeon given Lag0. The third dimension, Phase, serves as conditions, indicating the phase when the two-event chain occurred.

We fit the initial matrix into the log-linear model of complete independence (Lag0 + Lag1 + Phase). The test results indicate that the three variables are not mutually independent ($G^2 (1720) = 1964.627, p < 0.0001$). However, the test of conditional independence, including all main effects and all two-way interactions, fails to reject the null hypothesis that the sequential structures are independent of the phases given our initial matrix ($G^2 (1200) = 359.230, p = 1$). The results are not surprising, since there is sparseness in our high dimensional contingency table. In order to identify significant communication patterns in each phase, we split the initial matrix into four two-way contingency tables based on the phases and selected the partition that consisted of the rows and columns where both Lag0 and Lag1 were categories that had marginal frequencies greater than 5.

After applying the cutoff value, testing the partition of the original tables revealed a highly significant interaction between Lag0 and Lag1 in all four phases (Table 4). The results indicate that there are significant patterns in each of the four phases.

**Common Communication Patterns Shared among Phases**

We proceeded to identify the significant patterns, which are defined by the value of adjusted residual greater than 1.96\(^2\). There are seven patterns shared by two or more phases (Table 5). As shown in Table 5, the shared communication patterns include both content information sharing and process management.

**Information Transfer**

Knowledge for the task content was either directly added or elicited by queries. The consecutively repeated adding information (AI) by the attending surgeons is the common pattern in all four phases. The high frequency of this pattern in Phase 2 indicates that a vast amount of information is explicitly presented in order to allow the residents to develop a mutual understanding with the attending surgeons. A non-parametric Friedman test of differences among repeated measures was conducted to compare the pattern frequencies across phases and rendered a Chi-square value of 13.194, which indicates that the frequency of the adding information pattern varies over the phases (p = 0.004). The post-hoc comparisons identified that Phase 2 has the most frequent patterns of adding information (p = 0.028), whereas the other three phases have similar frequencies to each other.

In the meantime, we also observed the residents’ efforts in adding relevant information (AI) in Phase 1, 2 and 3. This pattern reflects that the residents understood the content and were able to provide new information to supplement their mutual understanding. It indicates an increase in the common ground that allows residents to make an effective introduction of information.

Compared to adding information, the pattern of query (Q) and reply (R) is less frequent over the course of surgery. However, we observed significance in the two patterns of query and reply. The direct reply from the residents to the attending surgeons’ query among all four phases indicates that residents were able to understand a certain amount of queries and answer it in the next turn. By providing a reply, residents gained information through the process of recognizing the query, mapping it to the content, and relating it to the context. With the residents’ reply, attending surgeons assessed if more information needed to be provided to maintain the common ground. On the contrary, the residents’ request of information in Phase 1, 2 and 3 revealed the extra effort in gaining the necessary information. The residents could not proceed to perform a task without necessary information to develop the common ground; they needed to expend extra effort in formulating a request to gain the information. With the low frequencies of Q and R patterns, we have limited power to identify any significant increases in any phases.

Checking Understanding

Another significant pattern found in Phase 2 and 3 pertains to the alignment (AL) and acknowledgement (AC) acts. Without any feedback from the residents, the attending surgeons have to repeat the presented information to request residents’ feedback. Residents often replied with acknowledgement, showing that they had already known the information. The high frequency of attending surgeons’ alignment indicates that the residents failed to provide timely feedback and often received redundant information from the attending surgeons.

Process Management

To coordinate the procedure, attending surgeons often provided repeated explicit instructions (MN) over the course of surgery. The significant occurrence of this pattern indicates that the procedure was frequently coordinated and updated. The increased frequency of this pattern in Phase 2 and 3 shows that the attending surgeons provided detailed instructions to guide the residents step by step in the intricacies of that particular surgical procedure as Phase 1 and 4 contain knowledge that are more common across surgeries ($\chi^2 (3) = 17.022, p = 0.001$).

Figure 1. Unique significant patterns in each phase.

Unique Communication Patterns in Each Phase

In addition to the common patterns, we identified 23 unique significant patterns in the four phases. Here we present the ones with higher observed frequency (Figure 1). The pattern in Phase 1 (patient preparation) shows that there is a significant connection between the attending adding information (AI) and then agreement (AG) with the course of the surgery (a process common ground dialogue act). This pattern reflects that after receiving relevant information from the attending surgeons, residents can make the right decisions for the process of the surgery. It indicates that with the mutual understanding of the content, the process common ground is easily achieved in Phase 1. In Phase 2 (gallbladder isolation), we observed
frequent patterns of attending management (MN) followed by attending agreement (AG) or resident query (Q). It shows that the attention of both attending surgeons and residents is focused on the process – attending surgeons provided explicit instructions and timely positive feedback to support residents moving forward, while residents follow the instructions and requests for further information to ensure that they share a mutual understanding with the attending surgeons. With increased content common ground, in Phase 3 (gallbladder removal), the communication pattern has changed from the residents requesting information to verifying their understanding of instructions (CH). This change indicates that residents have already developed the content common ground with regards to this particular surgery and have thus shifted their focus to the development of process common ground. In Phase 4 (cleanup), residents provide positive feedback to the instructions, indicating that they have achieved the mutual understanding of the process with the attending surgeons.

**Discussion**

Our study has aimed to identify the communication patterns and articulate the process of common ground development between a surgical attending and resident over the course of a laparoscopic surgery. These communication patterns reaffirm that information required to coordinate is embedded in the course of communication: through verbally sharing the information, surgeons and their trainees develop, maintain and update their common ground.

Our results illustrate different patterns between the development of content common ground and process common ground across phases. At the beginning of the surgery, both the attending surgeons and residents focused on developing the content common ground. As more critical moments occurred, they started to shift their attention to manage the process. This shift reflects the changes in residents’ information needs. In the initial phase, the adding of content information may help residents have a comprehensive operative view and become familiar with the anatomic structure. During the critical phases, such as Phase 2 and 3, residents began to make decisions about the process using information gained from previous phases. At these moments adding additional information may interrupt the residents’ thinking process and negatively influence their judgment and decision-making.

Based on the grounding process, we now discuss that how information needs emerge, how the information need is identified, and the cooperative nature of the communication. We identified that information needs emerge in three situations. First, the information need emerges when team members develop or update their mutual understanding of what is occurring during the different phases of the surgery. For instance, in the beginning of the surgery, there are a high number of communicative events regarding content between attending surgeons and residents – they needed to establish that they both engendered the same knowledge of the anatomic structures they were working on and their plans to perform the surgery. Secondly, as the surgery progresses the information need emerges when there is a need to understand a team member’s statements or decisions. There were situations when the residents could not understand the instructions. Instead of following the instructions, they verified their understanding or requested explanations from the attending surgeon. Finally, the information need is embedded in the information provided through discourse. This is reflected by the high frequency of consecutive acts of adding information by attending surgeons. After providing a piece of information, the attending surgeons realized there was other information that might support the residents’ understanding. Thus, we argue that the information needs are updated throughout the discourse, and communication is not merely an information transaction method, but a mechanism that generates information itself.

When there is an information need, the identification of this need is necessary for a communication event to be triggered. In this study, we found three ways for information needs to be identified. First, information needs can be identified through verbal requests. The verbal requests entail three different dialogue acts – query (Q), check (CH) and confirm (CO). The residents were found to commonly request new information from the attending surgeons, but they seldom confirmed their plans. This may be due to the high cognitive load in making plans compared to the limited efforts in accepting information. Secondly, information needs can be identified by the providers themselves, based on the mutual understanding between providers and receptors. For instance, the attending surgeons often elaborated on the typical instructions given to residents based on the inference that more information was needed. This direct act of adding information requires a mutual understanding developed between team members. Further, the information needs can also be identified through observing the actions. For example, after giving an instruction, the attending surgeons
identified the resident’s information need by observing how the residents executed this instruction. They would provide further instruction or add new information necessary for residents to accomplish the task. In this situation, the information providers are required to capture and understand their teammates’ action.

As we discuss above, communication is not only a way to transfer information, but also work that team members do to share and generate information – and this communication is a form of cooperative work. As is shown in the study, the attending surgeons provided instructions based on what their residents did or requested. The residents replied back based on the attending surgeons’ explanations of the instruction. In other words, they were mutually dependent in their efforts in communicating. Thus, the surgeons engaged in cooperative work of sharing information. If we regard the communication between surgeons as cooperative work, where multiple surgeons share and generate information, the articulation work that is required for communication is the work that supports the information accurately conveyed to and understood by the team. In this study, the articulation work entails knowledge level assessment, concept explanations, and feedback anticipation. For example, the attending surgeons asked questions at the beginning of the surgery to assess the residents’ knowledge levels, which informed them what kind of information to provide to the residents. When giving an instruction, the attending surgeons provided background knowledge or information about the operative field, in order for the residents to understand the content of the instruction and the context around the instruction.

Implications for Design of Information Display System

The understanding of the mechanisms through which common ground is developed and information needs change let us question the predominant direction for information display systems, which focuses on replacing verbal communications by directly retrieving and presenting the information to the team. Instead, the broad implication in our study is that the necessary information and the dynamic information needs are embedded in the communication between team members in the information-rich environment. For efficient communication it is not enough to simply allow surgeons to have more access to different kinds of information, but rather, timely mutual understanding of what content is presented, what is needed to be performed, and what should be verified. Thus, the direction for designing such systems should focus on encouraging efficient communication, as well as supporting the articulation work that is necessary to accomplish the communication.

This relates to our ongoing interests in developing interactive instructional systems that allow surgeons to add visual cues on the medical images to increase the efficient understanding of the utterances. In our previous work, we have identified the considerable work attending surgeons engage in in order to guide residents not only to capture but also to see anatomy within the videos in a laparoscopic surgery. In order to guide the residents’ gaze, the attending surgeons were found to put down the instrument and point at the video screen behind them, or to stop the task at hand and use the instrument to point at the structure, often coupled with an explanation. As indicated in this study, the pointing actions are articulation work required to convey the message. In order to support this work, we are designing a system that allows surgeons to sketch over or point at specific areas on the video in a touchless manner. This paper’s results show how the communication patterns, i.e. information transfer needs, change over the course of the surgery. We can use this knowledge to better understand which interaction mechanism is useful at which point in the surgery. For instance, according to our results, this system can be used by attending surgeons in adding information. Namely, adding information regarding content (i.e. anatomy) early in the surgery and then adding information regarding process (i.e. actions and locations to cut or move) during later phases. These engender different mechanisms of visualizing the information as well – i.e. mechanisms to circle anatomy for referring to anatomy versus mechanisms for pointing and gesturing direction of movement for process-related directions.

Further, we can use this knowledge to hypothesize what new visual interaction mechanisms can then actually help the communication during different phases. For example, we can support feedback anticipation by showing the residents’ understanding on the video. Eye gaze patterns can effectively provide point of attention to the partners. It has been shown that by indicating users’ attention allocation, eye gaze can improve the communication efficiency over visual representations. Eye gaze mechanism can be used in our system to visualize where residents are looking. Through identifying residents’ gaze variations, attending surgeons can provide instructions not only to train the eyes, but also to guide the residents in making decisions.
Limitations and Future Work

Our study is limited to laparoscopic cholecystectomy cases in the surgery department of one teaching hospital. Our results need to be further validated to be generalizable to communication patterns in different clinical settings. Residents also had a limited number of utterances. In our cases, residents manipulated the surgical instruments and performed major tasks, while attending surgeons served as the assistants retracting the gallbladder. In this situation, the attending surgeons needed to provide verbal instructions in order to lead the surgery. The residents, who were not as proficient, followed the instructions and performed surgical tasks. These practices elevated the residents’ cognitive load, which inhibited them to freely formulate utterances. Further, we only targeted the communication between attending surgeons and residents, without further exploring the process among all team members, including nurses, anesthetists and technicians. Other team members play essential roles in the successful coordination of the whole team. The communication patterns among all team members may be different from our results.

Our study shows that analyzing communication patterns based on the dialogue acts help us identify the change of information needs among clinical team members. In our future works, we plan to use this method to understand and evaluate new technologies deployed to support communication in the operating room. Any changes of communication patterns and information needs before and after the deployment may reveal the effectiveness of these technologies.

Conclusion

Communication is important for effective team cooperation. Our study shows the considerable amount of information generated in conversations over the course of a laparoscopic surgery and describes the process of common ground development between attending surgeons and residents. By scrutinizing the grounding process, we showed that information required to coordinate the process of surgery is embedded in the course of communication, and that the residents’ information needs varied across phases of surgery. Our results indicate that the design of information display systems in the operating room should not only encourage communication between team members, but also support the dynamic information needs that emerge through the efforts of grounding.

Abstract

Despite substantial advances in the treatment of end-stage renal disease, mortality of hemodialysis patients remains high. Several models exist that predict mortality for this population and identify patients at risk. However, they mostly focus on patients at a particular stage of dialysis treatment, such as start of dialysis, and only use the most recent patient data. Generalization of such models for predictions in later periods can be challenging since disease characteristics change over time and the evolution of biomarkers is not adequately incorporated. In this research, we explore dynamic methods which allow updates of initial predictions when patients progress in time and new data is observed. We compare a Dynamic Bayesian Network (DBN) to regularized logistic regression models and a Cox model with landmarking. Our preliminary results indicate that the DBN achieves satisfactory performance for short term prediction horizons, but needs further refinement and parameter tuning for longer horizons.

1. Introduction

As the ninth leading cause of death in the United States, with prevalence exceeding 10% in the general population, Chronic Kidney Disease (CKD) is one of the big health burdens of the 21st century1–3. Patients on hemodialysis are in the end stage of chronic kidney disease (ESRD) and rely on dialysis treatments to survive. Despite significant advances in treatment over recent decades, patients still face severe risks and are in a vulnerable health condition. Approximately 24% of patients die within the first year on hemodialysis and hospitalizations are frequent4. The identification and early mitigation of individual risk is a challenging task for physicians who often make treatment decisions under severe time and cost constraints. Robust models that support the assessment of risk of adverse events and outcomes can help to identify early warning signals of increased risk, enable clinicians to target high risk patients, and can be used in the discussion of future treatment options with patients. A variety of prediction models have been suggested in the literature, including simple risk scores, classical regression models and machine learning methods5–12. However, they mostly focus on predictions for patients starting dialysis and are static with respect to time on dialysis or the changes in covariates. In this study, we explore dynamic models that allow updating a prediction when an individual’s health condition changes over time.

With the increasing use of electronic health records (EHR) for patient management, detailed individual information being documented over time has grown rapidly13. Leveraging this highly granular, longitudinal data for both differentiation of patients by disease progression stages and the integration of time-dependent covariates into models is challenging, but offer great potential to yield more accurate prediction estimates. In particular for chronic diseases, where individual data is often collected multiple times per year, the integration of such longitudinal observations is appealing. In this research, we focus on dynamic models that allow updating a prediction when an individual progresses in time. More specifically, our goal is to calculate for an individual patient $i$ at time $s$ the probability that the survival time $T_{\text{surv},i}$ is longer than a fixed horizon $w$, with the knowledge that the individual has survived until $s$ and we have observed some time-dependent covariates, $X_t(s)$:

$$P(T_{\text{surv},i} > s + w|T_{\text{surv},i} > s, X_t(s)).$$

We concentrate on the first year of hemodialysis where the highest mortality rates are observed and predict one-year survival ($w = 12$) at the start of dialysis and the end of each subsequent month ($s \in \{0,1,...,12\}$). In the following, each time point $s$ for which a prediction is calculated is called a landmark. Three methods are examined for predictions in this dynamic setting. As a first benchmark, we develop multiple logistic regression models with elastic net regularization. We then adopt a simple version of the landmarking approach for prediction which results in a single Cox proportional hazards model with time-dependent covariates14. As a third model, we build a Dynamic Bayesian Network (DBN) with the appealing property that all covariates observed up to time $s$ influence the current prediction.
2. Related Work

Much research has been dedicated to the prediction of mortality for dialysis patients. Table 1 summarizes prior work that differ by chosen method, set of covariates, landmark s and prediction horizon w. One popular approach is the application of logistic regression to data available at initialization of dialysis9, 10, 12. To enhance adoption in clinical practice, derived odds ratios are often converted to a simple additive risk score10, 12. A second approach applies Cox proportional hazards models but choose different landmarks for their analysis5, 6, 11. Geddes et al. use data at the start of dialysis and compare a Cox model, a C5.0 rule based model and a modified Charlson Comorbidity Index (CCI)9. In contrast, Cohen et al. use snapshot data of prevalent dialysis patients, not distinguishing by time on dialysis11. They note that the performance of their model decreases for longer prediction horizons because the patient condition may have changed over time. Floege et al. utilize information on incident patients captured in the first 90 days on dialysis and transform the regression coefficients to a simple risk score6. Although trained with incident patients, they apply their model to a large external data set including many prevalent dialysis patients. The performance expressed as AUC decreases from 0.76 to 0.73 for prevalent patients. A further stream of research concentrates on methods besides classical regression models. Kusiak et al. apply rough-set theory and decision trees to obtain 16 rule-based classifiers, which they combine using a voting scheme7. Knorr et al. compare a Support Vector Machine, a rule based learner and a boosted meta classifier8. Their focus on the temporal structure of dialysis data is similar to ours, but they concentrate on methods to extract temporal features from time series and integrate those features into their classifiers. The landmark is fixed at 100 days after start of dialysis. In both studies, the chosen prediction horizon is close to the median survival time of the analyzed population. Thus, the proportions of the two outcome classes are balanced, which is advantageous for the applied methods.

Independent of the application to dialysis care, several methods exist that allow dynamic predictions or integrate time-dependent covariates. The Cox model with time-dependent covariates is one popular option to integrate longitudinal observations into the analysis of survival data. However, this method can mainly be used for exploring the relationship between time-dependent covariates and the event of interest. The usage as a predictive model is limited unless the distribution of future covariates is known15, 16. As one solution, van Houwelingen proposes a landmarking approach to extend Cox regression models for dynamic predictions19 and suggests different modeling techniques to account for the dependency of the prediction on the landmark s. Aside from multistate models and joint models, Dynamic Bayesian Networks (DBNs) are capable of dynamic predictions and have been applied to several medical problems17-20. In the area of dialysis, a DBN was proposed for estimation of the patient’s dry weight21. DBNs provide a simple approach to integrate expert knowledge, handle missing values, and allow complex interactions of covariates by specifying joint probability distributions. However, to the best of our knowledge, neither of these dynamic methods has been utilized yet to predict mortality of dialysis patients.

3. Data

The data set covers seven dialysis clinics managed by a community nephrology practice in Western Pennsylvania. It was gathered between January 2006 and February 2014 and includes electronic health records of 1,484 hemodialysis patients who started their treatment at one of the seven clinics. Records include demographic data, clinical data such
as laboratory values, medications, treatments, diagnoses and hospitalizations, as well as data from each dialysis session. Since logistic regression models cannot handle censored observations, patients who were not followed until the end of the prediction horizon are excluded for this model. More than 90 features are extracted and 41 features are retained that are considered relevant by the nephrologists and have an acceptable coverage with less than 20% missing values. Corrupt values and outliers are removed after inspection of each variable’s distribution.

For each patient, data is captured at multiple time points: demographics and known diagnoses are usually entered at the onset of dialysis. Laboratory tests are drawn weekly, monthly or irregularly, depending on the type of laboratory test. At each dialysis session, additional data is recorded. In order to convert those values to a homogenous format and to cushion the influence of measurement errors, they are binned to aggregated values over 30-day periods. Binary features are used for all diagnoses and indicate any history of hypertension, hypotension, anemia, diabetes and a Charlson Comorbidity Index (CCI) > 2 before the end of the 30-day period. In contrast, pneumonia represents a short-term critical condition and the associated binary feature only captures a recent diagnosis within the period. Mean values are used for all laboratory tests, duration of dialysis session, interdialytic weight gain and Body Mass Index (BMI). Binary features for medications depict any prescription within the 30-day period. The occurrence of any complication, edema or extreme pre-dialysis systolic blood pressure (SBP) is represented similarly. For each period, the counts of hospitalizations, no shows and sessions with decreased duration due to ‘patient request’ are modeled with numeric features. The type of vascular access is determined by the one that is mostly used within the 30-day period. We use the first date of dialysis as a reference point for each patient and start with a period of 30 days around this date to capture all relevant information at initialization of dialysis. After initialization, consecutive periods of 30 days are employed until the end of observation. Note that the last observed period of a patient might be shorter than 30 days because the censoring event (either death or end of follow-up) occurs within that period. Since this could bias some of the aggregated measures (e.g. observing complications is less likely in shorter periods), observations in the last period were not used. This is assured by only predicting survival for patients still at risk at the end of a period and using the aggregated measures of the previous period(s).

Table 2 describes the population in the first month on dialysis with respect to the chosen features. In contrast to patient characteristics reported by the United States Renal Data System (USRDS), we have an older population (+ 6.1 years) with slightly higher mean values for albumin (+ 0.2 g/dL), hemoglobin (+ 0.4 g/dL) and a higher prevalence of fistulas and grafts (+ 8%)\(^4\). We excluded CKD and diabetes from the calculation of the Charlson Comorbidity Index (CCI) due to the high prevalence in our population. Further, prescriptions of ACE-inhibitors, Calcium channel blockers and Clonidine are combined in the feature ‘antihypertensive medication’. The feature ‘autonomy degree’ is derived from the patient’s mobility recorded at each arrival at/departure from a dialysis session and the living situation. Autonomy of patients in a wheelchair or geriatric chair is defined as ‘limited’. Patients in a bed, on a stretcher or living in a nursing home are labeled as ‘special care’. The feature depicts the worst autonomy degree observed in the 30-day period. We also include an indicator for the patient’s pre-ESRD care, which is defined as having any appointment at the community nephrology practice during earlier stages of CKD.

4. Methods

Regularized logistic regression

As a first approach, one logistic regression model is fitted for each landmark \(s\). Although the number of models generated by this approach might be problematic in clinical practice, it serves as a solid benchmark for comparison. The cohort is reduced to patients who are still at risk at \(s\) and for whom the individual outcome \(y_i\) at \(s + w\) is known. The aggregated covariates \(X_i\) of the previous 30 days are used at each landmark. Observations with missing values are excluded from the analysis. The resulting subset consists of 819 patients at \(s = 1\) and monotonically decreases to 449 patients at \(s = 12\). The one-year-mortality rate decreases from 27% at \(s = 0\) to 23% at \(s = 9\) and remains stable at that level.

We use elastic net regularization to obtain sparse models and potentially better prediction performance through the bias-variance trade-off\(^{22}\). The penalty term is a compromise between the \(L_1\) penalty of lasso and \(L_2\) penalty of ridge regression. Highly correlated variables tend to be selected or dropped as a group, which appears advantageous in our setting\(^{22}\). Since optimization over \(\alpha\) values did not show a significant improvement, we use equal weights for both penalties with \(\alpha = 0.5\). Coefficients are estimated at each landmark by maximizing the penalized log-likelihood

\[
LL_{pen} = n^{-1} \sum_{i=1}^{n} y_i \log(P(X_i)) + (1 - y_i) \log(1 - P(X_i)) - \lambda \sum_{j=1}^{p} \alpha \beta_j^2 + (1 - \alpha) |\beta_j|
\]

for \(n\) individuals and \(p\) covariates. The value of \(\lambda\) is chosen by iterating over a sequence of values and the one with the highest performance is selected\(^{23}\). As a performance measure, we repeat 5-fold cross validation ten times and obtain the average area under the ROC curve (AUC). The alternative approach of choosing the largest \(\lambda\) that results in an AUC within one standard error of the best AUC is tested for comparison (1-SE rule).

Cox proportional hazards model with landmarking

Cox models with time-dependent covariates provide the opportunity to explore the relationship between the event time \(T\) and time-dependent covariates \(X(t)\). However, the ability to predict is very limited after introducing time-dependent covariates unless the future distribution of \(X(t)\) is known\(^{15, 16}\). The landmarking approach described by van Houwelingen is one method to overcome this limitation by fitting standard proportional hazard models for different landmarks \(s\)\(^{12}\). Each of the simple Cox models is fitted to the set of patients still at risk at \(s\), using the associated covariate values \(X(s)\) and censoring all events after \(s + w\). The hazard function is given by

\[
h(t|X(s), s, w) = h_0(t|s, w) \exp(X(s)\beta(s)) \quad \text{for} \quad s \leq t \leq s + w.
\]

Each corresponding data set is called a ‘landmark data set’. Several methods are proposed to consolidate the multiple landmark models with different coefficients \(\beta(s)\) to one single ‘super model’ with smooth landmark-dependent coefficients \(\beta(s)\)\(^{15}\). In this work, we use a simple ‘super model’ by combining all landmark data sets to one stacked data set and stratifying the Cox model by \(s\) to obtain landmark-specific baseline hazards. As a consequence, the coefficients are the same for all landmarks, but the estimates are based on landmark-dependent baseline hazards. For simplicity, we do not include further interaction terms of the covariates with the landmark, which would yield truly landmark-dependent coefficients. The sandwich estimators of Lin and Wei are used to derive robust standard errors for the estimated coefficients\(^{24}\). We estimate the model on the dialysis data and include right-censored patients. The stacked landmark data set consists of 1,219 patients and 9,763 complete observations for different landmarks. Furthermore, only features selected in at least one regularized logistic regression model are used for this analysis. Ten times 5-fold cross validation is conducted to obtain robust estimates of the AUC.
Dynamic Bayesian Network

A Bayesian Network (BN) is defined by a pair \((G, P)\) where \(G\) is a directed acyclic graph and \(P\) specifies the joint probability distribution of a set of random variables \(X = \{X_1, ..., X_n\}\). The nodes of \(G\) correspond to the random variables and the directed edges \(E \subseteq N \times N\) express dependencies between the variables. A BN provides a compact representation of the joint distribution by factorization into conditional probability distributions (CPDs)

\[
P(X) = \prod_{j \in N} P(X_j | \pi(X_j))
\]

where \(\pi(X_j)\) denotes the parents of \(X_j\) in \(G\). Random variables are allowed to be hidden and the associated CPDs can be of arbitrary form. If realizations of some random variables are observed, probabilistic inference can be used to update the beliefs about the state of any other \(X_j\).

A Dynamic Bayesian Network is a temporal extension of a BN and allows the modeling of probability distributions over semi-infinite collections of random variables \((Z_0, Z_1, ...)\). Thus, a set of random variables can be represented conveniently at different time points and stochastic processes can be modeled. Time is discretized into distinct time slices \(t\) and for each time slice a set of random variables is given by \(Z_t\). Dependencies can be modeled within each time slice (local arcs) and between time slices (temporal arcs). Usually, the Markov property is assumed and the parents of a node \(j\) in \(t\) (i.e. \(\pi(Z_{j,t})\)) have to be located in the same or previous time slice. If \(Z_{t-1}\) is a parent of \(Z_t\), this node is called persistent. Furthermore, the structure of the network is assumed to be invariant for all time slices. A DBN is then defined by a pair \((B_0, B_\infty)\) where \(B_0\) is a BN and \(B_\infty\) is a two-slice temporal Bayes net. \(B_0\) defines the initial distribution of \(Z_0\) at \(t = 0\) and \(B_\infty\) specifies the distribution of the random variables for subsequent time points by

\[
P(Z_{t+1}|Z_t) = \prod_{i \in N} P(Z_{t+1,i} | \pi(Z_{t+1,i}))
\]

where \(Z_{t+1}\) is the \(i\)-th node in time slice \(t\). It is always possible to “unroll” a DBN to a BN for a fixed number of time slices and apply the common inference algorithms. However, computational complexity can be decreased if algorithms are applied that exploit the repetitive structure of a DBN. Both structure and parameters of the CPDs can either be learned from data or specified using expert knowledge.

In this study, we model a DBN with discrete nodes and time slices for each 30-day period. The initial network structure is manually defined after extensive discussions with nephrologists, and parameters are learned from data. One big challenge is the number of parameters that need to be estimated from a limited number of observations. For each node, the size of the conditional probability table grows exponentially with the number of parents and number of parents’ states. Thus, we reduce the number of features to those that are considered highly relevant by the experts and have shown to have significant influence on mortality in prior research. Since our goal is prediction of mortality, we include one observable node ‘death’ and a hidden, persistent node ‘mortality risk’. The former depicts the separation of risk factors by such hidden variables reduces the number of parameters significantly. Additionally, some simplified but useful insights can be derived from the distribution of these abstract concepts when we want to explore the reasoning behind a survival prediction. More than thirty further network structures are evaluated with slight variations in modeled nodes and arcs. For example, we add persistencies for some risk factors that are relatively stable over time. Modeling such persistencies allows a more detailed forecast of the patient’s risk factors in future periods. For example, if we observe a patient with a low BMI at landmark \(s\) and the learned transition probability \(P(\text{Low BMI}_{t+1} = \text{true}|\text{Low BMI}_t = \text{true})\) is high, the belief about observing a low BMI at \(s+1\) will be high and will impact the mortality risk for that period. Parameters

\[
P(T_{\text{surv},i} > s + w | T_{\text{surv},i} > s) = \prod_{t=s}^{s+w-1} P(Z_{\text{death},t} = \text{false})
\]

Two further hidden and persistent variables are included that represent two major risks of mortality: ‘relative cardiovascular risk’ and ‘relative infection risk’. This approach follows that of Cornalba et al. who model similar relative risks for dialysis patients in a static BN. The separation of risk factors by such hidden variables reduces the number of parameters significantly. Additionally, some simplified but useful insights can be derived from the distribution of these abstract concepts when we want to explore the reasoning behind a survival prediction. More than thirty further network structures are evaluated with slight variations in modeled nodes and arcs. For example, we add persistencies for some risk factors that are relatively stable over time. Modeling such persistencies allows a more detailed forecast of the patient’s risk factors in future periods. For example, if we observe a patient with a low BMI at landmark \(s\) and the learned transition probability \(P(\text{Low BMI}_{t+1} = \text{true}|\text{Low BMI}_t = \text{true})\) is high, the belief about observing a low BMI at \(s+1\) will be high and will impact the mortality risk for that period. Parameters
are learned offline from data by maximizing the log-likelihood using the expectation–maximization (EM) algorithm since some of the variables are hidden\(^3\). We initialize the CPDs with manually chosen parameters reflecting our beliefs and results of prior work. We train the DBN on the dialysis data set and exclude all observations after \(s = 36\) to strengthen the focus on risk factors at the beginning of dialysis. In contrast to the previous two methods, missing values can be handled natively by the DBN and we utilize all 23,292 observed patient-periods from 1,484 patients for parameter learning. Nevertheless, cases with an unknown outcome, i.e. right-censoring between \(s\) and \(s + w\), have to be excluded from the evaluation of the DBN. Cases with missing covariate values are also excluded from the evaluation to enhance comparability with the other two models.

### 4. Results

Regularization of the logistic regression models leads to thirteen sparse models. On average, 18 of the 42 features are selected but the feature set differs considerably between landmarks. We highlight four observed patterns: features included consistently for most landmarks, never selected, only included for early landmarks and unstable selection. Seven risk factors are consistently found for at least ten landmarks: higher age, adj. CCI > 2, lower albumin, no antihypertensive medication, low pre-dialysis systolic blood pressure (SBP), lower autonomy degree and catheter as vascular access are associated with a lower probability of one-year survival. Most of the results are in line with existing research and expectations of nephrologists, though it might be counterintuitive that a low pre-dialysis SBP is a strong predictor of mortality. The covariate is included in 11 out of 13 periods with an average odds ratio of 1.55. In contrast, high pre-dialysis SBP shows a similar average odds ratio (1.44) but is only included in three periods. We test different thresholds but gain similar results. The effect is also observed in other studies and this controversy is discussed under the term “reverse epidemiology”\(^31, 32\). One hypothesis is that hypotension is a sign of an already severe state of a cardiovascular co-morbidity (e.g. congestive heart failure). Six features are not selected for any landmark: diagnosis of hypotension, phosphorus, transferrin saturation, calcium * phosphorus, number of no shows and number of sessions with decreased duration by patient request.

Many covariates are only included for few landmarks and interpretation is more difficult. The features ‘beta blockers’, ‘anticoagulants’, ‘BMI < 20’, ‘calcium’, ‘edema’ and ‘pre-ESRD care’ are mostly selected at early landmarks and might indicate a systematic change of predictors over time. For ‘pre-ESRD care’, the diminishing influence may be explained by the circumstance that pre-ESRD care has a big impact on patient’s condition at the start of dialysis (e.g. installed fistula, stable biomarkers, patient education), but these differences with other patients are likely to diminish over time because i) the physicians make up for missed preparation quickly (e.g. installation of a fistula), and ii) particularly fragile patients without pre-ESRD care may die within the first few months.

For a third group of features, a highly unstable selection pattern is observed. For example, ‘pneumonia’ is included in the models for \(s \in \{1, 4, 5, 6, 11\}\), though with a relatively high average odds ratio of 2.97. In this case, the limited number of observations is a potential explanation: with less than ten instances in most periods, the robustness of estimation may be impaired. However, for most other features with an unstable pattern, this explanation does not hold. Table 3 depicts representative features for each pattern and associated coefficients for seven landmarks. Even though inspecting coefficients provides useful insights, it is important to note that regularized estimates are biased in favor of lower variance. The models show an acceptable discriminative ability with an average AUC over all landmarks of 0.750. The performance decreases for models at later landmarks (Figure 2). Choosing \(\lambda\) according to the 1-SE rule results in sparser models (on average 13 features) and an average AUC of 0.745.

Many effects observed in the logistic regression models are reinforced by the Cox model with landmarking: age, sex, adj. CCI > 2, albumin, potassium, low pre-dialysis SBP and autonomy degree are significantly associated with mortality at a level of $\alpha = 0.05$. Additionally, the Cox model identifies beta blockers, shortness of breath, complaints about pain, edema, hospitalizations and pre-ESRD care as further significant risk factors. The estimated coefficients of all significant covariates are reported in Table 4. The discriminative performance ranges between 0.809 at $s = 2$ and 0.721 at $s = 11$ and is slightly better compared to logistic regression at each landmark (Figure 2). However, a similar trend of decreasing performance for later landmarks is observed.

After testing more than thirty different network structures, the DBN depicted in Figure 1 demonstrates the best average discrimination for the prediction horizon of one year (AUC = 0.745). Whereas short-term predictions yield a good performance (AUC = 0.86 for $w = 1$), a longer horizon of $w = 12$ leads to decreased AUCs (0.704 - 0.782). Hence, the DBN is inferior to the other two models for most landmarks (Figure 2). Adding more risk factors does not result in a better AUC since it increases the number of model parameters substantially and impairs the robustness of learned parameters.

Figure 1. One time-slice of a DBN with hidden nodes in grey and inter-slice dependencies depicted as dashed arcs.

Figure 2. Average AUC and standard error for different landmarks and a horizon of $w = 12$. 
A qualitative validation of the network was conducted by discussing the results for exemplary patients with nephrologists and how they would use it in the clinics. Two simplified cases are depicted in Figures 3 and 4. Both patients undergo dialysis for four periods ($s = 4$) and several adverse observations are noted in period four: Hemoglobin < 10, Potassium $\geq$ 6, Low SBP = true and Edema = true. Whereas Patient A has already exhibited the same risk factors in the previous periods, Patient B has been in good condition until period four (Hemoglobin 10-11, Potassium < 6, Low SBP = false, Edema = false). As depicted in Figure 3, the inferred probabilities for the node ‘relative risk (cardiovascular)’ are on a very different level for both patients in periods one to three and converge in period four. However, probabilities in period four are not identical (0.82 vs. 0.86), because the previous periods still have a small influence on current beliefs. The difference is also reflected in the probability of death (Figure 4), but fades away for future periods where patients’ states are more uncertain. This simple example illustrates two important characteristics of the DBN: past observations still impact beliefs at later landmarks and the random variables converge to a steady state for periods in the far future. In ongoing research, we are identifying and evaluating other clinically relevant and useful use cases based on actual patient data.

5. Discussion

In this study, we explored three different approaches to dynamically predict mortality of dialysis patients. Using observational data for model building is challenging and one should be particularly vigilant to avoid biases. On the current data set, the adjusted Cox model achieved the best discriminative performance. Nevertheless, further model properties should be considered to gain a comprehensive view of the opportunities and limitations of each approach. Regularized logistic regression might be advantageous if there are many (potentially correlated) features and the number of landmarks is small. However, the number of required models increases with landmarks and prediction horizons that are of interest. Usability in a clinical setting might therefore be impaired. One further challenge arises from the separate estimation of the models: selected features might be substantially different for two consecutive landmarks and hinder interpretability. A joint estimation of the models that encourages similar sparsity patterns in all models is an interesting extension that would mitigate this effect$^{33}$. Using a Cox model with landmarking can be a compelling alternative if many observations are censored and one single model needs to be derived. The dependency of the prediction on the landmarks can be achieved by employing simple modifications of the data set and the standard Cox model. In contrast to this work, more complex dependencies between landmark and covariate can also be modeled. Instead of binary survival prediction for a fixed horizon, the estimated models can produce informative survival curves over a complete period of interest. Yet, only the most recent observations are considered at each landmark and modeling many landmark-dependent coefficients leads to a large number of parameters. In contrast, a DBN incorporates all previous observations, allows complex interactions of variables, handles missing values and expert knowledge can be integrated easily. Once the DBN is trained, the prediction horizon can be chosen flexibly and it is possible to perform inference for any random variable included in the network (e.g. hospitalizations). The rapidly increasing number of parameters is one major challenge that limits the number of modeled risk factors and the number of bins for discretizing continuous variables. It is difficult to find a reasonable trade-off between the detailed representation of risk factors and parameters that can be learned from small data sets. Modeling techniques that reduce the number of parameters (e.g. Noisy-OR gates) may provide an interesting extension to our approach but introduce further assumptions on causal dependencies between risk factors$^{34}$. 

![Figure 3](image3.png) Relative risk (cardiovascular) for two patients with identical observations in period four, but different observations in previous periods.

![Figure 4](image4.png) Probability of death for Patient A and B in future periods.
The appropriate representation of long-term risks is also challenging and affects the performance of the DBN in this work. A continuous time BN could be an interesting alternative to our approach, since it would allow for completely flexible prediction horizons. In future work, we plan to test the performance of our models on a completely separate data set to assess generalization capabilities.

Three clinically relevant use cases have been identified in the discussions with nephrologists. First, at the onset of dialysis, patients are often anxious to know the prognosis of their condition. An individualized prediction has the potential to facilitate shared decision making and help in the communication with the patient. Second, once patients are on dialysis, their compliance is often insufficient. Individualized predictions with different scenarios can help to improve compliance with interventions, such as patient education, and to present potential consequences of their own decisions (e.g. a catheter leading to higher mortality risk). Third, the model can be used by clinicians for risk stratification of their patient population and identification of patients with elevated risk profiles. Future work will investigate the implementation and evaluation of the prediction models with their significant risk factors in the actual care delivery setting.

6. Conclusion

Patients on hemodialysis are in a vulnerable health condition and robust risk prediction models can support clinicians to identify and target high risk patients. The focus of this work is on predicting mortality but the methods can easily be adapted for other events of interest (e.g. hospitalizations or infections). In contrast to prior work, we explore three approaches to incorporate the temporal nature of EHR to dynamically adjust predictions when patients progress in time. The explicit representation of the time dimension is methodologically challenging, but offers great potential to exploit available EHR data and to represent changing patient characteristics more appropriately. We use variations of two common statistical methods, logistic regression and Cox regression, to allow dynamic predictions at different landmarks. Furthermore, using a machine learning approach, we build a DBN that allows complex interactions between risk factors and utilizes the complete patient history to predict future risks. The Cox model achieves the best discrimination performance with an average AUC of 0.767. The regularized logistic regression models are slightly inferior and use separate models for each landmark (average AUC: 0.750). The DBN demonstrates a good performance for short prediction horizons, but cannot achieve similar results for the horizon of one year (average AUC: 0.745). The large volume of data required for learning robust parameters of complex DBNs is one major challenge. The models provide interesting opportunities to monitor patients over time and can be used as a starting point for further extensions of dynamic models in the domain of dialysis care.

Acknowledgements

We are grateful to the physicians and staff of the nephrology practice that provided the data for this study, and Dr. A. Chouldechova at the Heinz College at CMU for many helpful suggestions and feedback on the study.

Multi-modal Patient Cohort Identification from EEG Report and Signal Data

Travis R. Goodwin, MS, Sanda M. Harabagiu, PhD
University of Texas at Dallas, Richardson, TX

Abstract

Clinical electroencephalography (EEG) is the most important investigation in the diagnosis and management of epilepsies. An EEG records the electrical activity along the scalp and measures spontaneous electrical activity of the brain. Because the EEG signal is complex, its interpretation is known to produce moderate inter-observer agreement among neurologists. This problem can be addressed by providing clinical experts with the ability to automatically retrieve similar EEG signals and EEG reports through a patient cohort retrieval system operating on a vast archive of EEG data. In this paper, we present a multi-modal EEG patient cohort retrieval system called MERCuRY which leverages the heterogeneous nature of EEG data by processing both the clinical narratives from EEG reports as well as the raw electrode potentials derived from the recorded EEG signal data. At the core of MERCuRY is a novel multi-modal clinical indexing scheme which relies on EEG data representations obtained through deep learning. The index is used by two clinical relevance models that we have generated for identifying patient cohorts satisfying the inclusion and exclusion criteria expressed in natural language queries. Evaluations of the MERCuRY system measured the relevance of the patient cohorts, obtaining MAP scores of 69.87% and a NDCG of 83.21%.

Introduction

Clinical electroencephalography (EEG) is an electrophysiological monitoring method used to record electrical activity of the brain. Clinical EEG is the most important investigation in the diagnosis and management of epilepsies and can also be used to evaluate other types of brain disorders. An EEG records the electrical activity along the scalp and measures spontaneous electrical activity of the brain. Unfortunately, as noted in by Beniczky et al., the EEG signal is complex and inter-observer agreement for EEG interpretation is known to be moderate. Such interpretations of EEG recordings are available in EEG reports. As more clinical EEG data becomes available, the interpretation of EEG signals can be improved by providing neurologists with results of search for patients that exhibit similar EEG characteristics. Searching the EEG signals and reports results in the identification of patient cohorts that inform the clinical decision of neurologists and enable comparative clinical effectiveness research. For example, a neurologist suspecting that her patient has epilepsy potential formulated the query (Q1) History of seizures and EEG with TIRDA without sharps, spikes, or electrographic seizures. When inspecting the EEG signals and reports of the resulting patient cohort, the neurologist was able to observe the specific features of the EEG for patients that exhibited epileptic potential. In another search instance, a neurologist researcher was interested in one of the research priorities for improving surveillance and prevention of epilepsy as reported by England et al., namely, to identify effective interventions for epilepsy accompanied by mental health comorbidities. This researcher formulated the query (Q2) History of Alzheimer and abnormal EEG. The patient cohort that was identified enabled the researcher to observe the treatment outcomes as well as the clinical correlations documented in the EEG reports.

To ensure that patients from a cohort satisfy the criteria expressed in the natural language queries formulated by neurologists, it is important to not only consider the narrative from EEG reports, but also the EEG signal data. Searching for patient cohorts by considering EEG signals and reports relies on (1) an index of the EEG clinical information and (2) relevance models that identify records of relevant patients against a query. Indexing EEG clinical information requires organizing both narratives from the EEG reports and signal data from the EEG recordings. Consequently, the EEG index needs to capture multi-modal clinical knowledge processed both from the reports and the signal recordings. While medical language processing enables the indexing of information form the EEG reports, the index must also comprise a representation of EEG signal recordings. In addition, the relevance models used by the patient cohort retrieval system must account for inclusion and exclusion criteria inferred from processing the natural language query. To address these problems, we have developed a patient cohort retrieval system which produces a multi-modal index of big EEG data. We have also implemented two relevance models to identify the most relevant patients based on their EEG reports and also based on the properties of the EEG signal recordings. The patient cohort retrieval system, called MERCuRY (Multi-modal EncephalogRam patient Cohort discoveryRY), uses medical language processing to identify the inclusion and exclusion criteria from the queries and to index the clinical knowledge from the EEG reports. In addition, MERCuRY has two novel aspects not present in previous approaches for patient cohort retrieval: (1) it uses deep learning to represent the EEG signal and to produce a multi-modal EEG index; and (2) it operates based on two EEG relevance models – one that uses only the clinical information from the EEG reports, and
a second one which also considers the EEG signal information. We evaluated MERCuRY by using expert judgements of queries against a collection of nearly 20,000 EEGs.

**Background**

The ability to automatically identify patient cohorts satisfying a wide range of criteria – including clinical, demographic, and social information – has applications in numerous use cases, as pointed out in by Shivade et al. including (a) clinical trial recruitment; (b) outcome prediction; and (c) survival analysis. Although the identification of patient cohorts is a complex task, many systems aiming to resolve it automatically have used statistical techniques or machine learning methods taking advantage of natural language processing (NLP) of the clinical documents. However, these systems cannot rank the identified patients based on the relevance of the patient to the cohort criteria. This notion of relevance is at the core of information retrieval (IR) systems. Thus, viewing the problem of patient cohort identification as an IR problem enables us to not only identify which patients belong to a cohort, but to also rank patients based on relevance to the inclusion and exclusion criteria used in the query.

Using information retrieval for patient cohort identification was considered in 2011 and 2012 by the Medical Records track in the annual Text REtrieval Conference (TREC) hosted by the National Institute for Standards and Technology (NIST). When patient cohort identification systems are presented with a query expressing the inclusion/exclusion criteria for a desired patient cohort, a ranked list of patients representing the cohort is produced where each patient may be associated with multiple medical records. Thus, identifying a ranked list of patients is equivalent to producing a ranked list of sets of medical records, each pertaining to a patient belonging to the cohort. In MERCuRY, we have adopted the same framework of identifying patients that are relevant to a cohort and ranking them according to their relevance to the given cohort criteria. However, unlike the TREC patient cohort retrieval systems, which considered only the clinical texts available from a large set of electronic medical records, MERCuRY uses a multi-modal index that encodes textual data available from EEG reports as well as signal data produced by EEG signal recordings.

Historically, the majority of multi-modal retrieval systems have operated on text and image data. For example, Demner-Fushman et al. designed a biomedical article retrieval system which allows users to not only discover biomedical articles relevant to a query, but to also discover similar images to those found in any retrieved articles. Their approach clusters images using a large number of visual features capturing color, edge, texture, and other image information. By contrast, our approach relies on unsupervised deep learning to generate a fingerprint of EEG data. As such, although designed for EEG data, our architecture can be easily adapted to support other types of (physiological) waveform data (such as ECGs). Other forms of physiological waveform data were previously investigated by the AALIM system which enabled cardiac decision support by allowing physicians to locate similar patients according to the ECG, echo, and audio data associated with the patient. However, unlike our approach, their system does not support search: it can only identify similar patients to provided ECG, echo, or audio recording and thus cannot be used to discover patients matching arbitrary criteria.

The MERCuRY system presented in this paper relies on medical language processing techniques that were informed by the experience gained from participating in the 2010, 2011 and 2012 Informatics for Integrating Biology and the Bedside (i2b2) Challenges on NLP for Clinical Records, which focused on the automatic identification of medical concepts and events in clinical texts. In contrast, the EpiDEA patient cohort identification system which also retrieves EEG-specific patient cohorts, operates on discharge summaries to recognize patients that are relevant only to some pre-defined queries obtained by relying on the EpSO ontology.

**Data**

The MERCuRY system was developed to identify patient cohorts from the big EEG data available from the Temple University Hospital (TUH) EEG Corpus (over 25,000 sessions and 15,000 patients collected over 12 years). This dataset is unique because, in addition to the raw signal information, physician’s EEG reports are provided for each EEG. Following the American Clinical Neurophysiology Society Guidelines for writing EEG reports, the EEG reports from the TUH corpus start with a CLINICAL HISTORY of the patient, describing the patient’s age, gender, and relevant medical conditions at the time of the recording (e.g., “after cardiac arrest”) followed by a list of the medications which may influence the EEG. The INTRODUCTION section is the depiction of the techniques used for the EEG (e.g. “digital video EEG”, “using standard 10-20 system of electrode placement with 1 channel of EKG”), as well as the patient’s conditions prevalent at the time of the recording (e.g., fasting, sleep deprivation) and level of consciousness (e.g. “comatose”). The DESCRIPTION section is the mandatory part of the EEG report, and it provides a description of any notable epileptiform activity (e.g. “sharp wave”), patterns (e.g. “burst suppression pattern”) and events (“very quick jerks of the head”). In the IMPRESSION section, the physician states whether the EEG readings are
normal or abnormal. If abnormal, then the contributing epileptiform phenomena are listed. The final section of the EEG report, the CLINICAL CORRELATIONS section explains what the EEG findings mean in terms of clinical interpretation\textsuperscript{15} (e.g. “very worrisome prognostic features”). Each EEG report in the TUH corpus is associated with the EEG signal recording it interprets. The signal information consists of 24 to 36 channels of signal data as well as an additional annotation channel providing markers identifying events of interest to physicians and technicians. EEG signals are sampled at a rate of 250 Hz or 256 Hz using 16-bits per sample. Each EEG recording from the TUH EEG corpus contains roughly 20 megabytes of raw data, stored in the European Data Format (EDF+) file schema\textsuperscript{16}.

Methods
MERCuRY is a multi-modal patient cohort discovery system which allows neurologists to inspect the EEG records as well as the EEG signal recordings of patients deemed relevant to a query expressing inclusion and exclusion criteria through natural language. As illustrated in Figure 1, the neurologist query is analyzed to identify the inclusion and exclusion criteria. The results of query analysis inform two different relevance models (illustrated as Case 1 and Case 2 in Figure 1) which rely on the multi-modal EEG index encoding information identified in the EEG reports and signal recordings. When EEG reports are indexed, the sections of the EEG reports are identified and medical language processing is performed to identify the terms and phrases of the dictionary and to create tiered inverted lists. When the EEG signal recordings are processed, they are represented by EEG signal fingerprints which are produced by deep learning methods. EEG signal recordings are converted into low-dimensional fingerprint vectors which are included in the multi-modal index. Additional details of the index are provided later in the paper. As shown in Figure 1, in MERCuRY we considered two relevance models designed to identify and rank patients based on their relevance to the patient cohort query: Case 1, in which the EEG signal fingerprints are ignored and only the EEG reports are used, and Case 2 in which both the EEG fingerprints and reports are used. These two cases allowed us to experimentally evaluate the impact of the EEG signal fingerprint representation on the overall performance of MERCuRY in identifying patient cohorts.

Figure 1: Overview of the MERCuRY Patient Cohort Discovery System

A. Indexing the EEG Big Data
The multi-modal index used by the MERCURY system organizes the information from the EEG reports as well as the information from the EEG signal recordings. It contains both a term dictionary and a medical concept dictionary, listing all the terms and medical concepts discerned from the EEG reports. We considered five medical concept types: (1) medical problems, (2) medical tests; (3) medical treatments (including medications); (4) EEG patterns and activities; as well as (5) EEG events. Because medical concepts often are multi-term expressions (e.g. “spike and slow waves”), the medical concept dictionary used term IDs to associate a concept with all terms expressing it (e.g. “spike and slow waves” is associated with the terms “spike”, “slow” and “wave”). Moreover, as illustrated in Figure 2, each entry from the term dictionary is linked to a pair of inverted lists: the first corresponding to positive polarity associated with the term while the second corresponding to negative polarity. By using polarity information (which is automatically processed from the medical language used in the EEG reports), we have designed a multi-tiered index. Each of the tiered inverted lists is implemented as a linked list. Each cell of those lists indicates for every occurrence of the term: (1) in which EEG report the term was observed; (2) the EEG signal fingerprint of that EEG report; (3) in which section of the EEG report was the term observed; (4) in which position of the EEG section; (5) whether the term belongs to a medical concept identified in the EEG report; and (6) if so, what position does the term have in the concept.
Figure 2: The Multi-Modal Tiered Index used in the MERCuRY Patient Cohort Discovery System

The EEG signal fingerprints are representations of the EEG signal recordings obtained through deep-learning techniques (described later in the paper) and organized in a similarity-based hierarchy which enables the discovery of relevant patients when the EEG signal recordings are also considered (Case 2 illustrated in Figure 1). When the EEG signal recordings are not used for identifying patient cohorts (Case 1 illustrated in Figure 1), only the term dictionary, the medical concept dictionary, and the tiered inverted lists from the index are used. Creating the multi-modal tiered index for the MERCuRY Patient Cohort Discovery System involves (1) the recognition of sections of the EEG reports; (2) medical language processing to determine (a) the terms from the dictionary, (b) their polarity and (c) the medical concepts; (3) generating the fingerprints for the EEG recording; and (4) organizing the EEG signal fingerprints in the similarity-based hierarchy.

Section Identification. Sections were identified through a rule-based section segmentation approach. Our rules were defined after manually reviewing 300 randomly sampled EEG reports. We detected a set of candidate headers by discovering all sequences of all capitalized words ending in a colon or line break, and normalized section titles based on simple regular expressions. For example, “description of the record”, “description of record”, and “description of the recording” would all be normalized to DESCRIPTION.

Medical Language Processing. In order to build (1) the term dictionary; (2) the medical concept dictionary and (3) the two polarity-informed posting lists we have used the following sequence of steps:

(Step 1) Tokenizing the EEG reports: we relied on Stanford’s CoreNLP pipeline to detect sentences and tokens from every EEG report.

(Step 2) Discovering the Dictionary Terms: Each token was normalized in order to account for any lexical variation (e.g. “waves” and “wave” or “markedly and “marked”) using Stanford’s CoreNLP lemmatizer. The resultant lemmatized terms formed the basis of the dictionary.

(Step 3) Identifying the Polarity: Term polarity was cast as a classification problem implemented as a conditional random field (CRF). Leveraging our previous experience with the i2b2 challenge, the CRF assigned a binary polarity value (i.e. positive or negative) to each term based on feature vector containing lexical information as well as information from external resources, such as the NegEx negation detection system, the Harvard General Inquirer, the Unified Medical Language System (UMLS) meta-thesaurus, and MetaMap. Specifically, we considered nine features: (1) the section name, (2) whether the term was considered a modifier by NegEx, (3) whether the term was within a NegEx negation span, (4) whether the term was in the ‘IF’ category of the Harvard General Inquirer, (5) the part-of-speech tag assigned to the token by Stanford’s CoreNLP part-of-speech tagger, (6) whether the term belonged to a UMLS concept, (7) whether the term belongs to a MetaMap concept, (8) the original cased term before lemmatization, and (9) the lowercased and lemmatized form of the term. The classifier was trained using 2,349 manual annotations.

(Step 4) Identifying Medical Concepts: An automatic system for medical concept recognition previously developed for the 2010 i2b2 challenge recognized medical problems, tests, treatments. In addition, we have produced 4,254 new annotations for EEG patterns and events as well as EEG activities and re-trained the concept recognizer to identify all these types of concepts. Concept extraction was cast as a classification task, in which a CRF was used to detect medical concept boundaries. A support vector machine (SVM) was used to classify each concept into one of five types: medical problem, medical test, medical treatment, EEG activity, or EEG event.
Generating Fingerprints of EEG Signal Recordings. In the TUH EEG corpus, the EEG signals are encoded as dense floating-point matrices of the form \( \mathbf{D} \in \mathbb{R}^{N \times L} \), where \( N \in [24, 36] \) is the number of electrode potential channels in the EEG and \( L \) is the number of samples (such that duration of the EEG recording in seconds is equal to \( L / 250 \) Hz). Thus \( \mathbf{D}_{ij} \) encodes the magnitude of the potential recording on the \( i \)-th channel during the \( j \)-th time sample. Both the number of channels and the number of samples vary not only across patients, but also across EEG recording sessions. These variations, particularly when considered with the large amount of data encoded in each matrix (typically 20 megabytes), make it difficult to not only characterize the relevance EEG signals to a particular patient cohort, but also to determine the similarity between two EEG signals. For example, consider that a single naïve pass over the TUH EEG corpus requires considering over 400 gigabytes worth of information. Consequently, we devised a representation of the EEG recordings that not only requires less memory, but enables rapid similarity detection between EEG signal recordings. This allows us to compactly encode the information from the EEG signals (reducing 20 megabytes of signal data to a few hundred bytes). Our representation is based on EEG signal recording fingerprints obtained with a recurrent neural network. Recursive neural networks are deep learning architectures which enabled us to generate fingerprints for each EEG in the TUH EEG corpus in a matter of hours instead of weeks. Because traditional neural networks have difficulty operating on sequential data (e.g. EEG signals) as they cannot consider relationships between successive inputs (e.g. between successive samples), we have used a recurrent neural network\(^{15} \) (a neural network with a loop) which allowed information learned at each sample to persist between samples in the same EEG signal. The learned information (known as the internal memory state) is updated with each sample until ultimately becoming the fingerprint for that EEG recording. Figure 3 illustrates the recurrent neural network used for EEG fingerprinting. As shown, the unrolled network (on the right) processes each sample from the EEG signal and predicts the value of the next sample \( (h_{t+1}) \) according to both the current sample \( (x_t) \) and the current fingerprint \( (f) \).

**Figure 3:** The recursive neural network used for generating EEG signal fingerprints.

Recursive neural networks are able to connect information from the previous sample to the current sample, allowing them to consider the structure of the EEG waves in each channel. However, interpreting EEGs requires considering not just the immediately adjacent signal information but also long distance signal patterns (e.g. alpha waves being interrupted by a sharp and slow wave complex or repeated bursts of high amplitude delta waves). In order to allow our EEG fingerprints to consider this type of long-distance information — that is, to consider the context of the entire signal when predicting the next sample, we adapt a special form of recursive neural network cell — the Long Short Term Memory\(^{16} \) (LSTM) cell — which are able to remember information for long periods of time.

The recursive neural network shown in Figure 3 is formally defined as follows. We define the parameter \( K \) as the fingerprint dimensionality, or the number of dimensions of the fingerprint vector such that \( K \ll N \times L \) (where \( N \) is the number of channels and \( L \) is the number of samples). This allows us to determine the fingerprint vector \( f \in \mathbb{R}^{1 \times K} \) for an EEG \( \mathbf{D} \in \mathbb{R}^{N \times L} \) by using the fingerprint as the internal memory state of the LSTM chain. In order to ensure that the fingerprint can be used to reconstruct portions of the EEG data, we define an additional parameter, \( W \), the sample window, which indicates the number of sub-EEG samples which should be predicted from each cell. This allows us to learn the optimal fingerprint for each document by determining the vector \( f \) which minimizes the cosine distance between the predicted values for each sample \( (h_t \ldots h_{t+W}) \) and the actual values \( (x_{t+1}, x_{t+2}, \ldots, x_{t+W+1}) \). Note, that the fingerprint vector and prediction vector are both \( K \)-dimensional, while each sample vector is only \( N \)-dimensional. Thus, before comparing, we must project the output vector \( h_t \) into \( N \) dimensions by defining a projection matrix \( \mathbf{W} \in \mathbb{R}^{K \times N} \) and a bias vector \( \mathbf{b} \in \mathbb{R}^{1 \times N} \). Unlike the fingerprint vectors, which are optimized for each individual EEG, \( \mathbf{W} \) and \( \mathbf{b} \) are optimized over the entire corpus. Thus, the optimal fingerprint vector \( f \) for each document was computed by minimizing the cosine distance between the output of the LSTM cell and the next \( W \) samples:
\[
f = \min_{f'} \sum_{i=0}^{L-W} \sum_{j=1}^{W} \cos(\text{lstm}(f', D^T) \cdot W + b, D^T)
\]

where \(\text{lstm}(f, D^T)\) refers to the standard LSTM loss function\(^{26}\). As defined, the recurrent neural network allows us to generate the optimal fingerprint \(f\) for each EEG signal by discovering the vector \(f\) which is best able to predict the progression of samples in each EEG recording according to the LSTM. In this way, the fingerprint is able to provide a substantially compressed view of the EEG signal while still retaining many of the long-term interactions and characteristics of the signal.

**Organizing EEG fingerprints in a similarity-based Hierarchy.** Rapid computation of similarity between EEG signals (or their fingerprints) is facilitated by the Fast Library for Approximate Nearest Neighbors\(^{25}\) (FLANN). FLANN provides implementations of a variety of highly-efficient structures for computing (or approximating) the nearest neighbors of vectors in high dimensions. This allowed us to not only compactly store the EEG signal information, but also to retrieve, for any EEG fingerprint, the most similar EEGs (i.e. the nearest neighbors) as measured by cosine distance. We used a k-means tree which allows for high precision retrieval of the nearest EEGs to any fingerprint by recursively clustering the fingerprint vectors using k-means clustering. The number of clusters is determined by FLANN’s auto-tuning mechanism.

**B. Query Analysis**

The purpose of query analysis is to identify the inclusion and exclusion criteria expressed in the query. For example, in the query “patients with shifting arrhythmic delta suspected of underlying cerebrovascular disease” two separate inclusion criteria are detected: “shifting arrhythmic delta” and “cerebrovascular disease”. Similarly, in the query “patients with dementia and no abnormal EEG”, there is one inclusion criterion, namely “dementia” and one exclusion criterion, namely “abnormal EEG”. To detect automatically the criteria, the following steps are used:

(Step 1) **Term Filtering:** Tokenization, lemmatization, and part-of-speech tagging using Stanford’s CoreNLP pipeline\(^7\) enables the filtering of terms that are not identified as a noun, verb, adverb, adjective, or preposition.

(Step 2) **Query Formulation:** Our approach for determining inclusion and exclusion criteria in the query relied on the same polarity and medical concept classifiers used (and previously described) for building the inverted index from EEG reports. Specifically, we considered two methods for recognizing inclusion and exclusion criteria: (a) phrase chunking using Stanford’s CoreNLP pipeline and (b) medical concept detection using the previously described classifier. In both cases, we relied on the previously described polarity classifier to distinguish between inclusion criteria (positive) and exclusion criteria (negative) based on the polarity of each phrase or concept.

(Step 3) **Query Expansion:** In order to account for the fact that many medical concepts can be expressed in multiple ways, we perform query expansion using the Unified Medical Language System (UMLS) to detect synonymous criteria. This is accomplished by expanding each criterion to include the set of all atoms in UMLS which have the same concept unique identifier (CUI) as the criteria. For example, “cerebrovascular disease” would be associated with 110 expansions, including “cerebral aneurysm”, “vascular ischemia”, “brain stem hemorrhage”, etc.

**C. Relevance Models**

The inclusion and exclusion criteria discerned from the query analysis were used by MERCuRY’s relevance models to assess the relevance of each EEG report against the given query. Two relevance models were considered (as illustrated in Figure 1): **Case 1**, which ignored the EEG signal fingerprints and **Case 2**, which incorporates them.

**Case 1.** This relevance model assigns a score to an individual EEG report based on the BM25F ranking function\(^{26}\). BM25F measures the relevance of an EEG report based on the frequency of mentions of each inclusion criterion and the absence of each exclusion criterion. Moreover, BM25F is capable of adjusting the score for each criterion based on the tiers in the posting list: that is, a criterion mention is scored according to both the polarity and the section of each mention. Formally, for an EEG report \(r\) and a query \(q = \{c_1, c_2, \ldots\}\) composed of individual inclusion and exclusion criteria \(c\), the BM25F relevance score is computed as:

\[
BM25F(r; q) = \sum_{c \in q} \frac{\tilde{x}_{r,c}}{K_1 + \tilde{x}_{r,c}} \cdot idf(c)
\]

where \(idf(c)\) is the inverse-document frequency of criterion \(c\) (i.e. the inverse of the number of documents mentioning \(c\)), \(K_1\) is a structuring parameter (in our case set to the standard\(^9\) value \(K_1 = 1.2\)) and \(\tilde{x}_{r,c}\) is a tier-normalizing criterion frequency measure. The tier-normalizing criterion frequency measure, \(\tilde{x}_{r,c}\), adjusts the frequency of criterion \(c\) in report \(r\) according to the polarity and section of each mention. Before defining this measure, we must account for
the fact that query analysis described above considers two ways of representing inclusion and exclusion criteria – (a) by phrases and (b) by typed medical concepts; thus, the tier-normalizing criterion frequency measure changes depending on which of these methods is used:

\[
\begin{align*}
\text{(a)} \quad \hat{x}_{r,c} &= \sum_{p,s} \frac{x_{r,c,s,p}}{(1+b)\left(\frac{t_{r,p,s}}{l_{p,s}}-1\right)} \\
\text{(b)} \quad \hat{x}_{r,c} &= \sum_{p,\ell} \frac{x_{r,c,\ell,p}}{(1+b)\left(\frac{t_{r,p,\ell}}{l_{p,\ell}}-1\right)}
\end{align*}
\]

(Case 1a) When an inclusion or exclusion criterion are expressed as a phrase, we defined \(\hat{x}_{r,c}\) (used by the BM25F function) in Equation (a), where \(x_{r,c,s,p}\) is the number of occurrences of criterion \(c\) with polarity \(p\) in section \(s\) of report \(r\); \(b\) is a normalizing parameter (in our case using the standard value \(b = 0.75\)), \(l_{r,p,s}\) is the number of terms with polarity \(p\) in section \(s\) of report \(r\), and \(l_{p,\ell}\) is the average number of terms with polarity \(p\) in section \(\ell\) across all reports.

(Case 1b) In this case, each criterion is represented as a medical concept. For this method, the tier-normalizing criterion frequency measure is restricted only to the sections pertinent to the type of medical concept. That is, medical problems, and medical tests are only searched in the HISTORY and CORRELATION sections; medical treatments are searched in the MEDICATIONS and CORRELATION sections; while EEG activities and EEG events are searched only in the DESCRIPTION and IMPRESSION sections. Consequently, the tier-normalizing criterion frequency measure (used in the BM25F function) is computed using Equation (b) where \(\ell\) indicates a section pertinent to the type of the medical concept used to express the criterion \(c\).

**Case 2.** The second relevance model considers both the information from EEG reports as well as the EEG signal fingerprints. It starts with the candidate patients discovered based on Case 1. The ranked list of patients is then updated based on the fingerprints associated with the most relevant patients’ EEGs. The rank updating procedure relies on two parameters: (1) \(\lambda\), the rank threshold parameter indicating how many of the initially retrieved patients should be used for re-ranking (in our experiments we set \(\lambda = 5\)), and (2) \(\delta\), the fingerprint selection parameter which determines the number of similar fingerprints to consider for each patient (in our experiments we set \(\delta = 3\)). The updated patient ranking is obtained as follows: for each patient \(p_x\) of the \(\lambda\)-highest ranked patients, we (i) find the fingerprint \(f_x\) associated with \(p_x\), (ii) use the hierarchy of EEG signal fingerprints (illustrated in Figure 2) from the multi-modal index to discover the \(\sigma\) most-similar fingerprints to \(f_x\), and (iii) insert the patients corresponding to these fingerprints into the ranked list of patients immediately after the patient \(p_x\), thus generating a new ranked list of patients.

**Evaluation**

We evaluated two aspects of the MERCuRY system: (1) the overall quality of patient cohorts discovered by the system and (2) the quality of the polarity classifier used to process the EEG reports and to detect exclusion criteria in queries.

**A. Evaluation of Patient Cohort Discovery**

We primarily evaluated the MERCuRY system according to its ability to retrieve patient cohorts. To this end, we asked three neurologists to generate a set of 5 evaluation queries each and then used them for evaluation. A sample of these queries is illustrated in Table 1. For each query, we retrieved the ten most relevant patients as well as a random sample of ten additional patients retrieved between ranks eleven and one hundred. We asked six relevance assessors to judge whether each of these patients belonged or did not belong to the given cohort. Moreover, the order of the documents (and queries) were randomized and judges were not told the ranked position of each patient. Each query and patient pair was judged by at least two relevance assessors, obtaining an inter-annotator agreement of 80.1% (measured by Cohen’s kappa).

</tr>
</tbody>
</table>

**Table 1:** Example queries used to evaluate the MERCuRY system

This experimental design allowed us to evaluate not only the set of patients retrieved for each cohort, but also the individual rank assigned to them. Specifically, we adopted standard measures for information retrieval effectiveness, where patients labeled as belonging to the cohort were considered relevant to the cohort query, and patients labelled as not belonging to the cohort were considered as non-relevant the cohort query. Because the relevance of a patient to a particular cohort can be difficult to automatically measure, we report multiple measures of retrieval quality.
Moreover, because our relevance assessments consider only a sample of the patients retrieved for each topic, we adopted two measures of ranked retrieval quality: the Mean Average Precision\(^{31}\) (MAP) and the Normalized Discounted Cumulative Gain\(^{31}\) (NDCG). The MAP provides a single measurement of the quality of patients retrieved at each rank for a particular topic. Likewise, the NDCG measures the gain in overall cohort quality obtained by including the patients retrieved at each rank. This gain is accumulated from the top-retrieved patient to the bottom-retrieved patient, with the gain of each patient discounted at lower ranks. Lastly, we computed the “Precision at 10” metric (P@10), which measures the ratio of patients retrieved in the first ranks which belong to the patient cohort. Although less statistically meaningful, the precision is the easiest to interpret in terms of clinical application in that a 100.00% Precision at 10 indicates that all of the patients returned above rank 10 completely satisfy all the criteria of the given cohort. By comparison, the other measures indicate the quality of the ranking produced by our system such that the MAP and NDCG scores capture the degree that a patient retrieved at each rank will more closely match the cohort criteria than patients retrieved at low ranks.

We measured the performance the MERCuRY system configured for the two relevance models illustrated in Figure 1: Case 1, in which only the EEG reports are considered and Case 2, in which both the EEG reports and EEG signal information is considered. In both cases, we considered both methods of representing inclusion and exclusion criteria: (a) using phrases composed of terms, and (b) using typed medical concepts. We compared these four combinations against three competitive baseline systems for text retrieval: Okapi BM25\(^{32}\) (BM25), language model retrieval using Dirichlet smoothing\(^{31}\) (LMD), and the Divergence from Randomness\(^{31}\) (DFR) framework using Poisson smoothing, Bernoulli and Zipfian normalization. Table 2 illustrates these results.

As shown, both configurations yield promising performance. Moreover, case 2 obtains the highest quality patient cohorts as measured by all three metrics. This shows that the multi-modal capabilities enabled by the EEG fingerprinting approach are able to identify patients who were missed when only the EEG reports were considered. The poor performance obtained by the baseline systems highlights the difficulty of automatically discovering patient cohorts. Moreover, the increase in performance obtained by MERCuRY Model 1 compared to Baseline 1 highlights the importance of medical language processing on EEG reports – particularly the role of the tiered index and the incorporation of exclusion spans. The highest performance was obtained by MERCuRY Model 2, showing the promise of including EEG signal information when discovering patient cohorts. This suggests that the content of EEG reports alone is not enough to adequately determine if a patient satisfies particular inclusion criteria. This finding is not surprising, as EEG reports were not written to completely replace the EEG signal, but rather to describe the important characteristics of the EEG recording which may be of interest to other neurologists. As such, EEG reports typically document only notable findings making it difficult to exclude patients based only on the text in the EEG reports. The superior performance obtained by MERCuRY Model 2 indicates that EEG fingerprinting is able to supplement the information in the EEG reports and bridge the gap between the high level description of EEG information in the text, and the low-level electrode potentials recorded in the EEG signal.

B. Evaluation of Polarity Classification

We evaluated the quality of our automatic polarity detection approach by performing 10-fold cross validation on the 2,349 manual annotations we produced and measured precision, recall and \(F_1\) -measure, as shown in Table 3. We compared our classifier against two baseline classifiers, (a) “Baseline: Word Only” which uses only word features, and (b) “Baseline: UMLS Only” which uses only UMLS concept features. The MERCuRY classifier obtains substantially higher performance. Moreover, the poor performance of the baseline systems suggests that determining exclusion spans in text requires more information that lexical context and can be improved by incorporating NegEx and medical ontologies.

**Table 3: Polarity classification performance**
Discussion
In terms of polarity classification, the most common types of error were due to confusion regarding the exact boundary of negative regions of text, for example, the sentence “No focal or epileptiform features were identified in this record” was classified such that only “no focal” was negative, rather than the entire phrase “no focal or epileptiform features.” This indicates a failure by the incorporated standard natural language processing modules (part of speech and phrase chunking) to adapt to the clinical domain. One obvious path to improvement would be to annotate basic linguistic information on clinical documents – particularly on EEG reports.

Another common type of error was related to the binary granularity of polarity. For example, the excerpt there is a suggestion of a generalized spike and wave discharge in association with photic stimulation” the phrase “generalized spike and wave discharge” was labelled as having a negative polarity, despite the physician clearly indicating the possibility of such an activity. This implies that future work would be well supported by a more fine-grained approach to capturing the physicians’ beliefs, for example, by considering the assertions used in the 2010 i2b2 challenge. Unfortunately, introducing assertions requires overcoming additional barriers including increased risk of misclassification, and accounting for the degree of similarity between different assertion values.

In terms of patient cohort retrieval, it is clear that the two methods of representing inclusion and exclusion criteria – (a) using phrases of terms and (b) using typed concepts – do not provide any significant changes to cohort performance. Based on our analysis, we believe this is primarily due to the fact that there is little ambiguity in the types of concepts used in EEG reports: a particular phrase or term (e.g. heart attack) was always associated with the same concept type. Moreover, the types of concepts are almost completely restricted by the section they occur in (e.g. EEG activities and events do not occur in the HISTORY, MEDICATION, or CORRELATION sections). This suggests that considering EEG concepts alone does not provide any additional value to considering terms directly. Moreover, because the index records positional information, multi-term concepts (e.g. “slow and sharp wave”) are handled identically to multi-term phrases. Despite this, a number of errors were observed. First, neither phrase chunking nor concept detection is sufficient to fully capture the semantics of all inclusion criteria. For example, epileptiform activities were often described as attributes of a particular wave (e.g. “slow rhythmic delta [waves]”) where the individual concept (i.e. “delta [waves]”) is far less meaningful than its attributes (“slow” and “rhythmic”). This suggests that performance can be improved by not only accounting for the attributes of epileptiform activities but by adjusting the relevance model to ensure that mentions of attributes actually modify the correct term – that is, to ensure that “slow” actually modifies the same wave as “rhythmic”.

Finally, the substantial increase in performance when using the full multi-modal index shows that EEG fingerprints are able to recover relevant information omitted from EEG reports. Unfortunately, as the rank of retrieved patient’s decreases, the quality of the cohort obtained by finding similar patients using EEG fingerprints decreases. We investigated multiple values of $\lambda$ (the number of patients to be used for re-ranking) and $\sigma$ (the number of similar fingerprints to retrieve), and found that increasing these values can result in a decrease in performance. Regardless, we did observe that the fingerprints often identify patients which were not retrieved using the report text alone. Moreover, we believe that by further refining the fingerprints we can improve the quality of patients retrieved with higher values of $\lambda$.

Conclusion
In this paper we describe a patient cohort retrieval system that relies on a multi-modal multi-tiered index that organizes clinical information automatically processed from a big data resource of EEGs. Generating the index involved both medical language processing on EEG reports, but also a novel and highly efficient representation of the EEG signal recordings provided by a highly-performant Long Short Term Memory network. When evaluating the quality of patient cohorts obtained when considering both EEG reports and signal recordings, we have a Mean Average Precision of 70.43%. This high performance highlights the promise of multi-modal retrieval from text and signal data. The remaining barriers of high-accuracy patient cohort identification from EEGs that need to be removed will rely on: (1) incorporating a more fine-grained representation of inclusion and exclusion semantics discerned from EEG reports, (2) extending medical language processing for capturing spatial and temporal information, and (3) tightly correlating the information from EEG reports with the EEG signal recordings. In future work, we plan to address these barriers using recent developments in neural learning.

Assessing patient and caregiver needs and challenges in information and symptom management: a study of primary brain tumors

Rebecca J. Hazen¹, Amanda Lazar, PhD², John H. Gennari, PhD¹
¹University of Washington, Seattle, WA; ²Northwestern University, Evanston, IL

Abstract
Brain cancer is a devastating diagnosis characterized by significant challenges and uncertainties for patients and their caregivers. Although mobile health and patient-facing technologies have been successfully implemented in many patient populations, tools and technologies to support these users are lacking. We conducted semi-structured interviews with 13 patients and caregivers, investigating experiences, challenges, interests, and preferences for managing symptoms and health information. We found that although current technology use in health-related activities was minimal, participants reported being highly willing to use such technologies to capture and manage information, provided they were designed according to the needs, interests, and abilities of these users. Participants felt that such tools could benefit patient care activities, and help to address information challenges for both current and future patients and caregivers. We present findings surrounding these challenges, behaviors, and motivations, and discuss considerations for the design of systems to support current and future patients and caregivers.

Introduction and Background
In 2016, nearly 78,000 US adults will be diagnosed with a primary brain tumor¹. Although rare, these tumors are a significant cause of morbidity and mortality, and are characterized by a high symptom burden, decreased health-related quality of life, and an often poor prognosis²-⁴. The delicate and complex structure and functions of the brain make these often aggressive tumors difficult to treat, with high recurrence rates contributing to poor long-term survival⁵. Despite advances in treatment technologies and approaches, nearly 42% of patients diagnosed with malignant disease will pass away within the first year after diagnosis¹. For these patients, overall 5-year survival rates fall at 34.4%, led by glioblastoma, the most common and aggressive high-grade tumor, which falls at 5.1%⁶.

In addition to poor prognosis, primary brain tumors are also associated with high symptom burden. As these tumors grow and invade the delicate tissues and spaces of the brain, patients experience neurological symptoms including headaches, seizures, issues with language, vision, memory, and hearing, as well as cognitive and motor impairments, and changes in behavior and personality⁵. The type and severity of these symptoms depend on the histology, location, and size of the tumor⁵. Treatments for these patients involves surgery to remove as much as the tumor as possible without damaging adjacent health tissues and functions, as well as radiation therapy and chemotherapy to kill any remaining tumor cells and prevent future growth or recurrence for as long as possible. Patients are often prescribed a variety of medications including steroids to reduce swelling in the brain, antiemetics to control nausea, analgesics for pain, and anti-seizure medications to provide symptom and side effect relief and prevent additional harm and neurological complications for the patient. Each of these medications and procedures bring their own risks, discomforts, and side effects, some of which may be lasting or even present years down the road. Because of these risks presented by these medications and procedures, and the high risk for recurrence associated with many primary brain tumors, the follow-up period of these patients typically lasts years, if not indefinitely.

Patients and their caregivers face many challenges as they take on new roles and responsibilities in navigating the diagnosis and treatment process. Many of these challenges center around the need for more data and information in the face of compounding uncertainties. In addition to taking an active role in decision-making activities, patients and their caregivers must work to manage complicated medication schedules and treatment protocols, endure complex neurological symptoms and toxic side effects, all while becoming experts in their own disease and care process.

With the increasingly pervasive nature of technology in daily life, mobile health and patient-facing technologies have been proposed and implemented as solutions to many challenging health issues including increasing medication adherence among individuals with HIV in Sub-Saharan Africa⁷, supporting self-management activities for patients with chronic diseases like diabetes⁸, and supporting personal health information management activities in breast cancer⁹-¹¹. Across health, reach of these technologies is great. A recent systematic review explored examples of self-tracking for health management in older adults, documenting the design and development of interventions across a wide range of health areas for these users¹². Additionally, there a multitude of applications are available to support mental health and individuals with mental illness, including PTSD Coach, an application
design by the Veterans Administration to support education, tracking, and management surrounding PTSD symptoms. Technology is also widely used in searching and accessing health information, with 25% of US adults acknowledging they use the internet for the purpose of self-diagnosis, and 72% of internet users reporting acknowledging using the internet to access or research health information in 2012. Electronic patient portals also provide a means for supporting communication, access, and health information management. Despite these impressive undertakings in the US and around the world, patient-facing tools and technologies to support individuals with rare conditions including primary brain tumors are still lacking.

Due to the nature of the disease and the potential for cognitive, physical, emotional, and behavioral impacts, caregivers often take on an active role in care, decision-making, and information seeking and management activities. In working to understand and address some of the challenges, several researchers explored the information needs of patients with brain tumors, as well as their caregivers. Although each of these studies provided a great deal of insight into different aspects of needs, challenges, and experiences for patients and caregivers, none sought to explore the use of health-related technologies in these activities in the context of designing future systems. In order to address this gap, and develop further understanding of the needs and challenges facing this population, we engaged patients and caregivers affected by primary brain tumors in semi-structured interviews. Through these interviews, we investigated symptoms and side effects, challenges, and current health tracking and information management approaches, as well as the use of technology in brain tumor related health activities. We also utilized brainstorming questions to generate ideas on how we as researchers, alongside participants serving as experts, might design tools to address some of these challenges, and better support future patients and caregivers.

Methods
Eligibility & Recruitment
Patients diagnosed with a primary brain tumor and primary caregivers of these patients were recruited to participate in semi-structured interviews coupled with a demographic, health, and technology use survey to explore needs, challenges, and experiences, as well as current and future use of health-related technologies. In addition to the eligibility criteria presented in Table 1, participants had to be able to understand the information presented during the consent process and make an informed decision regarding participation. In instances where cognitive impairment was a concern, participants were asked a series of questions during the consent process to ensure understanding of the purpose of the study and their rights as a participant. Patients could participate regardless of whether their caregivers chose to take part, and vice versa. Participants were recruited over a 9-month period through a local brain tumor support group as well as in the clinic at radiation therapy treatment centers in the Seattle area. University of Washington Institutional Review Board approval was obtained prior to commencing this research.

*This requirement was not used to exclude patients with aphasia or communication disorders, provided they were comfortable participating in the study, and could understand information presented and provide informed consent.

Data Collection
Demographic, Health, and Technology Use survey
Participants were asked to complete a survey to provide information surrounding demographics, diagnosis, and treatment history. The second component of this included questions regarding current use of technology in health related activities, with survey questions based on the 2012 Pew Health Tracking survey.
**Semi-Structured Interview**

Interviews were conducted as either 1-hour individual sessions (patient OR caregiver), or 2-hour patient-caregiver dyad sessions, according to participant preference. Individual interview sessions allowed patient and caregiver perspectives to be shared more freely and equally, and allowed for participation from individuals who did not have a patient or caregiver who was interested or able to participate (e.g. paid caregiver, severely impaired patient). Patient-caregiver combined sessions were offered both as a convenience, and as a way to allow for participation from individuals who may need extra support with language or memory, for example. Because many individuals travel long distances for care and then return home following the end of treatment, both in person and phone interview sessions were offered. Interviews were audio recorded and participants were compensated for their time.

**Data Analysis**

Interview data was transcribed and verified prior to data analysis. A thematic analysis was conducted with two separate coders analyzing the transcripts to identify codes and themes; each coder generated a codebook based on themes and codes. Codebooks were merged into a single codebook and additional codes were added and reconciled as additional transcripts were coded.

**Results**

A total of 13 participants (7 patients, 6 caregivers) were recruited to take part in this study, representing approximately 11 hours of interview data. Twelve individuals participated via in-person interviews, while one opted to do a phone interview due to location. Six participants opted for patient-caregiver dyad sessions, while one dyad participated separately, and 5 individuals participated independently. All interviews were conducted at the University of Washington Medical Center, however, many participants were treated outside of the UW Medicine system for part or all of their care. As such, information captured during these interviews was not limited to experiences at UWMC or its entities.

Demographic information for participants is presented in Table 2. Diagnoses included oligodendroglioma, anaplastic oligodendroglioma, oligodendroastrocytoma, astrocytoma, anaplastic astrocytoma, and glioblastoma, ranging from grades 2 to 4. Time since diagnosis ranged from 2 months to 4 years, 10 months, with one participant falling outside of the 5 year cut off, but having had a recurrence within the time frame of interest. All seven patient participants had undergone some form of radiation therapy, while six had also undergone surgery, and four had done chemotherapy. Four participants were currently in treatment, and three of the seven participants had reported recurrence or progression of disease. Participants represented a range of educational backgrounds with three participants having associate’s degrees, four with bachelor’s degrees, and six with graduate or professional degrees. Technology use information is discussed in findings section of this paper.

**Overall Findings**

Patients and caregivers faced a multitude of challenges as they worked to understand and manage complicated symptoms, side effects, medications, and treatment protocols. Participants looked to many different sources for information including clinicians, the internet, pamphlets and brochures, support groups, medication packaging information, scientific literature and clinical trials, patient advocacy groups, webinars, blogs and cancer forums, as well as trusted friends and family members to address different aspects of these challenges. Even with a wide range of information sources, many issues remained and in some situations, new challenges arose with increased access to information. Patients wanted to know what to expect in terms of symptoms and side effects, as well as what the future held for them. As a result of these experiences nearly all participants reported feeling lost, alone, scared, or overwhelmed at least once during the process. In this section, we present our findings, as outline in Table 3.
Throughout these interviews, participants reported experiencing over 60 different symptoms, side effects, and health events ranging from seizures, fatigue, nausea, anxiety and depression, to gross impairments in cognitive and motor functions, as well as changes in behavior and personality. While some were anticipated, others came as a surprise in terms of presence, severity, and duration. Many patients and their caregivers experienced challenges identifying and detecting these symptoms and side effects. Part of this challenge stemmed from the fact that symptoms can vary widely depending on the size and location of the tumor, and that they may be subtle in nature, or present slowly over time. A major contributing factor, however, was the fact that participants were not previously familiar with neurological symptoms. For example, five patients had experienced what they believed to be a stroke or dizzy spell, but was later diagnosed as a seizure. Additionally, one patient had been experiencing weakness on one side of their body during follow-up, but because they did not previously have any motor symptoms or impairments, they did not know to associate it with the tumor and report it to their clinicians. This later turned out to be a recurrence of the disease in another region of the brain. In several situations, caregivers noticed symptoms that patients were not aware of, mainly related to changes in cognition, behavior, and personality. In addition to challenges identifying and detecting symptoms, participants were also concerned with understanding the causes of the symptoms and side effects they were experiencing, and knowing how to manage and react to them. This involved trying to determine whether their experiences were related to the disease (i.e. progression or recurrence), or whether treatments or medications were responsible. Similarly, knowing what was normal or to be expected, when to be concerned, and what to do in response to these events was also a major challenge.

**Information Challenges: availability, depth, and presentation of information**

Having access to information was incredibly important to all participants across this study. There was a considerable amount of variation however, between participants in regards to overall satisfaction with the quality and quantity of information provided by their clinicians. In general, participants felt that they received more and better information during radiation treatment than while on chemotherapy at home. This was largely attributed to the fact that during radiation, patients were at the treatment center daily over a 6 to 8-week period, and met with clinicians once a week to discuss progress and questions. In contrast, patients on oral chemotherapy typically only saw clinicians once during each 6 to 8-week chemo cycle. The difference in quantity of face-to-face interactions, and the extended periods of time between appointments meant that patients and caregivers often waited longer to receive information, ask questions, and report concerns.

Participants also noted challenges involving the level of detail and presentation of information. Many participants stated that they would have appreciated more information surrounding diagnosis, treatment procedures, medications, side effects and potential complications, especially early on. P06 explained this in saying “I think [knowing more about] the medications [and] the treatments would have been helpful because you feel like you are jumping out of an airplane without a parachute when you start this journey.” For others, the amount and presentation of information was overwhelming, as described by P06 in saying “It’s actually kind of hard from my viewpoint, going

</table>
through this. I think they are talking at you a lot, and we're both pretty much in a little state of denial or something… You can’t keep track of all the information they are giving you and be able to register it enough to keep everything in your head.” Interestingly, C06, the other half of this patient-caregiver dyad, countered this, expressing frustrations over missing information several times, and summarizing in saying “Well, I would say that is true for you. I could keep track of everything they said because they didn’t tell me very much [both laughing]. I felt a lack of information, and you were overwhelmed by everything because of your state.” This feeling was most likely due to the fact that patients may not always be in a state cognitively or emotionally to take in and process the information being presented, especially following surgery and during treatment. At the same time, some caregivers felt they did not always receive the information they wanted or needed. One caregiver reported doing research on her own to learn the information and terminology so the clinicians would know and trust that she wanted more information.

Both patients and caregivers reported that they felt clinicians were often vague, unwilling, or unable to provide answers, especially related to prognosis. They acknowledged that at times, the information they wanted was not yet available, as was the case before biopsy to determine the type and grade of the tumor. In other cases, they attributed the hesitancy of clinicians to provide the level of information desired to the individualized nature of the disease and number of variables involved, as well as the lack of available clinical trial data for this small, rare disease population. Emotional considerations also came into play as participants believed that clinicians at times held back information or emphasized the positive extremes because they did not want to depress or upset the patients and their caregivers. This scenario was described by P04 in saying “Well I got the distinct impression that he was trying to invoke the power of positive thinking. He didn’t want to put any negative sort of doom-saying scenarios into the works because that can probably turn into a self-fulfilling prophecy.” Although this participant understood and appreciated the concern of their clinician, they went on to further describe that this information was also very important and necessary for setting expectations and making decisions about the future, as they often wanted to know whether they should be planning in terms of months or years.

Information Challenges: Applicability and the need for personalized information
It was nearly unanimously reported among patients and caregivers that they wanted to know what to expect throughout the treatment process and into the future, and that more and better information was necessary to make this happen. This included wanting to know what to expect for their individual situation in terms of symptoms, side effects, survival, quality of life, and the potential both long-term and short-term cognitive deficits. Participants frequently wanted to be able to compare their situations to information they found online or in the literature but experienced challenges in doing so. This was especially common when looking into information surrounding prognosis, where many factors can contribute to the likely outcome. Some participants were unable to find relevant studies or information at the time of decision-making, while others found that they were unlike the patients in the clinical trials due to factors including age, tumor size or location, and treatment history. Factors behind these challenges and frustrations extended beyond lack of availability in the literature, and into the clinic. Many patients reported repeatedly being told that every patient and every tumor is unique. Although likely intended to provide reassurance and discourage participants from reading into what they are finding in trials and on the internet, this type of communication lead to more confusion and uncertainty than relief. The frustrations associated with this type of communication were described by P07 in saying “What most of the doctors say is like… ‘oh well this is your tumor, and there is no other tumor like it. So your experience is your experience, and there’s no such thing as an average.’ And so they make these projections as to how I might or might not respond, but they don’t know, and they always quantify it saying ‘I can’t tell you because it’s you and your tumor, and it’s not somebody with their tumor that’s had the experience that’s in the statistics.’ And so the trouble with that is you come away without any knowledge whatsoever…” Concerns and the desire for in-depth, personalized and relatable information did not end once treatment was over. For certain participants, setting clear expectations relieved stress, and helped them prepare for and accept future possibilities.

Information Challenges: Credibility, cognitive impairment, and emotions
Patients and caregivers often looked to others for information, guidance, and support throughout the journey. As most participants did not know anyone else who had a brain tumor prior to their own diagnosis, they were often forced to look to the internet for information to learn about patient and caregiver experiences by way of blogs, personal websites, and online forums. Several participants felt that without being able to interact with the source of the information and assess their cognitive and emotional state, they could not be certain of the credibility of the information being shared. This concern was linked to the fact that changes in personality, behavior, and cognition are common in individuals with brain tumors, thus, there is increased potential for sharing of misinformation,
whether intentional or not. Interestingly, this sense of distrust and skepticism was more common amongst patient participants, whereas several caregivers reported more positive impressions, likely due to the fact that they were interested in learning different types of information from these sources. There were also great concern involving the internet, both in terms of the potential for discovering information that is scary or upsetting, as well as finding incorrect information. Most participants reported using the internet to look up information in the early stages of the disease and treatment process, but had since significantly decreased or completely stopped to avoid the stress and reduce the potential for misinformation.

**Current Behaviors: Tracking, Communication, Caregivers and Technology Use in Information Management**

*Tracking and recording health information*

Keeping track of health, symptom, and side effect information can be a valuable component of health information management. The majority of current tracking activities were informal in nature with participants largely relying on memory, or taking notes in journals or on pieces of paper. Participants primarily noted when they noticed changes in a certain symptom or side effect, or if something unexpected occurred that they wanted to bring up with their care team. For the majority of these participants, recording of information related to symptoms, side effects, and experiences was not intended to serve as a written record, but was used instead to support memory, communication, and organization of information. Motivations and reasons for tracking or taking notes varied. One caregiver was mentally tracking concerning symptoms for the patient in order to help identify the cause, and hopefully find some sort of solution or resolution. For another participant, tracking of seizure information led to the discovery of a correlation between the frequency of her seizures and her menstrual cycle. For the participant who was sharing caregiving responsibilities with another family member, tracking came about as a byproduct of communication and comparing notes rather than a deliberate decision to track or record information.

Reasons why formal tracking or recording health related information did not take place, using mobile health applications or otherwise, typically fell into three categories: (1) participants were not explicitly asked to capture data by their clinicians, (2) participants felt as though they were seeing the care team frequently enough that symptoms and side effects were being adequately assessed, or (3) participants felt that they did not know what or how to track health information. Category two was especially interesting with this population as this lead to the discovery that tracking and reporting needs and behaviors varied significantly depending on the stage in the treatment or follow-up process. As previously mentioned, patients are seen far more frequently when undergoing radiation therapy, as compared to at home oral chemotherapy. Two participants explicitly stated that they felt they didn’t need to track or record information related to their symptoms during this time period because the clinicians were already keeping track of the information that they were interested in. In contrast, during oral chemotherapy, patients were seen far less frequently, and often felt like they didn’t know how or what to track.

*Communication of Health Related Information*

Communication activities, preferences, and behaviors varied among participants as well. Email was by far the preferred method for contacting clinicians with routine questions and prescription refill requests. Several participants appreciated when clinicians were willing to use email, avoiding the inevitable game of phone tag that typically ensued when patients called in with questions. Despite being convenient and familiar, participants also experienced some issues with using email. Patients and caregiver feared overlooking important symptoms, but also did not want to burden healthcare providers with unnecessary or ‘stupid’ questions, despite their need for information. P07 described a situation where they had attempted to reach out to a clinician via email, but was conflicted and worried about being a bother. Others also reported that they had reached out to certain clinicians via email, but abandoned it as a method of communication after failing to receive a response. Clinician preferences for communication during treatment and follow-up, especially regarding email, were rarely made clear, thus, knowing who to contact, and how to reach them when help was needed remained a challenge. The use of secure messaging through the patient portal was used much less frequently, and was seen as much less convenient than email.

*Caregiver roles, responsibilities, and challenges in care and information management*

In several cases, patients were either unable, or unwilling, to participate in managing and capturing this information during parts or all of their care process due to the cognitive, emotional, and physical impact of the disease and treatment process. This meant that caregivers took on much of the responsibility for managing information provided by clinicians, accessing test results through the patient portal, transferring records between healthcare organizations, scheduling appointments, researching treatment options, medications, diets and nutrition, refilling prescriptions, dealing with insurance and managing financial and logistical aspects of the care process. At the same time,
caregivers faced unique challenges in that their questions and concerns often did not take priority, and at times went unaddressed despite the fact that they were often heavily involved in research, decision-making, and patient care activities. In several cases, caregivers felt as though they could not ask sensitive questions in front of the patient, or patients felt that their questions were more of a priority given the limited amount of time they had with the clinicians. In other instances, patients were feeling well enough to take on all of the information management activities, and didn’t feel that they needed caregiver assistance or participation in appointments, and may have blocked caregiver access to clinicians, despite the fact that they may have had their own questions and concerns. Additionally, cognitive impairments and issues with behavior and personality led to at least one patient becoming confrontational, and not wanting caregivers to talk about symptoms or ask questions during appointments. In three cases, participants felt that separate caregiver appointments might have been beneficial to getting caregiver questions answered. Another aspect of information management that arose was the issue of co-caregivers. Because caregiving is often time consuming and demanding, some caregivers shared responsibilities with a sibling or spouse. This meant that multiple people were involved in activities like scheduling appointments and managing medications, as well as capturing information about the patient’s condition, and comparing notes over time.

**Technology Use**

Despite the fact that all participants reported using technology in their daily lives, with 12 of the 13 participants owning and using a smartphone regularly, the use of personal technologies in health activities related to their cancer diagnosis was very limited. From the technology use survey, we found that all 6 caregiver participants reported helping to keep tracking of information for the patient, with 4 relying on memory, and 2 using paper. For the patients tracking their own health information, three relied on memory, and two used paper. Additionally, two patient participants reported using smartphone applications for other aspects of health and well-being, unrelated to their cancer treatment. A few participants mentioned using electronic calendars for managing appointment information, as well as spreadsheets for keeping track of appointment schedules, medications, and financial information. In two cases, email was used as a means of communication as well as a method for documentation and management of information. One caregiver had tried using a medication reminder application for the patient they cared for, but found that it was difficult to maintain, and easy to ignore. It was not worth the effort of making updates to reflect frequent changes in medication type, dosage, and frequency, especially as the patient was not responding to the alerts.

Several participants had used smartphone applications for tracking exercise and fitness, diet, menstrual cycles, meditation, and information related to other health conditions. Despite everyday use of technology, paper was largely considered to be the easiest, fastest, and most convenient option. For several participants, paper was more likely to be on hand and immediately accessible compared to cellphones, computers, or tablets. Other participants felt that they could not navigate these devices quickly or efficiently enough to record the information of interest. With paper, participants could jot down questions or notes whenever they came to them without having to go find a device, log in, and access a feature for recording information. In the clinic, participants could write out their questions beforehand, and quickly record responses alongside those questions during the appointment. Another benefit of paper, for one participant, was that they could practice cognitive and motor skills including hand-eye coordination when writing in their notebook. For these participants, limited technology use in health was not related to distrust, but convenience was a matter of functionality and convenience.

Patient portal usage was also explored in this study. The majority of participants had accessed their own patient portal at least once, or the portal of the patient they were providing care for. They felt that in general, the features and information was useful, but often limited. They reported accessing the portal to look at blood work, radiology reports, and other test results, and occasionally to verify appointment information. There were also challenges and limitations associated with patient portals, however. Access was an issue for several participants, as they had experienced difficulties with the system failures or had forgotten their log in information. For some participants, patient portal access was not offered until later in their treatment process, and historical information was not available through the system. Additionally, many caregivers did not know whether they could receive access to the portal of the patient they provided care for, and instead had to rely on having the patient log in and allow them to view the information. Some patients were receiving care from providers across different healthcare systems, or at healthcare systems without integrated portals so information was inaccessible or dispersed across portal systems. They also expressed frustrations related to missing data and the often limited nature of the information provided in reports. Participants felt that they should have immediate access to their own health data, and that delays in posting this information was unacceptable. In some cases, the patient and their caregiver already knew all of the information.
by the time it was posted to the portal. Other noted challenges and frustrations involving systems not being user friendly. Many of these challenges and limitations led to users to abandon the portals, instead relying on other means of communication or information access such as requesting print outs in during clinic visits. Several participants noted that these portals could be much more useful if they provided additional information, features, and functionalities including the ability to record their own information and notes, and access to information and resources about the patient’s diagnosis and resources would be helpful to have.

**Future Behaviors and Motivations**

*Self-tracking to support patient care and understanding*

Many participants felt that technology could potentially be beneficial for supporting tracking and managing health information, provided that it was designed to meet their needs, interests, and abilities. They felt that having a more complete record of information for clinicians to work through in making decisions and determining causes of symptoms and side effects could be helpful. Additionally, some felt tracking could be helpful in understanding and finding correlations in their own data, and could reduce the need for memory in recalling questions and information related to experiences in the days and weeks between appointments. However, because participants were not currently using any sorts or applications or tools in tracking or managing their health information, and because the only reference they had was the limited functionality of current patient portals, there was some reluctance to say with confidence that they would switch over if tools were to become available. Some of this was resistant to change as they had already developed methods that worked well enough for them, relying on paper and memory. As such, current behaviors and motivations, as well as the needs, interests, and abilities of these patients and their caregivers would need to be carefully considered in future technology design.

*Benefits for future patients and caregivers*

Thinking back on the challenges they faced, many participants felt that they could have benefitted greatly from the data and experiences of previous patients and caregivers, especially in helping to know what to expect, and to determine whether what they were experiencing was normal. One caregiver felt having access to such data, through the mediation and interpretation of clinicians, would have helped them to ensure that they were not being naïve in their expectations, while another felt that this would help them in reassuring and supporting the patient they were caring for, especially early on. Data of interest included quality of life and survival, and information surrounding type, severity, and duration of symptoms and side effects, as well as whether they resolved on their own or if intervention was necessary and effective.

Another area where this would have been useful is in working through information surrounding prognosis and what to expect as the disease progresses. As clinical trial data is incredibly limited for patients with primary brain tumors, clinicians are often forced to rely on their own experiences and anecdotal evidence when providing this information. Several participants felt having access to more complete tracked data could potentially help clinicians in providing more confident estimates of prognosis. Many participants were highly motivated by data and felt that having the option of knowing the potential possibilities, and having statistics to back that up would be of great comfort and benefit to themselves as well as future patients and caregivers. Although the majority of participants would have appreciated seeing such data or experience information, others had strong preferences about what they did and did not want to see. One participant indicated that they were not at all interested in seeing or hearing about experiences of previous patients with their condition because of the personal nature, and the eventual uncomfortable reality that it is a terminal disease. The same participant was comfortable with viewing data, but reaffirmed that they were not interested in anything related to personal experiences. They felt that the experience information may have been helpful for their caregiver, however.

*Willingness and motivation for Future Tracking*

Recognizing that patient and caregiver tracking and reporting of these data and experiences would be essential to having it available to address these challenges for future patients and caregivers, these participants were almost entirely unanimous in their willingness to provide that data. Some participants like P07 felt that this would be a good way to contribute, saying “I said right from the beginning, I would be happy to help down the road… I am not the last one that’s going to get this diagnosis, there’s people coming up all the time with it. If I can help somebody else, I would be happy to do that.” For others, the major motivation was mainly in having the data available for current patient care activities and psychological comfort.

**Discussion**
Some of the significant findings from this study was the participants strong desire for more information, a willingness to contribute to their own care and that of future patients and caregivers, and the desire for a better understanding of their current situation and potential future with this disease. Due to the number of variables involved and problematic uncertainty, it is currently impossible for clinicians to provide detailed estimates of prognosis for the majority of these participants, which is a major point of confusion and frustration. Optimism and positivity from clinicians was appreciated at times, but also detracted from overall understanding. Although likely intended to inspire optimism to ‘defy the median survival rates,’ the approach and telling patients that they are unique, and not like other patients was not helpful. Rather, participants felt that having access to actual data through clinicians, and to compare themselves to know whether their experiences were as expected, and to identify possible trajectories was incredibly empowering. They felt data could help patients, caregivers, and clinicians to have these honest conversations, even if it meant that there were still many possible trajectories and outcomes. Also, acknowledging that this data likely does not yet exist motivated these participants to be an active part of the data collection process, providing benefit beyond their own patient care.

In addition to these findings, we identified three major considerations for future design and development in this space. First, when discussing the design of technologies for users with complex medical conditions, the interests, needs, and abilities of the intended users require special attention. This is not unique to brain tumors, but because the brain controls so many functions, and these tumors can impact a wide variety of abilities, incorporating this information into design discussions from the start is important. For individuals with potential motor impairments or challenges with language, requirements for multiple methods of data entry (e.g. text, speech, pick list) may be necessary. Minimizing the need for memory, and streamlining the process to avoid redundancies was important. Participants felt that the technology should be ‘smart’ enough to pull relevant data directly from the medical record with minimal efforts from the patients and caregivers. They also emphasized that methods of data collection would be important for assessing reliability, preferring subjective measures over long narratives. Additionally, processes for verifying information would also be beneficial. Ultimately, data entry has to be convenient or else it will not occur. Considerations for shared access for caregivers was also necessary as some patients may be unwilling or unable to participate in tracking activities during part or all of their treatment process.

Second, because participants were satisfied with their current methods of tracking and managing information, there will likely be a barrier to overcome in incorporating technologies into their routines. For these participants, the potential benefits of having a more complete record to support discussions, and the potential that this data might help patients to support their own discovery process was valuable. Integrating the use of this data into clinical encounters might be one way of overcoming that barrier. Incorporation into the clinical encounter also provides an opportunity for clinicians to review the information with patients and their caregivers to ensure reliability and completeness prior to submitting it to a repository. Patients and caregivers were more trusting of the information that they were given when it came directly from or was verified by their clinicians. Although data integrity can be an issue with many types of patient-reported data, it is especially a concern here where cognitive, emotional, and behavioral factors may influence the data, and where the amount of data available is likely to be very small. Another benefit of integration of these applications and discussions into the clinical encounter is that patients may feel like they have the tools to help lead discussions surrounding likely causes or correlations between side effects and medications. Clinicians can also control the conversation and interpretation of data, and can guide conversations based on an understanding of patient values and preferences. As a final consideration, participants felt that any solution that is put into place needs to be easier and more convenient than pen and paper, which for these participants, would be very difficult to achieve. To overcome this, there must be significant motivation and benefit for them. For these participants, some saw benefit for patient care activities, while others were incredibly motivated by the chance to provide data and give back to future patients and caregivers. This may be generalizable to other patient populations where there are few patients, and many uncertainties.

There are two main limitations to acknowledge in considering the findings of this study. First, this study involved a relatively small number of participants due to challenges with recruitment, the rare nature of primary brain tumors, and the severe impact and burden they place on patients and their caregivers. Several potential participants were unable to participate due to demanding treatment schedules and the lasting effects of the disease. Additionally, these participants may not be truly representative of the overall brain tumor patient population, especially in terms of education and race. This was largely due to the fact that the patient population is small to begin with, and we only recruited within the Seattle area. Several of these participants however traveled from surrounding areas and states for specialized treatment at facilities in the Seattle area.
Mobile-health and patient-facing technologies are not yet readily available for this population, however, the potential for tool design in this area is vast. Not only would a smartly designed tool, created to overcome barriers and designed with the needs and abilities of these particular users in mind, support current patients and their caregivers, but also those who will be stricken with this disease in the future. These patients and caregivers face numerous challenges and uncertainties, for which this data could provide a tremendous amount of insight and relief. Designing a patient facing tool for this area of healthcare has great potential to benefit not only this subset of patients, but also provide insight into the overwhelming number of little understood diseases.

Abstract
Effective user training is important to ensure electronic health record (EHR) implementation success. Though many previous studies report best practice principles and success and failure stories, current EHR training is largely empirically-based and often lacks theoretical guidance. In addition, the process of training development is underemphasized and underreported. A white paper by the American Medical Informatics Association called for models of user training for clinical information system implementation; existing instructional development models from learning theory provide a basis to meet this call. We describe in this paper our experiences and lessons learned as we adapted several instructional development models to guide our development of EHR user training. Specifically, we focus on two key aspects of this training development: training content and training process.

Introduction
Effective user training has been recognized as an important factor to improve health information technology (IT) implementation success, but development of a successful training program remains a challenging task. Part of the reason is that health care organizations lack industry-wide best practices in electronic health record (EHR) training, so often have to learn from their organization’s own training experiences, with can be costly and inefficient. While current literature often introduces some design principles, there is still a gap in guidance on how to translate those principles into varied clinical practices or settings. This literature may report on how organizations conducted the training and general principles, but the detailed process of developing training programs is often underemphasized and underreported. The literature may also include lessons from costly “do-overs” after the training program go-lives. Ideally, by following an instructional development model, those issues might be detected before the go-live, which could save money and time for clinicians and health care organizations.

American Medical Informatics Association (AMIA) board members published a white paper entitled “Core Content for the Subspecialty of Clinical Informatics”, which identifies core educational content for clinical informatics. With continued national mandates for health IT adoption and use, the training needs for information systems in clinical settings, most notably EHRs, are expected to grow. Among the numerous knowledge and skill content areas addressed by the AMIA board members, knowledge under “clinical information system implementation” includes “models of user training and support processes that can meet clinician needs” as one of three sub-topics.

Instructional development is a well-established domain, with over 100 validated instructional development models, and some of them may be particularly applicable to EHR training. For example, the Instructional Systems Development (ISD) model is a generic model developed in the 1950s to meet the needs of military and commercial organizations. In ISD, training consists of five basic stages: analysis (A), design (D), development (D), implementation (I), and evaluation (E); referred to as the ADDIE model. The ADDIE model is comprehensive in content and systematic in procedure, and covers almost all necessary components needed to carry out an effective training program. To meet a variety of specific training needs, other models build on the ISD model, and improve some of these stages. For example, the development stage may take a long period of time, and may fail to meet the pace of technology updates, e.g., EHR. The rapid prototyping model tries to facilitate training development by performing several elements...
simultaneously, condensing the generic ADDIE model into a four-level process, including: a) performing a needs analysis, b) constructing a prototype, c) utilizing the prototype to perform research, d) implementing the final system. The ISD model also fails to embrace the fact that reality can be different from what was planned, and may change over time, which is typical in complicated health care settings. Therefore, the R2D2 model (Recursive, reflective, design and development) provides the ability to update the training plan over time. Reflection involves critically considering work to date, and revising training plans and materials based on observation and other feedback. The recursive nature of the process means making the same decisions many times throughout the design and development process, so initial decisions are not necessarily the “final ones”. The implication of this model is that a training design team should actively reflect on and revise current training to meet ever-changing situations.

The current accounts for successes or failures in current EHR training often focus on the final format of training, and it is rare to see detailed descriptions of the training development processes. In this paper, we try to bridge that gap by discussing our experiences developing an EHR training program. The primary focus of this paper is to detail the systematic process of developing the training and lessons learned through our iterative development process. We consider training development as a problem that should take a sociotechnical system perspective, and adopted an iterative approach similar to rapid prototyping model and R2D2. We also conceptualize a two-phased EHR training development focused on training content and training process. We discuss what we learned during the design and development process that led to a successful training session.

**Methods**

Instructional models typically suggest that before training program development, one needs to conduct a thorough analysis to define training needs. We first present how to conduct this type of detailed analysis from a sociotechnical systems perspective, and then detail how we designed and developed training content and processes based on these analysis results. Figure 1 outlines the conceptual model of training development we adapted from ISD, R2D2, and rapid prototyping for EHR training program development. We use the model to guide the design and development of EHR training for nursing students at a large public university, and we address how we conducted each stage of this model in this section, with focus on the development of content and process. We chose to use the clinical process of obtaining a medication history prior to the design phase, because it is an error-prone process involving comprehensive EHR-related competencies (e.g., information retrieval, documentation, decision making), and it has been used in comprehensive practice sessions in previous EHR implementation training in other health organizations.

![Figure 1. Conceptual model of training design and development process](image)

The authors of the AMIA white paper on “Core Content for the Subspecialty of Clinical Informatics” adopt a holistic sociotechnical systems perspective, depicting clinical informatics at the intersection of three domains: clinical care, information technology, and health systems. In order to develop a training program that fits the need of clinicians and reflects the complex nature of healthcare settings, it is necessary to...
consider EHR training as a sociotechnical systems problem. This view is particularly important during the analysis stage of an EHR training needs assessment, because these analysis results will influence decisions related to training design and delivery.

The training analysis phase should define training goals, and gain an in-depth understanding about the users and their required tasks, including their typical clinical practices, informatics needs, responsibilities, and current competencies. This information can be used to determine what resources, including EHR functions, physical environment, and infrastructure will best serve users’ needs.

**Analysis of training goals**

The goal of our training program is to help senior nursing students use an EHR efficiently and accurately while obtaining a patient’s medication history. More specifically, after training, nursing students should be able to:

- Use functions related to medication history taking to navigate, search for information, retrieve information, and document new information into EHR
- Reconcile any potential discrepancies in patient information in the system, such as omissions and out-of-date medications

**Analysis of stakeholders**

We involved a multi-disciplinary team in the training design process, including individuals with nursing, computer science, and human factors backgrounds. In addition, the targeted trainee group participated extensively in the development process.

**Analysis of trainees’ characteristics**

Training analysis must address the trainee’s current competencies in completing the clinical process of interest, and current EHR competencies, in order to define their training needs. If the trainee is insufficiently prepared to complete the clinical care process, training must first address that competency prior to conducting EHR-specific training. Studies reported best practice principles in EHR implementation training that align with this approach, which identified a need to “assess users’ skills and training needs” and “match training to users’ needs” as important best practices. The analysis must also assess any technical competency prerequisites for using the EHR (e.g., using a keyboard and mouse, opening software).

In terms of competencies, the nursing students in our program had received classroom training in pharmacology and obtaining a medication history, had some clinical experience with EHRs through their clinical experiences (though not the EHRs used during training), and were competent with basic operations with computers (e.g., using a mouse and keyboard, and opening software).

**Analysis of clinical tasks**

To determine what tasks to train users on, an analysis should start with a clinical care process of interest, rather than the technical capabilities or functionalities of the EHR. The analysis should also determine the trainee’s roles and responsibilities within the process. In our training analysis, we first analyzed the clinical process carried out by nurses when obtaining a medication history. We built on an existing clinical process flowchart defining required clinical tasks.

Starting training from the perspective of a familiar clinical process is consistent with adult learning theory, which states that adults are more motivated to learn things relevant to their needs and experience. This analysis can help avoid overloading the trainee with irrelevant information and EHR functionalities, which is a typical cause to ineffective training.

**Analysis of EHR technical functions**

The training analysis should determine what technical aspects of the EHR (e.g., functions) are used during the clinical process of interest. After extensive review of the literature and analysis of EHRs, we identified what EHR functions were required to complete the clinical process, including both overhead functions (e.g., logging into the system) and domain functions (e.g., reviewing the current medication list in the
EHR) as described by Zhang et al. Specifically, trainees need at least six EHR functions to complete the clinical task, including:

1. Login to the system
2. Search for and retrieve a specific patient’s chart
3. Retrieve basic patient information, such as allergy, identity, vitals
4. Retrieve and document a patient’s medication list
5. Retrieve and navigate through a patient’s problem list
6. Retrieve and navigate through a patient’s past history, such as social, medication, surgery

**Analysis of task-EHR integration/ workflow**

Sociotechnical systems models suggest that we need to analyze the often-unexpected impact of an EHR on existing system elements, such as workflow. For example, EHRs can impose high cognitive load for clinicians, making clinical tasks error-prone. Therefore we clearly mapped out the links between the clinical care process and the EHR use, including what tasks should be completed with the EHR, when in the process the EHR will be used, and how the technology will impact the trainee’s workflow for the clinical process of interest. The results from this analysis are used in a clinical task-EHR integration/work training section. As an EHR will likely impact the clinical care process, the analysis helps mitigate negative impacts of these changes, and explicitly address any redesigned clinical workflows in the training.

**Analysis of resources and constraints**

Based on nursing students’ typical schedule, an ideal training session should be no more than 90 minutes to achieve best attendance rate and keep trainees attention. The physical environment is a Class Lab in nursing school, with a projector and white board. The training utilized laptop PCs with Windows Operating Systems with each trainee using their individual computer. The EHR is web based, which is accessible using a web browser.

**Design and development**

Based on the analysis results, we needed to make two main decisions: what to train (content) and how to train (process). We first decided necessary sections in the training program, which include clinical process review, pre-training evaluation of EHR competency, EHR use training, workflow integration training, and post-training evaluation. Then we worked on content and process for each section. Before we involved students in the study, we obtained approval from the Institutional Review Board.

Following the idea from the instruction development models, the general strategy to develop training content was to prototype materials for each training section, then test the materials with real trainees as they used the materials and processes. We worked to understand their perceptions, and reveal any confusions and ambiguity in the training materials. We worked with six different trainees individually on materials and processes, until we could identify no issues to be addressed and we were ready to roll out the training.

With the first three trainees, we focused on the content of the training. We asked each trainee to go through the training materials in order, observed them learning without imposing any time limit, and documented their time and questions. We asked them to think out loud so we could understand points of confusion, and tried to clarify verbally until they understood. With the second three trainees, we focused on the process of the training. We followed specific training protocols, with time limits for each section. We observed and documented issues as trainees went through the training, and communicated with them about the issues and their concerns at the end of the training.

We summarize major issues identified with each participant, and our corresponding changes in Table 1.
<table>
<thead>
<tr>
<th>Participant</th>
<th>Major Issues</th>
<th>Training Design Changes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a. The trainee was unfamiliar with some EHR technical terms when the terms are not commonly used in clinical care.</td>
<td>a. Simplify or define terms to fit clinicians’ language. For example, “search for information” sounds more familiar than “information retrieval”, and “enter data/notes” may be more familiar than “documentation”.</td>
</tr>
<tr>
<td></td>
<td>b. The trainee lost attention when a video tutorial introduced too much information at a time</td>
<td>b. Instead of introducing all EHR functions at once, introduce two functions at a time, followed by a hands-on practice</td>
</tr>
<tr>
<td></td>
<td>c. The trainee remained confused about what she needed to do with EHR with different medication history sources after clinical process review</td>
<td>c. Add a review question about reconciling with multiple medication history sources and using EHR, and provide answers</td>
</tr>
<tr>
<td></td>
<td>d. The trainee did not understand why the EHR-workflow tutorial was related to “how they conduct clinical care”, and did not understand the task-EHR flowchart mapping</td>
<td>d. Redevelop task-EHR integration tutorial, making it more relevant to clinical care, and present the integrated workflow chart in resemblance to clinical process diagram</td>
</tr>
<tr>
<td></td>
<td>e. The trainee did not feel comfortable in the physical environment, feeling too hot</td>
<td>e. Conduct training in an air-conditioned environment</td>
</tr>
<tr>
<td>2</td>
<td>a. The trainee did not get some key details of instructions printed on paper</td>
<td>a. Add a training instruction transcript for all sections, and verbally communicate what to do before each section</td>
</tr>
<tr>
<td></td>
<td>b. The trainee did not know what to do during hand-on exercise besides repeating what was demonstrated in the video</td>
<td>b. Add specific goals and assignments to the hands-on exercise, which covers the contents just demonstrated</td>
</tr>
<tr>
<td>3</td>
<td>a. The trainee had a problem organizing and finding files</td>
<td>a. Distribute files only when they are needed for each section, and ask trainees to put away in a file folder in checklist</td>
</tr>
<tr>
<td></td>
<td>b. The trainee frequently asked “what’s next”</td>
<td>b. Add a file called progress checklist to list all training sections, tasks and time in order, so a trainee can have expectations and more control</td>
</tr>
<tr>
<td>4</td>
<td>a. The trainee was quicker to complete tasks than the time set for the training, and had to wait for next sections to begin</td>
<td>a. In the instruction/protocol, the time set for each section is changed to the maximum time allowance, making it more self-paced; a smaller learning group (1 to 3 trainees per training session) can better accommodate different learning capabilities.</td>
</tr>
<tr>
<td></td>
<td>b. The trainee’s cell phone rang during the training</td>
<td>b. Add a welcome PowerPoint slide projected to whiteboard with silenced cell phone reminder</td>
</tr>
<tr>
<td>5</td>
<td>The trainee seemed to miss some key information about task-EHR integration tutorial printed on paper</td>
<td>Provide video version tutorial in addition to paper version</td>
</tr>
<tr>
<td>6</td>
<td>The trainee went through the materials and processes very smoothly. Ready for go-live.</td>
<td>None.</td>
</tr>
</tbody>
</table>
After 6 iterations of development, we finalized the training program as described in Table 2.

**Implementation and Evaluation**

We implemented the final version of training program in the nursing school Class Lab for 9 groups of trainees (n = 18 in total); each group had 1 to 3 trainees based on their availability. After training, we evaluated key aspects of the program by analyzing their performance data, and conducted interviews to gather their opinions about the training. Every session progressed as expected. Most trainees managed to complete the training slightly faster than scheduled.

Preliminary analysis of their performance showed the training was effective as measured by trainees’ pre-post training performance comparison: 50% of trainees were able to correctly document the intended medication in case 1 (pre-training) compared with 100% of trainees able to correctly document the intended medications in the more complex case 2 (evaluation). Trainees were able to do it much faster too: for those able to complete case 1, it took them on average 532 seconds (95% CI = 455-609); Trainees took on average 430 seconds (95% CI = 373-487) to complete the more complex case 2. The reduced variance in duration is remarkable, because it is considered as one important indicator of an effective training, even with more trainees completing the task (n = 9 vs. n = 18). The results of their performance are summarized in Table 3.

**Table 3.** Performance metrics

<table>
<thead>
<tr>
<th></th>
<th>Pre Training Session (Case 1)</th>
<th>After Training Session (Case 2)</th>
</tr>
</thead>
<tbody>
<tr>
<td># of Trainees who completed the case</td>
<td>9 out of 18</td>
<td>18 out of 18</td>
</tr>
<tr>
<td>Duration of completion (in seconds with 95% confidence interval)</td>
<td>532 (77)</td>
<td>430 (57)</td>
</tr>
</tbody>
</table>

In addition to the quantitative measures, we conducted interview with trainees to gather their opinions about the program. We asked them to comment in terms of usefulness, clarity and any other aspects related to the training quality, and we recorded their comments. Their feedback was highly positive, and some frequent quotes include:

- “It (the training process) is smooth and well-planned.”
- “They (the materials) are really clear and well explained.”
Discussion

Instructional models, such as ADDIE or R2D2, can be helpful to guide a successful EHR training program development process. They help identify and remedy potential issues before the training program execution, to avoid potential costly failures and do-overs. It is a best practice to involve targeted trainees in the process, and understand their work, needs, characteristics, and current competencies, and update the training materials and processes to best serve their needs. However, the training design and development process can be frustrating during early stages; for example, during our early development phase, a trainee involved in testing told us, “do not teach us how to use the (cumbersome) system, go fix it.” While an ideal and user friendly system is the ultimate goal, a good training program is necessary for users to take full advantage of any EHR system.

In order to make progress toward the correct direction during design and development process, different models all suggest conducting extensive analysis to map out the specifics of the planned training, such as trainees, resources, training goals. Based on the analysis results, we can go through iterations of prototyping, testing, redesign and development until we are confident the program is ready to be implemented. It is difficult to have a perfect training program through just one round of development, and we can always learn new things based on different feedback. The trainees who involved in the development process could also serve as super user instructors to other trainees.

The development of an EHR training program should focus on content and process, which are both key factors to ensure success. The content and process are interactive factors, as different content may be best trained using different methods or durations. Our experience was to emphasize more on content clarity and learnability during early stage, and focus more on process toward later stage to avoid trainees’ loss of attention and fatigue, such as self-pace learning, video demonstration vs. paper based content presentation. The model presented in this paper provides guidelines and principles for the design of content and process, and can be applied to various settings and tasks. However, different training programs may vary in detailed content and process based on training needs and resources, and everything should be vigorously tested before implementation.

Abstract

Manual Chart Review (MCR) is an important but labor-intensive task for clinical research and quality improvement. In this study, aiming to accelerate the process of extracting postoperative outcomes from medical charts, we developed an automated postoperative complications detection application by using structured electronic health record (EHR) data. We applied several machine learning methods to the detection of commonly occurring complications, including three subtypes of surgical site infection, pneumonia, urinary tract infection, sepsis, and septic shock. Particularly, we applied one single-task and five multi-task learning methods and compared their detection performance. The models demonstrated high detection performance, which ensures the feasibility of accelerating MCR. Specifically, one of the multi-task learning methods, propensity weighted observations (PWO) demonstrated the highest detection performance, with single-task learning being a close second.

Introduction

Conducting research and quality improvement using manual chart review (MCR) remains widely used in traditional observational clinical studies aimed at assessing detailed information on patients to understand disease course or outcomes and is also a primary modality used for quality improvement, epidemiologic assessments, and for graduate and ongoing professional education and assessment.1-5. Prominent examples of healthcare quality improvement programs include the American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) and Centers for Disease Control and Prevention (CDC)’s National Healthcare Safety Network (NHSN), which employ MCR to retrospectively measure healthcare quality and patient safety outcomes.6 For example, NSQIP surgical clinical reviewers perform MCR to collect and report 21 surgical adverse events and related preoperative, intra-operative, and postoperative clinical data elements. Similarly, NHSN is a required healthcare-associated infection (HAI) tracking system, which also relies significantly on MCR. The reviewers for both of these programs utilize data from the electronic health record (EHR) and any paper records, including results of diagnostic tests, diagnoses information, and narrative text to ascertain outcomes.6-8 Though MCR provides high-quality data for further secondary purposes including research, it is very time-consuming and labor-consuming to conduct and may be a bottle-neck step in the research discovery process.

Among all postoperative complications, the most common types are surgical site infection (SSI), pneumonia, urinary tract infection (UTI), and sepsis, accounting for nearly 60% of all complications.9 Severe infections could trigger sepsis and even septic shock, particularly in people who are already at risk. Sepsis and septic shock are common and deadly, and CDC has listed “septicemia” as the 11th leading cause of death nationwide.8 In addition, postoperative complications are expensive to treat. According to a recent study, 440,000 of these adverse events happen annually and cost overall up to 10 billion dollars per year in the United States.9 Given the significant influence on the quality and cost of healthcare, postoperative complications are increasingly and widely viewed as a quality benchmark and are a strong emphasis of national initiatives for infection prevention and control.10 However, infection control departments at medical facilities spend considerable time and resources on MCR to collect infection outcome data for public reporting and surveillance, which has greatly increased the burden on already limited infection prevention and quality improvement resources.

To improve the efficiency of MCR, some groups have explored the feasibility of computerizing the process of MCR for reporting postoperative complications or for automatically collecting necessary data elements in quality improvement program, but these efforts have mainly been based on unstructured data such as physician narratives and nursing notes.11-14 In one example, relevant keywords and phrases were extracted from free text documents for adverse event detection.13 In another case, statistical and rule-based extractors were developed to automatically
abstract data elements such as procedure type and demographic information from clinical notes\textsuperscript{14}. According to standard NHSN definition, SSIs can be categorized into superficial, deep, and organ space\textsuperscript{15}. In our previous work, three subtypes of SSI and the overall SSI detection models were developed based on structured EHR data, including lab tests, vital signs, medications, and orders\textsuperscript{16}. These models have high specificity as well as very high negative predictive values, guaranteeing the vast majority of non-SSIs could be eliminated thus significantly reducing the burden on chart reviewers.

In this study, our aim is to build an automated platform for postoperative complications detection based on structured EHR data by using robust modeling techniques. Included in this analysis are the main postoperative complications of three subtypes of SSI (superficial, deep, and organ space), pneumonia, UTI, sepsis, and septic shock. We hypothesized that EHR data would include significant indicators and signals of postoperative complications and that sophisticated machine learning methods might be able to extract these signals, accelerating the MCR process of these adverse events. Compared with the gold standard MCR process, automated application has potential advantages. First, MCR lacks inter-rater reliability, while an automated abstraction system would provide an objective and consistent reporting protocol that can be applied across multiple medical institutions. Second, a successful automated abstraction system would allow for expansion to include other procedures where postoperative surveillance is not being performed currently.

Specifically, we explore several methods for developing postoperative complication detection models. The most straightforward way to detect each type of complications is to build an independent classifier for each of them, which could be viewed as single-task learning, where detecting each complication is a \textit{task}. When tasks are known to share similar features, we expect the resultant models to be similar. Learning models for these tasks together allows us to introduce inductive bias to make the resultant models similar, providing us with more robust models. Learning models for related tasks together is referred to as multi-task learning. For example, when our task is to identify a particular SSI subtype, a related task can be to detect any SSI (overall SSI). With an overall SSI model in hand, identifying a particular SSI subtype is easier, because the classifier only needs to learn the difference between overall SSI and the particular SSI subtype, rather than the difference between the SSI subtype and any other complication.

In our application, we have a hierarchy of tasks as shown in Figure 1. The first task is to distinguish patients with infection from those without. Next we distinguish among the various kinds of infections and finally, if the patient happens to have SSI, we distinguish among the three types of SSI. We assume that many infections share some characteristics that other diseases do not; and we further assume that many types of SSI share some characteristics that non-SSI infections do not. Our hypothesis is that by making a task-similarity hierarchy available to the multi-task learning methods as domain knowledge, they can utilize these information towards building more robust and better performing detection models.

![Figure 1. A hierarchical structure among postoperative complications](image)

In this work, we compare six methods for developing post-operative complications detection models. First we have single task learning, where predicting each complication is an independent task. We also explore five different methods for multi-task learning, assessing their value in improving the detection performance.
Materials and Methods

The overall methodological approach for this study included four steps: (1) identification of surgical patients and collection of associated data, (2) data preprocessing, (3) supervised single-task and multi-task learning model development, and (4) evaluation of a series of final models using gold standard data from the NSQIP registry. Institutional review board approval (IRB) was obtained and informed consent waived for this minimal risk study.

Data collection

Surgical patients at the University of Minnesota Medical Center are annually collected following strict inclusion and exclusion criteria. Their occurrences of postoperative complications are extracted and documented by chart reviewers, which are used as the gold standard in this study. We first identified surgical patients from 2011 to 2014 who had been selected for inclusion into the ACS-NSQIP. Clinical data for the identified patients were extracted from our clinical data repository (CDR) and their postoperative complication outcomes were retrieved from the NSQIP registry. The dataset was divided into training set (first 2.5 years) for model development and test set (last 1.5 years) for evaluation. The occurrences of postoperative complications in both training and test set are shown in Table 1. Overall SSI included any type of SSI.

We collected demographic information (e.g., age, gender), laboratory results (e.g., white blood cell count, glucose), microbiological results (e.g., urine culture, blood culture), relevant diagnosis codes (e.g., ICD_9 code 599.0 for UTI, ICD_9 code 995.91 for sepsis), orders and procedures for diagnosis and treatment (e.g., chest radiological exams for making diagnosis of pneumonia, CT guided drainage to treat SSI), antibiotic use, vital signs (e.g., temperature, heart rate), and medications.

Data preprocessing

Data preprocessing generally included data cleaning and missing data imputation. Our previous work on missing data imputation methods suggests that filling in the average value of patients without complications (normal value) in the training set and the test set introduces the least bias\(^7\). Accordingly, in this research, we chose to follow this imputation method.

For longitudinal lab results and vital records, we used aggregated features. We included the most recent value before the operation as the baseline, and the extreme and mean values from day 3 to day 30 after the operation during follow-up. We assembled a list of relevant antibiotics for each specific outcome, and extracted different classes of antibiotics as features. For relevant orders, procedures, and diagnosis codes, binary variables were created to denote if they were assigned to a patient. Additionally, we not only considered whether a microbiology test was ordered or not, but also looked at the specific bacterial morphological types (e.g. gram positive rods, gram negative cocci). Two binary features were built for each test to represent a culture placed or not and a positive/negative result, separately.

Modeling Methods

After data collection and preprocessing, the six modeling techniques were applied.

When building our detection models, we face three key challenges. The first one is the skewed class distribution. A mere 10% of patients in the training set have any complications and some complications, like septic shock, occur in only .6% (half a percent) of the patients. The second challenge is the small sample size. Some complications, like septic shock, only have 34 observations in the training and 17 in the test set. While our problem does not appear particularly high dimensional, for these rare complications, the number of predictors (approx. 200) exceeds the number of samples. The third challenge is the heterogeneity of the outcomes. We have 9 outcomes, each having their own specific characteristics and there are also variations among patients who do not have any complications. A successful detection algorithm has to address some of these challenges.

Below, we explain each of the six methods and describe which of the above challenges they address.
**Method 1: Single-task learning**

The nine outcomes are modeled independently using Lasso-penalized logistic regression. Lasso-penalized regression constructs a sparse model, where some of the coefficients are set to exactly 0. This performs automatic variable selection and also helps with the small sample size for some of the outcomes. This method does not specifically address the other challenges.

**Method 2: Hierarchical classification**

Let us consider the hierarchical structure among surgical patients as shown in Figure 1. All tasks are divided into three levels and models are constructed in a top-down fashion. The top-most task identifies patients with any postoperative complication. Next, in patients who are predicted to have complications, a 2nd level task is carried out to distinguish between SSI, pneumonia, UTI, sepsis, and septic shock. If a patient is predicted to have SSI, a further 3rd level task is also carried out to identify the SSI type: superficial, deep, and organ space SSI. Each task utilizes Lasso-penalized logistic regression. When more than two classes are possible, the one-vs-all approach is used to break a multi-class classification into a set of binary classifications.

As the method progresses from the top towards the bottom of the hierarchy, it gradually focuses on subpopulations that are enriched in the outcome of interest. This addresses heterogeneity by explicitly ignoring patients without indication of the outcome and also addresses the skewed class distribution. The adoption of LASSO model can overcome the problem of small sample size.

**Method 3: Offset method**

Similar to the hierarchical method, the classifiers for different tasks are built in a top-down fashion. For the top level task (i.e. complication classifier), a LASSO logistic regression classifier is built directly. For the lower-level tasks, we essentially model the difference between the parent and the child task. For example, the deep SSI classifier models the difference between overall SSI and deep SSI. This is achieved through penalizing the child model against the parent model: the predictions from the parent model are included as an offset term (a term with fixed coefficient of 1) in the child model, which is a LASSO logistic regression classifier. Due to the Lasso penalty, variables that have the same effect in the parent and child model will have a coefficient of 0; and conversely, variables that have non-zero coefficient are the variables in which the parent and child tasks differ. The method addresses the challenge of small sample size in two ways. First, in contrast to method 2, it uses the entire population at each level, thus the problem does not become overly high dimensional. Also the offset biases the child classifier towards the parent model. This method only offers limited ability to address heterogeneity.

**Method 4: Propensity weighted observations (PWO)**

The propensity weighted observations method also builds classifiers from the top level to the bottom level. The classifier of the top-level task, the complication classifier, is LASSO-penalized logistic regression (same as all of the previous methods). The classifiers for the second level task are built on the entire population, however, the observations (patients) are weighted by their propensity of having a complication. The propensity is obtained from the higher-level (complication) classifier. Patients, who are likely to have a complication receive a relatively large weight, while patients who are unlikely to have a complication receive a small weight. Therefore, patients with complication contribute more to the 2nd level classifiers than those who are unlikely to have complications. Similarly, the 3rd level classifiers, which distinguish between the three kinds of SSI, are also built on the entire population. The weights of the patients are their propensity of having SSI, thus the patients who likely have SSI contribute more to these classifiers than patients who are unlikely to have SSI. Similarly to the offset method, the PWO method uses the entire population, but by applying weights, it reduces outcome heterogeneity (patients with unrelated complications receive small weights) and reduces the skew of the class distribution by enriching the training set with patients having the outcome of interest (these patients receive high weights).

**Method 5: Multi-task learning with penalties (MTLP)**

Unlike the previous methods, the objective of multi-task learning with penalty (MTLP) method is to learn the regression coefficients $\beta_i$ for all tasks simultaneously. In the MTLP method, we assume that the parent task and its child tasks share some features and the respective models should have similar coefficients for those features. Similarly, to the offset method, this similarity is enforced through penalizing the child model against the parent model. Unlike the offset method, which builds models in a top-down manner, MTLP builds all models simultaneously. Specifically, the objective function is
argmin_{\beta \in \mathbb{R}^p} l(\beta_t) + r_1(\beta_{level,2}) + r_2(\beta_{level,3})

(1)

It consists of three parts, the negative log likelihood of logistic regression, \( l(\beta_t) \), and two regularization terms, \( r_1(\beta_t) \) and \( r_2(\beta_t) \), as shown below.

\[
l(\beta_t) = -\left[ \frac{1}{T \times N_t} \sum_{i=1}^{T} \sum_{t=1}^{N_t} \left( y_{t,i} \cdot (x_{t,i}^T \beta_t) - \log(1 + e^{x_{t,i}^T \beta_t}) \right) \right]
\]

(2)

\[
r_1(\beta_t) = \lambda_1 \sum \| \beta_{level1 \ parent \ task} - \beta_{level2 \ children \ tasks} \|
\]

(3)

\[
r_2(\beta_t) = \lambda_2 \sum \| \beta_{level2 \ parent \ task} - \beta_{level3 \ children \ tasks} \|
\]

(4)

where \( T \) and \( N_t \) are the number of tasks and training set for each task, respectively; \( x_{t,i} \) and \( y_{t,i} \) are the feature vector and the label for the subject \( i \) in task \( t \), respectively; \( \beta_t \) is the coefficient vector for the task \( t \). The two regularization terms, \( r_1(\beta_t) \) and \( r_2(\beta_t) \), restrict the difference in coefficients between the level 1 parent task and its level 2 child tasks; and the difference between the level 2 parent task and its level 3 child tasks, respectively. Penalizing the difference between the parent and child models makes them similar. The MTLP method addresses heterogeneity by explicitly making the parent and child models similar, thereby essentially only modeling the difference between them; and it addresses the small sample size through the use of the entire population and regularization.

**Method 6: Partial least squares regression (PLS)**

As with the MTLP method, partial least squares (PLS) regression models all tasks simultaneously. PLS regression is similar to principal components regression in the sense that both methods reduce the dimension of input data by projecting the outcomes and predictors into new spaces and then build regression models in those new spaces. PLS differs from MTLP in that the task hierarchy is not explicitly given to the fitting algorithm; the algorithm has to autonomously learn the relationships among the tasks.

**Evaluation**

Outcomes based on MCR from ACS-NSQIP were used as gold standard to be compared with the results of postoperative complication detection models. The evaluation metric is area under the curve (AUC), which is commonly used to compare detection models. The range for AUC is between .5 and 1, .5 indicating a random model and 1 indicating perfect discrimination among the outcomes. We report the cross-validated AUC on the training set. To assess the variability of the detection performances on the test, bootstrap replication was applied and the 95% (empirical) confidential interval (CI) and mean AUC scores are reported, as well. Since all methods were evaluated on the same bootstrap samples, paired t-test was used to compare each pair of methods and assess the statistical significance of the observed differences in performance.

**Results**

**Evaluation results of six detection methods**

Figure 2 depicts the performances of the six methods. Each plot in Figure 2 corresponds to a task (complication) and each column in each plot corresponds to a method. Methods are numbered in the same order as they appear in the Methods section: #1 corresponds to Single-task, #2 to Hierarchical, #3 to Offset, #4 to Propensity Weighted Observations (PWO), #5 to Multi-Task Learning with Penalty (MTLP), and #6 corresponds to Partial Least Squares (PLS). The vertical axis is AUC. For each method, the mean AUC (across the bootstrapped test samples) is represented by a disk and lines extending out of the disk correspond to the 95% CI.

To assess the statistical difference between some of the methods, in Table 2, we show the results of pairwise (paired) t-tests among the various methods. The rows of the table correspond to tasks, the columns to a comparison between two methods. Each cell contains a number, which indicates which method has a significantly better performance and we also provide the p-value in brackets. ‘NS’ means ‘not significant’. The methods are numbered in the same way as above.

For the detection of all complications, Single-task, Hierarchical, Offset, PWO, and MTLP have the same good performance, and are significantly better than PLS. To detect superficial SSI, Offset and PWO have virtually identical performance (difference is not significant) and they perform significantly better than the other four methods. PWO performs best for detecting deep SSI and overall SSI. Single-task, PWO, and MTLP all perform
similarly (no statistically significant difference) in detecting organ space SSI but perform significantly better than the other methods. To detect pneumonia and UTI, Single-task and MTLP are not significantly different from each other but are significantly better than other four methods. Single-task, PWO, and MTLP are the top three in detecting sepsis and PWO is also the best method for detecting septic shock. In general, PWO is the best method for detecting most complications. Single-task and MTLP are close seconds (and they have virtually identical performance) and PLS is the method with the worst overall performance.

Figure 2. Detection performance of six models for all nine tasks, showing the mean and 95% CI
Detailed information about the performance of the methods is depicted in Figure 2 and the statistical significance of the pairwise comparisons between the various methods is shown in Table 2.

**Significant variables selected**

Lasso-penalized regression performs automatic feature selection. In Table 3, we provide a list of the most important features selected by the model that aims to identify whether a patient has a complication. This model is common across most methods. Due to space limitation, we cannot provide a list for all methods and all complications. Below we provide some examples of features selected by the best performing method for each of the complications.
**Superficial SSI** detection model based on Offset and Propensity Weighted Observations methods selected antibiotic use, gram stain ordered, and the ICD_9 code of SSI.

Besides diagnosis codes, antibiotics use, gram stain culture, **deep SSI** detection model based on PWO selected more features from laboratory results (mean value of creatinine and maximum value of WBC) and two more microbiology tests (tissue and wound culture).

**Organ space SSI** models based on Single-task, PWO, and MTLP methods have quite similar detection performance and important variables. The selected variables include four features of bacteria type (streptococcus, gram positive cocci, enterococcus, and escherichia. coli), three microbiology cultures (abscess and fluid culture), and the imaging orders of treatment. Interestingly, the diagnosis code of sepsis and imaging orders of sepsis treatment are selected as well. These can be explained by the fact that there are over 30 patients in our cohort have sepsis and organ space SSI together.

**Overall SSI** detection models based on weighted observation and offset methods perform with no significant difference. The important variables selected are antibiotic use (UTI, superficial and deep SSI), microbiology cultures (abscess, fluid, and wound culture, and the gram stain test), two types of bacteria (escherichia. coli and staphylococcus) and two relevant order features (imaging orders for diagnosis and procedures of treatment).

Besides the diagnosis code and antibiotic use, **pneumonia** models based on Single-task and MTLP include two features from microbiology test (bronchial and sputum culture), one binary feature of image-guided diagnosis orders, and two aggregate features from lab tests (the mean value of PCAL and PH).

**UTI** models based on Single-task and MTLP selected diagnosis codes (for UTI), antibiotic use, placement of urine culture, and two bacteria types (proteus and escherichia. coli).

For **sepsis** models, the top performing methods, Single-task, PWO, and MTLP, selected features including antibiotic use, microbiology cultures (abscess, blood, fluid, and urine culture, and the gram stain), two bacterial types (enterococcus and escherichia. coli), and the image guided orders of treatment.

For **septic shock** detection, most models only selected diagnosis codes. However, PWO included more variables, such as laboratory tests (maximum value of partial thromboplastic time, PH, mean value of lactate), bacteria types (stentotrophomnas and staphylococcus) and the tracheal culture.

**Discussion**

Manual chart review for post-operative complications is very resource intensive. In this work, we examined whether EHR-based state-of-the-art predictive modeling approaches can learn characteristics of various types of complications and subsequently detect them reliably. With detection performances (measured as AUC) exceeding 0.8 for all complications and even 0.9 for some complications, the answer is affirmative: machine learning detection models definitely have the potential to help detect post-operative complications automatically. The question is which modeling approach is best suited for this application.

Post-operative complications are heterogeneous; they cover a wide-range of conditions, each having their own diagnostic methods, diagnoses codes, laboratory tests, and diagnostic and therapeutic procedures. They can be organized into a hierarchy and complications on the same level of the hierarchy are more similar to each other than to complications on a higher level of the hierarchy. Multi-task learning methods have the ability to exploit such similarities towards achieving better detection performance and more stable models even when the sample sizes are small.

We compared six approaches to building post-complication detection models. One of them was single-task learning, where we build independent models for each task; four methods were multi-task learning methods that can utilize the hierarchy of complications; and finally, we also utilized Partial Least Squares (PLS), which can simultaneously model multiple outcomes, but it tries to autonomously detect the relationship among the outcomes. PLS thus stands in sharp contrast with the other multi-task learning methods, as PLS automatically infers the relationships among the complications, while the other multi-task learning methods receive this information from an expert.

We found PLS to have the overall worst performance. This is not surprising, since PLS receives less information than the other multi-task learning methods. We expect PLS to bias the models based on the relationships among the outcomes, but we do provide it with these relationships. If PLS infers the relationships among outcomes incorrectly, it will bias the models incorrectly, eroding detection performance. With some of the complications having small sample sizes, it is unsurprising the PLS failed to infer the correct relationships. If we had substantially more samples,
Hierarchical modeling also had disappointing performance. The essence of hierarchical modeling is to build classifiers in a subpopulation that is greatly enriched in the outcome of interest. For example, distinguishing among the three types of SSI is easier in a subpopulation of SSI patients than it is in the general population. The performance of the method did not live up to our expectation for two reasons. First, while these outcomes are rare (deep SSI occurred in 76 patients out of 5280), they still occur in sufficient numbers for a Lasso-penalized logistic regression model. The second reason concerns the way the subpopulations were constructed. If the higher-level classifier (does this patient has SSI?) predicts the patient to be free of SSI, then this patient does not enter the subpopulation and the deep SSI detector has no opportunity to learn from this sample. We could have built the deep classifier on the true SSI patients (rather than the predicted SSI patients), but then the distributions of the training SSI patients (true SSI patients) and the test SSI patients (predicted SSI patients) would be different, leading to degraded detection performance. Our results with the Propensity Weighted Observations method tell us that the concept of enriching patients with SSI for (say) the deep SSI classifier is valid; the hierarchical method simply implemented this concept suboptimally.

The Propensity Weighted Observations (PWO) method achieved the overall highest performance with a margin that is statistically significant. PWO is closely related to the hierarchical method in that it enriches the training sample with patients who have the outcome of interest. In contrast to the hierarchical method, it achieves this enrichment through constructing a new sample, which is a propensity weighted version of the original population. For example, to identify patients with deep SSI, PWO uses the entire population, but patients with high propensity for SSI receive high weight and patients with low propensity for SSI receive low weight. The hierarchical method is a binary version of PWO, where the weights are either 0 or 1. Having the propensity weighted population removes the problem of excluding patients based on an incorrect prediction. Suppose our SSI classifier misclassifies a deep SSI patient as not having SSI. This patient will still be included in the training set for the deep SSI classifier; this observation will receive a slightly lower weight. Admittedly, using propensity score weighing for multi-task learning is rather unusual; we did not expect this method to perform so well.

The offset method, like PWO, always uses the entire population for classification. Its performance falls short of that of PWO, because its ability to remove heterogeneity is limited. It can bias a child model against the parent model, which helps with small sample sizes (it performed well on superficial SSI), but has limited effect on removing the variation in (say) normal patients. PWO is more effective at removing heterogeneity: patients with unrelated complications receive a low weight and contribute to the model only minimally.

MLTP is essentially identical to the offset method, except MLTP optimizes all outcomes simultaneously (as opposed to sequentially in a top-down manner). In a top-down construction scheme, only the parent task can influence the child task; the model from the child task cannot influence the parent model. When all tasks are carried out simultaneously, the child models can influence the parents, as well. As a result, MLTP was either the best or second best method for almost all rare (<3% of patients) outcomes. The caveat of simultaneous optimization is the increased potential for overfitting. Indeed, comparing MTLP’s cross-validated AUC scores on training set to those on the test set, reveal signs of overfitting. For example, to detect sepsis, it has a very high training AUC (>0.96), but the 95% CI of AUC on test set is only (0.8986, 0.9183).

Conclusion

Developing machine learned models to automatically detect post-operative complications definitely has the potential to accelerate the manual chart review process. We found that multi-task learning, specifically, the propensity weighted observations method, statistically significantly outperformed the single-task learning approach. While the difference in detection performance was relatively modest (albeit significant), the additional cost of implementing this method over the standard single-task learning method is minimal. Thus, we would recommend trying both single-task learning and PWO.

Our application was relatively easy: we had sufficiently many samples for Lasso-penalized logistic regression to construct a good model even for the most infrequent outcome. In an application, where fewer samples are available or outcome distributions are more skewed, we would expect the performance gap between multi-task learning and
single-task learning to open up, providing a more attractive implementation cost versus detection performance proposition for multi-task learning.

Our future work includes building postoperative complications detection models using both structured and unstructured EHR data. We hypothesize that the combination of structured and unstructured clinical data would include more significant indicators and signals of postoperative complications, and improve the performance of detection. The performance of the models with only structured data and that of the models with both structured and unstructured data will be compared and evaluated.

Abstract

Prediction of microscopic tumor spread to regional lymph nodes can assist in radiation planning for cancer treatment. However, it is still challenging to predict tumor spread. In this paper, we present a unique approach to modeling how tumor cells disseminate to form regional metastases. This involves leveraging well established knowledge resources and commonly held notions of how cancer spreads. Using patient data, we utilized our approach to create a model of metastasis for the subset of head and neck squamous cell carcinoma that arises in the mucosa of the lateral tongue. The model was created using a training set extracted from the clinical records of 50 patients with tumors of this type who presented to the University of Washington head and tumor board over a three and half year period. The test sets consist of four case series drawn from the literature.

Introduction

Head and neck squamous cell carcinoma (HNSCC) is the most common form of cancer of the upper aerodigestive tract. The mainstays of treatment consist of surgery and/or radiation therapy. Radiation therapy involves identifying the target region in the patient (the neoplastic area requiring treatment) and then customizing a treatment plan that achieves a therapeutic dose of radiation to this zone while minimizing the dose to the surrounding area. Reports from the International Commission on Radiation Units and Measurements (ICRU)\(^1,2\) define several kinds of volumes to guide radiotherapy planning. The Gross Tumor Volume (GTV) is defined as “the gross palpable or visible/demonstrable extent and location of malignant growth.” The GTV is typically defined using computer drawing tools on computed tomography (CT) or other imaging modalities by an attending physician. Even with the best imaging technique, the boundaries of such a volume may be very uncertain, and much clinical judgement is involved. The Clinical Target Volume (CTV) is defined as the volume that includes the GTV and/or microscopic malignant disease. At present, the radiation oncologist uses his/her knowledge of the pathology literature, clinical experience and knowledge of anatomy to draw the CTV. This leaves much room for improvement, in particular in the ability to predict the extent of subclinical microscopic disease.

Prediction of microscopic spread of tumor cells is becoming critically important in the decision making process of planning radiation therapy for cancer. Until relatively recently, standard radiation treatment of HNSCC incorporated relatively large treatment areas. With the onset of Intensity Modulated Radiation Therapy (IMRT), treatment can be more precisely applied, such that if it is known that regional spread is confined to a specific set of lymph nodes, a more focused treatment can be considered. The resultant payoff is reducing or eliminating the collateral damage due to over-irradiation of surrounding tissue. Imaging methods such as CT or magnetic resonance imaging (MRI) can only show evidence of gross disease that has caused enlargement of the lymph nodes. Functional scans, such as positron emission tomography (PET), can demonstrate smaller metastases, but even with PET imaging it is not possible to determine with certainty whether nodes are involved and should be treated.\(^7\) None of these imaging modalities can detect micro-metastases, which can currently only be confirmed post-surgery by pathologic evaluations of surgical specimens.

The initial work on this project\(^8,9\) showed that a model of tumor dissemination based on an anatomy ontology and some simple assumptions can produce predictions that have a fair agreement with published surgical data. The modeling strategy uses the idea of a Markov chain. Each lymphatic chain\(^1\) can be described in terms of the probability

\(^1\)We are using the term “chain” in two ways here. A lymphatic chain is so called because it typically consists of a series of vessels connecting several lymph nodes in a linear string. That unit as a whole is modeled as a Markov chain, meaning its state is represented as a stochastic process, or sequence over time.
for it to be in any of five possible states, numbered 0 through 4. State 0 means no tumors present. State 1 means a little tumor, state 2 somewhat more, and so on, to state 4 which is a big palpable node. The only way a lymphatic chain can go from state 0 to state 1 is by some tumor cells migrating downstream from the upstream chain, but once some tumor cells are there, they can transition to the states of larger growth on their own. The simplest way to think about the spread of tumor cells is to imagine that the process happens in discrete time steps. The tumor is in some initial state, and each lymphatic chain is as well. The states change with each time step.

The idea of a Markov chain is that a system can undergo state transitions. Lymphatic chains can go from state 1 to state 2, and so on, with some transition probability, and the probability that the system is in any state at time \( t + 1 \) depends only on the present state, the state of everything at time \( t \), and not the history of how it got there.

If each lymphatic chain were independent of all the others, the probabilities would form a state vector with five components, one probability for each possible state of the lymphatic chain could be in. For each possible transition we would have some probability, \( p_{ij} \), the conditional probability that the system is in state \( j \) at time \( t + 1 \) given that it is in state \( i \) at time \( t \). Strictly speaking, this transition probability can depend on time. Processes in which the transition probabilities do not depend on time are homogeneous. In such cases, the transition probabilities form a matrix, and the relation between the state vector at time \( t + 1 \) and the state vector at time \( t \) is just multiplication of the state vector by the transition matrix, to get the new state vector.

In this paper, we introduce a new Markov chain model for nodal spread of head and neck cancer using data by T stage, tumor site and nodal stage to flexibly compare the output with patient data from surgical pathology of head and neck cancer. We decided to use the lateral tongue as our primary site of interest because it was a primary tumor for which we had a relatively large group of patients (50 patients) with which to find the parameters of the model, and were able to identify a number of studies in the literature that contained data by both T stage and lymph node involvement. To evaluate the accuracy of the model derived from the patient data, we systematically compare the predictions of the model for against the results found in the literature data.

**Methods**

**Assumptions**

We make a number of simplifying assumptions in building the current model. We assume that lymphatic chains are not “skipped” so that if disease is present in the fourth chain in the lymphatic path from the primary site, it is also present in the first three. Although skips do occur, they are relatively infrequent.\(^{10} \) We assume that the process of primary growth and the process of dissemination from one lymphatic chain to the next are independent of each other and their rates are independent of time. Since the density of lymphatic channels varies greatly by primary sites, we assume that the probability of initial metastasis may be different for different first echelon lymphatic chains. However, as an initial simplifying assumption, once a tumor is within the lymphatic system, we assume that the probability of dissemination from one chain to the next along a lymphatic path is the same for all paths and all chains. We also make a simplifying assumption that the probability of growth from one T stage to the next is the same for all T stage transitions. We assume that the probability of diagnosing a tumor may change as the size and metastatic spread of the tumor increases. We start with these simplifying assumptions, and find out from comparing model predictions with data how to refine this set of assumptions as the model is further developed.

**Structure**

Instead of modeling each chain as having several states with varying amounts of tumor, and using the T-stage as a proxy for how many iterations to run in the initial model,\(^8 \) we propose a richer but simpler model: a single Markov chain that represents the patient’s disease status using two layers of two dimensional array of states, indexed by T-stage for the primary tumor location and by the number of steps of metastasis along a lymphatic pathway as illustrated in Figure 1. The T-stage can take on 4 values, 1-4, corresponding to the standard clinical definition of T-stage for HNSCC. The metastatic progression along the lymphatics can be 0 for no metastasis, 1 for metastatic disease present in the first echelon of lymphatic vessels, 2 for disease present in the first and second echelons, and so on. For example, a patient with T-stage 2 and metastatic progression 2 has a primary tumor clinically defined as stage 2 and metastatic disease in the first two echelons of regional lymphatic nodes.

This describes a dynamic process whereby at each step a tumor can either grow in size to a larger T stage, metastasize further down the lymphatic pathway, or stay in the same state. With this model, given enough time, all tumors will invariably end up as the largest size with the most extensive metastasis. Of course, this is not what is actually observed in the clinical setting; at some point in this process the tumor is diagnosed, evaluated and a therapeutic intervention initiated. The size of tumor and degree of metastasis at the time of evaluation and/or management is what is typically
reported in the literature or clinical record. In order to model this process, we added an emission layer for each state, representing the probability of the tumor being diagnosed at that state. Once in the emission layer there is no further tumor growth or metastasis (the tumor has been diagnosed and recorded.) This approach provides several advantages. It allows us to model a clinical process that is inherent in the patient and literature datasets that we use to train and test the model.

The transition matrix for this set of states can be thought of as a four dimensional matrix indexed by the initial T-stage and lymphatic path depth, and the final T-stage and lymphatic path depth. Only stepwise transitions are hypothesized so the transition matrix is mostly zeros, and can be represented by a sum of delta functions. The definitions of parameters used in our Markov model are as follows: $g$ represents the probability of primary tumor growth by one T-stage. $m$ represents the probability of metastasis one step further down the lymphatic path. $h_1$ represents the probability of initial metastasis from primary site to one of the first echelon lymphatic chains, the Submandibular LC (Level I) in Figure 2. $h_2$ represents the probability of initial metastasis from primary site to the Superior cervical LC (Level II) as demonstrated in Figure 2, which is both a first echelon lymphatic chain via one pathway and a second echelon lymphatic chain from the Submandibular LC. $f$ represents a linear function with two variables, $\alpha$ and $\beta$, the probability of moving from a node to its corresponding emission layer node.

We represent the probability of being in state $s, c$ at time $t$ as $P_{s,c}(t)$ and the Markov chain then consists of the successive time states, where each state can be computed from the previous state by Equation 1.

$$P_{s,c}(t + 1) = \sum_{i=0, j=0}^{s, c} M_{s,c,i,j} P_{i,j}(t)$$

The sum is only taken up to the state indices of interest, since there is no contribution from a higher T-stage to a lower T-stage and there is no contribution from a downstream lymphatic chain to an upstream one.

**Training set and test set**

For our training set, we used data abstracted from the records of 50 patients who presented to the University of Washington head and neck tumor board over a three and half year time period with an initial diagnosis of non-treated
Figure 2: Diagram of lymphatic drainage pathways for the Lateral Tongue Tract. Arrows indicate sequential dissemination of metastatic tumor cells through lymphatic chains (LC). 12, 13, 14

...squamous cell carcinoma of the anterior tongue (excluding specific tumors of the base of tongue or ventral tongue.) This provided a dataset. Primary tumor stage was taken from the tumor board report and nodal involvement from the review of pathology reports of neck dissections. In some cases of low stage tumors (T₁ or T₂) without radiographic or clinical evidence of nodal involvement and very low suspicion of metastasis, a neck dissection was not performed. In these cases we assumed the absence of nodal metastasis. While the number of patients in the training set is smaller than some of the literature datasets, the patient dataset contains discrete information about the involvement of each nodal level at each T stage.

In the patient dataset that we used as a training set, the rate of metastasis was reported as the number of patients with a given T stage that had metastasis to a particular level of the neck, along with the number of total patients with that T stage. However, any individual patient may have metastasis to more than one level. In order to compare our model to the dataset, we converted our state probabilities to an analogous measurement. For each T stage, we determined the probability that a given echelon was involved with tumor by adding the probabilities of all states that included metastatic involvement of that echelon.

For our test sets, we selected four studies from the literature that record aggregated values for nodal involvement and T stage distribution. These studies were typically performed to test the utility of treatment modality, not necessarily to describe the patterns of lymph node metastasis. We chose two studies (Dogan, Dias) 5, 6 that provided aggregated information on all four potential lymph node levels. We also chose two studies (Lim, Sparano) 3, 4 which provided aggregated information on Levels I-III only. This was due to the fact that these studies utilized a type of neck dissection that does not include Level IV, due to a clinical decision that the probability of metastasis in these patients was too low to warrant removal of these lymph nodes. In these studies, we assumed that if Level IV was not treated then it did not contain metastases. (This correlates with our assumption in corresponding cases in the patient dataset.) While these literature studies do not provide discrete information about each individual nodal level by T stage, they have the advantage of larger numbers in some cases. Since each study draws patients from a somewhat different distribution of T stages, different studies allow us to test the predictive ability of our model across different T stage distributions.

Finding parameters
In order to execute the model, we need the parameters of m, g, h₁, h₂, α, and β values, in which m represents the probability of further metastasis along the lymphatic pathway, g represents the probability of primary tumor growth to a higher T stage, h₁ and h₂ represents the probability of initial metastasis to the two potential first echelon nodes, and α and β are coefficients in a linear function that represents the probability of diagnosing a tumor in that specific state. The strategy of finding parameters was to execute the model with a set of possible cases with a training dataset and get the optimal case where the output matrix is closest to the training dataset. We then identified the parameters based on the output of the case.

To generate a set of possible cases, we used a single layer grid search with a combination of m, g, h₁, h₂, α, and β values with the following ranges: m, g, h₁, and h₂, between 0 and 1 with a step size of 0.05 and α and β between 0 and 1 with a step size of 0.025. This generated 326,922, 561 (≈ 21 × 21 × 21 × 21 × 41 × 41) cases. We then excluded...
cases if the sum of the probabilities of the outgoing edges from each node was not 1 (one of the Markov chain rules).

After that, we judged closeness of the output of the case and training dataset by calculating the root mean square (RMS) error using the Equation 2. The distance between our model output and the training data is smaller when the RMS error is small. Let $A$ and $B$ be a matrix, $a_{ij}$ and $b_{ij}$ is an element with row $ai$ and column $j$. $C$ is the number of echelons and $S$ is the number of $T$-stages.

$$rms(A, B) = \sqrt{\sum_{i=1}^{C} \sum_{j=1}^{S} (b_{ij} - a_{ij})^2}$$

(2)

**Execution**

We ran the model with four literature data as test datasets using the parameters, $m$, $g$, $h_1$, $h_2$, $\alpha$, and $\beta$, we found from a training dataset. We ran our model until the sum of the probabilities on the emission layer becomes greater than 0.99. Prior to running the model, the initial probability matrix $P$ used in the Markov chain model for the initial tumor site is given below:

$$P_{init} = \begin{pmatrix}
1.00 & 0.00 & 0.00 & 0.00 \\
0.00 & 0.00 & 0.00 & 0.00 \\
0.00 & 0.00 & 0.00 & 0.00 \\
0.00 & 0.00 & 0.00 & 0.00
\end{pmatrix}$$

$P_{11}$ has probability 1, indicating the site of our primary tumor. All other probabilities are 0, indicating that there is no prior metastasis or tumor growth. The model is then run for $n$ iterations where $n$ is the number of the states. The number of iterations was the number of the states because our model calculates the final probability for each state. For each iteration, the probability being in each state is calculated using the transition matrix that corresponds to our two-dimensional model as illustrated in Figure 1.

**Results**

**Parameters**

After systematic runs with a range of parameter values, we identified 18 out of 188,039 (top 0.01 percent) combinations of parameters, $m$, $g$, $h_1$, $h_2$, $\alpha$, and $\beta$, based on the RMS value. Since we aimed to find the parameters that fit most with a training dataset, The average values of the 18 sets of parameters are as follows: $m = 0.1473 \pm 0.0203$, $g = 0.325 \pm 0.0917$, $h_1 = 0.0278 \pm 0.0249$, $h_2 = 0.1667 \pm 0.0236$, $\alpha = 0.0014 \pm 0.0058$, and $\beta = 0.1889 \pm 0.0356$. The box plots in Figure 3 demonstrate the range and interquartile range of parameters, $m$, $g$, $h_1$, $h_2$, $\alpha$, and $\beta$. 

![Variability of parameters among 18 sets of parameters that fit best with a training dataset based on RMS values. $m$ represents the probability of further metastasis along the lymphatic pathway, $g$ represents the probability of primary tumor growth to a higher T stage, $h_1$ and $h_2$ represents the probability of initial metastasis to the two potential first echelon nodes, and $\alpha$ and $\beta$ are coefficients in a linear function that represents the probability of diagnosing a tumor in that specific state.](image-url)
Table 1: Comparison of our model’s predictions with patient data of the Lateral Tongue Tract when $m = 0.15$, $g = 0.4$, $h_1 = 0.05$, $h_2 = 0.2$, $\alpha = 0.0$, and $\beta = 0.175$. The numbers in the table demonstrate the number of patients for each site, one from our model and the other from the patient dataset.

Model validation

The model was validated using data from four previously published original articles. Similar to the internally collected data used to train the model, datasets from published article only contained patients data for their initial presentation and excluded recurrent cancer. External datasets report information on $T$ stage of the patient’s the as well as the anatomical nodal echelon of metastasis. Unlike internally collected data, the previously published data is sparse and incomplete therefore staging and nodal echelon data is reported in aggregate. Thus, the model is tested against the cumulative values across all T stage per nodal echelons and the cumulative values across nodal echelons per T stage. Of note, of the five external datasets, two come from studies that where patients underwent a supra-omohyoid neck dissection and level IV and V information is not available. Given the clinical rationale for a supra-omohyoid neck dissection (extremely rare metastasis to level IV or V) it is reasonable to assume a zero values for all level IV and V metastasis probabilities.

In order to test our model prediction, we produced an output after running our model using the following set of parameters that fit best with a training dataset: $(m, g, h_1, h_2, \alpha, \beta) = (0.15, 0.4, 0.05, 0.2, 0.0, 0.175)$. We obtained the number of patients for each site and compared it with one from the patient datasets as shown in Table 1. For comparing our model predictions with other external datasets, we calculated cosine similarity to measure the similarity between our model output and each external dataset using the Equation 3. The cosine similarity between our model output and the training dataset is closer when the cosine similarity approaches to 1. Given those two vectors, $A$ from our model output and $B$ from a training dataset, the cosine similarity is defined as follows:

$\cos(A, B) = \frac{A \cdot B}{\| A \| \| B \|}$ (3)

Table 2 shows cumulative values across all T stage per nodal echelons from our model output and each external dataset. With the cumulative values, we created two vectors, $A$ and $B$, each of which consists of cumulative values across all T stage per nodal echelons from our model output and external datasets, respectively. We then calculated the cosine similarity between our model output and each external dataset. Table 3 shows the cosine similarity values between our model prediction and each external dataset.

Discussion

We have proposed a novel Markov chain model for prediction of HNSCC tumor dissemination through the lymphatics of the head and neck. In establishing parameters, we focused primarily on a subset of HNSCC, the case in which the primary tumor arises in the lateral tongue region. As such, we were able to generate predictive probabilities using our
Table 3: Cosine similarity of our model’s predictions with one patient and four literature data of the Lateral Tongue Tract when $m = 0.15, g = 0.4, h_1 = 0.05, h_2 = 0.2, \alpha = 0.0, \beta = 0.175$. The values of cosine similarity are given.

model and validate them against known clinical data. Now that the foundations of our model have been established and tested, we can proceed in future work to expand the Markov chain model to include further subsets of HNSCC that arise from different primary sites in the upper aerodigestive tract. There are many such different permutations for metastasis along the lymphatics which we hope to ultimately be able to incorporate into an expanded version of our model. Additionally, we aim to refine our Markov chain model to account for factors such as potential contralateral tumor dissemination. Such factors could be addressed by adding new dimensions onto our existing array. Ultimately, once our Markov chain model is fully expanded, we hope to use it to accurately and precisely predict the extent of micro-metastases dissemination in all cases and subsets of HNSCC, thereby creating a powerful new tool that clinicians can use to provide necessary care to patients while minimizing the deleterious effects of over-irradiation.

**Limitations**

The primary site was chosen due to the relatively large number of patients in our dataset with anterior tongue primary tumors (not including the base of tongue.) Our model only considers ipsilateral metastasis. Contralateral metastasis can occur and we are working to incorporate bilateral metastases into our model. Our model does not include the possibility of skip metastasis. While skip metastases are relatively infrequent, we are investigating ways of incorporating the possibility of skip metastases into future models.

In regard to test and training sets, the literature datasets we used as test sets contain aggregated probabilities for both T stage and lymph node level. We compared the involvement of each nodal group in the test set to what was predicted by the model for the same T stage distribution of that test set. This is a limitation of the existing literature. The patient dataset we used does contain discrete (non aggregated) probabilities that we calculated for each T stage and lymph node level. However, the training set is relatively limited in size, which results in small numbers of observations particularly for more advanced tumors (since most tumors are treated before they reach an advanced stage.)

We assume that $m$ is the same but we could add other parameters that release this assumption. We realize that this is likely an oversimplification and the model may be able to achieve better performance with more variables. Increasing the number of variables with the current amount of training data runs the risk of overfitting. A reasonable assumption is that the probability of tumor metastasizing between different nodal regions may have somewhat different values. However, the probability of tumor metastasizing from one specific nodal region to another specific nodal region is likely independent of the primary site (since all of these tumors are of the same histologic type.) Our future work is to build additional models for different primary sites that share all or part of the same lymphatic drainage pathways. This will allow us to use additional data to fit specific parameters that represent the probability of metastasis between specific lymphatic chains.

We also assume that the probability of growth is a constant parameter. As above, this is likely an oversimplification. However, the TNM tumor stage has been designed to divide each primary tumor site into four “clinically relevant” divisions, which span different primary sites. We therefore felt that this was a reasonable simplification as increasing the number of growth parameters carries the same risk of overfitting described above.

A Novel Schema to Enhance Data Quality of Patient Safety Event Reports

Hong Kang, PhD, Yang Gong, MD, PhD
School of Biomedical Informatics, the University of Texas Health Science Center at Houston, Houston, TX, USA

Abstract

The most important knowledge in the field of patient safety is regarding the prevention and reduction of patient safety events (PSEs). It is believed that PSE reporting systems could be a good resource to share and to learn from previous cases. However, the success of such systems in healthcare is yet to be seen. One reason is that the qualities of most PSE reports are unsatisfactory due to the lack of knowledge output from reporting systems which makes reporters report halfheartedly. In this study, we designed a PSE similarity searching model based on semantic similarity measures, and proposed a novel schema of PSE reporting system which can effectively learn from previous experiences and timely inform the subsequent actions. This system will not only help promote the report qualities but also serve as a knowledge base and education tool to guide healthcare providers in terms of preventing the recurrence of PSEs.

Introduction

Retrospective analysis of health data holds promise to expedite scientific discovery in medicine and constitutes a significant part of clinical research. Informatics technology has helped improve the efficiency by replacing paper-based systems in many healthcare organizations and garnering rich health data. For example, dozens of patient safety event (PSE) reporting systems have been established to enable safety specialists to analyze events, identify underlying factors, and generate actionable knowledge to mitigate risks, such as PSRS (Patient Safety Reporting System) and AHRQ Common Formats (Common Definitions and Reporting Formats). These systems are initiatives to improve patient safety because data supports further learning and actionable knowledge. However, the success of such systems in healthcare is yet to be seen because the data quality could not reach the satisfying level. Therefore, maintaining the quality of healthcare data is widely acknowledged as problematic but critical to effective healthcare.

A PSE is any process, act of omission, or commission that resulted in hazardous health care conditions and/or unintended harm to the patient. Improving the data quality for PSE reporting systems is a challenging task since many factors are involved: inadequate management structures for ensuring complete, timely and accurate reporting of data; inadequate rules, training, and procedural guidelines for those involved in data collection; fragmentation and inconsistencies among the services associated with data collection; and the requirement for new management methods which utilize accurate and relevant data to support the managed care environment. Sometimes reporting systems cannot guarantee qualities because many reporters complete the task halfheartedly. For example, in the AHRQ Common Formats reports, we found more than 80% reporters tend to choose ambiguous options such as “Unknown” which are meaningless for learning rather than explicit “Yes” or “No” options. These systems will become redundant databases as more and more low-quality reports emerge, from which researchers cannot learn any experience from previous cases. Also, there is a lack of connections among different PSE resources due to the diverse report formats. Users have to spend plenty of time manually investigating helpful information from previous cases. Therefore, facing the gap that end-users cannot receive any perceived benefit during and after the reporting, there is an urgent need of a new generation PSE reporting system which can continually enrich the PSE knowledge base by annotating new reports and solutions according to their features, and provide all necessary information (e.g., solutions and prevention options) to the reporters’ cases by measuring the similarities of PSE reports. The quality of the reports will be improved consequently since reporters can receive “benefits” for their reporting rather than passively completing the tasks.

The primary challenge of the new reporting system is measuring the similarity of PSEs, specifically, how to calculate the similarity score between two PSE reports. Different fields provide diverse definitions for the term “similarity”, but there is still no an explicit definition in PSE domain. Based on the theory of cognitive science, such a system handles tasks in the case-based reasoning (CBR) cycle including retrieve, reuse, revise, and retain. Specifically, we firstly measure the similarity of the current problem to previous ones stored in a sort of database with their known solutions, then retrieve one or more similar cases and attempt to reuse the solution of one of the retrieved cases. The solution is assessed and revised before being proposed. At last, the problem description and its
solution is retained as a new case learned by the whole system to solve new problems. Therefore, the measurement should be based on an assumption that similar PSEs have similar solutions.

AHRQ Common Formats\textsuperscript{6} and International Classification of Patient Safety (released by WHO)\textsuperscript{12} defined incident types and event categories for PSE, which are widely accepted and commonly used in patient safety community. Recently, researchers are trying to develop new sets of categories in order to better serve the reporting. Nevertheless, the data formats of individual case were all in the form of ontology (a hierarchical data structure to manage terms and their relationships). Therefore, the comparison between two PSEs could be technically processed through semantic similarity measure as a function that, given two ontology terms or two sets of terms annotating two entities, returns a numerical value reflecting the closeness in meaning between the two\textsuperscript{13}. The semantic similarity algorithms have been generally applied in many fields, such as bioinformatics\textsuperscript{13-15}, geoinformatics\textsuperscript{16}, linguistic\textsuperscript{17} and natural language processing (NLP)\textsuperscript{18, 19}, etc. The Gene Ontology (GO)\textsuperscript{20} is the main focus of investigation of semantic similarity in molecular biology, because not only it is the ontology most commonly adopted by the life sciences community, but also comparing gene products at the functional level is crucial for a variety of applications. Numerous researches have demonstrated that the functional relatedness between genes products with GO annotations can be well measured by semantic similarity algorithms\textsuperscript{13, 21-25}, which provide major significance for gene function studies. Similarly, the patient safety community also need an approach to compare PSEs, then offer the users potential hints of solutions to current cases. Intuitively, the form of PSE seems similar to that of GO, since a number of taxonomies have been designed for labeling case through ontology annotations. Accordingly, the methods that work effectively to compare GO products might be also feasible when identifying similarities in PSEs. However, to our best knowledge, the semantic similarity algorithms have never been adopted and assessed in patient safety area.

In this study, we hypothesize that 1) the similarity between PSEs can be measured if they are annotated by the same ontology/taxonomy in patient safety domain, and 2) similar PSEs have similar solutions. We utilized and assessed the semantic similarity measures on the PSE datasets of AHRQ WebM&M (Morbidity and Mortality Rounds on the Web)\textsuperscript{26} and AHRQ Common Formats\textsuperscript{6}. Based on this model, we proposed a novel schema which can process the comparison tasks for PSEs and provide the reporters pertinent suggestions about solutions and prevention options for their cases. The schema will help develop a new generation of PSE reporting system which could improve the data quality of PSE reports by arousing the enthusiasm and motivation of reporters, and hold promise in preventing the recurrence and serious consequences of PSEs.

Method

Datasets of PSE Reports

AHRQ WebM&M: As a public assessable resource, AHRQ WebM&M Web site\textsuperscript{26} represents illustrative cases of confidentially-reported PSEs on the internet, accompanied by straightforward evidence-based expert commentaries. It also provides a taxonomy with 219 terms to describe the features of PSE from six perspectives: safety target, error type, approach to improving safety, clinical area, target audience and setting of care. Each case in the database has an individual set of annotations on this taxonomy labeled by experts. As of January 7, 2016, 366 cases have been posted on the site. The data size cannot hinder WebM&M from becoming an adequate resource for researching purpose because of the high-quality contents and the diversity of event profiles.

AHRQ Common Formats: AHRQ created the Common Formats to help providers uniformly report PSEs and to improve health care providers’ efforts to eliminate harm\textsuperscript{6}. The Common Formats is a group of standardized questionnaire-based forms with nine subtypes defined by PSO (Patient Safety Organization), including blood or blood product, device or medical/surgical supply including health information technology, fall, healthcare-associated infection, medication or other substance, perinatal, pressure ulcer, surgery or anesthesia, and venous thromboembolism. There is an individual questionnaire for each subtype which contains 10 to 30 single or multiple choice questions, or subjective questions. Missouri Center for Patient Safety (MCPS), a PSO institute and the collaborator of this study, started to collect real PSE reports from several hospitals in Missouri since 2008. So far the database has included more than 41,000 PSE reports. As part of the national level database, the data provided by MCPS can represent all PSE data of PSO program.

Semantic Similarity Measures

Semantic similarity assesses the degree of relatedness between two entities by the similarity in meaning of their annotations. There are two types of semantic similarity approaches when comparing terms, edge-based and node-based (Table 1). Edge-based approaches are based on counting the number of edges in the graph path between two
terms\textsuperscript{27}, for instance, the shortest path or the average of all paths. Correspondingly, node-based approaches focus on comparing the properties of the terms themselves, their ancestors or descendants. Information Content (IC), the most commonly used approach in GO studies, belongs to this category. IC gives a measure of information for every term and makes them comparable. Edge-based and node-based approaches are intended to score the similarity between two terms, and must be extended to compare sets of terms such as gene products and incident cases. Pairwise and groupwise approaches are the two types of strategies for this issue. Every term in the direct annotation set A is compared against every term in the direct annotation set B in pairwise approaches, then the semantic similarity is considered by every pairwise combination of terms from the two sets (average, the maximum, or sum) or only the best-matching pair for each term. Groupwise approaches calculate the similarity directly by set, graph, or vector. Set approaches are not widely used since they only consider the direct annotations that would lose a lot of information; based on set similarity techniques, graph approaches represent entities as the subgraphs of the whole annotations and calculate the similarity using graph matching techniques; vector approaches compact the information in vector space as binary fingerprints which are more convenient for comparison.

<td>Compare term combinations from a macro view instead of relying on integrating similarity between individual terms; time-saving.</td>
<td>Excessive choices could be a trouble.</td>
</tr>
</tbody>
</table>

We applied and compared three typical semantic similarity measures in this study:

**Information Content (IC).** As a classic node-based approach, IC gives a measure on how specific and informative a term is. Towards PSE reports, it assumes that a term with higher probability of occurrence may contribute less when measuring the similarity. In this study, the pairwise strategy which calculated the similarity for all pairs of terms and assessed them with average score was adopted. And we used Lin’s measure of similarity\textsuperscript{28} which accounts the IC values for each of term \( t_1 \) and \( t_2 \) in addition to the lowest ancestor shared between the two terms.

**Normalized Term Overlap (NTO).** NTO\textsuperscript{21} considers the set of all direct annotations and all of their associated parent terms. Theoretically, NTO might be applicable if the ontology of WebM&M data has been well defined and annotated. The only concern is that the depth of its tree structure is not deep enough which may decrease the comparison resolution. However, in order to further study the applicability of this typical graph-based groupwise approach, we also enrolled it in our assessment.

**Vector Space (VS).** VS compacts the annotations of a set of terms into a binary vector which is more comparable because the model is based on linear algebra with lots of mature algorithms which can measure similarity, such as cosine measure\textsuperscript{29}. Similar to IC, a variation of VS approach has been used in ontology-based similarity. The approach generates a weight for each term based on the frequency of its occurrence in the corpus, and then replaces the non-zero values in the binary vector with these weights. As the WebM&M cases are well annotated in an ontological structure, VS measure, a vector based groupwise approach, may be potentially applicable to measure the similarity between PSEs.

**Expert Review Based on 4-Point Likert Scale Measure**
To each query case, the semantic similarity algorithms ranked all the other cases in the database according to the similarity scores. A group of cases with the same interval were chosen from the rank for expert review. To assess the result given by the algorithms, we adopted a 4-point Likert scale measure which contains 1-irrelevant, 2-somewhat irrelevant, 3-relevant, and 4-highly relevant. Three experts were invited to label every case with one of the four scales according to the degree of similarity between this case and the given query case. After the experts completed the review, two rounds of discussion were opened for them to provide a final review result. If they cannot reach an agreement to certain case, the case would be labeled by a majority. The final expert result was treated as a golden standard. Any case that was labeled by either 1 or 2 in both expert’s result and algorithm’s result was regarded as “agreement” and judged as being irrelevant to the query case; conversely, the one that was labeled either 3 or 4 in both of the two results was also regarded as “agreement” but classified as being relevant to the query. The agreement ratio between final expert review and algorithm (sample agreement ratio) was calculated by dividing the numbers of agreement cases by the number of total cases. Then we randomly labeled the same group of cases for 10,000 times and calculated the agreement ratios respectively (random agreement ratios). To evaluate the performance of certain algorithm of the three, one sample t-test was adopted to examine the mean difference between the sample agreement ratio and the random agreement ratios mean (power analysis). The main steps of the evaluation are shown in Figure 1.

Figure 1. Performance evaluation for the similarity searching model. 1) A 4-point Likert Scale measure which contains 1-irrelevant, 2-somewhat irrelevant, 3-relevant, and 4-highly relevant was adopted; 2) Three experts labeled every case with one of the four scales according to the degree of similarity between this case and the given query case, meanwhile the model ranked the sample cases according to the similarity scores and labeled them with the four scales; 3) The sample agreement ratio was calculated by dividing the numbers of agreement cases by the number of total cases. 4) The performance of the model was evaluated by comparing the sample agreement ratio to the random agreement ratios.

Results

A Similarity Searching Model for PSE Reporting System

To provide solutions for a given PSE report, it should be figured out that which previous cases are similar to the given case. The similarity between PSEs can be measured by comparing their annotations on the same taxonomy. Similar annotations would obtain a high similarity score. AHRQ WebM&M is an appropriate dataset to implement and evaluate the similarity searching model since it provides a taxonomy with 219 terms to describe the features of PSE from six perspectives. In this study, to each pair of the 366 PSE reports, similarity scores were calculated by the three semantic similarity measures (VS, NTO, and IC) separately. As a result, three individual similarity matrices were generated to store all similarity scores.
We developed a local web server to present and evaluate the similarity searching model. Users can either report a new PSE or choose an existing case in the datasets of WebM&M or AHRQ Common Formats as a query case to initiate a similarity searching session. The server will calculate the similarity scores between the query case and every other case, and rank all these cases according to the scores (high to low). Figure 2 shows a screenshot of the similarity searching result when using one of the case in WebM&M named: *Ebola: Are We Ready* as a query. The similar cases calculated by VS method were presented on the right side with case topics, dates, and authors. When any case is selected by the user, its annotation will be presented on the left side. Any click on these terms will trigger a new searching session using the clicked term as a new keyword. The system also provides three action buttons on the right side of each similar case including: 1) *ask for details* (the paper icon), to show the details of this case, as well as the commentaries; 2) *choose as a query* (the magnifier icon), to launch a new similarity searching session using this case as a query; 3) *I agree* (the thumb up icon), to receive user feedback and improve the similarity matrices.

![Figure 2](image.png)

**Figure 2.** Similar cases of the query case “Ebola: Are We Ready?” calculated by the PSE similarity searching model (Vector Space method)

**Model Assessment via Expert Review**

We conducted a detailed study of the three semantic similarity algorithms based on AHRQ WebM&M taxonomy. Case 241, a typical event of nosocomial infections, was chosen as the test query. All the other cases were ranked by our similarity searching model according to the similarity scores, and there were 49 of overall 365 cases carrying nonzero similarity scores in the result list. We randomly extracted 15 cases from the ones with nonzero scores, and 5 cases from the rest, since we supposed the irrelevant cases may occupy 25% of the list according to the natural proportion of the 4-point Likert scale. Three experts with clinical experience reviewed and rated the 20 cases without implication. The result showed that the agreement of the three experts was 90% before the group discussion, and 100% after the first round of discussion. It was even more encouraging that the only two cases judged as “relevant” to the query by the experts have the highest similarity scores calculated by our model.

Further analysis was then processed to figure out the agreement between algorithms and experts. By comparing with random model, the VS model and NTO model reflect a significantly higher consistency with the experts’ review (Table 2). It is feasible and practical to apply semantic similarity model to measure the similarity of PSEs.

Recommending Solutions to Query Reports

We collected solutions for the most common PSE subtype, patient falls, which occurred about 700,000 to 1,000,000 times each year in U.S. hospitals\(^3\). The solutions were collected and curated from three resources: 1) Pennsylvania Patient Safety Authority Site\(^3\); 2) AHRQ WebM&M commentaries; 3) Staff of a PSO institute, Missouri Center for Patient Safety (via interviews). According to the 13 questions in the fall form of AHRQ Common Formats, the solutions of the fall events were divided into two categories: general solutions (applicable to any fall event) and specific solutions (applicable when certain answer options are chosen). Totally 15 general solution entries and 40 specific solution entries were refined as the solution dataset for fall events. In order to provide a succinct solution recommendation to the query case, we further grouped the general solutions into six subtypes: event reporting, education, patient monitoring, risk assessment, communication, and assistive devices.

---

**Figure 3.** Solution recommendation for a fall event reported in AHRQ Common Formats. The specific solutions are recommended dynamically according to the report options. E.g., the solution entry “Re-evaluate types of assistive devices used by the facility to prevent falls” was presented because the reporter chose “b. Ambulating with assistance and/or with an assistive device or medical equipment” to answer the Question 6.
As shown in Figure 3, when a user completed a fall report in AHRQ Common Formats (case ID 399), the system provided both similar cases and potential solutions for the user to switch at will. All the specific solution entries have been directly linked to the specific answer option(s), which means an entry will be presented only if the associated option(s) is(are) chosen during the reporting. For example, the solution entry “Re-evaluate types of assistive devices used by the facility to prevent falls” was presented because the reporter chose “b. Ambulating with assistance and/or with an assistive device or medical equipment” to answer the question what was the patient doing or trying to do prior to the fall (Question 6). The general solutions were presented for all fall events. In this way, reporters will spontaneously improve their reports since the quality of the reports relates directly to the quality of the specific solutions they received. It will be a win-win situation that reporters really learn something from the system, and the report quality gets improved.

Discussion

In this study, we proposed a novel workflow to improve the data quality of PSE reporting system, which includes seven key modules: data collection and management, algorithm implementation based on semantic similarity measures, expert review, agreement analysis, statistical test, user interface, and user feedback mechanism (as shown in Figure 4). Using fall events as an example, the proposed schema for PSE reporting system can process the comparison tasks and provide the reporters pertinent suggestions about solutions and prevention options for their reporting cases. The schema will be applied in all PSE subtypes in our future work. It will mend the gap that most current PSE reports are in low quality because the end users cannot receive any perceived benefit during and after the reporting. The task of learning and analyzing from previous experiences will be completed by the intelligent system instead of solely relying on healthcare providers. The more detailed users report, the more accurate suggestions they will receive. Such benefits would greatly enhance the quality of PSE reports. Moreover, the semantic similarity module was embedded into the reporting system which allows users to provide feedback such as whether they agree or disagree with certain similar case or solution by clicking a user feedback button. All the feedback will be returned to the algorithm implementation step and help update the weights of related similarity matrices. In this way, the performance of the similarity searching model will be improved dynamically. The model will be progressively stable and enhanced as the involvement through the users’ feedback.

Figure 4. The workflow to improve the data quality of PSE reporting system. Data collection and management, algorithm implementation based on semantic similarity measures, expert review, agreement analysis, statistical test, user interface, and user feedback mechanism are the key modules to improve the data quality of the proposed PSE reporting system.

A challenge of the future work is how to standardize PSE storage and management in order to overcome the lack of interoperability and communication. In this study, we found that PSEs can be compared to each other if they are managed by a hierarchical data structure (e.g., taxonomy) according to their characteristics. Therefore, our future plan is developing a knowledge base in patient safety domain to standardize PSE reports and solutions at the data
level. This standardization will make connections not only among diverse reporting formats but also between solutions and PSE reports. The solutions will be recommended based on the similar cases instead of answer options, which will make the recommendations more targeted. This plan is feasible and low-risk since we are not going to develop a brand-new knowledge base, instead, we will extend part of the terms and relationships defined by International Classification for Patient Safety (ICPS)\textsuperscript{35} to a knowledge base in patient safety domain. The ICPS is carried out under the World Alliance for Patient Safety of the World Health Organization (WHO). ICPS represents the knowledge related to PSE that occur to patients during hospital stays. For the time being, the representation has focused on falls and pressure ulcer incidents. To construct this knowledge base, we plan to extract the sub-classes including terms and relationships about PSE from ICPS. Then we will use Competency Questions (CQ), a classical method for designing and evaluating knowledge bases\textsuperscript{36}, which are interview questions that require candidates to provide real-life examples as the basis of their answers. Two reviewers with background knowledge in patient safety will participate in the CQ development. To each subtype of PSE, they will review a group of cases and generate the CQs. Each CQ must not be duplicated in its meaning with any of the others to the best of reviewers’ judgment. Then we will merge the CQs with the same meanings and break down the subdivisible ones. Thereafter, corresponding classes will be selected and combined with those extracted from ICPS, and a knowledge base describing each PSE subtype will be generated. The developing schema holds promise in improving patient safety and potentially triggering a revolution for data management and analysis in health care industry.

Clinical Decision Support Systems (CDSS) link clinical observations with health knowledge to assist clinical decisions\textsuperscript{37}. The systems influence clinician’s decisions and consequently enhance health-care quality. However, most CDSS suffer from common problems in usability, which have received significant attention in the patient safety community\textsuperscript{38-41}. Several subtypes of PSE are associated with clinical decisions, for example, a medication event may lead a drug-drug interaction. Therefore, in the future work, we will design several specific interfaces to CDSS, embed the key function models of our system to some widely used CDSS, and help detect potential risks at the early stage, thus provide better decision support and eventually improve patient safety.

**Limitations**

**Database** The main defect of AHRQ WebM&M dataset is the small sample size which comprises only 366 PSE reports by January 2016. The selection criteria are unclear, however, based on our observation, the cases in WebM&M may have been chosen as the most typical ones in each category. Taking patient fall as an instance, as the most common event type, it only has four records in WebM&M, which does not mean patient fall is infrequent, but rather indicates the other cases might be similar to the four typical samples and thus were not included by the experts. This is probably the main reason that the algorithm Information Content (IC) has the worst performance on this dataset. IC treats the frequency of each term as an important parameter that high frequency means low information content. This rationale does not apply to this experiment because the frequencies in WebM&M dataset cannot represent the real PSE distribution.

The limitation of AHRQ Common Formats is the low report quality. Many hospitals are using the Common Formats to report their events because of the requirement of PSO, which helps PSO collect a large sum of PSE reports. However, the quality of the reports is unsatisfactory since not all the reporters reported their cases spontaneously. We found that some reporters tended to choose the obscure options rather than the explicit ones which may cost more time to figure out the details. For example, reporters are more likely to choose the option “Unknown” if provided. Unfortunately, most “Unknown” choices are least meaningful for further analysis, and called missing values. This is consistent with our previous finding\textsuperscript{42}.

However, according to the status quo, these two report formats seem to be the best choices for this study since they are by far the only accessible PSE databases with hierarchical feature labels. We believe the quality of reports will be improved if reporters can really learn something from the system during and after their reporting. That is one of the reasons we propose this study.

**Assessment Strategy** All the assessments in this study were processed with the help of health care experts since there is no golden standard for PSE similarity. Each expert likely brings various biases on his/her different perspectives. For example, a clinician may judge the similarity between PSEs by measuring their severity, while a nurse may judge the similarity based on solution finding. The biases cannot be fully avoided. However, we provided more targeted introductions before every round of expert review, and adopted interviews rather than questionnaires in order to help the experts better understand our purpose.

**Conclusion**
Voluntary PSE reporting systems have a great potential for improving patient safety through wide adoption and effective use in healthcare. The similarity analysis of PSE is a key to the success of such systems. Focusing on the quality issue of current reporting systems, this study proposed a novel schema to improve the data quality by gathering information from previous experiences and informing subsequent action in a timely manner. Healthcare providers can learn how to avoid hazardous consequences and prevent their recurrence after they report their PSEs to our system. These benefits encourage the reporters to spontaneously provide reports with higher quality, since the more detailed they report, the more accurate suggestions they will receive. Furthermore, the schema holds promise in developing a new generation of self-learning PSE reporting system based on a standard knowledge base in patient safety domain. As the system being used by more organizations for a longer period of time, the internal knowledge base will become more intelligent, eventually provide better services.

Public Health Data for Individual Patient Care: Mapping Poison Control Center Data to the C-CDA Consultation Note

Aly Khalifa, Guilherme Del Fiol, MD, PhD, Mollie R. Cummins, PhD, RN, FAAN
University of Utah, Salt Lake City, UT, USA

Abstract

We are developing a new process of health information exchange supported collaboration that leverages the HL7 consolidated CDA standard through four document types (consultation note, history and physical, progress note and discharge summary). The focus of the present study is the C-CDA consultation note template that will be submitted from poison control centers (PCCs) to emergency departments (EDs) with treatment recommendations. Specifically, we aimed to (i) create computable mappings between a poison control center database and the C-CDA consultation note template; and (ii) assess the extent and nature of information types that successfully map to discrete data elements in a poison control center database. The resulting template and mappings can be used to implement standards-based health information exchange between PCCs and EDs in the U.S. This is a part of the first formal effort to leverage health information exchange standards to support PCC-ED collaboration.

Introduction

Poison Control Centers (PCCs) are responsible for handling poisoning cases all over the U.S.1. PCCs receive telephone calls from both the general public and healthcare facilities2, especially emergency departments (EDs). EDs ask for the consultations from PCCs via an iterative telephone call process, that carries a lot of inefficiencies and vulnerabilities that may greatly affect patient safety and the provided healthcare quality3. Therefore, electronic health information exchange (HIE) between EDs and PCCs is a promising and complementary alternative to the telephone-based approach4. The overall goal of our research is to enable standards-based HIE between PCCs and EDs to improve the efficiency and quality of care for poisoning cases.

Most PCCs use information systems that allow PCC staff to record information about and keep track of active poisoning cases. Although PCC information systems allow the Specialists in Poisoning Information (SPIs) to capture detailed information about poisoning cases, current PCC systems do not support standards-compliant HIE or implement document standards, such as the Health Level Seven (HL7) Consolidated Clinical Document Architecture (C-CDA)5. In addition, existing HIE standards provide no specific guidance to support PCC-ED information exchange. In previous studies, we developed a model for PCC-ED HIE, including: (i) identification and analysis of information types exchanged between PCCs and EDs via telephone calls6; and (ii) mappings between PCC information types and C-CDA documents, sufficient to support communication and information requirements in a poisoning care episode (i.e., referral request, consultation note, progress report, discharge summary)5,6.

The focus of the present study is the C-CDA consultation note that will be transmitted from PCCs to EDs. This document contains essential patient information along with poisoning case information and initial treatment recommendations. Specifically, we aimed to (i) create computable mappings between data elements in the Utah PCC system, an instance of the widely used PCC information system toxiCall67, and the C-CDA consultation note specifications; and (ii) assess the percentage of poisoning communication information types that could be successfully mapped to discrete data elements in toxiCall67. The resulting mappings can be used to guide the implementation of standards-based HIE for PCCs and EDs across the US. This is a part of the first formal effort to leverage HIE standards to support PCC-ED communication process.

Background and Significance

PCCs and their information systems. There are 55 PCCs that serve all 50 U.S. states and territories, 24 hours per day and 7 days per week1. The PCC staff who consult with the public and ED care providers on poison exposures are the SPIs, typically licensed pharmacists or nurses, and medical or clinical toxicologists. The American Association of Poison Control Centers (AAPCC) owns and manages the National Poison Data System (NPDS), to which all U.S. PCCs regularly upload a set of standard data elements describing human poison exposure cases8. These data are used
for epidemiology and surveillance. AAPCC produces an annual report on the aggregate statistics of NPDS data, in addition to providing specialized reports to national agencies\(^1\,^9\). A PCC uses one of four specialized information systems to support the tasks of data entry, retrieval and data transmission to the NPDS\(^10\).

**PCC-ED health information exchange.** Although the management of poisoning cases is an information and communication intensive process that can benefit from HIE, little has been done to enable HIE between PCCs and EDs. Previously, we identified important legal, operational, and clinical considerations in relation to PCC-ED HIE\(^4\). We also analyzed telephone conversations between poisoning specialists and ED staff to (i) identify inefficiencies and vulnerabilities\(^3\); and (ii) to identify and analyze the information requirements for ED-PCC collaboration\(^6\). In a current study funded by the Agency for Healthcare Research and Quality (AHRQ), our goal is “to develop, implement, and evaluate a replicable, scalable infrastructure for HIE supported ED–PCC collaboration”\(^11\). The project started in September 2013 and is expected to complete in September 2018.

**PCC-ED HIE and the C-CDA standard.** C-CDA is an HL7 messaging standard that specifies a common structure and content for electronic clinical documents, according to document type, e.g., history and physical note vs. discharge summary. The ultimate goal of the C-CDA standard is to make a document that is both human and machine readable by combining narrative blocks with coded entries\(^12\). Extensible Markup Language (XML) is used to represent the document content in a structured, computable way. Viewed through a styling sheet (i.e., XSL file), this XML file is formatted for human reading, without visible XML markups\(^13\).

Generally, a C-CDA document is divided into two main parts, the document header and the document body. The C-CDA header contains metadata about the healthcare encounter and information necessary for document housekeeping and management. Specifically, the C-CDA header includes patient demographics, document author(s), document recipient, document type, patient encounter, and document type. The document body represents the clinically relevant information, structured within a set of sections that are specific according to the C-CDA document type.

The C-CDA standard is an implementation guide that includes specifications for 13 C-CDA document types\(^12\). The specification provides a library of templates that can be used to support various HIE use cases. The detailed constraints on document and section levels are provided within the C-CDA Implementation Guide\(^12\). In a previous study, we linked our proposed PCC-ED information exchange events to four C-CDA document types; and mapped poisoning information types identified in previous work to specific C-CDA sections. The four identified C-CDA document types are Consultation, History & Physical, Progress Note and Discharge Summary\(^5\). The present study builds on our previous work by providing physical mappings between a PCC information system (toxiCall\(^6\)) and the C-CDA Consultation Note document type, which is a necessary step towards the interoperability between PCC and ED information systems.

**Methods**

The approach used in this study consisted of three main steps. First, we developed consultation note mockups and sample documents containing the required information content, as determined in previous studies\(^5\,^6\). Second, we developed a computable mapping between the C-CDA schema (conforming to consultation note constrains) and the Utah PCC database, an instance of toxiCall\(^6\). Last, we assessed the percentage and nature of information types that successfully mapped from the PCC database to the C-CDA. An overview of the steps and their sequence is depicted below (Figure 1) where each step is labelled by a letter and these letters are used in the following paragraphs.

**Mockups and sample document.** Mappings between the information types and consultation note sections were previously established (Step - A)\(^5\). We elicited preferences for information content and presentation format from emergency medicine physicians at our collaborating sites. Based on the mappings and physician preferences, we developed two sample mockups using HotGloo prototyping tool (Step - B)\(^14\). The mockups were then validated by SPIs, ED clinicians and project members to ensure that the content of the consultation note meets their needs. We collaborated with these users to make iterative changes to the design, then manually developed a sample consultation note XML file, and validated that file according to the C-CDA R2.1 Implementation Guide and its schema (Step - C)\(^12\). This sample document was valuable as it identified the actual location of data within the document XML structure, especially for the document header part that was not represented within the initial mapping\(^5\).
PCC database and computational mapping. The Utah PCC provided us with access to a copy of their database, an instance of toxiCall®. Filled with a small set of anonymized patient data. The data were anonymized by replacing all patient demographics, SPI related information and identifiers with fictitious information. Therefore, we identified tables that contain the required information for the C-CDA Consultation Note (Step - D); and created mappings between the PCC database and C-CDA Release 2.1 XML schema (Step – E)12, with the permission of Computer Automation Systems, Inc7. We created the mappings using Altova MapForce® version 2016, which allows mappings between different data sources and targets through a graphical user interface15. The mapping process consisted of “dragging and dropping” toxiCall® database fields to the corresponding elements and attributes in the C-CDA Release 2.1 XML schema. We used custom data transformations to map data from multiple source tables and columns to a single element within the XML structure and to represent them in a proper format.

Once the mapping was completed, we used Altova MapForce® to automatically generate consultation notes for the anonymized case records. We validated these instances against the C-CDA schema and the NIST online validation toolkit, (Step - F)16. Also, a human validation was done by the study co-authors and collaborators from the Utah PCC and EDs (Step – G). For human validation, we transformed the documents into HTML using the Extensible Stylesheet Language (XSL) style sheet provided with the C-CDA R2 Implementation Guide12. Once validated, we used Altova MapForce® to automatically generate source code for the mappings in the Java programming language. The Java code was then wrapped with a RESTful Web services layer to be integrated with other systems.

Extent of structural mapping. For comparison with previous efforts, we calculated the percentage of information types that successfully mapped to the C-CDA from the Utah PCC database. For this calculation, the information type was considered to be present when it was available in a discrete (non-narrative) form within the PCC database, and not present otherwise. For data found to be not present, we identified potential alternative sources such as poisoning knowledge bases and additional data entry fields to be collected by SPIs. Details on alternative sources are subject for a future study. The information content to be used in the C-CDA header was not considered in this analysis as the focus was on clinical information requirements represented in the C-CDA body.

Figure 1. Mapping of PCC database fields to CDA R2, in the context of C-CDA consultation note development
Results

Mockups and sample document

Figure 2 shows a sample mockup of a PCC consultation note for a poisoning exposure due to snake bite. This mock-up includes additional HTML formatting within sections, to implement ED user preferences related to information presentation. Figure 3 shows the manually developed XML consultation note, rendered in HTML format. The actual XML file is available at (https://github.com/alykhalifa/PCC-ED-C-CDA-Consultation-Notes). The header section contains metadata such as patient demographics, document author, intended recipient and encounter information (e.g., data and time of the call). The body contains 8 sections: (i) reason for referral; (ii) chief complaint; (iii) history of present illness; (iv) general status; (v) assessment; (vi) plan of care; (vii) past medical history; and (viii) medications. The history of present illness section contains information about the poisoning exposure such as poison information and observed symptoms. The assessment section consists of two main parts. The first part contains patient-specific information, while the second part contains general information about the poisoning exposure itself, such as its toxic dose, common effects and the time to peak concentration. The plan of care section consists of three main parts: (i) recommended diagnostic testing and monitoring; (ii) recommended observation time; and (iii) supportive care. The other sections contained standard information as defined in the C-CDA standard. The sample XML document was successfully validated with no errors using the C-CDA R2.1 schema and the NIST online validation toolkit16.

![Poisoning Consultation Note](image)

---

**Figure 2.** Mockup of a consultation note for a poisoning due to snake bite.

---
Figure 3. Sample C-CDA Consultation Note rendered in HTML format using the XSL style sheet provided with the C-CDA R2.1 standard specification.

**PCC database and computational mappings.**

Mappings between the C-CDA standard and the Utah PCC database, an instance of toxiCall® involved 8 tables and over 250 columns in the PCC database. Out of 38 information types needed to create a C-CDA compliant consultation note that supports poisoning communication, 21 (55%) successfully mapped to discrete fields within the PCC database. Seventeen information types did not successfully map. We defined over 130 constant variables within Altova Mapforce® to support required elements and attributes according to the Consultation Note C-CDA R2.1 constraints.

Table 1 shows the information types that successfully mapped, along with associated data transformations, where “D” means retrieval of code label from the code dictionary table, and “MC” means collection of required information from multiple columns in the PCC database. Table 2 shows the information types that did not successfully map. A snapshot of the auto-generated consultation note is shown on Figure 4. The validation of the generated documents against the C-CDA R2 schema and through the NIST online toolkit showed no errors or warnings, and was validated by domain experts, with only minor, iterative adjustments. The actual mapping file and the generated Java code are available upon request, with the permission of Computer Automation Systems, Inc., as they contain some information proprietary for toxiCall®, while the generated sample consultation notes are available at (https://github.com/alykhalifa/PCC-ED-C-CDA-Consultation-Notes).
One of the challenges faced during the mapping process is that data for a single information type may be present over multiple tables and columns. For example, recommended therapies and interventions are scattered over 68 columns, where each column represents a single therapy/intervention that may be set to certain numeric values if recommended, or left as null otherwise. A user-defined transformation function was developed using Altova MapForce® to identify columns with numeric values, parse their column name (i.e., the treatment name), and instantiate a corresponding treatment instance in the C-CDA R2.1 format.

Discussion

In this study, we mapped a large proportion of the information content necessary to support poisoning communication from a PCC database to the HL7 C-CDA consultation note. The mappings are an important step towards enabling standards-based HIE between a proprietary system (i.e., toxiCall®) used by most PCCs in the US and various EHRs available at emergency departments. These mappings serve two main functions (i) identify existing data sources to automatically populate the consultation note, and (ii) identify informational gaps that need alternative input sources (e.g., data entry fields and/or a poison knowledge base). The Utah PCC information system (like most) was primarily designed to support the public health mission of poison control centers, namely case documentation and collection of NPDS data elements for the purpose of surveillance and epidemiology. PCC information systems are not designed for interoperability or communication with healthcare facilities. Therefore, much of the information needed by the ED clinicians is either orally conveyed through telephone calls and/or documented within a combined narrative field of the PCC database.

This clinically relevant information includes the expected common effects of the poison, time to peak concentration of the poison, more detailed plan of care, history of past illness, and past/current medications taken by the patient. Also, some information currently collected by this PCC lacks adequate detail of structure for the C-CDA. For example, patient age is stored within the PCC database, but the C-CDA requires date of birth. In anticipation of HIE, the Utah PCC has managed to solve these issues via workarounds. For example, date of birth is being collected in a generic PCC database field. However, a more standard approach to collecting information essential to HIE processes, such as date of birth, is preferred. Furthermore, some of the successfully mapped information types (e.g., clinical effects) may need to be presented in a more expressive form in order to be sufficiently meaningful for clinical use. In this case, some potential alternative sources (e.g., additional data entry fields and a poison knowledge base) may be used to provide this intended level of expressiveness, which is the same approach proposed for handling unsuccessfully mapped information types. As a solution, we are currently developing software that enables poison centers to create and send CCDAs using both template narrative data and coded data contained in the Utah PCC database. That software is currently under development and testing.

The PCC database consists almost entirely of NPDS data elements, data elements collected by all U.S. PCCs, and all of the database fields that successfully mapped to the C-CDA represent NPDS data elements. Given the public health oriented nature of PCC data, it is not surprising that many of the information types necessary to support communication
and collaboration in the context of a poison exposure cannot be mapped. However, the capability to partially construct a C-CDA document using the PCC database greatly lowers the manual effort required for data entry on the part of PCC specialists. This would save a lot of the time needed by the SPI to generate the consultation note, and ensure its validity and accuracy, directly supporting rapid communication in these emergency situations and improving usability for the SPIs. Moreover, since the mappings correspond entirely to NPDS data elements, they may potentially be adapted for use by any U.S. poison control center. The Utah PCC database is a local instance of one vendor solution for poison control centers, toxiCall®. U.S. PCCs use one of four different information systems. However, all U.S. poison control center information systems collect NPDS data elements and support the same essential clinical workflow/domain, and so there is some de facto standardization and similarity among different poison control center information systems. The AAPCC, the owner of NPDS, specifies the required data elements and has the authority to add or modify data elements. However, the purpose of NPDS is to support surveillance and epidemiology, and AAPCC hasn’t yet addressed interoperability in support of direct patient care.

This study has three main strengths that support generalizability of the results. First, we involved the intended users of the consultation note during design, development, and validation. Second, we validated the generated consultation notes using both human (i.e., intended users) and machine approaches. Third, the PCC database is an instance of toxiCall®, a widely used system among U.S. PCCs, and all mappings involved NPDS data elements. All U.S. PCC systems are NPDS complaint, so the developed mapping can be implemented or adapted for implementation at most PCCs with minor adjustments, providing an important building block for a nationwide PCC-ED HIE. A limitation of the mapping is the absence of coded entries in the generated consultation note. We conducted the mapping using the CDA level 2 conformance, which does not specify these coded entries, and therefore limits computation for purposes such as clinical decision support and analytics. Nevertheless, the mappings are a critical step towards enabling HIE between PCCs and EDs to support the care of patients exposed to poisoning.

The current telephone-based ED-PCC collaboration process contains safety vulnerabilities and inefficiencies and there is an evident need for better access to PCC consultation information by other healthcare providers, which is not limited to US PCCs. U.S. PCCs are not alone in facing challenges related to interoperability. An identified top barrier for achieving meaningful use stage 3 criteria among primary care practices is suboptimal HIE capabilities. Where a main challenge for realizing effective HIE is the lagging effort in deploying HIE standards. This project created an important building block to achieving HIE for U.S. PCCs by bridging a gap between PCC data and existing HIE standards. Ongoing efforts are now focused on: (i) mapping free-text entries and NPDS codes to standard terminologies (e.g., SNOMED-CT, RxNorm); and (ii) integrating the generated mapping as a module within software that supports the creation, sending, and receipt of HL7 C-CDA documents.

**Conclusion**

As a step toward standards-based HIE between PCCs and EDs, we mapped fields within a PCC database to corresponding fields of the C-CDA consultation note, according to previously defined information requirements. Much of the data was readily available in a discrete form within the PCC database, while other data were available only as part of a combined narrative field, or not at all. We validated the generated notes for their conformance to the C-CDA R2 standard and fulfillment of ED and PCC clinical information needs. The resulting mappings are an important step towards national adoption of HIE between PCCs and EDs. Ongoing efforts include integration of the mappings as a module within software that supports the creation, sending, and receipt of HL7 C-CDA documents.

Abstract

Depression, despite its high prevalence, remains severely under-diagnosed across the healthcare system. This demands the development of data-driven approaches that can help screen patients who are at a high risk of depression. In this work, we develop depression risk prediction models that incorporate disease co-morbidities using logistic regression with Elastic Net. Using data from the one million twelve-year longitudinal cohort from Korean National Health Insurance Services (KNHIS), our model achieved an Area Under the Curve (AUC) of the Receiver Operating Characteristic (ROC) of 0.7818, compared to a traditional logistic regression model without co-morbidity analysis (AUC of 0.6992). We also showed co-morbidity adjusted Odds Ratios (ORs), which may be more accurate independent estimate of each predictor variable. In conclusion, inclusion of co-morbidity analysis improved the performance of depression risk prediction models.

Key words: Depression, Risk Prediction Model, Co-morbidity, Korea National Health Insurance Services Longitudinal Cohort Data, Chronic Conditions Data Warehouse (CCW) Condition Algorithms, Logistic Regression, Least Absolute Shrinkage And Selection Operator (LASSO), Elastic Net

Introduction

Depression is a highly prevalent disease with a large societal burden. Major depressive disorder has the one-year prevalence of 6%, and the lifetime prevalence of 17%³, while persistent depressive disorder (dysthymia) has the one-year prevalence of 2%, and the lifetime prevalence of 3%⁴. The estimated societal burden of unipolar depression was 83 billion dollars per year in the US alone in 2007⁵.

However, despite this burden, depression is under-diagnosed at large across the healthcare system in all care settings. A meta-analysis in 2009 concluded that the weighted sensitivity of primary care physicians’ diagnosis on depression was only about half (41.3-59.0%) without the assistance of screening tools⁶. This lead to the under-diagnosis or delayed diagnosis of depression, because many of depressed patients initially present with somatic symptoms to the primary care clinics. In general, 69-73% of depression patients presented to their primary care physicians with somatic symptoms, such as pain, fatigue, and sleep problems⁷.

Data-driven risk prediction models can be beneficial by rapidly classifying high-risk patients who need further evaluation. Risk prediction models can be implemented on Electronic Health Record system (EHRs) in order to provide high-risk alert, as well as clinical decision support. Risk prediction models can also be implemented in health insurance claims data in order to classify high-risk patients, and can be used for accountable care strategy⁸.

Previous work on the prediction modelling of depression include a regression-based depression risk prediction model based on Electronic Health Record data, developed at Stanford University, which reported an area under the receiver operating characteristic (AUROC) of 0.80 for current classification, 0.712 for 6-month prediction, and 0.701 for 12-month prediction⁹. Another work of the depression risk prediction model based on clinical trial data, developed at University of Southern California, reported to have a current classification with an AUROC of 0.81, as well as a sensitivity of 0.65 and a specificity of 0.81 at the institution’s optimized threshold⁹.

However, both these approaches did not explicitly apply co-morbid medical conditions as independent predictors in the depression prediction model. Many medical conditions can affect depression, and depression can also affect certain medical conditions¹⁰. Therefore, application of co-morbidity analysis can improve the performance of the risk prediction models.

Hence, our main hypothesis and the research question to be addressed in this study was whether the co-morbidity analysis can improve the performance of prediction models for depression risk. Our preliminary results indicate that the inclusion of co-morbidity analysis improved the performance of depression risk prediction model.
Study Setting and Data

In this study, co-morbidity analysis and risk prediction modeling was made from one million twelve-year longitudinal data from Korea National Health Insurance Services (KNHIS)\textsuperscript{11}. The sample cohort (N= 1,025,340) was established in 2002 from 2.2% of 46,605,433 individuals from the National Health Information Database, in order to provide public health researchers and policy makers with representative information regarding the utilization of health insurance and health examinations\textsuperscript{12}. The data include demographic profile, health insurance claims data (including in-patient, out-patient, and pharmacy claims), death registry, disability registry, and national health check-up data. With the combination of 18 age groups, 2 genders, and 41 income groups, total 1476 strata were undergone systematic stratified random sampling with proportional allocation\textsuperscript{13} within each stratum, using the individual’s total annual medical expenses as a target variable. During the follow-up years, annual drop-out by death was 0.5% (ranging from 4,929 to 5,229). Each year, a representative sample of newborns (ranging from 7,782 to 9,581), sampled across 82 strata (2 for gender, 41 for parents’ income group), was added to ensure the representativeness of the data.

The diagnosis codes in KNHIS are based on the Korean Classification of Diseases, Sixth Revision (KCD-6), which is compatible with International Classification of Diseases, Tenth Revision (ICD-10). These diagnoses were classified with Chronic Conditions Data Warehouse (CCW) Condition Algorithms (rev. 01/2016) by Centers for Medicare & Medicaid Services (CMS)\textsuperscript{14}. The CCW condition category algorithms are claims-based algorithms to indicate whether treatment for the condition appears to have taken place, which include 27 chronic condition categories and 33 other chronic or potentially disabling conditions categories. Table 1 shows the ICD-10 codes of the depressive disorder, bipolar disorder, schizophrenia in the CMS-CCW algorithm. The ICD-10 codes for depressive disorder, bipolar disorder, schizophrenia were used in the operational definition of the depression case group in this study. The study subjects had two or more encounters with depression diagnosis codes, but less than two encounters with either bipolar or schizophrenia diagnosis codes. The inclusion and exclusion criteria is based on the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)\textsuperscript{15}.

The univariate and bivariate statistics of selected demographic and co-morbidity variables between the depression case group (N=28,256) and complement comparison group (N=1,085,400), based on the operational definition of the case group described in the method section, are shown in Table 2. The case group showed significantly higher percentage of females (68.1%), age (mean 48, standard deviation 19), income decile (mean 5.8, standard deviation 2.5), limb disability (3.3%), neurologic disability (0.9%), visual disability (0.7%), hearing disability (0.6%), but showed significantly lower percentage of social security beneficiaries (1.0%). The case group showed no significant difference in the percentage of residents in Seoul metropolitan area, and cognitive disability. Most of the co-morbidity variables showed statistically significant difference between the case group and comparison group, except cerebral palsy (p = 0.121). The most noticeable difference in the co-morbidity by the ratio of percentage (twelve-year prevalence) was personality disorder (0.9% vs 0.1%), followed by anxiety disorder (31.8% vs 4.9%), dementia & Alzheimer’s disease (2.0% vs 0.4%), and osteoporosis (5.2% vs 1.3%).

Analytic Approach

The operational definition of diagnosis of depression was analyzed in a logistic regression model with socio-economic and co-morbid predictors. Among the available socio-economic variables and co-morbid conditions in KNHIS data, variables for the final logistic regression model was selected with Elastic Net\textsuperscript{16}. The performance of the final logistic regression model with co-morbidity analysis was compared with that of the traditional logistic regression model without co-morbidity analysis.
When the number of predictors is large compared to the sample size, traditional variable selection methodologies may have poor prediction performance for external datasets by overfitting random error or noise, and it has been criticized that the goodness of fit\textsuperscript{17}, significance\textsuperscript{18}, and degrees of freedom\textsuperscript{19} do not reflect the reality. In order to overcome this problem, regularization and shrinkage methods for regression have been developed\textsuperscript{20}. Elastic Net is a regularization method for regression and classification models which compromises the Least Absolute Shrinkage And Selection Operator (LASSO) penalty (L\(_1\)) and the ridge penalty (L\(_2\))\textsuperscript{16}. The LASSO (L\(_1\)) penalty function performs variable selection and dimension reduction by shrinking coefficients, while the ridge (L\(_2\)) penalty function shrinks the coefficients of correlated variables toward their average. The overall Elastic Net is a function of parameters \(\lambda\) and \(\alpha\) (\(0 \leq \alpha \leq 1\)), where \(\lambda\) being a parameter for the level of penalty, while \(\alpha\) being the weight of L\(_1\) penalty and \((1 - \alpha)\) being that of L\(_2\) penalty function. Hence, in this work, we performed variable selection and penalization of collinear predictors by Elastic Net for developing the final logistic regression model.

A robust way to determine the best combination of \(\lambda\) and \(\alpha\) is via a k-fold cross-validation. For the validation of the predictive model, 10\% of the data (\(N = 111,366\)) was set aside as a test data, and 90\% of the data was used as a training data (\(N = 1,002,290\)). We used 10-fold cross-validation on training data, where total observations of the dataset are randomly divided into 10 folds, or partitions. One of the 10 folds is reserved as the internal validation data (\(N = 100,229\)), and the rest of the folds consist the internal training data (\(N = 902,061\)), where statistical models are fitted. After fitting the models, or calculating the coefficients, the models are validated against the reserved fold. This overall process is iterated (repeated) 10 times, so that each fold can be a validation set. This is a preferred method especially when the prediction models need to perform prediction for external datasets, that is, outside of the overall dataset used in the research.

The variables for the traditional logistic regression model without co-morbidity analysis was driven by performing the stepwise backward selection using Akaike’s Information Criterion (AIC)\textsuperscript{21}. The selected variables for the traditional logistic regression model include sex, age, income decile, and disability registration. The variable selection for the final logistic regression model was applied with Elastic Net from the training data, as described above. The selected value of \(\alpha\) was 0.75, and the optimized values of \(\lambda\) was 0.001390648 (\(\log(\lambda)\) -6.577986), although other \(\alpha\) values, including 0.25, 0.5, and 1, did not change the results much. The plot obtained from cross-validation of Elastic Net, showing the change of the Area Under the Curve (AUC) of ROC with different \(\lambda\) (in log scale) for a model assuming an \(\alpha\) of 0.75, is shown in Figure 1. This gives a minimum of 28 variables needed for building an optimized model. Two more variables, acute myocardial infarction and dementia, were added to the final model, because even though those conditions were separated by the CMS-CCW algorithm, the conditions were in spectrum with ischemic heart disease and Alzheimer’s disease, respectively. Therefore, 30 variables were selected for the final logistic regression model. These variables include: sex, age, income decile, acquired hypothyroidism, acute myocardial infarction, Attention Deficit Hyperactivity Disorder (ADHD) and conduct disorder, Alzheimer’s disease, anemia, anxiety disorder, arthritis, atrial fibrillation, brain injury, chronic kidney disorder , colorectal cancer, chronic obstructive pulmonary disease (COPD), dementia, diabetes, epilepsy, glaucoma, hearing impairment, hyperlipidemia, ischemic heart disease, liver disease (except viral hepatitis), migraine and chronic headache, mobility impairments, osteoporosis, peripheral vascular disease, personality disorders, stroke and transient ischemic attack (TIA), and viral hepatitis.

In order to get more robust Receiver Operation Characteristics (ROC) that reflect the prediction performance also for external datasets, another layer of validation on the test data (\(N = 111,366\)), which was set aside and unseen during the training phase, was applied to derive ROC. With the variable selected via Elastic Net, we developed a final logistic regression model with co-morbidity analysis, and obtained the ROC of the final logistic regression model with co-morbidity analysis on the test data. We then compared the ROC with that of the traditional logistic regression model without co-morbidity analysis. R version 3.1.3\textsuperscript{22} with R software packages, glmnet\textsuperscript{23}, and pROC\textsuperscript{24} were used for this study.
Table 2. Univariate and bivariate statistics of selected demographic, socio-economic, disability registry and co-morbidity variables between the depression case group (N=28,256) and complement comparison group (N=1,085,400). For categorical variables, the observed frequencies of the categories and percentages (twelve-year prevalence) were reported, and for numerical variables, means (and standard deviations) were reported. P-values were of chi-square tests for categorical variables, and t-tests for numerical variables.

Results

The Odds Ratio (OR) plot for the traditional logistic regression model without co-morbidity analysis is presented in Figure 2(a) and the same for the final logistic regression model with co-morbidity analysis in Figure 2(b). It is noticeable that adjusted ORs for the same variables differs between the two models. For example, the adjusted OR of being female is 2.07 from the traditional logistic regression model without co-morbidity analysis, but is 1.63 from the final logistic regression model with co-morbidity analysis. Likewise, the adjusted OR of age is 1.03 from the traditional logistic regression model without co-morbidity analysis, but is 1.01 from the final logistic regression model with co-morbidity analysis. Finally, the adjusted OR of income decile is 1.04 from the traditional logistic regression model without co-morbidity analysis, but is 1.02 from the final logistic regression model with co-morbidity analysis. The ORs for the disability registration variables in the traditional logistic regression model without co-morbidity analysis ranged from 1.03 (cognitive disability) to 1.42 (hearing disability). The ORs for the co-morbidity variables in the final logistic regression model with co-morbidity analysis ranged from 0.78 (acute myocardial infarction) to 5.81 (ADHD and conduct disorder).

Receiver Operating Characteristic (ROC) curve of the traditional logistic regression model without co-morbidity analysis and the final logistic regression model with co-morbidity analysis on the test data, which were unseen during the training phase, are shown in Figure 3. The Area Under the Curve (AUC) of the ROC increased from 0.6992 (the traditional logistic regression model without co-morbidity analysis) to 0.7818 (the final logistic regression model with co-morbidity analysis). Selected performance measures for the 30-predictor co-morbidity model, including sensitivities, specificities, Positive Prediction Values, Negative Prediction Values, Accuracies, and F measures for nine distinct threshold points on the ROC are shown in Table 3.

Figure 1. The plot obtained from cross-validation of Elastic Net, showing the change of the Area Under the Curve (AUC) of Receiver Operating Characteristic (ROC) with different λ (in log scale) with α of 0.75. The numeric values above the plot indicates the number of variables selected in the between 28 and 61. In other words, 28 (when log(λ) is -6.577986) is the minimum number of variables that guarantees the maximum AUC.
Figure 2(a). Odds Ratio (OR) plot of the traditional logistic regression model without co-morbidity analysis. The point values indicate the adjusted Odds Ratios, horizontal lines indicate the 95% confidence intervals, and the asterisks indicate the level of statistical significance (***, p < 0.001, **: p < 0.01, *: p < 0.05). The variables included in both the traditional model without co-morbidity analysis (a) and the final model with co-morbidity analysis (b) are highlighted in yellow. The adjusted Odds Ratios can differ if variable selection is different. For example, the adjusted OR of being female is 2.07 from the traditional logistic regression model without co-morbidity analysis, but is 1.63 from the final logistic regression model with co-morbidity analysis.
Discussion

Given that depression remains significantly under-diagnosed in all settings of the healthcare system, data-driven prediction models can play an important role in the screening of depression patients. Although previous work has shown promising results on the ability to predict future diagnoses of depression, such models have not explicitly applied co-morbid medical conditions as independent predictors. Depression is a characteristic disease which can be affected by many medical conditions, and can also affect certain medical conditions. In 2013, psychological factors affecting medical conditions (PFAOMC) was included as a new diagnosis in DSM-V. PFAOMC are the factors which may precipitate or exacerbate the medical condition, interfere with treatment, or contribute to morbidity and mortality. The mechanism of PFAOMC include promotion of known risk factors (i.e. smoking), influence on the underlying pathophysiology (i.e. bronchospasm in asthma), and the interference on the treatment (i.e. poor compliance). Therefore, addressing the co-morbidities related to depression will be a rationally important step in understanding the course of depression, and the analysis of these co-morbidities will likely improve the performance of depression risk prediction models.

In this study, we showed that the AUC of the ROC increased from 0.6992 (the traditional logistic regression model without co-morbidity analysis) to 0.7818 (the final logistic regression model with co-morbidity analysis), after applying the optimized variable selection from Elastic Net. Because neither questionnaire-based screening results (i.e. Patient Health Questionnaire) nor physician clinical notes are available...
in claims data, there is no direct information about patients’ moods or symptoms. Given this limitation, this improvement could be interpreted very significant improvement, and the inclusion of co-morbidity analysis could be a key component in improving the performance of depression risk prediction models.

Furthermore, since odds ratio estimates change for some variables after adjusting for co-morbid conditions, the adjusted OR in the final logistic regression model with co-morbidity analysis could reflect estimates closer to the truth. For example, the adjusted OR of being female is 2.07 from the traditional logistic regression model without co-morbidity analysis, but is 1.63 from the final logistic regression model with co-morbidity analysis (Figure 2). Given that, females have a higher co-morbidity burden in general, the traditional logistic regression model will give higher OR for females, by not adjusting for co-morbidities.

The one million twelve-year Korea National Health Insurance Service (KNHIS) longitudinal data used in this study has many advantages for analyzing large scale statistical models. As KNHIS is the only health insurance system which covers all Korean citizens, the random sample cohort from KNHIS can be considered as a nationally representative health data. Factors arising from multiple health insurance systems effecting diagnosis of depression (i.e. some health insurance plans might have lower coverage for mental health) can be avoided in the single health insurance system, and therefore higher statistical power can be achieved. Therefore, adjusted ORs from the logistic regression model with co-morbidity analysis may represent the risks of each variable in the population.

Cautions are needed when interpreting the epidemiologic results from this study, however. The large sample size in this study is over-powered to detect small effects, so more emphasis should be placed on the magnitude of estimates rather than the statistical significance. Furthermore, the operational definition of depression case group is based on the diagnosis codes in the claims data. Therefore, the depression risk prediction model in this study is predicting the probabilities of each person’s visiting physicians and diagnosed as depressed by physicians, and this will limit the ability of detecting the underdiagnosed depressed population. However, it is noticeable that the findings are consistent with previous studies revealed the relationship between co-morbidities and depression in Korean population with cross-sectional survey study, as well as Korean Longitudinal Study of Aging.

In order to develop a better depression risk prediction model which can also address the currently underdiagnosed depressed population, reaching out to the underdiagnosed depressed population with gold standard screening tools will be necessary. Further work is also needed to investigate possible difference in the co-morbidity patterns in different gender, age-group, and socio-economic status. Higher prevalence of depression among female has been discussed to be related to both biological and environmental factors. Features of depressions can also vary among different age-groups, and certain age-groups may have additional risks. Socio-economic factors of depression and disparity in depression treatment are also very important topic in public health.

Additional research is needed for optimizing the chronic conditions clusters, or categories. Although CMS-CCW algorithm is a well validated algorithm using ICD codes, optimized clusters developed using insurance claims data might be different when compared to actual clinical manifestation of depression. Even within the clinical practice, the disease classification or categorization can differ among various clinical specialties and subspecialties. Therefore, optimization for co-morbid conditions clusters will be needed for better prediction models. Furthermore, integration of medication prescription data will allow better operational definitions with lesser false positives. Further research is also needed for variable interactions (i.e. epilepsy of young female may have different effect from epilepsy of elderly male), as well as time-to-event analysis (i.e. Cox Proportional Hazard regression), dealing with time-dependent covariates.

Although the focus of this study was on the prediction of the existence of depression based on health insurance claims data, further studies will be needed to confirm if co-morbidity analysis can also improve the performance of the prediction model for treatment response, or prediction model based on lexical data, as well as on electronic health records.

**Conclusion**

In conclusion, the inclusion of co-morbidity analysis could improve the performance of risk prediction for depression, and the co-morbidity adjusted ORs may indicate the true independent OR of each predictor variable. Further studies will be needed to cover the currently underdiagnosed depressed population, as well as optimizing the chronic conditions clusters.

Parental Perceptions, Experiences, and Desires of Music Therapy
Ha-Kyung Kong, Karrie Karahalios, PhD
University of Illinois Urbana Champaign, Champaign, IL, United States

Abstract

Music therapy (MT) is a therapeutic practice where a therapist uses music to enhance the life quality for their patients. Children have an innate enjoyment of music, making music an effective medium for exploring their potential. In this study, we explore the parental perception of MT through an online survey. Contrary to the public perception that MT only addresses emotional needs, 47 out of 59 parents reported seeing improvements in other areas including behavioral, cognitive, linguistic, and social changes. All but one parent indicated that they would recommend MT to others. The survey results further revealed that even parents of children participating in MT had misconceptions regarding MT, which we describe in the paper. Parents reported inaccessibility and cost as other major limitations surrounding MT adoption. We conclude by discussing how technology solutions could mitigate issues with definition, distance, and cost, while maintaining the benefits of MT.

Introduction

Music Therapy is defined by the American Music Therapy Association (AMTA) as “the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program.” This definition provides three qualities of MT that distinguish it from therapeutic music, a broader use of music for alleviating a physical, emotional, or mental concern. First, MT is evidence-based and has a strong research foundation. Secondly, the interventions are individualized with a therapeutic goal and conducted over several planned sessions. Thirdly, it is practiced by a Board-Certified Music Therapist (MT-BC), and the therapy occurs within a therapist-patient relationship.

Although MT has been established as a profession for over 60 years, there is “a lack of recognition and understanding of what music therapy is and its benefits [...] many people still have not heard of the profession.” Even people who have heard about MT hold widespread misconceptions about MT including: the client must be musically inclined, music therapists are not real therapists and cannot handle “serious issues,” and more. In actuality, MT can benefit a wide spectrum of people ranging from premature infants, children with autism, adults with traumatic injuries, to older adults with Parkinson's disease. MT is especially effective for children since they naturally enjoy and respond to music; this innate and universal musicality has been termed as “The Music Child” by Nordoff and Robins, and has been used to explore “receptive, cognitive, expressive, and communicative capabilities” of children with developmental delays. Many parents avidly testify about the results they have seen, and research studies show the effectiveness of MT for children and adults. This discrepancy between the potential benefits of MT and the lack of public awareness calls for an exploration of the landscape of MT and development of ways to overcome the challenges that lead to the underuse of MT.

Our research goal is to explore the parental experience of MT through an online survey to identify the current status of MT. Through the research process, we found that even parents of children participating in MT had misconceptions and confusions regarding MT, which we aim to clarify through the paper. We discovered that along with the definition and expectation misconceptions of MT, the inaccessibility and the cost were major limitations surrounding MT-adoption. We conclude the paper by discussing two technology directions that might address the definition, expectation, and accessibility challenges.

Music Experiences and Origins of Approaches in MT

Music therapists use four fundamental music experiences in MT: improvisatory, re-creative, composition, and listening. A MT approach can use one or more music experiences to meet the clinical goals of the session. Darrow, a professor in MT, categorizes the approaches based on their origins are in music education, psychotherapy, or medicine. In this section, we provide a description of each music experience with a list of possible clinical goals for each experience. The clinical goals and the intervention used vary greatly depending on the client's diagnosis and condition, so the list of clinical goals and approaches presented here are not exhaustive.

1) Improvisatory MT focuses on the spontaneous creation of music such as song improvisation and body improvisation. Clinical goals of improvisatory MT experiences include developing creativity and group skills, and establishing non-verbal channels of communication and self-expression.
2) **Re-creative** MT involves singing and playing pre-composed music and is used to work with clients of wide ranging diagnosis from aphasia, attention deficit hyperactivity disorder (ADHD), and cerebral palsy. Clinical goals of re-creative MT experiences include increasing self-confidence and attention span, and developing a sense of mastery.

3) **Composition** methods involve creating vocal and instrumental pieces as a means of self-expression. Clinical goals of composition include raising self-esteem through decision making and reaffirmation of the therapist, “development of self-image, and dealing with emotional loss and trauma”.

4) **Listening** MT is a receptive musical experience involving listening and responding to live or recorded music. Clinical goals of listening MT include evoking and supporting emotional responses, promoting self-expression, and verbal processing of meaningful ideas.

These music experiences are used in different approaches in MT that come from three different origins: a) music education, b) psychotherapy, and c) medicine. We provide below an approach from each of the origins and how the four music experiences are used within each approach.

a) **Orff-Based MT** approach is based on Orff Schulwerk, a multisensory music education approach based on learning by doing that emphasizes using elemental music in which everyone is able to participate. In an Orff-based MT session, the children start by exploring the musical possibilities, and then are led to imitate a pattern the music therapist presents (re-creative). Once they successfully imitate, they improvise using body percussion (eg. snapping), non-pitched percussion (eg. drums), then pitched percussion (eg. xylophones) and the music therapist organizes the musical ideas to fit the goal of the session (improvisational). Children learn turn taking, looking out for subtle cues, and collaborating towards a common goal through this exercise. The final stage is creation where they combine what they have learned in the previous stages (composition). The choice making process and affirmative response from the music therapist raises the children's confidence and can improve their decision-making skills.

b) **Bonny Method of Guided Imagery and Music (BMGIM)** originates from psychotherapy. Since this approach involves verbal reflections of the clients' experiences, clients have to be cognitively and physically capable of verbalizing their thoughts. A BMGIM session consists of a preliminary conversation (to build rapport and to set the tone of the session), relaxation, music listening, and a post-session review (listening). The listening section begins when the music therapist turns on pre-recorded music for the child that is pre-selected based on its therapeutic usefulness. The music therapist provides an opening imagery scene and lets the child verbalize the imagined scenes throughout the music while providing encouragement and empathy. The child is encouraged to make interpretations and parallels to his/her life in the post-session review. Through the focused and pre-planned discussion, music promotes psychodynamic healing and growth of interpersonal relationship between the therapist and the child.

These types of psychotherapeutic music listening techniques have to be clearly distinguished from informal therapeutic experiences involving music (ex. listening to relaxing music at home to lighten one's mood) and formal therapeutic music (ex. bedside musicians playing for patients in the hospital). Sound therapies, where the inherent properties of music itself are considered as the agent of change, are not considered MT by music therapists either. However, some branches of sound therapy refer to themselves as MT. In fact, our study participants termed sound therapies as MT. The schism between music therapists' view of clinical MT and the outsiders' view of MT is elaborated further in the Discussion Section.

c) **Neurologic Music Therapy (NMT)** is a medical approach to MT developed by Dr. Michael Thaut and his colleagues that investigates the effects of music on the brain and behavioral functions. NMT methods are used for sensorimotor training, cognitive training, and speech and language training through different properties of music and sound such as pitch, timbre, and rhythm. Melodic intonation therapy (MIT) is a type of NMT that has been effective for treatment of children with apraxia of speech. The learning occurs in a gradual pattern while music therapist taps the rhythm. The phrase is first hummed by the music therapist and imitated by the child through signing, then repeated “speech singing,” and eventually spoken in normal speech (re-creative).

Based on this wide range of music experiences and approaches in MT, different clients have different perceptions, experiences, and desires of MT. In this study, we surveyed parents whose children had participated in MT to address the following research questions:

**RQ 1** Why do parents choose music therapy for their children?
RQ 2 Why do parents stop music therapy?
RQ 3 What benefits do parents expect from music therapy sessions?
RQ 4 What benefits did parents see through music therapy sessions?
RQ 5 What changes do parents want to see in the field of music therapy?

Methodology

Our study was conducted through an anonymous online survey on parental satisfaction of MT in the U.S. and South Korea. The survey was designed based on existing MT literature with input from music therapists and consisted of 19 closed-ended questions and 8 open-ended questions that explored the types of MT in which the child had participated as well as the parents' expectations and thoughts on MT. We recruited participants through mailing lists; posts on online forums (e.g., Reddit); flyers in cafes, libraries, and healthcare centers around three large universities; and music therapists. Additionally, we contacted approximately thirty-five health care centers offering music therapy in the U.S. and South Korea through email. Recruiting participants proved difficult and took over a year. We first started by recruiting participants in the U.S. and expanded our study to include participants from South Korea when Korean music therapists showed interest in our study. The Korean parents were mainly recruited through music therapists and therapy centers in South Korea. As an incentive, each participant was entered into a raffle for a $50 Amazon gift card.

Participants

Between March 4, 2014 and February 6, 2015, we received 59 responses through a Korean and an English version of an anonymous online survey: 38 from South Korea and 21 from the U.S. The details of the survey results are provided in Table 1. All but two (n=53) of the respondents who indicated their relationship to the child who participated in MT were mothers; one respondent was the father and one respondent was a legal guardian. The majority of the parents surveyed (n=46) had one or two children currently living at home, with the number of children at home ranging from one to seven (Eng: $\mu=2.19$, $\sigma=1.47$; Kor: $\mu=1.58$, $\sigma=0.80$). Ages of the focus children ranged from 15 months to over 25 years old, with the mean age of 12.

Procedure

Survey Design

After presenting the consent form on the introductory page, the survey collected demographic and basic information about the focus children. Next, the survey asked about the respondent's relationship to the child who had taken MT and the total number of children at home to probe the possible influence on the amount of parental involvement in MT. The survey then targeted RQ1 by asking where the participants had heard about MT, what prompted them to try MT, and what other therapies they had tried. To answer the second research question, the survey asked if the child is currently receiving MT services. If no, the survey asked for the main reasons for discontinuing MT.

The next seven questions focused on the specifics of the MT sessions by asking how long the child has received MT, the type of music experiences in MT sessions, and the location, frequency, duration, and the type of MT sessions (personal, group, family, other). The survey then asked the participants to rate the parental involvement during and outside of MT sessions, the music therapist's understanding of the child's needs and strength, and whether the child looked forward to the MT sessions on a five point Likert scale.

Next, the survey presented multiple-choice questions to ask for areas they would most like to see improvements through MT (for RQ3) and for areas they saw a satisfactory improvement (for RQ4). We followed these questions open-ended questions to elaborate on the improvements they saw and how they would improve MT. We then asked whether they would recommend MT to family and friends. The survey ended by asking for the participant's birth date to filter out spam and ensure that the participant was over 18. We also filtered out responses that did not answer any of the open-ended questions.

Data Analysis

We analyzed the open-ended questions by establishing a list of common themes through open coding and categorizing each response into one of the themes. The emerged themes are mentioned in the results section. Two raters categorized all 90 responses independently; the intercoder reliability between the two coders was substantial,

1 Parental involvement outside of MT sessions includes, but is not limited to, learning new ways of using music at home and eliciting skills that the child learned during MT sessions.
κ = .77, p < 0.05. They resolved the differences by discussing each response till they came to an agreement for all the responses. All of the Korean open-ended questions were translated by one of the researchers and proofread by a graduate student who has an English Education degree from a Korean university.

We analyzed responses from the two surveys (English and Korean) separately and did not make comparisons between the two samples because the participants were not randomly sampled from the two populations. Four of the five Likert scale responses were combined into a composite score given that the results from the two samples are significantly equivalent based on the two one-sided tests for equivalence (p < 0.05, ε = 1). The last Likert scale response is reported separately. The responses from the two countries’ surveys were also combined to compare the desired areas of change to actual areas of change. We used a paired-sample test that compared each respondent’s desired changes and actual changes. Fourteen Korean responses relating to the music therapists were discarded. This is because they were collected directly through a music therapist and it is possible that those respondents felt pressured to answer more positively to questions regarding that music therapist. That left us with 21 English responses and 24 Korean responses for those two questions relating to the music therapist.

Results

The average response rate for each question in the survey was very high (97%) with all but one question getting a response rate higher than 95%; the last opened ended question asking for areas for improvement had a 58% response rate. Most of the parents first learned of MT through a health care provider (e.g., doctor, therapist), friends, and online sources (e.g., blog, SNS, search engine). Other sources of information came from school, family, rehabilitation centers, magazine articles, and television. The location of the sessions was split between home (n=8; 38%) and clinics (n=7; 33%) for the English survey while the majority of the Korean survey respondents (n=34; 89%) answered clinics. Personal therapy was the most common form of therapy followed by group therapy for both the American and Korean clients. One respondent answered that the child participated in both personal and group sessions. However, one parent commented that they would prefer if her child had access to a group MT session, indicating that not everyone has access to all types of MT.

    | Age of the child (in years) | Sessions / Week |
    |-----------------------------|-----------------|
    | 0-5            | 6-10           | 11-15 | 16-20 | 20+   | 1   | 2   | 3   | 4 or more |
    | 5 | 5 | 6 | 13 | 3 | 10 | 4 | 6 | 3 | 4 | 17 | 27 | 1 | 9 | 1 | 1 | 2 | 1 |
    | Total number of children at home | Location of MT |
    | 1 | 2 | 3 | 4 | 4+ | school | clinics | home | other |
    | 8 | 14 | 7 | 17 | 3 | 4 | 2 | 0 | 1 | 0 | 3 | 0 | 7 | 34 | 8 | 3 | 4 | 1 |
    | Duration of MT (in months) | Type of MT |
    | <= 12 | 13-24 | 25-36 | 37-48 | 48+   | personal | group | family | other |
    | 9 | 19 | 3 | 4 | 4 | 5 | 1 | 4 | 2 | 5 | 16 | 31 | 4 | 7 | 0 | 0 | 1 | 0 |
    | Became aware of MT through | Minutes / Week |
    | health care provider | family | your child’s school | friend | online | less than 30 | 30 to 60 | 60 to 90 | more than 90 |
    | 6 | 18 | 2 | 1 | 2 | 1 | 3 | 5 | 2 | 5 | 3 | 0 | 14 | 25 | 1 | 9 | 3 | 4 |
    | Other therapies taken | Reasons for discontinuing MT |
    | occupational therapy | speech therapy | behavioral therapy | none | other | lack of improvement | schedule conflict | reached max benefit | availability of MT | cost of service |
    | 19 | 3 | 17 | 23 | 8 | 10 | 1 | 5 | 6 | 17 | 1 | 0 | 2 | 0 | 2 | 0 | 4 | 0 | 1 | 1 |
    | Child still participating in MT | Willing to recommend MT to others | Music experiences |
    | yes | no | yes | no | improvisatory | re-creative | composition | listening | other |
    | 11 | 35 | 10 | 3 | 19 | 38 | 1 | 0 | 12 | 35 | 15 | 30 | 3 | 14 | 14 | 23 | 1 | 12 |

Table 1. Table of survey results. Responses reported as Eng | Kor (out of 21 | 38)
Most of the children received MT once a week or twice a week. The duration of the sessions was primarily 30 minutes to 60 minutes (n=39) or 60 minutes to 90 minutes (n=10). This frequency and duration of MT is common for developmental treatments while rehabilitative MT can be more intensive. For example, the regimen for MIT, previously mentioned in section 2 can be as intensive as 1.5 hrs/day for five days/week as it utilizes brain plasticity for recovering speech”.

In addition to MT, parents had also tried speech therapy (n=40), occupational therapy (n=21), and behavioral therapy (n=18). Eight of the Korean parents had tried art therapy. This can be explained by the options of therapies commonly offered in social welfare centers and clinics, the location of MT sessions for the majority of the Korean clients.

1. Motivations for starting and discontinuing music therapy
Motivations for starting MT mostly consisted of the diagnosis of the child. Six parents specified autism spectrum disorder (ASD); eight parents specified speech delay, disorder, or a non-verbal child; six specified developmental delay as the diagnosis. Other parents reported Down Syndrome (n=2), ADHD, episodes of seizures, anxiety disorders, Williams Syndrome, and encephalopathy as reasons for starting MT. Parents further reported seeking MT to see specific benefits such as reduced frequency of seizures, improved self-expression, and stress relief. Six parents indicated the children's interest in music. Respondent 15 wrote, “Due to seizures music was one of two ways she would respond to stimuli.” Similarly, Respondent 18 wrote, “my daughter has Down syndrome, has many areas of delay, and also loves and responds to music.” This response to music regardless of the child's delay in other areas is a key factor in “the Music Child” and how MT can bring out the child's potential.

Out of 13 parents who reported that their children were not currently receiving MT services, four reported unavailability of MT, three reported a conflict in schedule, two reported that they had received maximum benefit. The others reported unwillingness of the child to participate, ineffectiveness of therapy, cost of service, and recommendations from the child's teacher to stop. Throughout the survey and other correspondence with parents of children who had participated in MT, it became apparent that one of the main limitations of MT was the unavailability of MT as 8 participants listed it as a change they would like to see in MT, and 7 out of 13 who discontinued MT had difficulty accessing MT.

2. Experiences in music therapy
The most common types of music experience were improvisation (n=47) and re-creative (n=45). Listening was also widely used for the American patients (n=37) while composition was not as commonly used in either population (n=17). Most parents (n= 47) reported that the child had experienced more than one type of musical experience in MT. Parents were satisfied with the level of their involvement during and outside of MT sessions overall. The mean score to the statement “I was satisfied with the amount of parental involvement during the session” on a Likert scale from 1(strongly disagree) to 5 (strongly agree) was 3.93 (σ= 0.95), and the mean score for involvement outside of the session was 4 (σ= 0.84). The scores were significantly greater than a neutral response of 3 according to the Wilcoxon signed rank test (Inside session: V = 579.5, p-value < 0.001; Outside of session: V = 601, p-value < 0.001). Parents thought that the music therapists' understanding of the child's strengths was satisfactory (µ= 4.36, σ= 0.86) and that the music therapists' understanding of the child's needs was satisfactory (µ= 4.47, σ= 0.81). Both groups reported that the children looked forward to the MT sessions, but the average value was slightly higher for the Korean respondents (Eng: µ= 3.76, σ= 1.22; Kor: µ= 4.29, σ= 1.12).

3. Desired changes and satisfaction
To address RQ3 and RQ4, we asked the participants to indicate the areas of desired changes prior to MT and perceived outcomes of MT, respectively. The results for these questions, “In which of the following areas would you most like to see improvements through music therapy? Select up to 3 answers” and “In which of the following areas did you see a satisfactory improvements through music therapy? (Select all that are true),” are shown in Figure 1.

The seven developmental areas used to indicate desired and perceived changes were: cognitive, behavioral, language, physical, social, emotional, and musical. These areas were chosen based on the target areas listed by AMTA and prior research on MT outcomes. Emotional, behavioral, and cognitive were respectively the first, second, and third areas in which Korean parents would like to see changes, while behavioral and cognitive were first and second in the English survey. Language and emotional tied as the third. One hypothesis explaining the Korean parents' emphasis on emotional improvements is that the intense academic pressure in South Korea might adversely affect children's emotional stability.
Figure 1. Y-axis is the percentage of parents who indicated the area for desired (left) or actual (right) changes. If all parents marked one area, its total value would be 2.0 (1.0 for Korea and 1.0 for the U.S.). Note that parents could mark all areas of actual changes, but only the top three desired changes.

If a parent selected a desired area for change and selected that area again as a perceived improvement, we noted that that area was met with satisfaction via MT. Desires for musical changes were most likely to be satisfied, with 89% of parents who checked it as desired also checking it as a perceived outcome. Desires for emotional changes were the second most likely to be met at 79%. Desires for cognitive improvement were least likely to be met through MT with 44% of parents wanting to see cognitive changes reporting perceived changes. In one noteworthy case, a parent reported continued satisfaction for their 22-year old child with autism, who had participated in MT for 15 years (Respondent 21). In addition to the three standard therapies mentioned in our survey – occupational therapy, speech therapy, and behavioral therapy, the child had participated in numerous other therapies including “physical therapy, interactive metronome therapy, cranio-sacral therapy, hippotherapy, pet (dog) therapy, Fast ForWord, Listening Program, [and] auditory integration therapy.” The parent had checked cognitive, behavioral, and emotional for the desired changes and all the categories for perceived outcomes showing high satisfaction with MT.

All but two of the participants responded that they would recommend MT to family and friends (n=57) indicating their overall satisfaction with MT. One participant stated that she would not recommend MT because she perceived no changes, and one participant did not provide a response.

4. Benefits of music therapy

The survey asked, “Could you give an example of an improvement? (ex. my child can focus longer)” to investigate specific changes parents perceived through MT. Out of 56 parents who provided a response, many reported changes in multiple developmental areas. The majority of the reported changes were emotional changes (n=19). Parents reported emotional stability (n=8) and enhanced emotional expressiveness (n=7). For example, Respondent 12 wrote, “We received receptive & expressive emotions, listening, and increased happiness and a connection via eye contact/smiles.”

Seventeen parents reported behavioral changes including an increase in the following of directions and decreased frequency of tantrums. Respondent 33 wrote that her child “doesn’t throw tantrums as often, doesn’t hit the younger sibling as often, does homework, washes more often, [and] started going on school field trips (translated from Korean).” Similarly, Respondent 37 wrote, “ADHD symptoms became less severe, reduced impulsive and violent behaviors and shouting. Reduced roaming around, throwing fits, and gluttony (translated from Korean).”

Language changes were also prevalent in the responses (n=14). Parents reported improvements in vocalization, timing and rhythm of speech, pronunciation, and self-expression. Respondent 6 stated that “[her] son could speak in sentences instead of phrases. Better attention. Quicker processing of questions he was asked and shorter time to respond.” Relating to the phenomenon that some people who struggle to speak can still sing the words, Respondent 17 wrote, “[my daughter] will sing to talk to us, before she couldn’t tell us her needs.” This activation of language through singing is often cited as a major strength of MIT mentioned in Section 2. Other major reported improvements included cognitive (n=12) and musical (n=10) improvements such as learning how to read music. Respondent 34 wrote that her child “sang for the first time, unique accents and pronunciation became better, more focused when studying, doesn’t get irritated or angry as often (translated from Korean).”

5. Desired changes in the field of MT

Parents reported various limitations surrounding MT in response to the final question, “How can music therapy be improved for your child?” Of the 34 submitted responses, the following themes emerged: more
individualized/diverse programs (n=9), accessibility (n=8), awareness (n=6), lowered cost (n=4), and acknowledgement from organizations (n=3).

Parents often sought out specific programs, environments, and opportunities that addressed their children's needs such as receiving therapy in a larger, sound-proof space. Respondent 21 requested more social and language-related programs; Respondent 33 requested opportunities for her child to play ukulele with other children. Two parents requested programs that are currently available in other regions but not in their own (ex. group therapy). Some parents currently did not have access to MT at all. Concerning the accessibility of MT, one mother wrote, “We need providers in central Illinois that [are] affordable and available. We found no one in the area to help. We travelled to Texas for our initial treatment and then continued at home with very little outside help. I am not a music teacher and this took the fun element out of the therapy for my son.” Other parents wanted to raise the awareness of MT as the treatment had been effective for their children.

Cost is a major concern of many parents. One respondent (8) stated, “We paid $100 for a consultation with an occupational therapist. She played special music for my daughter during the session them [sic] recommended that I purchase a $25 mp3 soundtrack, $50 headphones and a $150 MP3 player because the soundtracks were only sold as mp3. I'm interested in music therapy but not at that price!” This burden of cost could be alleviated if the service was run by schools. However, schools are often unfamiliar with MT or skeptical of its effectiveness. Respondent 6 stated that one way to improve MT is through “convincing my child[sic] school administration on how beneficial it is. Having them also realize it's a related service recognized by the Department of Education.” Respondent 10 mentioned that “It would be nice if schools would recognize music therapy as an educational tool for children with disabilities. As it stands school districts do not want to allow it in schools or to be used within a school environment.” Respondent 32 stated that the reason for discontinuing MT was because the child’s kindergarten teacher told them to stop. No further explanation was given to explain this recommendation.

Two respondents indicated that there was nothing they would change. Respondent 14 wrote:

Our therapist is amazing. She understood our daughter's strengths and used those to help her speak. [...] For example “I want to go outside” is to the tune of Mary Had a Little Lamb. Because it is music, our daughter will now sing that when she wants to go outside to play instead of just fussing. She now sings when she is hungry, thirsty, wants to play the piano, wants TV, or to listen to music, or needs a diaper change.

Discussion

The results of this anonymous online survey convey parents’ original desires and experience with MT and suggestions for the field. Additionally, the results and the process of research revealed a sense of confusion and unawareness of the exact definition of clinical MT. The schism in the MT and sound therapy communities aggravated the confusion of parents and schools. In the following section, we shed some light on this confusion. Then, we propose how technology could enhance the field of MT based on the results from the survey and our discussions of this survey with music therapists.

Ambiguities of music in health and healing

Our survey responses highlighted that parents of children who received Samonas Sound Therapy classified it as MT although it does not meet the third criteria established above. Samonas Sound Therapy is an auditory intervention program that uses physical properties of processed music and sound “to re-map and restore the brain's ability to process sound.” Thus, specific music features such as shifted pitch are the agent of change rather than the musical experience as in clinical MT. Since the healing power is inherent in the music in sound therapy, a child can listen to a selected recording at home without a therapist-patient relationship and still receive therapeutic benefits of Samonas Sound Therapy. Furthermore, although sound therapy often requires training as well, the certification processes are considerably different; for example, the authors of this paper received “Therapeutic Listening” certification via a 12-hour online training course. Most of the participants in the course were trained occupational therapists who were interested in extending their programs to include sound therapy. To become a Music Therapist-Board Certified (MT-BC), one must obtain a bachelor's degree or higher in MT, perform 1200 hours of clinical training, and pass the national board certification.

Music therapists with whom we corresponded confirmed that sound therapy was absolutely distinct from clinical MT. They considered it important to distinguish therapeutic music and sound therapy from MT because this mislabeling could diminish the credibility of MT. Their main concern was the lack of evidence-based research and the lack of therapist-patient interaction in sound therapies. Thus, although sound therapy is also an authentic way of
using music for healing, it should be distinguished from MT because the two disciplines’ fundamental philosophies in the use of music are different.

**Assistive Technology for MT**

The value and the need for MT at a distance became apparent after the parental reports in this study aligned with comments we had received in our lab over the year from parents missing appointments or struggling to reach our speech and hearing clinic. In this study, we found that the unavailability of MT was the leading cause for discontinuing MT with four people out of 13 who discontinued MT articulating this in the survey and eight parents listing accessibility as the area of improvement in an open-ended question. In 2011, there were 3,352 AMTA members in the U.S. As the majority of them work in urban regions, people in rural areas had limited access to MT. To date, few teletherapy approaches to MT have been explored. This idea of using technology to augment MT, however, was met with a strong opposition from select music therapists. The main objection was that technology, or rather, a lack of direct therapist-patient involvement, might negatively impact the outcome of a therapy session. In this section, we explore two technology directions for MT that address the limitations surrounding MT while attempting to maintain the benefits of MT. These are (1) teletherapy and (2) clear and definitive MT resources that raise awareness, advance understanding of MT, and enhance therapist-parent communication to encourage continuous therapy at home.

**Teletherapy: supporting remote MT**

Teletherapy, also referred to as e-therapy, is emerging as an alternative that offers equal access to different therapies regardless of one’s geographical region. Although teletherapy can be synchronous or asynchronous and comes in different modalities (e.g., email, chat, and video-conferencing), in this paper, the term “teletherapy” refers to the use of videoteleconferencing (VTC) to deliver therapy sessions when distance separates the client and the therapist. Clinicians have been investigating telecommunication methods for patients in remote areas since the mid-1950s. Previous teletherapy studies have shown the acceptability and feasibility of teletherapy for children and youth. One such study measured Therapeutic Alliance (TA), the relationship between a healthcare professional and a client in teletherapeutic settings. The maintenance of TA is especially important in MT since the therapeutic changes are made through the relationship between the therapist and the client. The results supported that “TA can be developed in psychotherapy by videoconference, with clients rating bond and presence at least equally as strongly as in-person settings across a range of diagnostic groups.” This shows that MT could potentially be conducted at a distance while maintaining the essential therapist-patient relationship. One possible MT teletherapy scenario: MIT can be conducted using VTC where the therapist leads a singing session while the child sings along wearing an augmented wristband or a glove that taps the beats on the wrist. This allows the two research-supported therapeutic elements of MIT – melodic phrasing and rhythmic tapping – to be incorporated in teletherapy. Bandwidth and network limitations in rural areas pose a challenge for this approach. Remote music collaborations are difficult as sound lags disrupt synchronization, which in turn may erode the benefits of MT. These limitations suggest more abstracted low bandwidth interactions between the remote participants that do not rely on traditional VTC.

An alternative and perhaps preferred usage of technology for addressing the inaccessibility of MT is educating the parents in real-time so that the therapy could be conducted at home under the supervision of the therapist, thus minimizing travel. The idea is presented in “Coaching Parents of Young Children with Autism in Rural Areas Using Internet-Based Technologies: A Pilot Program” and could be extended to explore how Internet-based technologies could enhance communication between the music therapist and the parent to encourage continuous treatment. In this scenario, a clinician observes the parent-child interaction via VTC and gives real-time parental guidance via an earpiece worn by the parent to assist the parent in a parent-child clinician guided session. This approach mitigates the remote syncing challenges of the remote participation approaches while encouraging direct social interaction between the parent and child.

**Information organization: raising awareness and receiving acknowledgement**

Out of 34 parental suggestions for MT, nine (26%) addressed the need to promote MT through raising awareness for the general public (n=6) and receiving acknowledgement of MT efficacy from schools (n=3). Even parents themselves experienced difficulty in understanding the exact definition of MT – shown through parents who mistook sound therapy and MT – and the interventions used in MT – shown through two parents who responded that they did not know what methods were used during their children’s therapy sessions. The music therapist who sent us a collection of responses further indicated that some parents do not understand the precise purpose of MT and rather perceive it as a method for relieving a child’s stress. This limited view of MT can be problematic as parents and the
general population undermine the effects of MT and do not consider it for treatment in non-emotional areas. Even if a person is interested in MT, it is currently difficult to access a list of the major methods and interventions used in MT and how each method of MT benefits the clients. The AMTA website offers general information on how MT can be applied to a specific population or situation (e.g., young people, Alzheimer's patients, pain management). However, it does not provide specific interventions that are frequently used for young children (e.g., Nordoff-Robbins Music Therapy). Although relevant information can be found by searching online and reading academic journals, the search is not only burdensome but also confusing for time-challenged parents who are not familiar with the area and lack a starting framework.

We propose a site where a collection of interventions categorized by music experience, origins, target population, clinical goals, etc. is presented with case studies and research findings. This MT archive would help clarify the clinical definition of MT to the public, and would be useful for informing schools and other organizations of the uses and benefits of MT. It could also have evidence based MT research for those who are interested in pursuing the literature to date. After logging in, parents could also view a summary of their children’s MT sessions and a list of parent-child exercises that can be done at home to enhance their understanding of MT sessions and enable continuous treatment. The official Autism Speaks site is an exemplary site that presents everything starting from basic information such as the definition and symptoms of autism to resources for parents and novel research findings.

Since the site has many of the elements we are exploring, it could be used as a model for raising the public awareness and receiving organizations' acknowledgement.

Limitations
While the findings of this study contribute to the understanding of parental experience of MT and prompt a discussion on technological applications, this study is not without limitations. The recruitment of the participants through music therapists and clinics might have biased the results to over-represent certain approaches of MT over others and participants predisposed to the benefits of MT resulting in overly positive responses. Even with aggressive advertising for approximately one year, we struggled to reach participants and did not have enough participants from each country to make a cultural comparison. The non-random sampling, the small sample size for each population, and the self-selection bias might limit the generalizability of the findings. However, we found commonly recurring themes in responses of participants from both countries suggesting consensus for the specific benefits and limitations of MT.

Conclusions
In this paper, we presented findings from a survey designed to make sense of parents’ expectations and experiences of MT for their children. The study contributes to the understanding of MT in three areas: survey findings highlighting satisfaction, limitations, and desires of MT; the discovery of the parent-clinician misalignment of the meaning of music therapy; and a discussion of future directions using simple existing technologies to create a united MT face and to create computer-mediated technologies to explore remote accessibility for MT.

Through the survey we found that parents: (1) expressed strong satisfaction with MT and 57 out of 58 parents stated that they would recommend MT to others; (2) indicated that they would like MT to be more accessible, affordable, and publicly recognized. Throughout our survey preparation and analysis, we discovered parents and MT clinicians had different models representing music therapy – parents often included therapeutic music techniques in their MT umbrella. Finally, we presented two future directions to address the MT limitations that arose from the survey and research process: teletherapy for making MT more accessible and information organization for raising the awareness and being acknowledged by the public and institutions.

Abstract

Natural Language Processing (NLP) is essential for concept extraction from narrative text in electronic health records (EHR). To extract numerous and diverse concepts, such as data elements (i.e., important concepts related to a certain medical condition), a plausible solution is to combine various NLP tools into an ensemble to improve extraction performance. However, it is unclear to what extent ensembles of popular NLP tools improve the extraction of numerous and diverse concepts. Therefore, we built an NLP ensemble pipeline to synergize the strength of popular NLP tools using seven ensemble methods, and to quantify the improvement in performance achieved by ensembles in the extraction of data elements for three very different cohorts. Evaluation results show that the pipeline can improve the performance of NLP tools, but there is high variability depending on the cohort.

Introduction

Extracting concepts from narrative clinical notes using Natural Language Processing (NLP) techniques is essential to enhance cohort identification processes. Researchers have developed many clinical NLP concept extraction tools (NLP tools), such as cTAKES⁴ (clinical Text Analysis and Knowledge Extraction System) and MetaMap.⁵ An NLP tool may be suitable and powerful for certain concept extraction tasks; there is hardly an NLP tool that is general enough to deal with all extraction tasks. This issue becomes more challenging when the types of concepts to be extracted are numerous and very diverse. For example, in the task of extracting data elements (important concepts related to certain medical conditions, such as encounter information, laboratory tests, imaging tests, and medications) from clinical notes, there are usually several types of data elements that need to be extracted (e.g., 183 data elements in our three cohorts), and different categories of data elements may be better extracted by different NLP tools because of the difference in concept dictionaries or extraction algorithms/pipelines. To address this issue, we propose to apply ensemble methods to integrate NLP tools. Ensemble methods have been proven to be effective to boost the performance of classifiers.⁶ The superiority of ensemble methods has been shown empirically in a wide range of data mining and NLP competitions.⁷,⁸,⁹,¹⁰ Many ensemble methods are available, including basic methods (union and intersection) and advanced ones (Binary Relevance (BR),¹¹ Multi-Label K-Nearest Neighbor (MLKNN),¹² Instance-Based Logistic Regression for Multi-Label (IBLR-ML),¹³ Random k-Labelsets (RAkEL),¹⁴ and Ensemble of Classifier Chains (ECC)¹⁵), spanning a large spectrum of sophistication. Advanced ensemble methods can weigh the importance of component NLP tools by applying machine learning to learn the best set of weights.

Although ensemble methods are empirically known to improve classification performance in several problems, it is not clear to what extent ensembles of NLP tools improve the extraction of numerous and diverse data elements from clinical notes. Several recent studies applied ensemble methods to extract concepts from clinical text.¹⁶,¹⁷,¹⁸ However, most of them focus on the extraction of a few concept types, such as identifying 6 types of medication information,¹⁹ predicting 3 types of concepts (problem, test, or treatment),¹⁰ classifying 9 types of radiology concepts,²¹ or determining 8 concept types related to heart disease.²² It is unclear whether these methods are suitable for dealing with numerous and diverse concepts such as the 183 data elements from our project.

Phenotyping (i.e., characterization of disease states using electronic health records) relies heavily on structured data items, as well as on NLP for data element extraction from narrative text, and is a critical component of precision medicine.²³,²⁴,²⁵,²⁶,²⁷ Our goal was to quantify the improvement in performance achieved by ensembles of popular NLP tools in the phenotyping of three very different cohorts for (1) congestive heart failure (CHF), (2) weight management/obesity (WM/O), and (3) Kawasaki disease (KD). These three conditions are use cases for the pSCANNER (patient-centered SCAlable National Network for Effectiveness Research) clinical data research network, a stakeholder-governed federated network that utilizes a distributed, service-oriented architecture to integrate data from multiple health systems²⁸.
In order to evaluate the ensemble approach, we developed an NLP ensemble pipeline to integrate two popular NLP tools, cTAKES\(^1\) and MetaMap.\(^2\) Our pipeline can integrate these NLP tools using the basic and advanced ensemble methods mentioned previously, and allows us to evaluate the performance of NLP tools when they are applied alone and when they are integrated using different ensemble methods.

**Methods**

**NLP Ensemble Pipeline**

Figure 1 provides an overview of our pipeline. Inputs are clinical notes, which are preprocessed before they are ready for NLP tool extraction of data elements. The output of the NLP tools is integrated by the ensemble methods, and either structured-formatted files or annotated files serve as outputs. The output formats of our pipeline include extraction results such as structured data that are ready to be exported in a Common Data Model (CDM) format (such as the one pSCANNER uses, the Observational Medical Outcomes Partnership CDM (http://omop.org/CDM)), as well as annotation tags in the format used by the Brat Rapid Annotation Tool (BRAT),\(^4\) a Web-based graphical interface for text annotation that allows users to visualize and correct outputs if necessary.

In this paper, we focus on three cohorts of pSCANNER: CHF, WM/O, and KD. Subject matter experts identified important data elements for research on patients with these conditions. To extract these data elements, we integrated two NLP tools: cTAKES\(^1\), an NLP tool for concept extraction from free text clinical notes in an EHR; and MetaMap,\(^2\) a tool for recognizing UMLS\(^9\) concepts in text. These tools cover a wide range of applications of NLP for clinical note concept extraction and clinical note processing.

**Data Elements and Mapping Tables**

We worked with subject matter experts to identify 183 common data elements related to each cohort (50 for CHF, 96 for WM/O, and 37 for KD). The resulting data elements for CHF, WM/O and KD are shown in Tables 1, 2 and 3, respectively. PR and CNH mapped all data elements to the most specific standard codes (SNOMED-CT,\(^6\) LOINC,\(^7\) RxNorm,\(^8\) or UMLS\(^9\)) using the BioPortal web service\(^10\) and created a data-element mapping table for each condition. We used the data-element mapping tables to normalize the output formats of the NLP tools that we integrated. The output standard codes of cTAKES include SNOMED-CT and RxNorm. MetaMap outputs UMLS. These standard codes were mapped to unique data elements in the table. If the output of any tool contained multiple standard codes for an extracted concept, we mapped all standard codes to the unique data elements. This way the outputs of all NLP tools were normalized and ready to be inputs for the ensemble methods.

### Ensemble Methods

Our pipeline can integrate NLP tools using two basic ensemble methods: Union, which extracts the data element if any of the NLP tools detects the data element; and Intersection, which extracts the data element if both NLP tools detect the data element.

Although basic ensemble methods can combine the results of multiple NLP tools, the relationships (e.g., category, similarity, shared procedure or component) among data elements are not considered. To explicitly consider the relationships among data elements, we further converted the ensemble problem into a binary Multi-Label Classification (MLC) task, where each instance is a sentence in a note, features are the binary extraction results of each data element for each NLP tool, and labels are the binary ground truth of whether the data element exists in that sentence or not. For example, suppose there are 10,000 sentences in the data repository, 50 data elements to be extracted, and 2 NLP tools for the ensemble, then the corresponding MLC problem consists of 10,000 instances, 50 labels, and 100 (50 * 2) features.

To solve the MLC problem, we used five well-known algorithms to build our advanced ensemble: BR, which trains a binary classifier for each label independently; MLkNN, which is an instance-based method that extends the k-Nearest Neighbor (kNN) method to multi-label data; IBLR-ML, which is based on a formalization of instance-based classification as logistic regression and takes the correlation among labels into account; RAkEL, which randomly selects subsets of the label powerset (treating each distinct combination of labels as a different class) and combines them using a voting scheme; and ECC, which trains several classifiers in random order on a random subset of data, and combines them by voting. All advanced methods, except BR, learn relationships among labels (data elements) during training process.

### Test Corpus

We tested the above mentioned NLP tools and ensemble methods on 130 clinical notes (100 from the public domain and 30 private).

- **For public** clinical notes, TTK, PR and CNH collected 45,136 notes from MT Samples, i2b2 Challenges 2006, 2008 - 2012, 36, 37, 38, 40, 41, 42, 43 and ShARe CLEF eHealth Tasks 2013 Task 1 and 2, and 2014 Task 1, 44, 45, 46. Then, for each condition, the notes were selected based on keyword combinations: we used “congestive heart failure” for CHF, “weight management AND obesity” for WM/O, and “Kawasaki OR (fever AND rash AND red AND child) for KD. It should be noted that these rules only serve as simple filters for sampling notes, thus we did not consider synonyms or stemming. After narrowing down the search by keywords, we randomly selected notes for the evaluation from the filtered notes: 33 notes for CHF, 34 notes for WM/O, and 33 notes for KD. The total number of public domain notes was 100.

- **For private** clinical notes, TTK and CNH randomly sampled 30 notes, from a pool of 381 notes collected by JDC for KD (from Rady Children’s Hospital and the Emory University; Institutional Review Boards approved this study).
For the 130 notes, PR and CNH manually annotated 6,914 mentions of data elements (1,885 for CHF, 1,728 for WM/O, 1,678 for KD-Public, and 1,623 for KD-Private). TTK and CNH applied Stanford CoreNLP\textsuperscript{10} to split the 130 notes into 9,320 sentences (3,045 for CHF, 1,778 for WM/O, 2,824 for KD-Public, and 1,673 for KD-Private). We tested a total of four datasets: CHF (33 notes), WM/O (34 notes), KD-Public (33 notes), and KD-Private (30 notes). For each dataset, we randomly selected 50% of these notes for training, and held out the remaining 50% for performance reporting. We used 10-fold cross validation in training.

**Evaluation Metrics**

We considered a data element extraction to be correct using two different levels: corpus-level and sentence-level. For corpus-level, the prediction of a data element in a clinical note is considered correct if the data element does appear in the ground truth annotations in the same note (not necessarily in the same sentence). For sentence-level, the prediction is considered correct if the data element does appear in the ground truth annotations in the same sentence. It should be noted that the predictions are binary for both levels, thus multiple concepts of a corrected predicted data element would only count as a single true positive.

We computed Precision, Recall and F1-Scores for each method as our evaluation measures, and computed the corpus-level and sentence-level of each metric. The corpus-level F1-Score is defined as $\frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$, where corpus-level precision $P = \frac{\# \text{of correctly predicted data elements}}{\# \text{of all predicted data elements}}$, and corpus-level recall $R = \frac{\# \text{of all correctly predicted data elements}}{\# \text{of all ground truth data elements}}$. The sentence-level F1-Score is defined as $\frac{\sum_{i} F_{i}}{N}$, where $N = \# \text{of sentences}, F_{i} = \frac{2 \times P_{i} \times R_{i}}{P_{i} + R_{i}}$ for each sentence $i$, sentence-level precision $P_{i} = \frac{\# \text{of correctly predicted data elements in sentence } i}{\# \text{of predicted data elements in sentence } i}$, and sentence-level recall $R_{i} = \frac{\# \text{of correctly predicted data elements in sentence } i}{\# \text{of ground truth data elements in sentence } i}$.

**Implementation**

We utilized the implementation of the MLC algorithms available in the MULAN\textsuperscript{11} package for ensembles, and applied J48\textsuperscript{12} as the base learner for the MLC algorithms. For cTAKES,\textsuperscript{3} we utilized the Dictionary Lookup Fast Pipeline\textsuperscript{5} and the built-in concept dictionary, which was a subset of UMLS\textsuperscript{13} containing SNOMED-CT,\textsuperscript{14} RxNorm,\textsuperscript{15} and all of the synonyms. The system was implemented in Java, Python, and Shell Scripts. Also, we released the ensemble component in our pipeline. In this component, there were three inputs: (1) ground truth annotations in BRAT format, (2) annotations generated by an individual NLP tool (also in BRAT format), and (3) the beginning and ending position of each sentence in notes (generated by the sentence splitter). This component can perform basic and advanced ensembles, compare the ground truth annotations, and output the corpus- and sentence-level evaluation results. The code is available at https://github.com/tsungtingkuo/ensemble.

**Figure 2.** Corpus-level F1-Scores for NLP tools, basic ensemble, and advanced ensemble methods.
Results

Figures 2 and 3 show corpus- and sentence-level F1-Scores for the four datasets using the two NLP tools, two basic ensemble methods, and five advanced ensemble methods. The detailed Precision (P), Recall (R), and F1-Scores (F) for corpus- and sentence-level results are shown in Tables 4 and 5. In general, the scores of corpus-level evaluation are higher than those of sentence-level. We believe this is due to the aggregation of corpus-level results from sentence-level results, as sentence-level extraction is more challenging than corpus-level extraction.

For basic ensemble methods, Union generally improved performance over a single NLP tool, indicating that coverage is a critical concern for these data element extraction tasks (Figures 2 and 3). The importance of coverage can also be seen in Tables 4 and 5, where single NLP tools show high precision but relatively low recall. This also explains why Intersection consistently performs worse than all other methods (even worse than single NLP tools).

For advanced ensemble methods, although no method consistently performed the best, we did observe an interesting phenomenon: these MLC ensemble algorithms boosted performance on WM/O and KD-Private datasets, but they did not perform well on CHF and KD-Public datasets. This is related to label density, which is the number of ground truth annotations per sentence. For example, for WM/O the label density was (1,678 annotations) / (1,778 sentences) = 0.94, while for CHF the label density was only (1,885 annotations) / (3,045 sentences) = 0.62. Since the advanced ensemble methods applied multi-label learning, the datasets with higher label density (WM/O and KD-Private) provided better training examples for the classifiers and better recall (as shown in Tables 4 and 5). It should be noted that although we only use two NLP tools in our experiment, advanced ensemble methods may still be very useful to improve the extraction results. For example, consider we are extracting CHF data elements from this sentence: “Mr. X is being discharged on Lasix, Digoxin and Toprol daily.” One NLP tool may successfully extract “Lasix” as the data element “Diuretics,” while the other tool may successfully extract “Digoxin” as “Antiarrhythmics,” but both tools may fail to extract “Toprol” as “Beta-Blocker.” In this scenario, neither union nor intersection can improve the extraction results. However, if these three data elements ("Diuretics," "Antiarrhythmics," and "Beta-Blocker") are usually mentioned together in the training clinical notes, MLC ensemble algorithms may be able to recover “Beta-Blocker” even if both NLP tools miss the mention “Toprol.” We believe this is the reason why advanced ensemble methods are able to largely improve the results compared to individual NLP tools.

Also, the performance of the advanced ensemble methods is bounded by the limited availability of the annotated clinical notes. We anticipate that, when more annotated clinical notes become available for training and testing, the performance improvement of the advanced ensemble methods will be more consistent and obvious, especially for data with high label density. Additionally, in some settings (such as clinical notes from primary care providers with patients facing multitudes of conditions), the number of data elements might be on the order of hundreds of thousands, and thus more training examples are required for learning MLC models.
We also conducted qualitative analysis of our results. For each dataset, the data elements with highest and lowest F1-Score, extracted using the Union ensemble method (because it consistently performed better), are listed in Table 6 to illustrate which data elements were the most or the least successful in the extraction. A comparison of data elements with the highest and lowest F1-Scores suggests that, in general, items in the category history and progress are harder to accurately extract than those in comorbidities. However, for some categories such as medications and laboratory tests, the extraction performance varies for each data element. This observation also indicates that adding more diverse tools (e.g., specifically designed to extract history and progress, or to extract the data elements of medications or laboratory tests) may further boost overall performance. Our average processing time (seconds per note) is 1.14 for cTAKES, 44.29 for MetaMap, 0.19 for basic and 2.10 for advanced ensembles.

Conclusion

We developed an NLP ensemble pipeline to extract data elements from clinical notes, using state-of-the-art NLP tools and ensemble methods. We tested our pipeline on public and private notes for CHF, WM/O and KD. The results indicate that the Union ensemble method provides consistent improvement, while the MLC-based ensemble methods may be useful on datasets with higher density of concepts in the clinical notes. However, our study was limited to data elements selected for three cohorts only and limited by the size of clinical notes. Additionally, we used ensembles of only two NLP tools, thus our current evaluation results might not generalize to other pairs of systems nor to larger sets of systems. Nevertheless, we demonstrated that our proposed ensemble pipeline can improve the performance of NLP tools, and it may provide a practical solution for the extraction of data elements from clinical notes.

In the future, we plan to test our pipeline on a larger number of clinical notes, include additional data elements for these three and additional cohorts to increase generalizability, wrap additional NLP tools into the pipeline, and add more concept dictionaries to improve coverage (e.g., dictionaries that include acronyms). Furthermore, we will add additional ensemble methods to improve the overall extraction accuracy and sensitivity of our pipeline (adding more NLP tools enables us to use voting and include more complex ensemble algorithms). We also plan to perform additional analysis to explain the differences in the corpora and the performance of the ensemble methods (e.g., learning curve, execution time, and tool-category performance analysis), adopt parallel computing to increase scalability, and release annotations for the public domain clinical notes. We will disseminate our methods to other researchers, and test our processes in other clinical data research networks like pSCANNEr.

Plexlines: Tracking Socio-communicative Behaviors Using Timeline Visualizations

John Lee, MS, Ha-Kyung Kong, Sanny Lin, Karrie Karahalios, PhD

Abstract

In this paper, we visualize children’s coordinated gaze, gesture, and vocalization to better understand communicative behaviors and to identify developmental delay, specifically in the domain of Autism Spectrum Disorders. To date, existing behavioral data from clinical assessment instruments are often stored in raw text files or spreadsheets. This wealth of data is then represented as a single number summarizing behavior. Our approach transforms this data into a graphical story of a child’s behavior. To do this, we created Plexlines, a graphical record of a child’s social and communicative behavior. When presented with Plexlines, clinicians and researchers formed their own strategies for exploring the visualizations and independently identified children in need of further evaluation. Feedback showed that Plexlines has the potential to be integrated into existing behavioral evaluation processes, aid in the detection of developmental delays in young children, and serve as a visual artifact to better communicate with parents.

Introduction

In cases of Autism Spectrum Disorder (ASD), early intervention—as young as six months old—is critical to successful treatment and can mitigate developmental delays [1]. However ASD is difficult to diagnose early, as there are no easy medical tests to diagnose the disorders, and each patient needs individual attention. Often times social and language delays do not show until children interact with their peers in preschool [2], which is considered a late detection and reduces the effectiveness of treatment [3]. Researchers and clinicians are now turning to quick screeners for early assessment that observe the communicative behavior in young children [4]. However, it is difficult for clinicians to make an accurate behavioral model based on data in its current text-based format. We developed Plexline as a graphical representation of behavioral data for use in understanding communicative behavior and spotting developmental delay in children under 30 months of age.

We seek to reveal the hidden layers of human behavior in a visual format, ready for rapid interpretation. Current clinical interfaces include charts and tables, but they do not provide a full picture for making behavioral assessments quickly. Instead of following complicated coding guidelines and instruments to produce a number that represents a level of social engagement, Plexline combines multiple data types to reveal the unique dynamics of a child’s behavior that cannot be observed first hand. For our visualizations, we gathered behavioral data from annotations of the Rapid Attention Back and Forth Communication Test (RABC) conducted by our collaborators. The RABC is a structured experimental 5-stage social play protocol (greet, ball, book, hat, and tickle) between a child and an examiner. It was developed jointly by Emory University and the Georgia Institute of Technology for children aged 9-30 months to collect data about a child’s social and communicative behavior as a pre-screener for ASD [5].

Using hand-coded annotations, we categorize RABC communicative behaviors into gaze, gesture, and vocalization. The categories are color-coded and each behavioral event is drawn on the timeline as a colored circle. Laying out these circles along a timeline creates an overview of an individual child’s behavior. By taking advantage of a common visual language, we reveal complex patterns of coordinated behavior.

Two Plexlines

In this section, we introduce a use case for Plexlines by presenting two contrasting Plexlines from two different children (see Figure 1). A legend for Plexlines can be seen in Figure 1c. In this stage of the RABC, the examiner presents a ball to the child and says, “Look at my ball.” Typical reactions to the examiner’s statement (also referred to as an examiner bid) include looking at the examiner (blue circle) as they are speaking, and using either gesture (green circle) or speech (red circle) to ask for the ball. Figure 1a shows the Plexline of a child that display this common pattern of behavior. The diameter of the circle is proportional to the duration of the annotated behavior.

There is a variance in the timing and behavior responses in the Plexlines of typical children. However, the Plexlines share a common rhythmic pattern of overlapping circles representing coordinated gaze, gesture, and vocal behaviors. Notice how the Plexline of the second child in Figure 1b compares to that of the first child. Unlike the first Plexline,
the green circles for the gestures are small and there is lack of blue circles representing gaze towards the examiner. When watching the corresponding video for this Plexline, the child appears sociable to an untrained eye. However, the child fixates on the ball and rarely makes eye contact with the examiner. This lack of interest in the examiner is a critical sign of developmental delay [6, 7].

Plexlines allow users to quickly spot outliers in communicative behaviors such as those exhibited by the second child, and capture nuances in behavior that are difficult to spot in person or in video. We will provide more detail on the design of the Plexlines and the tool for manipulating Plexlines later in this paper.

![Figure 1. Two Plexlines showing different levels of communicative engagement during the ball stage of the RABC. In (a), the child’s gestures (green) are punctuated by gazing at the examiner’s face (blue). In (b), the child shows no gaze toward the examiner, a warning sign for developmental delay. (c) is the legend of the annotation categorizations. An Examiner Bid is an attempt by the examiner to initiate a response. The blue gaze circle denotes gaze towards the examiner. The green gesture circle denotes any communicative gesture. The red speech circle denotes vocalization and verbalization. Hatch marks represent other non-directed behaviors.](image)

Related Work

Current work in behavioral visualization is often limited to one aspect of behavior, such as visualization of only speech or only eye gaze (e.g. [8-10]). In addition, there is little application of behavioral visualization in current clinical processes. We tackle the challenge of visualizing multimodal behavior on a temporal graph. In this section, we will discuss our main inspirations from visualization work in healthcare, though this is not an exhaustive list of work in the field.

Prior work in visualization in healthcare focuses on electronic health records. Rind et al. have reported on the extensive literature in information visualization for electronic health records in their recent work [11]. The ongoing work of LifeLines2 [12] and EventFlow [13] have produced powerful tools for visualizing sequences of events, notably for visualizing a patient’s treatment history. Hsu et al. built a tool which generates a timeline interface showing the change of medical condition of patients to understand and summarize patients’ conditions [14]. Ozturk et al. showed that visualizing a patient’s medication history can be helpful, especially in emergency care, and developed an application that converts a patient prescription history data into a simple timeline visualization [15]. Visualization of medical records not only aid doctors in presenting data in an efficient manner, but also in discovering insights. Klimov et al. and Shahar et al. both focused on building an intelligent interactive visualization system which dynamically presents relevant clinical data to the clinicians by utilizing existing domain knowledge [16, 17]. Work by Gotz et al. visualized patient data based on similarity to allow human experts to refine and reference comparable patient data [18]. Similarly, Stubbs et al. proposed an interactive system for exploring and visualizing data to identify similar patients from a database [19].

While there is extensive work in visualizing personal medical histories, visualizing behavioral data is underrepresented in this field, especially for diagnosing and pre-screening for ASD. However, more researchers are applying similar technology for screening and diagnosing ASD to supplement existing procedures. Boraston et al. have utilized eye-tracking behavior to investigate gaze behavior [20], and Hashemi et al. used computer vision to assess visual attention in children [21]. More recently, Han et al. presented a visualization that allows for a comparison of any two behaviors in the RABC dataset that occur at or around the same time across multiple sessions [22]. In our work, we focus on presenting many co-occurring events of a single child in a compact visualization, which allows clinicians and researchers to examine and compare behavioral records of multiple children.
Project Background and Motivation

We focus on techniques for behavioral imaging of social and communicative behaviors and creating graphical visualizations to aid clinicians in making a diagnosis. Currently, researchers and clinicians often collect quantified scores of various behaviors from the behavioral coding stage. Well-known protocols such as the Autism Diagnostic Observation Schedule (ADOS), or the Autism Diagnostic Interview-Revised (ADI-R) result in a single number or binary evaluation representing social communicative engagement with no convenient way to interpret and explore behavior data temporally [23, 24].

In order to create graphical visualizations of child behavior, we have collected data of over 100 children, aged 9 to 30 months, engaged in a five-minute RABC session. The examiner evaluates the child’s responses to the explicit social bids and the ease of engaging the child. Specifically, the examiner seeks to elicit social attention, back-and-forth interaction, and social communication from the child. The dyadic nature of the RABC allows us to break interactions down into smaller parts and observe engagement at different levels of granularity. Our collaborators collected the RABC data as part of a NSF Expeditions effort and annotated each RABC video. Via a training codebook, three independent coders were trained to code the RABC sessions. After reaching at least 90 percent overlap for each of the annotations, they proceeded to annotate the remaining video corpus frame by frame, categorizing the child’s gaze, gesture, and speech.

Annotation Taxonomy

As a human-centered timeline, Plexlines are styled to focus on the child, with brightly colored circles representing the child’s socio-communicative behaviors. We are mainly interested in the child’s reactions and responses to the examiner bids. We separate the social behaviors of the child into gaze, gesture, and speech, which are color-coded blue, green, and red, respectively. Because we are primarily interested in behavior directed toward the examiner, only such behaviors are included in the default circle categories. Thus, an annotation labeled gaze at the examiner is visualized as a blue circle, while gaze at the ball is not. However, we still include the annotations of the non-directed behaviors in the visualization for reference. Non-directed behaviors are grouped into an independent category and visualized as hatch marks on the Plexline, regardless of type of behavior (see Figure 2c).

The examiner’s speech is categorized as social bids or verbalization. They are usually social bids, which consist of a question or a demand, such as “Can you turn the page?” or “Look at my hat!” Social bids have a limited range of expected reactions and are marked by small black points on the Plexline (see Figure 2b). They pop out among the colored circles and indicate the start of an interaction. All other verbalizations (except when calling the child’s name) by the examiner are visualized as small, unfilled black circles (see Figure 2c).

Visual Design

Plexlines’ abstracted approach of using shapes and symbols can be more concrete than numbers. People perceive perceptual structure—patterns of quantities, color, relative size, and shapes—better than patterns of numbers or words [25]. The latter uses single units, while the former operates as a whole through our cognitive ability to quickly perceive spatial relationships.

Through an iterative design process [26], the design of Plexlines was adapted to be heavily informed by the patterns clinicians look for in behavioral coding. Based off of the annotation taxonomy, Plexlines use overlapping circles along a timeline to highlight coordinated behaviors. The temporal nature of the sessions makes it natural to lay the information out horizontally as a timeline [27]. This layout also facilitates comparing a list of Plexlines.

Coordinating Co-occurring Behaviors

The coordination of these three behaviors indicates high social engagement. It is one of the motives behind the choice to use circles to represent the child’s behavior. To show coordinated behavior on a timeline, the design must...
accommodate overlapping behaviors. After iterating through many visual styles, slightly transparent circular shapes were found to be the most legible for identifying overlapping behaviors with minimal occlusion.

The diameter of the circle scales relative to the duration of the child’s behavior. Although this creates a non-linear scale between the area of the circle and the duration of the annotation, exponential scaling assists users in identifying co-occurring behaviors quickly to then explore in more detail. In cases where circles overlap, the smallest circle is always brought to the top to minimize occlusion, regardless of color. Circles are also transparent to allow for ease in spotting overlaps. A clinician interested in complex coordinated behaviors would look for instances of two, or even three, circles of different colors overlapping or lack thereof (see Figure 2c). Examiner speech throughout the RABC is consistent and short, so the circles for the examiner do not scale to duration. They act as anchor points along the Plexline for comparison across multiple Plexlines.

Defining Initiation-Response Stages

Joint attention - characterized by the shared focus of two or more people on one object - is another critical measure of social engagement [28]. The fluidity of back-and-forth interactions is one way to measure joint attention. Much of the RABC centers engagement around objects—a ball, book, and hat. When the examiner presents the object to the child, she is probing for signs that the child is able to identify her intent. Ideally, the child will draw attention to the object by means of gaze, pointing, or verbal behavior to create a shared experience between the child and the examiner.

Examiner bids followed by a series of colored circles (or lack thereof) before reaching the next social probe may be isolated as one initiation-response sequence. One initiation-response sequence shows how soon and how much the child responds to the examiner. A child-examiner pairing that is highly synchronous would have a rhythmic pattern of initiation-response sequences along the entire Plexline (see Figure 1a). The Plexline of a distracted or object-centered child would have extended breaks throughout the Plexline (see Figure 1b).

Building and Exploring A Plexlines Library

In demonstrating Plexlines to our audience, we do it in a browser-based environment that allows them to compare multiple Plexlines (see Figure 3). Facilitating comparison is critical in establishing the baseline metrics and demographic profiles necessary to spot deviations. The interface follows Shneiderman’s mantra of “overview first, zoom and filter, then details-on-demand” [29]. Users start by viewing a single child against an archive of all the Plexlines laid out as small multiples for simple comparison [30]. While the visualization is designed to stand alone without video, a video can be loaded with each Plexline. The Plexline acts as a seekbar for navigating the video which is provided to assist in learning and to clarify points of interest that may be confusing.

Figure 3. The main view of the webtool with one Plexline selected.
Comparing Apples to Apples

Behavioral development is highly dependent on age, especially in young children. For instance, we do not expect to see much vocalization in children less than 12 months old. Filtering the archive by age and gender in the webtool sets the expectations for what patterns of behavior are common among the age groups. We provide an aggregate view, where all other Plexlines—besides that of the child in focus—are layered on top of each other (see Figure 4). Patterns become even easier to compare when the user places one child’s Plexline against an aggregation of all of the other Plexlines in the filtered population of children.

As an exploratory tool, filtering and sorting by certain age groups confirms what we know about developmental milestones and helps identify different trajectories of behavioral development. Aggregation allows clinicians and researchers to create experimental “templates” of behavioral styles and develop predictive patterns of behavior for different populations of children. This is exemplified in the comment, “I really liked being able to look at one child’s performance compared to the [aggregate view] of all the others” (P5). All of our study participants commented on the value of the aggregate display (see Figure 4), with five commenting it as one of their favorite features. Clinicians further suggested we include aggregate templates for age ranges at three-month intervals and templates for specific behavioral disorders.

Figure 4. One Plexline compared against an aggregate of the same sequence of events.

Customization

Plexline uses predefined groups for 21 different annotations of child behavior. The directed behaviors are classified into color-coded circles, and the non-directed behaviors are displayed as hatch marks. While we initialize each category for users, the users can customize the Plexline by adjusting these categories. We provide users with a simple drag-and-drop interface that allows them to move the annotated child actions into other categories (see Figure 5). With this functionality, users can tailor Plexlines to their specific needs. If one would like to focus only on one specific child behavior such as pointing, all other behaviors can be removed from the Plexline to show a simplified version highlighting that one behavior. To visualize “gaze at ball” annotations as circles instead of hatch marks on a Plexline, a user can move “gaze at ball” from the others category to the gaze category through the annotation module. The flexibility of the webtool accommodates researchers and clinicians with distinct needs and provides an opportunity for users to delve deeper by showing less.

Figure 5. Customization and authoring in the webtool tool allows the user to change annotation categorizations and simplify the Plexline. This image shows three stages of filtering. From top to bottom: (a) all annotations visible, (b) only gestures visible, (c) only pointing gestures visible
Evaluation

To evaluate Plexlines, we recruited eleven (9 female, 2 male) researchers and clinicians with research and/or clinical experience in developmental health, including early childhood education, intervention, and autism research. Six of the participants reported that they had more than five years of research experience. The remaining participants were doctoral candidates.

We began the study with a five-minute introductory video, which explained the details of the RABC, Plexlines, and the webtool. The participants were then given approximately thirty minutes to familiarize themselves with the webtool. During this time, the participants explored the functionality of the webtool and described how they might use it in their workflow. We observed the participants using the tool and recorded notes describing their use of the webtool and Plexlines and any comments they shared while using it. After the subjects explored the webtool, they were given a Plexline comprehension worksheet, which asked the participants to describe the behaviors represented by four different Plexlines without the assistance of video or the webtool. Lastly, the participants were given a survey that included questions to evaluate Plexlines and the webtool, and indicate their knowledge of developmental health and ASD behaviors on a 5-point Likert scale. In addition, we included open-ended questions to list the strength and weaknesses of Plexlines and the webtool. The study lasted roughly one hour for all participants.

Despite our initial concerns that researchers and clinicians would be hesitant to embrace unfamiliar behavioral visualization technologies, Plexlines and the webtool were well received. On a 5-point Likert scale ranging from strongly disagree (1) to strongly agree (5), participants rated that they were satisfied with Plexlines ($\mu=4.11$, $\sigma^2=0.33$) and the webtool ($\mu=4.33$, $\sigma^2=0.24$). We found that the participants grasped the concept of Plexlines quickly, and they were able to make interpretations from the Plexlines.

We used an open-coding method to label and summarize comments and observations while participants were exploring the webtool. We discovered that in general, participants used the following strategies to navigate Plexlines and draw interpretations, going through each stage at different rates depending on their level of familiarity with ASD and their research goals:

1) Rapidly explore the archive through a browsable interface.
2) Compare one child against many using customizable zooming, filtering, and aggregation tools.
3) Interpret Plexlines by spotting specific moments of concern.
4) Use Plexlines as a narrative to share their interpretations of a child.

Exploring the Archive

Facilitated by the webtool interface, the participants initially browsed the library of Plexlines displayed as a list to get an overview of the tool and familiarized themselves with Plexlines. After spending a few minutes browsing, each of the participants in our study independently developed their own search plans for exploring the Plexlines. The goals varied depending on their previous research, clinical experiences, and familiarity with behavioral analysis. Some participants focused primarily on finding patterns among different age groups, while others focused on spotting specific behaviors in children, catered to their own research goals or interests.

Interpreting Plexlines

After the exploration stage, the webtool allowed users to customize the Plexlines display to focus on specific points of interest. One participant described her hypothesis and investigation strategy as such: “If you are working with children with ASD, the first thing you want to look [for] is gesture and gaze because they usually avoid eye contact and have fewer gestures compared to children with disabilities” (P10). Participants used relationship comparison and details-on-demand strategies to verify their hypotheses and to make interpretations about the child’s activity on the Plexline.

On a 5-point Likert scale ranging from strongly disagree (1) to strongly agree (5), participants found Plexlines interpretable ($\mu=4.22$, $\sigma^2=0.39$) and exhibited visual literacy of the Plexlines within the first thirty minutes. One participant stated, “I’ve been here 15 minutes and already [they’re] a lot easier to read” (P1). Every participant commented on atypical behaviors they observed throughout the Plexlines, and were able to independently pick out a child that was suspected to be at risk for autism. When spotting an outlier, the participants would make remarks that indicated they wanted to pursue a deeper investigation: “I can see that this guy is not responding to these bids much at all” (P4), “I really want to know what is happening with the little girl!” (P4), and “RA052 stands out the most”.
Most subjects then spent considerable time on one child, closely inspecting the corresponding Plexline and using it to scroll to the video to verify their hypotheses. The ability of the participants to identify children in need of further evaluation based solely on a graphic demonstrates the salience of Plexlines.

Participants also distinguished between the subtleties in interaction styles. There was consistent agreement among the participants about what types of behaviors the children were showing at specific times. Four participants also felt comfortable expressing concern for specific children based solely on the Plexline without any video or aggregation for comparison.

Making Comparisons

One popular strategy that the participants displayed was filtering by age and then searching for patterns within the age group. One participant described their process as follows: “Watching her, I immediately think something is going on. She is making a lot of gestures, she is making sounds, but it is not clear to me what is happening yet, so I am filtering down to a tighter age range” (P4). The ability to filter profiles and create aggregates for that group proved to be critical for providing the right context for making comparisons. Common filtering strategies include creating profiles by age or focusing on specific behaviors.

Participants were able to quickly glance over the small multiples to make comparisons against other children in the library. One participant wrote that one of the most positive aspects of Plexlines is “the ability to examine patterns across multiple subjects in one visual field” (P11). Beyond simple browsing, the aggregate view (see Figure 4) is a popular and effective method for making comparisons. Five participants specifically stated that the ability to view the aggregate was one of the biggest strengths of Plexlines in providing anchors for behavioral expectations. Being able to conduct a data analysis on the whole data set is especially critical in explaining visualizations to other people.

For researchers that were interested in a specific type of behavior, they preferred to filter by hiding all other behaviors besides the ones they are most interested in. The customizability of the annotation schedule allowed the participants to tailor the Plexlines to their expertise. One particular participant adjusted the settings to show only 3 gestures: point, reach, and tap. When asked to explain his process, he said, “I am interested in gesture because he is trying to say something, but he is not able to vocalize it” (P11). After spotting an unusual Plexline, participants formed hypotheses about what they thought was happening and confirmed their interpretations by focusing on specific stages of the Plexline.

Using Plexlines to Tell a Narrative

Visualizations can be made even more accessible by allowing the users to filter out noise and frame the information around a narrative [31]. The ability to omit data and break down behavior by type or stage proved to be valuable in telling a story to non-experts. After completing an evaluation session and interpreting the results, clinicians in our study wanted to engage a parent in the next stage decision-making process. In describing something as complicated as behavior, showing is more informative than telling.

As a colorful graphic, Plexlines are less intimidating than a spreadsheet or a number rating. Because of this quality, Plexlines act as a catalyst for discussions between clinicians and parents. A clinician can navigate a Plexline in part or in whole to tell a story with a beginning, middle, and end to the parent through the visualization. In an example situation that a participant gave us, clinicians would “use it to say, ‘Four different times I asked your child to do this and he didn’t respond. Our expectation is that with the first or second bid, [the child would respond]’” (P2). The ability of a graphic to show a causation of events and allow the viewer to discern the relationship among them creates a narrative that engages the reader beyond a text-only report.

To further reduce complexity for the parent, the clinician can break the session down into tasks by segmenting the Plexlines and filtering out unnecessary annotations. For example, parents may have misconceptions about their child’s developmental health. One participant gave an example of a parent that believed a highly vocal child indicated no developmental delay: “A dad linked [social engagement] to language. So let’s remove all the vocalization. Let’s [focus on] where the child is looking to show a parent” (P2). By isolating the visual narrative around eye gaze and having a concrete representation of behavior as an artifact for discussion, the clinician can more easily explain her interpretations.

Study participants described telling stories to clinicians, to parents and to research audiences. For example, a researcher stated, “Once I had done data analysis on the whole data set, I still might present [the] data aggregate and see [the] prototypical [18 months old child that was engaged] like for a talk. Then show a prototypical for a
child who is impaired” (P1). In this same context, the archival capabilities of the webtool allow users to create a comprehensive story that extends beyond just one child. According to a participant, Plexlines “display a visual story to others without worrying about confidentiality. Plexlines replaces the need of sharing videos” (P9).

Discussion and Future Work

Plexlines do not replace the existing evaluation processes, but can assist in understanding child behavior. In general, visualization is an underutilized technique in behavioral science, and Plexlines demonstrates the potential of this approach. From our user feedback, we found that Plexlines complement traditional behavioral evaluation processes, especially by providing salient visualization of social behavior. We identified opportunities to use Plexlines in rapid screening, tracking child development, and training.

Screening a Spectrum of Children

We intentionally did not create profiles of prototypical children because we realize that no two children are alike and there is no such thing as an “average” child. Visually comparing a child to their age group, or even just comparing a child to another is not a trivial task with existing tools. Currently, we suggest how a child might behave by showing the aggregate view, but this can be visually cluttered and misleading. The additive nature of transparent colors exaggerated the characteristics of a typical child, yet we discovered that comparing aggregates and averages was one of the most important exploration strategies, helping the users form frames of reference (see Figure 4). After a few minutes exploring the tool, participants familiar with RABC and had experience with ASD were comfortable stating, “Here’s a good example of a typical kid” (P1).

While we were initially hesitant to create any Plexlines that are suggestive of an ideal child for a specific profile, the participants’ desire for a normative graph with normative data changed our perceptions. A single normative Plexline that is informed by the dataset can be valuable in all stages of the process from exploration to interpretation to sharing. This is an opportunity for us to explore in the future.

Plexlines as a Personal Archive

While our user study focused on the Plexlines, there is room for improvement in making the interface more robust and usable. In particular, we plan on allowing the user to focus on and track the records of a single child. In our dataset, there are several children who were brought back for a follow-up evaluation. These children have two Plexlines in the library. These follow-up RABC sessions open up opportunities to track a child’s progress consistently over a longer period of time. This personal record can be used by parents and clinicians to build a cohesive, sharable snapshot of each child as they navigate the child’s future, from pre-screening for autism to evaluating the effectiveness of intervention strategies. Users will need the ability to mark and annotate points of interest on the Plexline for later reference. Each added Plexline contributes to a growing archive of Plexlines that help researchers and clinicians understand communicative child development.

In creating such a record, we are exploring Plexlines in other types of behavioral evaluation beyond the RABC. A few of our participants have shown interest in visualizing their own datasets featuring dyadic interaction with Plexlines. We are exploring alternate visualizations for dyadic interaction where one person is visualized above the center line and the other person is visualized below.

Plexlines as a Teaching Aid

Not only are Plexlines valuable for explaining the evaluation process and outcomes to parents, but they can also be used for training clinicians in the RABC. Trainees can see a series of Plexline visualizations to understand a typical session and use the exploration strategies to understand the structure of the protocol and the expected behaviors that follow. Used as an artifact in conversation, visualizations can help improve memory and support interpretations [30]. Several participants commented on the use of Plexlines as a teaching tool. On in particular emphasized that Plexlines can reveal patterns that are difficult to spot in videos: “I think this would be helpful [for training]. For example, Amy Whetherby’s videos for training say what’s typical and not typical. [Plexlines let you] see the whole thing - like a condensed ADOS. [I’d go] through an example of what I’m looking for: verbal, nonverbal, social non-directedness. It’s a hard skill to train” (P4).

Limitations

Our approach to visualizing behavior on Plexlines relies heavily on annotation availability. Our current RABC dataset may not contain many cases of children on the autism spectrum. Most children participate prior to a
diagnosis. Additionally, the annotations are limited by the accuracy of coding, and the rigidity of the handcrafted annotation schedule. We realize annotations are imperfect and not inclusive of every possible behavior.

Coding schemes improve iteratively over time. The features we are coding may not be optimized for our screening goals, and the taxonomy for Plexlines is highly influenced by the taxonomy of the existing RABC annotations. We currently distinguish between gaze, gesture, and speech behaviors. Smiles and affect are examples of annotations that may be useful, but not yet annotated. Annotations for other red flags of autism, such as echolalia, unusual prosody, and stereotypical repetitive behaviors [31, 7] could also be explored.

The time to code the RABC videos is another limitation. Ideally, a clinician may want to show a parent their child’s Plexline immediately following the session. Other members of the research team are exploring vision and audio techniques to automatically extract annotations from the RABC videos. Classification accuracy rates for gaze, speech-like vocalization, smiles, and emotion are improving. Until we can reliably annotate data automatically, we begin by using time-intensive hand-coded annotations for our visualization.

Conclusion

We presented Plexlines, a technique for visualizing multiple layers of socio-communicative behaviors on one timeline. The visual presentation of behavioral data provides researchers and clinicians with a novel way of understanding and interpreting behavioral communicative data beyond traditional charts and tables. While initially fearful that alternative visualizations were not the norm in clinical and research practice, feedback from researchers and clinicians shows that Plexlines serves as an engaging and effective method of providing a compact overview of a person’s behavior.

Our study revealed that Plexlines has the potential to be integrated into existing behavioral evaluation processes, aid in the detection of developmental delays in young children, and serve as a visual artifact to better communicate with parents. Through exploration and customization of Plexlines, researchers and clinicians were able to independently identify two children at risk for ASD. Participants used Plexlines to interpret the RABC data and reflect on their own personal research questions. They created stories around Plexlines and imagined using Plexlines to facilitate conversations with parents and larger audiences. Personalizable and shareable, Plexlines aid in expanding our shared understanding of human behavior and child development. While more studies are needed, we envision integrating Plexlines into early screening and clinical evaluations in hopes of increasing rates of early detection for timely intervention, a critical element in minimizing developmental delays among children with ASD [32].

Improving Endpoint Detection to Support Automated Systematic Reviews

Ana Lucic, MS¹, Catherine L. Blake, PhD¹
¹School of Information Sciences, University of Illinois, Champaign, IL

Abstract

Authors of biomedical articles use comparison sentences to communicate the findings of a study, and to compare the results of the current study with earlier studies. The Claim Framework defines a comparison claim as a sentence that includes at least two entities that are being compared, and an endpoint that captures the way in which the entities are compared. Although automated methods have been developed to identify comparison sentences from the text, identifying the role that a specific noun plays (i.e., entity or endpoint) is much more difficult. Automated methods have been successful at identifying the second entity, but classification models were unable to clearly differentiate between the first entity and the endpoint. We show empirically that establishing if head noun is an amount or measure provides a statistically significant improvement that increases the endpoint precision from 0.42 to 0.56 on longer and from 0.51 to 0.58 on shorter sentences and recall from 0.64 to 0.71 on longer and from 0.69 to 0.74 on shorter sentences. The differences were not statistically significant for the second compared entity.

Introduction

Scientific literature in the field of biomedicine continues to grow at a staggering rate. The number of abstracts in PubMed already exceeds 24 million and every week, the National Library of Medicine adds thousands of new abstracts. Although systematic reviews can help both frontline health care professionals and researchers by accurately synthesizing high quality evidence, the manual processes used to conduct a systematic review are time consuming. A systematic review, which is the cornerstone of Evidence Based Medicine (EBM), can take 5-6 people more than 1000 hours to complete¹, so help is urgently needed to reduce the time between the publication of new results and their integration into practice. Figure 1 shows clearly that the number of meta-analyses (a systematic review that integrates results using quantitative methods) on diabetes have increased from 40 to 974 since 2000.

Automating the systematic review process was first introduced almost a decade ago² and since then there have been several efforts to that focus on the information retrieval³-⁸, and information extraction stages of the process⁹ have been developed. In addition to automated strategies, manual efforts are underway to capture data required in a systematic review and tools are available to help with writing the manuscript. Our goal is to support the systematic review process by automatically identifying results from full-text articles.

In this paper we focus on comparison sentences. Within the context of biomedical collection of articles, comparison sentences frequently communicate the results of a study and include the information about the entities that were compared and the basis on which they were compared, which we call an endpoint. Although not a frequent structure in scholarly articles, comparison sentences contain a wealth of information that, when viewed in aggregate, can assist policy makers, health care providers, patients and general consumers of health information with insights about the entities of interest and their comparative characteristics. An analysis of clinical questions in the National Library of Health (NLH) Question Answering Service (http://www.clinicalanswers.nhs.uk) revealed that 16% of the 4,580 questions referred to direct comparisons of different drugs, treatment methods and intervention¹¹. Although comparisons have been identified as an information need, current systems do not allow the extraction and synthesis of comparative data from scholarly articles. More broadly, the structure of comparison sentences and the methods that allow parsing of the comparison structure in an automated way can be seen as particularly relevant to Comparative Effectiveness Research whose goal is to provide evidence on the effectiveness, benefits, and drawbacks of different treatment options. Identifying comparison facets in an automated way can assist the process of generating a comparative summary and thus highlight the areas where comparative work has or has not been done. More recently, there has been a shift towards the identification of indirect comparisons in scholarly articles¹².
High quality evidence consisting of systematic review of randomized clinical trials that provide direct (head-to-head) comparison of two interventions are commonly rare, sometimes non-existent or inconclusive; occasionally, indirect comparisons can be more reliable than direct evidence due to methodological inadequacies of trials.

In this study we pay particular attention to direct comparisons (direct mention of at least two compared entities and the endpoint in the comparison sentence) and to the expression of endpoints in comparison sentences. In the following example, fast-track and slow-track patients represent the compared entities whereas HbA1c, blood pressure and serum creatinine levels represent the basis on which slow-track and fast-track patients were compared. This sentence is considered a direct comparison sentence:

(1) HbA1c [Endpoint_1], blood pressure [Endpoint_2], and serum creatinine levels [Endpoint_3] were significantly higher in fast-track [Entity_1] than in slow-track patients [Entity_2].

The following is an example of a comparison sentence that features hypoglycemia as the endpoint modifier:

(2) Glucagon levels [Endpoint_1] were significantly lower (P < 0.0001) during hypoglycemia [Endpoint_1_modifier] with tolbutamide [Entity_1] than without tolbutamide [Entity_2].

In the above example, hypoglycemia is used to modify the main endpoint, glucagon levels, and to compare it with relation to drug tolbutamide.

Sentence (3) features body weight, as an endpoint:

(3) Body weight [Endpoint] of the high-fat-fed C57BL/6J mice [Entity_1] was 28% higher at 3 months (P < 0.001) and 69% higher at 15 months (P < 0.001) compared with the normal diet-fed C57BL/6J mice [Entity_2].

Sentence (4) features fasting plasma glucose (FPG) as an endpoint that indicates the difference that was observed in ZDF rats at 12 weeks of age versus 6 weeks of age:

(4) The fasting plasma glucose level [Endpoint] of ZDF rats [Entity_1] was significantly elevated at 12 weeks of age [Entity_1 modifier] compared with the level observed at 6 weeks of age [Entity_2 modifier].

These examples demonstrate that comparison sentences represent a convenient medium for examining and identifying endpoints reported in biomedical literature. Furthermore, this paper will demonstrate how by focusing on comparison sentences in biomedical articles we can facilitate a better identification, retrieval, aggregation as well as examination of endpoints. Once entities and endpoints are identified information from comparison sentences can be organized into a tabular summary that shows a detailed summary of which comparisons have already been made and which comparisons are currently missing from the current biomedical literature (see ref 18 for details). Such a summary can be used when writing a systematic review to establish areas where there is enough literature and to identify areas where the results between studies differ.

Several automated methods have been developed to identify comparison sentences from text and we extend that work by identifying the specific noun phrase within a sentence that fulfills each of the entity and endpoint roles. Previous work achieved good results with respect to Entity 2 where 0.74, 0.80, and 0.91 were reported for precision, recall and accuracy; however, differentiating between Entity 1 and the endpoint is challenging because they are used in similar contexts and with similar grammatical structures. This paper introduces a new method to improve the predictive accuracy of Entity 1 and the endpoint. The approach employs a set of heuristics that capture measurements, and leverages a multi-class classifier instead of a binary classifier. The hypothesis of this study is that endpoints frequently, although not exclusively, represent dependent entities that lend themselves to measurement. Also, we hypothesize that this property can be useful for separating endpoints from other entities in the sentence and for improving the precision and recall for this comparison facet.

Materials and Methods

A set of 100 comparison sentences from the journals Diabetes, Carcinogenesis, and Endocrinology (TREC Genomics collection) that comprise 641 noun phrases used in an earlier study were enriched with information about whether the head noun of the candidate noun is likely to be categorized as an Amount or whether it is more likely to be as a (population) group. This set of 100 comparison sentences was used for training the models (training set). A locally created dictionary consisting of 91 terms was used for the purpose of enriching the feature set with the information on whether the head noun of the candidate noun phrase in a comparison sentence was likely to be an...
Amount or a population group. 71 unique terms such as level, concentration, rate, mass, proportion, and degree were categorized as an Amount and 20 terms were used to indicate a population group such as, control, arm, trial, treatment. Drugs were also identified as a group because drugs, within the context of comparison sentences extracted from biomedical scholarly articles, are frequently used as a population group that is compared to another group of drugs. Drugs were identified using the UMLS Pharmacologic Substance semantic class. A number of candidate nouns that occur in comparison sentence will not be identified with either Amount or Group semantic class and was assigned a Null value.

Once the models were built (Table 1), they were then applied to the entire collection and evaluated on a test set of 132 sentences with <=40 words that were drawn at random from the collection. The test set comprised 939 noun phrases. Results are also shown for a sub-sample of the test set consisting of 66 short sentences (<=30 words) comprising 385 noun phrases18 to explore the impact of sentence length on system performance. Our research question is to determine if the additional amount and group information improves classification performance for the three crucial facets of a comparison sentence – the two compared entities and the endpoint on which they are compared (Entity 1, Entity 2, and Endpoint).

</table>

Earlier work reported results for Support Vector Machine algorithm and linear kernel18. We were interested in contrasting linear to Gaussian kernel as well as binary to multi-class classification method. Each of the experiments in Table 1 was run with linear and then contrasted with Gaussian kernel method. Of particular interest is whether the non-linear separator and transforming data into an n-dimensional space may provide better results than the linear equation on the attributes in the data set. Two types of multi-class classification experiments were conducted: 1) prediction of 2 compared entities, endpoint and all the rest of the nouns that did not belong to either of these categories (4 classes) and 2) prediction of Entity 1, Endpoint and all the rest of the nouns that did not belong to either of these categories (3 classes). Oracle Data Miner, version 3.2 was used as the platform.

The baseline approach used the same set of lexico-syntactic features was used as in earlier study (See ref 18) although a different version of the parser was used: Stanford dependency parser, version 3.5.1. Multi-class classification methods used 26 features from the previous study for the baseline model whereas binary classification method used 26 features for Entity 1 and 21 for Endpoint and Entity 218. The features used in the earlier and this study rely on the syntactic parse of the sentence provided through Stanford dependency parser and measure the syntactic but also raw distance of each of the candidate nouns from each comparison, evidence, and change anchor in the sentence. Comparison anchors represent the phrases such as compared with and similar to, different from. A set of 65 comparison anchors is used. Evidence anchor represent verbs that indicate a finding such as demonstrate, explain, transform etc. The system uses a set of 432 evidence verbs. Change anchors represent verbs that demonstrate change, such as increase, decrease, and accelerate. The system uses a lexicon of 770 change verbs. Syntactic paths that connect the syntactic root of the sentence as well as comparison anchor to each candidate noun.
are also included as the features in the model. Finally, the classifier is provided with the information on whether the candidate noun appears as a terminal leaf in the syntactic parse of the sentence. The only new features that are added in this experiment is the information on whether the head noun of the candidate noun phrase is more likely to be identified as an Amount or as a population group.

Results

Entity 1 Prediction

For prediction of Entity 1, Table 2 indicates that the results do not improve when multi-class classifier was used and no additional features were added to the model. When four classes were predicted and no additional information was added, precision dropped 0.01 point and recall 0.30 points. When we reduced the number of classes to three (focus on Entity 1 and Endpoint only), the precision increased 0.01 point but recall dropped 0.14 points. However, adding information about whether the head noun of the candidate noun phrase is likely to be categorized as Amount or Group improved precision and recall with binary classifier and linear kernel (BC + A & G). Compared to baseline (BC), precision increased 0.05 points and recall 0.02. The combination of a multi-class classifier and Gaussian kernel plus additional features (MC4 + Amount and Group) also improved the results. Precision increased from 0.39 to 0.53 (0.14 increase) and recall from 0.47 to 0.57 (0.10 increase). However, given that baseline recall was 0.58 (BC, linear) this actually represents a drop in recall of 0.01 point.

Table 2. Entity 1 results for all test set sentences (95% confidence intervals are shown in parenthesis).

With shorter sentences that are not longer than 30 words and that typically have fewer candidate nouns, precision improved from 0.46 using binary linear kernel classifier (BC, linear) to 0.68 using multi-class classifier and Gaussian kernel (0.22 increase) (MC3 + A & G) while the recall dropped 0.01 point from 0.63 to 0.62 (see Table 3).

Given that a series of 12 classification tasks was conducted and given that six of them did not include Amount and Group information and six did include Amount and Group information the question of interest was whether these apparent differences in the results can be attributed to chance. To establish whether adding the Amount and Group information boosts the performance by chance, a series of matched t-test on the two contrasted groups (BC, MC4, MC3—Linear and BC, MC4, MC4—Gaussian) versus (BC + A & G, MC4 + A & G, MC3 + A & G—Linear and BC + A & G, MC4 + A & G, MC3, A & G—Gaussian kernel) for each of the reported metrics was conducted. For Entity 1 prediction, the differences for individual metric—precision, recall, F1, and accuracy—on the entire test set (939 noun phrases, 132 sentences) were statistically significant (P < .05).

Table 3. Entity 1 results for short sentences (95% confidence intervals are shown in parenthesis).
In conclusion, associating the head noun of a candidate compound noun with categories such as Amount and Group improved the precision of identifying Entity 1. Compared to the baseline method, recall did not increase and typically dropped 0.01 or 0.02 points except with binary classifier, linear kernel when additional features were used \((BC + A \& G)\). Generally, multi-class classifier with additional features (regardless of the number of classes predicted) raised precision of the classifier while the recall dropped minimally.

**Endpoint Prediction**

Table 4 indicates the results for endpoint prediction. Similar to Entity 1 classification, setting the problem as a binary or multi-class classifier does not make a difference until information about the type of head noun is added. Such an addition boosts performance with both binary and multi-class classification methods. More particularly, using multi-class classifier, linear kernel, and additional features \((MC_3 + A \& G)\) on all 132 sentences improves the precision from 0.42 to 0.56 (0.14 points) and recall from 0.64 to 0.71 (0.07 improvement). Consequently, \(F_1\) measure improves to 0.62 (0.09 improvement) and accuracy to 0.79 (0.06 improvement) (Table 4).

**Table 4.** Endpoint results for all test sentences (95% confidence interval in parentheses).

With respect to short sentences ($\leqslant$30 words), the multi-class classifier with the Gaussian kernel and additional features improved the results from 0.51 (BC) to 0.58 (MC3 + A & G) and 0.59 (MC4 + A & G). Similarly, recall improved from 0.69 (BC) to 0.74 (MC3 + A & G). Consequently, the $F_1$ measure and accuracy increased to 0.63 and 0.78 (MC3 + A & G) and 0.65 and 0.78 (MC4 + A & G) (see Table 5).

With endpoint prediction, both precision and recall increase when multi-class classifier and additional information are used and we do not see the precision-recall trade-off as with Entity 1. Both types of multi-class classifiers (MC3 and MC4) and both kernel methods, linear and Gaussian, benefit from the addition of Amount and Group features. To illustrate, compared with baseline (BC) precision of 0.42, multi-class Support Vector Machine, linear kernel classifier (3 classes) achieved precision of 0.56 (0.14 increase) while recall went from 0.64 to 0.71. With shorter sentences, multi-class (3 classes) and Gaussian kernel achieved precision of 0.58 compared to 0.51 earlier best result (0.07 increase) and recall of 0.74 compared to earlier 0.64 (0.10 increase).

In conclusion, the endpoint prediction was similar to Entity 1, where the differences between results achieved with or without Amount and Group information could not be attributed to chance. The differences were statistically significant for each individual metric (precision, recall, $F_1$, accuracy) ($P < .05$).

**Entity 2 Prediction**

Interestingly, the identification of Entity 2 does not benefit from additional information. As Table 6 indicates, the performance of the linear kernel classifier dropped after the additional information was added with both binary and multi-class classifiers.

Earlier work18 reported the closeness of Entity 2 to comparison anchor terms such as compared with, similar to, and different from. Thus, some of the best indicators for the location of Entity 2 were accompanied with a drop in precision: 0.66 compared to 0.74. In conclusion, the addition of the new features boosted the performance for Entity 1 and Endpoint but not for Entity 2 that already boasts a high level of precision and recall. (0.74 precision and 0.80 recall on longer sentences). The implication is that shattering of the search space (multi-class classifier) for Entity 2 was not helpful and did not result in better prediction results.

With short sentences, recall also increased using Gaussian kernel and binary classifier with no additional features (BC) (0.87 compared to 0.83). However, this was accompanied with a drop in precision from 0.77 to 0.71 (Table 7). In conclusion, Entity 2 prediction does not benefit from additional information and setting up the problem as a multi-class classification did not bring any improvement over binary classifier (BC). A spike in recall was recorded with Gaussian kernel and binary classification method and no additional features.

When the results of the experiments that use the additional information were compared to the results that do not use additional information were contrasted it was not clear that these individual differences cannot be attributed to chance only—the difference between these two groups for each individual metric (precision, recall, F₁, accuracy) was not statistically significant (P > .05).

Discussion

The concept of mechanism in the sciences is useful to understand the nature of comparison sentences. Mechanisms consist of entities and activities: entities are the things that engage in activities and activities are producers of change. Entities, within the context of a comparison sentence, represent things that are compared whereas activities represent the change that has occurred between the entities. The endpoint can be seen as part of the activity process, an entity, a dependent more likely than a continuant, whose role is to communicate the change that has occurred between the entities. Seen from this perspective, compared entities and endpoints would likely belong to different semantic classes. We contend that it is the addition of a semantic class to the feature set that would help separate the first compared entity from endpoint. The question, however, is how to obtain the information about the semantic
class for compared entities and endpoints? From an ontological point of view, entities that occur in comparison sentences can be matched to an ontological class such as species or population group. For example, the Unified Medical Language System Metathesaurus semantic class Population group can be seen as helpful for their identification. Consider the following sentence:

(5) The plasma insulin concentration [Endpoint_1] at 8 weeks of age [Modifier] and the pancreatic insulin content [Endpoint_2] and the beta-cell mass [Endpoint_3] on day 8 and 8 weeks of age [Modifier] in STZ-treated rats [Entity] were severely reduced compared with those of normal rats [Entity] (P < 0.001). 14988244

In this sentence, STZ-treated rats and normal rats represent two entities that can be seen as two population groups that were compared. And yet matching these two concepts to their semantic classes using the UMLS Metathesaurus does not bring us to the Population but rather to the Animals class. Neither STZ-treated rats nor normal rats has its full match in the UMLS because they represent very specific groups of rats: rats treated with streptozotocin versus rats that were not treated. With both of these examples, however, it is the head noun—rats—that provides sufficient basis for inferring the semantic class for these two entities—Mammals—and then, through its parent relation, to Vertebræ and Animals higher up in the hierarchy. Animals, however, do not link directly to Population group in the UMLS. In the higher levels of semantic network, Animals is an Entity, the broad type used for grouping conceptual and physical entities. Population group in the UMLS Metathesaurus is defined as “an individual or individuals classified according to their sex, racial origin, religion, common place of living, financial or social status, or some other cultural or behavioral attribute” and as such does not extend to Animals. Similarly, matching endpoints to an ontological class is far from being a straightforward process. Endpoints represent the processes, mechanisms, activities that are happening on the molecular, cellular, tissue, organ, or body level and as such can span semantic classes or be comprised of several semantic classes. By their nature, endpoints represent very specific processes and are typically expressed as a compound noun. In the sentence above, plasma insulin concentration, pancreatic insulin content and beta-cell mass were identified as endpoints. Matching plasma insulin concentration to its semantic class would fall under the category of a complex match as plasma insulin would be matched to one concept and concentration to another. What complicates things further is the fact that concentration also represents the case of overmatching because it is identified as a Mental Concept but also as a Quantitative Concept. It is the surrounding context that can determine the concept that should be used for concentration which in this case is a Quantitative Concept. Pancreatic insulin matches to Neoplastic Process which is not an ideal match for pancreatic insulin content. Ideally, we would have pancreatic insulin content matched to one semantic class that would be identified as the measurement of insulin in the pancreas. It is the head noun content in this compound noun that adds this quantitative quality to pancreatic insulin and steers the meaning of the noun in the direction of measurement. The situation is somewhat better with beta-cell mass, an example of a complex match. Beta cell matches to Cell semantic type and mass to Quantitative Concept semantic class, both of which identify the parts correctly.

Most often, endpoints are specific phrases and terms that sometimes indicate the outcome measure and sometimes the property of a compared entity that experienced a change. The following sentence is used to demonstrate the level of endpoint specificity:

(6) Nonfasting plasma glucose levels [Endpoint_1] and the overall glycemic excursion (area under the curve) to a glucose load [Endpoint_2] were significantly reduced (1.6-fold; P < 0.05) in (Pro_3) GIP-treated mice [Entity] compared with controls [Entity] 16046312

The endpoints in this sentence are nonfasting plasma glucose levels and glycemic excursion to a glucose load. While plasma glucose gets matched to the semantic type Laboratory procedure, nonfasting is matched to semantic class Finding which in this case is not ideal. Within the context of a comparison sentence and the information it conveys, the modifier, nonfasting provides a very important nuance for the meaning of the entire sentence and it should be retrieved as part of the endpoint.

Previous research reported a number of endpoints related to metformin drug comparison to other interventions. That study reported the following endpoints that relate to insulin: proinsulin concentrations, insulin, insulin action, insulin concentrations, serum insulin concentrations, insulin sensitivity, % suppression by insulin. The following endpoints relate to glucose: glucose, fasting glucose, hepatic glucose production during hyperinsulinemia, glucose disposal, glucose disposal rate, serum fructosamine, glycated hemoglobin (HbA1c). These endpoints were grouped based on the main substance they were measuring, insulin or glucose, whereas in this study we grouped the endpoints based on the property that they frequently share: measurement characteristic. The question remains what kind of grouping or matching system is better for the particular and specific nature of endpoints and at what modifier
and what level we can start to draw the line. These questions require a medical specialist to intervene and assist with the process of endpoint categorization.

The problems described above fall under the categories of complex, partial matches, gapped partial matches and overmatching. Most typically, endpoints are very specific phrases and it is this level of specificity that prevents them from being matched to an ontology effectively. This study showed that the fact that many endpoints lend themselves to measurement was the feature that improved their overall identification and retrieval. And yet, not all endpoints lend themselves to measurement. Consider the following sentence:

(7) There is evidence to suggest that the somatic mutational pathway \([\text{Endpoint}_1]\) may differ between invasive \([\text{Entity}_1]\) and LMP ovarian tumours \([\text{Entity}_2]\) and invasive tumours \([\text{Entity}_1]\) are more likely than LMP \([\text{Entity}_2]\) to exhibit \(p53\) overexpression \([\text{Endpoint}_2]\).

Somatic mutational pathway is identified as one of the endpoints in this sentence. It is not clear that the concept of mechanism can extend to pathways\(^2\) but even if this is the case, this type of mechanism and the change that is indicated in the above sentence does not involve measurement of any kind, only the statement that the pathway was different. Clearly, in this case, the endpoint does not lend itself to measurement in the same way as the endpoints that comprise the head noun, such as concentration, level, degree, or mass. The second endpoint, however, \(p53\) overexpression, can be measured. This sentence provides an example where one of the endpoints lends itself to measurement and the other does not indicating that the endpoints, even within the context of the same sentence, do not need to share the same characteristics.

Word ambiguity, context of the article, precision of grammatical and semantic parsers are standing in the way of better alignment of the free form of textual information in scholarly articles and with entries in ontologies and their definitions. Commonly, a large number of pre-processing tasks is needed in order to convert the text of scholarly articles to a format in which it can be matched to an ontology to enable semantic processing of the text. This study demonstrated that the identification of crucial facets of comparison sentences has benefited from additional information about the meaning of the candidate noun. The method outlined in this study requires testing on a larger dataset. Also, this work invites the examination of which semantic classes in the UMLS, or the subsets of them, can be used to indicate a Population Group effectively in the biomedical scholarly articles. Future work will also strive to examine the role of the Quantitative Concept UMLS semantic class in assisting with the process of identification, retrieval and definition of endpoints. Finally, given that not all endpoints lend themselves to measurement (for example, pathway) future work will need to establish other possible ways of modeling endpoints and establishing their significant properties that that can enable their more effective identification and retrieval.

Conclusion

The results from this study suggest that establishing if the head noun is an amount or measure enables the Support Vector Machine to differentiate nouns that play an endpoint role from other candidate noun phrases in a comparison sentence more effectively. Thus treating endpoints as an activity and seeing them through the lens of measurement provided a boost in performance with reference to their identification and retrieval. Classification performance on the test set improved for both entity 1 and the endpoint roles when amount and measure were provided as features and the improvement was statistically significant. The results were not statistically significant for Entity 2 prediction. This improved accuracy provides authors of a systematic review with more specific information about how treatments are compared. In addition, improved retrieval of endpoints will allow us to better examine and assess endpoints in aggregate and track changes over time.

Controlling testing volume for respiratory viruses using machine learning and text mining

Mark V. Mai, MD, MHS¹, Michael Krauthammer, MD, PhD²
¹The Children’s Hospital of Philadelphia, Philadelphia, PA; ²Yale School of Medicine, New Haven, CT

Abstract

Viral testing for pediatric inpatients with respiratory symptoms is common, with considerable associated charges. In an attempt to reduce testing volumes, we studied whether data available at the time of admission could aid in identifying children with low likelihood of having a particular viral origin of their symptoms, and thus safely forgo broad viral testing. We collected clinical data for 1,685 pediatric inpatients receiving respiratory virus testing from 2010-2012. Machine-learning on the data allowed us to construct pre-test models predicting whether a patient would test positive for a particular virus. Text mining improved the predictions for one viral test. Cost-sensitive models optimized for test sensitivity showed reasonable test specificities and an ability to reduce test volume by up to 46% for single viral tests. We conclude that diverse forms of data in the electronic medical record can be used productively to build models that help physicians reduce testing volumes.

Introduction

Upper respiratory infections comprise one of the most common emergency department (ED) diagnoses in the pediatric population accounting for up to 25% of visits during influenza seasons¹². In the majority of children, the respiratory viral infection is mild and considered self-limiting with adequate supportive care³–⁵. A large variety of viruses may cause respiratory symptoms and routine testing for key viruses is now available for children visiting the ED⁶–¹¹.

The clinical utility of routine virus testing has been demonstrated previously, with children testing positive receiving less antibiotics and incurring fewer overall charges¹²,¹³. Also, children with positive results that are admitted after their ED visit may be properly isolated to prevent the spread of hospital-acquired infections¹⁴. However, with most children testing negative for the majority of viruses on the routine panels, the high billable charges of these panels, and the self-limiting nature of most virus infections, there are open questions about the overall utility of routine viral testing for ED visits.

There has been growing interest in the secondary use of EMR data to aid in clinical decision making and test ordering. Recognizing the prevalence of overtesting in the ICU setting, one group used fuzzy modeling of readily available data, like vital signs, urine collection, and transfused products, to identify tests that likely would not contribute to information gain in patients with gastrointestinal bleeding¹⁵. Other studies have looked to clinical documentation as a source of variables for developing classifiers that screen for disease. For example, emergency department free-text reports were used as the source of data for machine learning classifiers that outperformed expert Bayesian classifiers in the detection of influenza¹⁶. Another study has also employed the use of natural language processing of clinical notes to identify patients who may have Kawasaki disease, a diagnosis that is notoriously difficult to make¹⁷.

Our goal was to develop a practice-based workflow for the evaluation and optimization of respiratory virus test utilization in the pediatric population. The workflow would use data that is available at the time of the ED visit. The workflow would be helpful in identifying children with low likelihood of having a particular viral origin of their symptoms, who could safely forgo broad viral testing. The overall goal would be the design of smaller, custom viral test panels that test only those viruses that are most likely present given the pre-test patient data.

Using a retrospective study design, we collected clinical, seasonal, and demographic data for patients that underwent viral testing, and identified key characteristics that are indicative for patients with subsequent negative test results. Using machine learning, we thus optimized a classifier for the robust identification of patients with negative test results based on pre-test data. Based on current clinical knowledge of pediatric respiratory virus infections, we hypothesized that age and season would be the strongest predictors of test result when used in machine learning.
classifiers. We also hypothesized that the inclusion of clinical concepts in admission notes as predictive variables would enhance classifier performance.

Methods

The study population consisted of general pediatric inpatients who received respiratory virus laboratory testing between March 2010 and March 2012. The following inclusion criteria were employed: adequate nasopharyngeal swab sample, 18 years of age and younger, general inpatient admission, and test ordering within two days of admission. The following data were collected and de-identified for each patient: age, gender, season of test ordering, test results, and history and physical admission notes. Patients were tested with DFA and/or PCR panels. The DFA panel consisted of tests for adenovirus, influenza A/B, parainfluenza 1-3, and RSV. The PCR panel tested for the same viruses in addition to human metapneumovirus and rhinovirus. The study was performed using protocols reviewed and approved by the Yale University Institutional Review Board.

Of the clinical natural language processing (NLP) tools available, MetaMap 2013 was used to identify medical concepts in the History of Present Illness of each note. MetaMap 2013 is a program made available by the National Library of Medicine that allows users to map biomedical text to the Unified Medical Language System Metathesaurus\textsuperscript{18,19}. While clinical NLP frameworks exist that are arguably more powerful, like cTAKES, HITEX, and Sophia, MetaMap was chosen for its ease of implementation. The following options were used in MetaMap: restriction of terms to the SNOMED CT terminology, limitation of semantic types to “signs and symptoms” and “diseases and syndromes”, utilization of all derivational variants of a word, allowance for concept gaps, expansion of acronyms and abbreviations, and identification of negated concepts. The presence or absence of each mapped concept was added as additional variables for model development. To determine the precision of the MetaMap software when run on the corpus of clinical notes, concepts identified by MetaMap were compared to the original text. For 100 randomly selected notes, the identified concepts were reviewed and compared to the original statements by the physicians. Partial-match precision was calculated, as previously published\textsuperscript{20}. Recall was not calculated because we were primarily interested in the concepts that MetaMap was actually able to identify and not terms outside of its matching capabilities.

Based on these variables, we developed models using machine learning algorithms to predict the likelihood that a given patient would test positive or negative for a specific virus. For each viral diagnosis, three models were built based on: 1) billing data alone, 2) MetaMap concepts, and 3) billing data in addition to MetaMap concepts. For this task, we used Weka 3.7.9, a freely available Java based implementation that implements numerous machine learning algorithms, as well as common tools for data mining, such as data pre-processing and attribute selection\textsuperscript{21}. Using Weka, we performed attribute selection on the variables to determine which variables provided the greatest gain of information, given the specific viral test to be modeled\textsuperscript{22,23}. Attribute selection reduced the number of variables for inclusion in each model from over 400 to less than 20, depending on the test. A cost sensitive classifier was applied on top of machine learning algorithms to weigh against false negative model predictions with varying cost thresholds\textsuperscript{24}. The decision tree learning algorithm, J48 (the Java implementation of C4.5), was chosen for use in the development and evaluation of each model\textsuperscript{25}. To reduce the likelihood of overfitting, we employed ten-fold cross-validation. Hyperparameter optimization was not explored in this study.

Using the sensitivities and specificities resulting from the numerous cost thresholds, we constructed a specialized receiver operating characteristic (ROC) curve, also referred to as an ROC instance-varying transformation\textsuperscript{26}. We calculated the area under the curve (AUC) for each model using the trapezoidal rule. The standard error for each model’s ROC was calculated, as previously published\textsuperscript{27}. To simulate a scenario in which tests can be selected individually for a customized panel (e.g. in house PCR vs. multiplex PCR), we created three different types of customized panels and modeled the performance of the panels on the study sample. For each type of customized panel, a given patient would be serially tested until either a test returned positive or the patient had received all of the recommended testing. We created a control panel in which patients were assigned a panel with a random order. A second panel was composed of a fixed order based on the prevalence of diagnoses. The third and experimental panel took into consideration the predictions generated by the decision tree models. Patients would be tested for viruses, based on the recommendation of the model and then ordered from highest to lowest prevalence, and testing would cease after a positive result or all negative results for the recommended tests.

1911
Results

In total, 1,972 orders for respiratory virus testing were placed during 1,848 visits. For each patient, the test consisted of a panel of 6 viruses - adenovirus, influenza, parainfluenza, RSV, hMPV, and rhinovirus. Each hospital visit was associated with 1 or more orders for respiratory virus testing. Table 1 summarizes the age, gender, and season of the study population by etiology. Negative test results accounted for 69.5% of all tests ordered during the study period. Males comprised around half of each viral diagnosis except for adenovirus diagnoses of which males comprised 68.8%. The mean age for all viral diagnoses was less than 5 years of age, except for positive cases of influenza, where the mean age of diagnosis was 8.24.

Both DFA and PCR panels are ordered throughout the year and show similar patterns in peak months of test ordering, during the winter seasons. DFA panels (n = 2152) were ordered 3.9 times more often than PCR panels (n = 550). Figure 1 shows the distribution of positive test results aggregated by month during the study duration. Adenovirus and rhinovirus are detected in all months with no clear pattern. Cases of co-infection, influenza, hMPV, parainfluenza, and RSV demonstrated regular seasonal fluctuations. The distribution of co-infected cases were present at low rates during the entire year, although demonstrated peaks in the winter months of each year. No cases of influenza occurred outside the winter or spring months in the study population. Test results for hMPV had a similar distribution to influenza infections. Cases of RSV arose primarily during the winter months, although the onset of the RSV season differed between the two years.
In order to reduce viral testing in patients, we evaluated models for their predictive ability, based on pre-test data, to identify patients with low likelihood of a particular virus. Some models consumed data from text mining clinical notes. We evaluated the performance of the MetaMap program in identifying concepts by calculating the partial-match precision. The partial-match precision was calculated to be 0.724 across a random sample of 100 notes.

Figure 1. Positive test results as a proportion of all test results for each detectable virus, by month.
Using Weka, models based on the decision tree algorithm, J48, were derived. By varying the type of data used to derive the models, three types of models were developed for the detection of each virus. A basic model was derived using age, gender, and season. A text-mining model was derived using MetaMap concepts as predictive variables. A combined model was derived using age, gender, season, and MetaMap concepts. The ROC curves are depicted in Figure 2 and the corresponding AUC values are presented in Table 2. Basic models showed some predictive ability (AUC > 0.65) for four of the six viruses under study: influenza, parainfluenza, RSV, and hMPV. The text-mining models showed no predictive ability, except for RSV, where the text-mining model performed similarly to the basic model (AUC: 0.661 vs. 0.658, respectively). The combined models showed similar discriminative ability to the basic models for all viruses, except for RSV, where the combined model outperformed both the basic and text-mining.

To determine how the MetaMap terms factor into the combined model for RSV, we mapped out the decision tree of the combined model (Figure 3). Age was the first branching point followed by branching points based on a combination of season, MetaMap concepts, and other age ranges.
Figure 3. The graphical representation of the J48 decision tree classifier for RSV when based on both billing data and MetaMap concepts. Thresholds for age and season were determined by the J48 algorithm based on the information gain provided by the attribute splits. These are denoted by the single lines. The presence or absence of clinical terms in the HPIs are shown as branching nodes, followed double lines and dashed lines, respectively.

To assess how the models would perform as “in silico” screening tests prior to actual diagnostic testing, we computed the test characteristics for the combined models. Unlike the general model presented above, we would assess models with specific performance thresholds. At a target sensitivity of ≥ 95% for the combined models for each virus, we calculated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) (Table 3). The target of ≥ 95% sensitivity (i.e. no more than 5% of cases with a respiratory infection are missed) was achieved by using a cost sensitive classifier that was applied on top of machine learning algorithms to weigh against false negative predictions. As detailed in Table 3, specificity ranged from 3.7% to 45.5% for all of the models at a sensitivity ~95%. A cost-sensitive classifier was thus able to safely sort patients into those that will eventually test positive for a virus (with at least 95% sensitivity), while robustly identifying patients that will not test positive (no viral infection). Some models were able to identify up to 45.5% of patients with no viral infection, and thus would lead to a sizeable reduction in test volume, as no testing is warranted. Models for adenovirus and rhinovirus showed the lowest specificities. While the PPV ranged from 50.1% to 64.7% for all models, the NPV ranged from 52.1% to 100%. For influenza, parainfluenza, RSV, and hMPV, the NPV was above 80.7%.

A minimum threshold sensitivity of 95% was set for each of the combined models (sensitivity of Rhinovirus was slightly below the set threshold).

In order to assess how model predictions might be useful in clinical practice, where patients are routinely tested for all 6 viruses, we simulated the effects of “customized panels” on the average number of tests that a given patient in the study population would need to undergo. In an environment where tests for individual viruses could be serially performed without being prohibitive in regard to time, we developed three types of customized panels that might be employed, as described in the methods section: 1) random order, 2) order based on the prevalence of a virus, 3) order based on model predictions. Each panel would test a patient serially until either a positive test result was returned or all tests on the panel had been performed. For the model based on random order, an average of 4.93 tests (SD = 1.69) would be performed; for the model based on prevalence, 4.52 tests (SD = 2.03; p < 0.001); and for the model based on the predictive models, 3.93 tests (SD = 1.64; p < 0.001). For the customized panel based on the predictive models, 22 patients would have been untested, who would have otherwise tested positive for a virus and 57 patients would have been missed for an additional viral co-infection.

Discussion

This retrospective study evaluated respiratory virus testing in the general pediatric population at a tertiary academic children's hospital. Of the tests that were ordered, the vast majority resulted in a negative finding. Our objective was to develop clinical models using information available at the time of test ordering that might reduce test volume, while ensuring that patients with detectable infections are still tested, given the previously published benefits. This study found that predictive models built on clinical variables were able to discriminate patients who should receive testing better than chance. For 4 out of 6 viruses included in our study, age, season, and gender could be used to build models with fair predictive ability. We also hypothesized that concepts contained in the history of present illness portion of the clinician’s admission documentation could improve the predictive ability of our models. In the case of RSV, a model based only on concepts in the HPI had the same predictive power as the model based on billing data. Combining these two sources of data improved prediction of RSV. The precision of our concept matches via MetaMap were in line with previously published results. Our findings suggest a useful role for admission notes, aside from documentation.

Effective implementation of these predictive models as screening tests requires practical understanding of the test characteristics as they relate to an institution’s clinical goals. By limiting testing of patients who would otherwise test negative, the population receiving diagnostic testing would be enriched for positive cases. A practical, cost-saving clinical model would thus strive for the highest possible sensitivity that is associated with a reasonable specificity. That is, high test sensitivity (almost no patient missed that will test positive) may be achieved while still achieving above zero specificity (patients with low likelihood of testing positive). We show, for example, that for influenza testing, we could achieve 100% sensitivity at 46% specificity. In other words, we can build a pre-test model that safely identifies all patients that are going to test positive for influenza, while identifying many patients that will not test positive, and for which no testing needs to be carried out. The model, as seen in Figure 1, is mostly determined by assessing the season of the patient visit.

It is important to note that the presented predictive models are not designed to predict positive cases with high accuracy. While we sought models that resulted in the highest sensitivities, these models often had very high false positive rates. Thus, in our models, the predictive model should be considered to predict “high risk for positive result” and “low risk for positive test result.” The distinction is important to the proposed function of the models, as the models were intended to aid the practitioners in reducing the number of overall tests that they order.

From a practical point of view, predictive models could act as “in silico” screening tests for whether or not patients should receive testing. If the models are validated against a prospective dataset, they might find practical application via integration into the electronic medical record, running in the background as the clinician is entering data about a patient. At the time of test ordering, the physician would be presented with information regarding what tests are likely negative or potentially positive. As a clinical decision tool at the point of care, the results of this model might encourage providers to limit testing to only those cases where the results would change clinical management. The use of basic variables, as well as documented clinical symptoms, can reduce test volume for certain tests by up to nearly half with a low false negative rate. In addition, the use of customized panels based on
the predictive models would further reduce test volume. While the actual cost of testing is not transparent at most institutions, the amount charged for performing a respiratory virus panel is estimated to be around $1500, although this varies by institution and the exact type of testing performed. Ordering clinicians and patients could therefore expect the average charge to drop to $1000 if customized panels were employed. Future work will focus on refining the text mining approach and concept identification, as well as exploring the concept of customized panels, based on the prediction results of the models.

Our study has several limitations. The study population included only patients who received respiratory virus testing and selection criteria were not based on diagnostic codes. As a result, the seasonal prevalence of test results may not be reflective the true prevalence of viral infections. Furthermore, the focus on pediatric patients only accounted for about 20% of total respiratory virus testing volume, whereas testing on adults comprises the majority of testing. In addition, the numerous exclusion criteria may limit the generalizability of the models. While the billing data are true independent variables, the variables collected by text mining with MetaMap may not be fully independent. Because the timing of when admission notes were written could not be controlled, there is the possibility that some notes may have been written after test results were communicated. We took several measures to prevent this, including selecting the oldest admission note on record and manually reviewing notes for mention of testing. The text mining approach recorded concepts as “mentioned” versus “unmentioned,” which may not fully capture the whole clinical picture for a patient, as pertinent positives or negatives may have been unknowingly omitted by the author of the HPI. Our study also did not differentiate between different strains of viruses, which some of the tests are able to do (i.e. influenza A and B, parainfluenza 1-3). Initially, we expected that concepts from clinical notes would provide more robust prediction performance than we encountered. The reasons are likely multifactorial. First, the sample size that we used was small, compared to other NLP and machine learning efforts, making it less likely that we would be able to find concepts that would be able to differentiate between viruses. Second, given the high variability between providers’ styles when writing notes, the values for many concepts were left blank and were not subsequently imputed. Finally, the clinical manifestations of upper respiratory viruses are very similar with few distinguishing symptoms (i.e. barking cough for parainfluenza, gastrointestinal symptoms with adenovirus, and myalgia for influenza), making it difficult for physicians or the program to accurately diagnose viruses based on clinical history and exam alone, thus giving value to respiratory virus testing as a means of making a final diagnosis.

Conclusion

The results presented here offer a new perspective on analyzing testing practices for respiratory viruses using data mining and natural language processing techniques. We find that in a tertiary academic children’s hospital, the majority of respiratory virus testing returns negative. Furthermore, our results suggest that additional clinical factors may be used in a clinical model to predict the likelihood of an infection and the need for further diagnostic testing. Text mining of clinical notes may augment the predictive power of future models, as demonstrated in our models of RSV. This work contributes to the growing body of evidence that diverse forms data in the electronic medical record, not just billing data, can be used productively to build models that aid physicians in decision making, and may help in reducing test volumes.

Abstract

Observational data recorded in the Electronic Health Record (EHR) can help us better understand the effects of therapeutic agents in routine clinical practice. As such data were not collected for research purposes, their reuse for research must compensate for additional information that may bias analyses and lead to faulty conclusions. Confounding is present when factors aside from the given predictor(s) affect the response of interest. However, these additional factors may not be known at the outset. In this paper, we present a scalable literature-based confounding variable discovery method for biomedical research applications with pharmacovigilance as our use case. We hypothesized that statistical models, adjusted with literature-derived confounders, will more accurately identify causative drug-adverse drug event (ADE) relationships. We evaluated our method with a curated reference standard, and found a pattern of improved performance \( \sim 5\% \) in two out of three models for gastrointestinal bleeding (pre-adjusted Area Under Curve \( \geq 0.6 \)).

Introduction

Confounding is present when factors aside from given predictor(s) affect the response of interest. For example, one may wish to understand the association between cigarette smoking and the risk of developing cancer while asbestos exposure or genetic predispositions may be present\textsuperscript{1}. Stuart Mill noted a related disparity between laboratory conditions and raw observation in nature in his System of Logic (1943)\textsuperscript{2}. Since confounding variables may not be known at the outset, we propose a scalable and computationally inexpensive method for confounding variable discovery (CVD). In this paper, we apply our method to pharmacovigilance (PV). However, confounding is a challenge to multiple fields including epidemiology, biosurveillance and pharmacogenomics.

Pharmacovigilance and FAERS. Some 770,000 adverse drug events (ADEs) occur annually in the United States alone, resulting in morbidity, mortality, and increased cost\textsuperscript{3,4}. PV aims to address the set of challenges posed by ADEs, including those detected after drugs are released to market. Recognizing the need to systematically monitor adverse effects of drugs, regulatory agencies, such as the US Food and Drug Administration (FDA), have implemented spontaneous reporting systems, through which physicians and administrators of clinical trials can report potential adverse events as they are observed. However, spontaneous reporting systems (e.g., FAERS\textsuperscript{5}) have limitations, such as incomplete clinical information, under-reporting of side-effects, and unacknowledged sources of bias\textsuperscript{3}.

Confounding in EHR. Clinical text (notes) recorded in EHRs are another potential primary source of ADE data, yet drawing reliable conclusions from routinely collected clinical data is notoriously difficult\textsuperscript{6,7}. In the PV literature, the term “signal” refers to data that are pertinent to the therapies or outcomes under study. Unlike the case of clinical trials where subjects are deliberately monitored for side-effects, clinical data were not collected for the purpose of pharmacovigilance, and are often beset with redundancy or missing data, use of non-standard abbreviations, misspellings, and so on. In addition, clinical data contain confounding variables\textsuperscript{8}. By developing more powerful methods to identify and adjust for confounding variables, we should be able to discriminate better between drug-ADE signal and noise. This in turn would facilitate the timely compilation of more comprehensive pharmaceutical risk profiles and improve public safety.
Background

Definitions. A confounding variable influences or biases the magnitude of correlation between a predictor variable (e.g., drug exposure/treatment) and a response variable (i.e. outcome/ADE). In the context of creating models for PV, when a confounding relationship exists between a falsely associated drug-ADE pair and adjustments are made to account for its influence, the association strength for that relationship, should be diminished. For example, given a set of observational clinical notes, it is observed that fish oil intake is highly correlated with acute liver injury (ALI). However, after adjusting the model for the presence of known causal agents of ALI, (e.g., acetaminophen, liver cirrhosis, hepatitis c), that correlation should approach zero. Let us consider another example of an acetaminophen exposure (predictor) and a hepatitis B infection (predictor) where the patient subsequently suffers ALI (response). In this case, each of these predictors, independently, are sufficient preconditions for ALI. As they occur together, these two predictors confound each other. When the association of either predictor is adjusted in the absence of the other predictor, the association may be diminished, but not as dramatically as in the first example. Li et al. introduced a taxonomy of confounding in PV with the following categories: confounding by indication (e.g., preexisting conditions), confounding by comorbidity (e.g., diabetes), and confounding by co-medication (e.g., aspirin) \(8\).

A mediating variable (also called an intervening variable), by contrast, lies distinctly along the causal pathway between the predictor variable and the response variable themselves and may be neither necessary nor sufficient to cause an ADE by itself. Mediators may sometimes be thought of as “risk factors” or as aspects of the etiology of the ADE itself \(8,9\). Examples of mediators include bile duct obstruction for ALI or hypertension for myocardial infarction (MI). Mediators tend to be collinear with both the predictor and the response variable, which is to say they tend to be observed together. For more detailed discussion of mediation, see Pearl \(9\).

Confounding control in PV. The two most common approaches for the control of confounding are control by design (which entails the use of case control matching, for example, where patients are matched by practice type and sometimes demographic cohort) and control by analysis \(6\). The main thrust of this paper will be the latter (while still others exist, such as counterfactual intervention, they are beyond our scope) \(6,10-13\). Control by analysis often implies the application of domain knowledge and experience to identify proxy variables in order to control for confounding. Traditionally, statisticians have depended upon the knowledge of domain experts to identify relevant confounding factors. While this is likely to result in the identification of confounding variable candidates (CVCs) pertinent to an individual study, it would be financially intractable to hire the quantity and diversity of experts needed to conduct PV across large numbers of marketed drugs and each of their potential ADEs. Li et al. recently utilized extensive search for CVCs (of the “comorbidity” subtype in PV) in observational clinical data found in EHR using penalized multivariate regression methods, specifically lasso regression \(8\). Lasso regression is a variable selection technique that shrinks multivariate predictor coefficients that fall beneath a threshold down to zero \(14\). In general, the lasso produces results that are easy to interpret and parsimonious and, in this case in particular, the results of this study are very encouraging. However, Least Angle Regression (LAR), the algorithm that is most commonly used to perform lasso regression, can be computationally expensive, depending on input, being either quadratic O(n\(^2\)) or cubic O(n\(^3\)) in its computational complexity, though recent innovations such as cyclic coordinate descent, have produced improvements in this regard \(15,16\). Other innovative signal detection approaches have involved combining multiple data sources via meta-analysis, or applying omic or biochemical substantiation techniques to verify the plausibility of the causal mechanisms that may underlie putative drug-ADE associations \(8,17-19\).

The methods of CVD mentioned above are to varying degrees financially intractable or computationally expensive, and it has been argued that brute force methods miss the “causal story” in the observational data \(20\). The purpose of our current work is to assess the extent to which feasibly-sized sets of CVCs that have been observed in the literature can be used to identify concepts for the task of confounding adjustment of clinical data. In doing so, we aim to find a middle ground between human-intensive expert-guided CVD, and computationally intensive selection of such variables based on empirical data alone.
Literature-based Discovery (LBD) is an idea first developed by Don Swanson as a means of using the biomedical literature to discover therapeutically useful associations. Swanson's approach involves finding implicit relationships between concepts that suggest an as-yet undiscovered therapeutic relationship. Recent work has incorporated semantic relations extracted from the literature using natural language processing to constrain the search space of associations. For example, the pattern of semantic relationships "drug INHIBITS x; x ASSOCIATED WITH disease" may indicate a therapeutic relationship between this drug and this disease. These patterns of relationships are known as “discovery patterns.” Our work in this area leverages high-dimensional vector space representations of the concept-by-predicate-by-concept relationships concerned to facilitate rapid search and efficient inference, using an approach called Predication-based Semantic Indexing (PSI).

To recap, our operative assumption is that if we can identify plausible therapeutic relationships in a knowledge base of literature (arguably the main focus of LBD work to date), then we can also identify confounding associations, such as associations between concepts that are exogenous to the etiology of an ADE of interest. Such concepts may be predictive of entities that tend to co-occur along with drug-ADE pairs of interest in observational clinical data. We hypothesize that statistical models of drug-ADE association will more accurately identify causative drug-ADE relationships in observational clinical data after adjustments have been made for the influence of CVCs.

Methods

Derivation of CVCs from the literature. We developed an LBD-based method that automates CVD using “false discovery patterns” (FDPs), leveraging existing NLP tools and knowledge resources.

From Predications to FDPs. MedLEE was used to perform automated coding of concepts of interest in our EHR collection. MedLEE has been shown to perform accurately on clinical notes (for example recall of .77, and precision: ~.89 for the task of extracting clinical concepts, and coding them with concept unique identifiers from the Unified Medical Language System (UMLS)). The purpose of SemRep, a publicly available NLP system developed intramurally at the US National Library of Medicine (NLM), is to identify and normalize predications - relationships in which pairs of concepts are connected by predicates (or “verbs”, e.g., “TREATS”, “CAUSES”) in biomedical literature. SemRep operates with low recall, but high precision: Kilicoglu et al. reports precision of .745, recall of .640, and an F-score of .689. SemMedDB, used as our knowledge base of biomedical literature, is a publicly-available NLM product that contains the output of SemRep processing of the entirety of MEDLINE, where concepts and predicates have been recognized and normalized, and all extracted propositions can be retrieved from a MySQL database in the following form: \texttt{ARGUMENT}_1 + \texttt{PREDICATE} + \texttt{ARGUMENT}_2. This representation disallows semantic constructs such as degree, tense, narrator reliability, or verb ditransitivity. From a practical perspective, such predication constructs are computable, since the concepts and predicates are normalized, and they facilitate our method’s inferential power.

Vector Symbolic Architectures. To process SemMedDB, which is used as our biomedical knowledge repository, we apply a representational technique called Predication-based Semantic Indexing, or PSI. PSI owes its existence ultimately to a contentious debate within the cognitive and neuroscience community in the 1980s over what became known as the parallel distributed processing (PDP) or connectionist paradigm. A number of scalable approaches to the problem of efficiently representing nested compositional structures (such as those encountered in natural language) in neural networks emerged following Smolensky’s seminal work, which utilized the tensor product as a compositional operator (Holographic Reduced Representations [HRR], Binary Spatter code, Multiply Add Permute [MAP]). This is the origin of vector symbolic architectures (VSAs), described in detail elsewhere.

PSI for efficient inferences. VSA theory provides the infrastructure for PSI. In PSI, concepts are represented by randomly generated real, binary, or complex values of high dimensionality (the more dimensions that are used generally, the better the recall and precision of the model, with a tradeoff against computational efficiency). These
are called “elemental vectors”. These elemental vectors can be superposed upon each other to generate composite semantic structures called semantic vectors \(^{39-45}\).

Random vectors are an effective way to represent elemental components, since there is a high probability of mutual near-orthogonality, particularly in higher dimensions. Semantic vectors on the other hand are composed as superpositions of the “bound products” of the elemental vectors of predicate-argument pairs (as extracted from literature using SemRep). The binding operator, which varies in implementation across VSAs, is a multiplication-like operator that provides the means to encode additional information, such as the nature and context of a relationship, into the resulting vector space. Since the same predication can be encountered in multiple documents, PSI can be thought of as a distributional model of predications. Critical to PSI, semantic representations of concepts are built up as vectors from relations found in the literature. PSI facilitates rapid search for, and retrieval of, concepts that are related to one another in particular ways (i.e., through particular predicates). As such a space is distributional, concepts in which a relationship of interest occur more frequently will be retrieved first (analogous to the way in which other information retrieval systems facilitate ranked results). In the current work, PSI is used to facilitate rapid retrieval of concepts related to other concepts in specific ways. PSI can be used to retrieve the most strongly associated concepts (called “bridging terms”) across any particular predicate pathway of interest. A discussion of predicate pathways that indicate FDPs will follow. PSI and its applications are discussed in detail elsewhere \(^{25,39-41}\).

**SemRep Predications.** For the current work, we used a PSI vector space derived from the version 24_32 of SemMedDB (processed June 20th, 2014 with version 1.5 of SemRep), containing 23.9 million citations and 70.4 million semantic predications \(^{39}\). The PSI space was built using the Semantic Vectors package (version 5.9), with 48,000-dimensional binary vectors as the elemental vectors \(^{44}\). A small number of predicates were excluded, indicating negation (such as DOES_NOT_TREAT). Terms with occurrence ≥ 500,000 were excluded.

**FDPs for CVD.** A browser interface called EpiphaNet has been developed for querying PSI-based representation of SemMedDB using a query language with meta variables that specify predicate vectors, elemental vectors, semantic vectors along with binding and superposition operators \(^{40-41,44-45}\). We can query our PSI vector space model of SemMedDB to identify CVCs (the “bridging terms” mentioned above) for each drug-ADE pair with PSI queries that represent FDPs. Below in Table 1, we present the FDP queries that we used to evaluate our CVD method. We identified these FDPs while studying how expert users of the EpiphaNet interface interpret results of drug-ADE queries, when we noticed that EpiphaNet would generate reasoning pathways that suggest confounding relationships. Also, note that “DRUG TREATS x: x COEXISTS_WITH ADE” is referred to as a “double predicate” in that it is composed of two predicates that yield CVCs that link to both the drug and ADE cue terms.

<table>
<thead>
<tr>
<th>FDP</th>
<th>PV Confounding Type</th>
<th>Examples (drug: allopurinol, ADE: liver failure)</th>
</tr>
</thead>
<tbody>
<tr>
<td>“x CAUSES ADE”</td>

<td>infection, sodium</td>
</tr>
<tr>
<td>“DRUG TREATS x: x COEXISTS_WITH ADE”</td>
<td>comorbidity</td>
<td>gout, kidney failure, pericarditis</td>
</tr>
</tbody>
</table>

In our evaluation, in order to exclude spurious associations (as all vectors in the space are a measurable distance apart) from our CVCs, we made use of a frequency threshold, such that only bridging terms with association strengths ≥ 2.5 standard deviations were included.

---

1923
Figure 1. This graph illustrates EpiphaNet queries in the context of our method.

Data and Analysis

Reference Set and Data Collection. To derive our data set, we used a reference set of curated drug-ADE associations that was developed by Patrick Ryan and his colleagues as a standard for evaluating PV methods. This reference set includes 399 medications/ADE pairs and 4 ADEs with both positive (drug-ADE relationships supported by the literature and other sources, including package labeling events) and negative (drug-ADE relationships without support) control groups per ADE. The four ADEs are as follows: acute kidney injury (AKI), acute liver injury (ALI), gastrointestinal bleeding (GIB), and acute myocardial infarction (AMI). These ADEs were chosen for their importance to PV space, their diagnostics, and their impact on financial and personal cost.

Figure 2. This graph illustrates our workflow.

Analysis of Observational Clinical Data. The steps that we took for evaluation of our method are as follows both in the text below and in the corresponding items in Figure 2:

1. Map and expand drug/ADE synonyms to expose data of interest in the EHR index for extraction and additional processing [1]. We used RxNorm to identify drug synonym CUIs in the UMLS. For ADEs, we mapped the reference set’s OMOP terms (several are provide for each ADE of interest) to concepts in the UMLS, using exact string match of the preferred name field.

2. Process EHR with MedLEE to represent concepts (drugs, ADEs, CVCs) as CUIs in the UMLS. This is a subset (~2.1 million documents from ~364,000 in- and outpatients in the Houston metropolitan area between 2004 and 2012) of records from the UTH BIG clinical data warehouse.

3. Build Lucene EHR index (software that efficiently tabulates the concept co-occurrence so as to facilitate rapid document retrieval).
4. Query PSI vector space for CVCs given each drug-ADE pair for CVCs and extract data from index.
5. Extract drugs, ADEs, and CVCs from the EHR index (as lists of document IDs where respective concepts are in evidence) into concept-by-document vectors.
6. Establish baseline and CVC-adjusted scores for co-occurrence of drug-ADE pairs by constructing contingency tables [6a] and by computing area under curve (AUC) from receiver operator characteristic (ROC) curves from ranked-order of coefficients from logistic regression models [6b]. In descending order of co-occurrence count between drug, ADE, and CVC concepts (with an intersection threshold of 10), construct contingency tables as input for statistical models (using forward stepwise logistic regression), and calculate aggregated performance statistics from AUCs of ROCs. Finally, compile results into tables [6c].

In the course of building models iteratively in step 6 above, when or if a model that has incorporated a new CVC statistically converges, that CVC would be incorporated into subsequent models. This process continued for each drug-ADE pair until CVCs have been exhausted for that FDP. When such models fail to converge, the offending concept is added to a list of exclusions for that pair so that it would not be included in subsequent builds and for manual investigation of interesting patterns. If none of the models for a drug-ADE pair converge using CVCs, then the score from the unadjusted, or baseline, logistic regression coefficient is used to calculate AUC.

Results and Discussion

Table 2. This table presents the baseline and adjusted AUCs from ROCs that were calculated from ranked order of drug coefficients from logistic regression models from each ADE and FDP combination. caus="x CAUSES ADE", pred="x PREDISPOSES ADE", tcoe="DRUG TREATS x; x COEXISTS WITH ADE". Counts=number of positive/negative examples. AUCs in bold indicate that an adjusted model drug coefficient is higher than baseline.

</tbody>
</table>
There are two groupings of result data in Table 2, labeled Complete Results and Constrained Results. Complete Results indicates that the AUCs have been calculated from the full data set without imposing any additional criteria. In the Constrained Results, the following criteria were applied to calculate performance metrics values for each field per ADE/FDP row: all logistic regression models must have converged, the count for drug instances was \( \geq 100 \), the count for intersections was \( \geq 10 \) between med-ADR pair, and that the calculations derive exclusively from cases where CVCs were included in the logistic regression models. As a result, the count of positive and negative controls for the same ADE will vary, since CVCs differ between FDPs.

**Wordclouds.** We have generated word clouds below in Figure 3. The first two word clouds represent the CVCs of ALI and GIB with the “\( x \text{ CAUSES ADE} \)” pathway. The third and fourth show the word clouds for the AMI groups using the “\( x \text{ CAUSES ADE} \)” FDP. The fifth word cloud represents the CVCs that were excluded in building the logistic GLMs for GIB using “\( \text{DRUG TREATS } x; x \text{ COEXISTS_WITH ADE} \)” FDP. The reader will notice that CVCs from single predicate FDPs (e.g., “\( x \text{ CAUSES ADE} \)” that were associated only with the ADE were of both the comorbidity and co-medication confounding subtypes, whereas CVCs from “\( \text{DRUG TREATS } x; x \text{ COEXISTS_WITH ADE} \)” are constituted exclusively by comorbidities. The fourth word cloud from the left is interesting in that the most prevalent CVCs are comorbidities and likely mediators of myocardial infarction.

![Wordclouds](image)

**Figure 3.** These word clouds represent CVCs for ADEs and FDPs with font size proportional to aggregated term frequency (across all drugs for a group [positive or negative control] of a given ADE and FDP) in the EHR index.

**Observations.** There were \( \sim 55,000 \) instances in our EHR index for each of ALI, AMI, and GIB. AKI was the outlier with only \( \sim 5,000 \) instances. In the case of AKI for the “\( x \text{ PREDISPOSES ADE} \)” pathway, no co-occurring CVCs were identified, so no adjustment could be made. In the case of ALI, one might reason that the set is heavily weighted toward the positive examples, so little gain is to be had by adjusting with CVCs.

**Analysis of Complete Results.** Our method performed the best when there was sufficient baseline support (AUC \( \geq 0.6 \)). For example, gastrointestinal bleeding had the best baseline AUCs, and there were notable gains in both Complete Results and Constrained Results for both “\( x \text{ PREDISPOSES ADE} \)” and “\( \text{DRUG TREATS } x; x \text{ COEXISTS_WITH ADE} \)” FDPs. In general, CVCs that derived from the double predicate “\( \text{DRUG TREATS } x; x \text{ COEXISTS_WITH ADE} \)” FDP were more effective than those from single predicate FDPs. Such FDPs discover concepts with associations with both predictor and response variables, what Turing award winner Judea Pearl, a seminal influence on the field of causal reasoning, refers to as “true confounders”.

1926
Analysis of Constrained Results. In the Constrained Results, for models that include CVC adjustments, performance improved in 8 of 11 cases. The “DRUG TREATS x; x COEXIST WITH ADE” FDP improved performance in 3 of 4 cases, while same can be said in 2 of 4 for “x PREDISPOSE ADE”. In only one case, AKI, was there an improvement using the “x CAUSES ADE” FDP.

Error Analysis. While using the single predicate FDPs that imply causation or risk factors, e.g., “x CAUSES ADE”, “x PREDISPOSE ADE”, respectively, make sense in terms of their ostensible causal association for adjusting negative controls, this intuition was not supported by the results of our analysis. Such FDPs uncover concepts that exist in the gray area between mediators, risk factors (Pearl’s “indirect effects” predictors), and concepts which could manifest confounding effects, e.g., smoking with respect to a positive control drug and AMI. For example, the following examples of mediation-like CVCs from this FDP were identified: stenosis, obstruction, thrombosis, and thrombus. Such concepts are suggestive of mediating concepts that relate to the causal mechanisms for AMI. Since mediators tend to be collinear with response variables, inclusion of such CVCs may be detrimental to performance.

One perplexing CVC from “DRUG TREATS x; x COEXIST WITH ADE” FDP for acute myocardial infarction is fibroid tumor. Fibroid tumors of the gastrointestinal tract are relatively rare and usually appear on the uterus. However, review of the predication database suggested that at times anti-inflammatory agents may occur in TREATS relationships with fibroid tumors, as they are used to control the pain associated with this condition. Though the “DRUG TREATS x; x COEXIST WITH ADE” FDP is intended to retrieve terms that are associated with both the drug and the ADE, the underlying implementation involves vector superposition - so though we would anticipate terms that are bilaterally connected being retrieved first, terms that are unilaterally connected may still meet the threshold. Such spurious CVCs could be eliminated by using a higher threshold of associational strength than the 2.5 standard deviation level and by making bilateral connection a prerequisite for retrieval.

Future Work. In future iterations of our research in this area, we hope to explore more FDPs, to put in place temporal feasibility constraints, and to experiment with other reference sets. We plan to incorporate data from other sources (e.g., FAERS, plausibility models), apply causal Bayesian networks instead of regression models, explore automatically inferring FDPs from strongly associated False Positives, and experiment with interactive refinement of literature-derived CVCs.

Conclusion

With the aim of surmounting the obstacle of confounding, a phenomenon which diminishes the validity of information that can be extracted from observational data, we have proposed a scalable and computationally inexpensive LBD-based CVD method. Our results show when there is sufficient support above random for an ADE, i.e., AUC ≥ .6, that statistical models that incorporate adjustments for the influence of dual-predicate FDP-derived CVCs exhibit modest (.05 AUC or higher) performance gains for the task of re-identifying drug-ADE pairs from observational clinical data. While in the current paper we have presented a use case for our method in the domain of PV, we posit that our method is of potentially broader applicability as a tool complementary to other tools for tasks that involve enhancing signal detection from observational data within biomedicine.

Adoption of Secure Messaging in a Patient Portal across Pediatric Specialties

Mary Masterman¹, Robert M. Cronin, MD, MS¹, Sharon E. Davis, MStat¹, Jared A. Shenson¹, Gretchen P. Jackson, MD, PhD¹
¹Vanderbilt University Medical Center, Nashville, TN

Abstract

Few studies have explored adoption of patient portals for pediatric patients outside primary care or disease-specific applications. We examined use of patient-provider messaging in a patient portal across pediatric specialties during the three years after implementation of pediatric portal accounts at Vanderbilt University Medical Center. We determined the number of patient-initiated message threads and clinic visits for pediatric specialties and percentage of these outpatient interactions (i.e., message threads + clinic visits) done through messaging. Generalized estimating equations measured the likelihood of message-based interaction. During the study period, pediatric families initiated 33,503 messages and participated in 318,386 clinic visits. The number of messages sent (and messaging percentage of outpatient interaction) increased each year from 2,860 (2.7%) to 18,772 (17%). Primary care received 4,368 messages (3.4% of outpatient interactions); pediatric subspecialties, 29,135 (13.0%). Rapid growth in messaging volume over time was seen in primary care and most pediatric specialties (OR>1.0; p<0.05).

Introduction

Patient portals are secure online applications that give patients convenient, 24-hour access to personal health information with an Internet connection.¹ Government regulations like the Health Information Technology for Economic and Clinical Health Act (HITECH) and Meaningful Use (MU) have helped drive the development and implementation of patient portals.²,³

Secure messaging between patients and their providers is one of the most popular features of patient portals.⁴ Research indicates clinical care is delivered through portal message exchanges—for example, patients may report new problems or request treatment.⁵,⁶ A recent systematic review suggests secure messaging can improve medication adherence and clinic attendance.⁷ Other studies report messaging may increase patient satisfaction, improve efficiency for patients and providers, ease reporting of laboratory results, reduce costs, and increase productivity.⁴,⁸

Much of the research about secure messaging through patient portals has focused on adult primary care or chronic disease settings.⁴,⁹–¹⁴ At our institution, we have demonstrated broad adoption of secure messaging across diverse clinical specialties, with the majority of use occurring in medical or surgical specialties.¹⁵,¹⁶ A systematic review of patient portal implementation in pediatrics¹⁷ highlighted that existing research has largely focused on subpopulations of children with chronic diseases or ongoing medical conditions,¹⁸–²⁰ or have been done in primary care. The review recognized an ongoing need for more quantitative research on volume of messaging, frequency of use over time, and the impact of portal use on other types of patient contact following portal adoption.¹⁷

In this study, we aimed to characterize adoption of secure messaging by pediatric specialists, patients and their families after broad deployment of a portal at a large academic medical center. We specifically focused on uptake of messaging by primary care pediatricians and pediatric subspecialists, and examined differences in messaging rates by adolescents and their parents or other caregivers.

Methods

Setting

This retrospective cohort study was conducted at Vanderbilt University Medical Center (VUMC), which includes the tertiary care Monroe Carell Jr. Children’s Hospital at Vanderbilt (MCJCHV). VUMC implemented the My Health at Vanderbilt (MHAV) patient portal in 2005, which is available to all patients seen at VUMC. MHAV provides typical patient portal functions including secure messaging, appointment scheduling, access to selected portions of the electronic health record (EHR), account and bill management, and delivery of personalized health information. MHAV accounts for pediatric patients and their families were launched in 2007 and were fully deployed across pediatric specialties by 2008.²¹ VUMC policies for pediatric patient and parent or guardian access are similar to those for portals at other major children’s hospitals.²² Parents and guardians may access their
children’s health information through MHAV until the child turns 18 years of age. MHAV allows adolescents ages 13 years or older to have parent-controlled MHAV accounts with access to functions determined by the parent.

**Study population**

We examined all outpatient interactions at VUMC for pediatric patients between January 1, 2008 and December 31, 2010, the first three years after deployment of MHAV to pediatric patients and providers. Patients were stratified by age into three groups: children (<13 years), adolescents (≥13 and <18 years), and adults (≥18 years). MHAV users consisted of either VUMC patients (over the age of 13 years); delegates, individuals whom a patient designates to access MHAV on their behalf; or surrogates, parents or guardians who have access to their child’s or adolescent’s health information through MHAV. We defined an outpatient interaction as either a traditional face-to-face clinic visit or a patient-initiated message thread (i.e., initial message and all replies) between MHAV users and pediatric providers. For this study, we defined pediatric use as accessing of the MHAV portal by pediatric patients or any of their delegates or surrogates. Clinical providers have a designated message basket in which they receive messages from patients through MHAV, as well as through inter-departmental provider-to-provider messages. Providers access their message basket through the EHR. Each clinical unit and individual providers handle messages differently; some providers choose to answer their own messages, while other baskets are triaged first by administrative assistants or allied health professionals.

**Measures**

We collected data on all traditional outpatient clinic visits to pediatric providers during the study period. For each clinic visit, we recorded the age, gender, and race of the patient, and the specialty of the clinic. Pediatric specialties were categorized as primary care, cardiology, development, endocrinology, gastroenterology, genetics, hematology/oncology, infectious disease, neonatology, nephrology, neurology, pulmonology, and rheumatology. Visits to multidisciplinary clinics involving more than one specialty were excluded from analysis.

We also recorded the number of secure message threads initiated by pediatric accounts during the study period. For each message thread, we recorded the role of the sender (i.e., self, delegate, or surrogate); age, gender, and race of the pediatric patient; and specialty of the receiving provider. Messages threads were assigned to the same 13 specialties as the clinic visits. Messages sent to multidisciplinary or administrative message baskets were excluded.

**Analysis**

We determined the total number of unique MHAV users, message threads, recipient message baskets, and outpatient visits for each month of the study period and for each pediatric subspecialty. We constructed descriptive distributions and summary statistics for patients seen in clinic visits and patients about whom messages were sent. Generalized estimating equations with logit link controlling for age, gender, race, and time in months measured the likelihood of message-based versus clinic outpatient interaction across pediatric specialties. This analysis was conducted in R version 3.0.1, and the models were fit using the geeM package. The VUMC Institutional Review Board approved this study.

**Results**

**Patient demographics**

The demographic distribution of the pediatric patients who visited clinics or were the subjects of portal messages is shown in Table 1. Message-based interactions were more common among male and Caucasian patients (p<0.05). In models adjusting for patient demographics and clinical characteristics, the odds of a message-based rather than clinic-based interaction for African American and Hispanic patients were lower than those for Caucasian patients. Over half of all messages (58%, n=19,405) were in regard to children, with 23.8% (n=7,976) regarding adolescents and 18.3% (n=3,404) regarding adults.

**Clinic visit and messaging volumes**

During the study period, pediatric patients participated in 318,386 outpatient clinic visits. The total number of visits across specialties was relatively stable over the course of the study (Figure 1A). Primary care had the most clinic visits at 122,773 visits during the study period, followed by endocrinology (37,337), hematology/oncology (34,831), and gastroenterology (22,506). Infectious disease, neonatology, and palliative care had the fewest clinic visits. 81 Palliative Care outpatient visits were excluded, as there were no message threads associated with the specialty. 3430 encounters with Allergy and Immunology and 148 messages and encounters associated with Adolescent Medicine.
were excluded as these services are multidisciplinary. For the purposes of the analysis, 47 encounters and messages associated with Heart Transplant were grouped with Cardiology.

\(^a\)Odds ratios were computed using the generalized estimating equations model. This model controlled for age, gender, race, and time in months in order to measure the likelihood of message-based versus clinic outpatient interaction across pediatric specialties.

Figure 1. Volumes of outpatient interaction types. Number of (A) outpatient clinic encounters, (B) message threads, (C) recipient message baskets, and (D) the messaging percentage of outpatient interaction per month. Month 0 corresponds to January 2008; month 35 corresponds to December 2010.
From 2008 to 2010, pediatric patients and their families initiated 33,503 message threads, with the number of messages increasing from 2,860 in the first year to 11,871 and 18,772 in the second and third years, respectively (see Figure 1B). The number of provider baskets receiving messages increased from 346 in the first year to 701 and 1017 in the second and third years, respectively (Figure 1C). As there was only one message thread associated with Emergency Medicine, and this specialty is not associated with traditional outpatient visits, the message was excluded from the analysis. 894 messages associated with Allergy and Immunology were excluded for the reason stated above.

Users and user roles

Message threads were initiated by 19,049 unique users, including 13,848 surrogates (72.7%), 4,747 patients themselves (24.9%), and 454 delegates (2.4%), and received by 2,064 unique provider message baskets. The distribution of user types sending messages by month for children and adolescents is shown in Figure 2. Of the 10,747 users who messaged on behalf of children younger than age 13, 10,452 (97.3%) were surrogates and 261 (2.4%) were delegates. Forty-six messages (1.3%) were sent by the children themselves; in the early stages of pediatric account deployment, some children did have their own accounts created inadvertently. Of the 4,202 users who messaged on behalf of adolescents, 3,328 (79.2%) were surrogates, 99 (2.4%) were delegates, and 775 (18.4%) were the adolescents themselves. Although the number of adolescents using messaging increased from 103 in 2008 to 304 and 368 in 2009 and 2010, respectively, the percentage of total users who were adolescents decreased over time. Of the message exchanges with pediatric providers regarding adult patients, 68 (1.7%) of the 4,100 who messaged on behalf of adult accounts were surrogates, 94 (2.3%) were delegates, and 3,938 (96%) were the patients themselves.

Messaging across clinical specialties

Pediatric gastroenterology received the most messages (n=9,399; 28.1%) over the study period, followed by endocrinology (n=6,037, 18%), primary care (n=4,368; 13%), and neurology (n=3,717; 11.1%) (Table 2). Specialties receiving the fewest messages included development, infectious disease, genetics, and neonatology. With the exception of genetics, neonatology, and hematology/oncology, all pediatric specialties experienced significant growth (p-value<0.05; OR>1.0) in message volume over time during the study period when compared to primary care.

Over the study period, pediatric patients and their families used messaging for 10% of all outpatient interactions (i.e., message threads plus clinic visits). The proportion of pediatric outpatient interaction conducted through messaging rose from 2.7% in 2008 to 10.3% in 2009 and 14.6% in 2010 (Figure 1D). The proportion of message-based outpatient interaction for pediatric primary care was 3.4%, while the mean proportion of outpatient interaction across pediatric subspecialties was 19.1%. The specialties with the highest utilization of messaging as a form of outpatient interaction were gastroenterology (29.5% of outpatient interactions), pulmonology (15.5%), neurology (14.7%), and rheumatology (14%) (Table 2). The specialties with the lowest percentage of messaging-based outpatient interaction were neonatology (1.5%), infectious disease (1.2%), genetics (0.1%), and palliative care (0%).

^a Odds ratios were computed using the generalized estimating equations model. This model controlled for age, gender, race, and time in months in order to measure the likelihood of message-based versus clinic outpatient interaction across pediatric specialties.

Discussion

This study demonstrates rapid adoption of secure messaging through a patient portal by pediatric patients, families, and providers, with the total volume of messaging increasing by more than six times during the first three years after deployment of pediatric accounts. There was also substantial growth in the proportion of outpatient interaction involving messaging rather than in-person encounters, increasing from 2.7% in 2008 to 14.6% by 2010. In this study, a large number of adolescent patients exchanged messages with their providers; by 2010, 16% of all those users who were messaging on behalf of adolescents were adolescents themselves. To our knowledge, this study is the first to characterize adoption of portal messaging across a diverse set of pediatric patients and clinical specialties.

We found pediatric primary care experienced lower volumes and less growth in messaging relative to pediatric subspecialties, which differs from usage patterns that have previously been reported for other institutions, primarily in adults. Although primary care clinics handled over a third of all pediatric clinic visits, only 13% of all messages were sent to pediatric primary care providers. There are several possible reasons for this observation. First, children seeing primary care physicians tend to be healthier than children seeing subspecialists, with a large proportion of outpatient visits dedicated to well child visits which may not need a lot of follow-up or extended communications that would be well-suited to portal-based messaging. Second, acute issues seen by pediatric primary care providers may typically resolve without needing follow-up, such as viral infections. Third, the MCICHV is a tertiary care center with a large rural referral base. Some families may have visited specialist clinics for specific needs and then followed up with pediatricians outside the VUMC network. The middle Tennessee area has many private pediatrics practices not affiliated with VUMC. These providers would not have access to the MHAV patient portal and may have their own patient portal; thus, such patients and their families would be less likely to use MHAV messaging.

In contrast, pediatric specialists, such as gastroenterologists, who managed a high volume of messages over the course of the study (29.5% of outpatient interactions), frequently provide care for children who have chronic diseases, such as short gut syndrome and inflammatory bowel disease, which require long-term nutrition and symptom management. Management of such long-term care may lend itself to message-based interactions between clinic visits. Gastroenterology is also a highly procedural specialty, and patients and their families may use the portal to follow up on the results of biopsies from endoscopies and other procedures. Pediatric endocrinology, neurology, and pulmonology, which also experienced high volumes of messaging, are also specialties that involve chronic conditions (e.g., diabetes, seizure disorders, and cystic fibrosis) that may require repeated interactions between
Figure 3. Use of secure messaging across pediatric specialties. Number of office visits, number of message threads, and the percentage of outpatient encounters that are messages are shown for each specialty. Number of office visits and message threads are plotted on the left y-axis. % of outpatient encounters as messages is plotted on the right y-axis. Months are plotted on the x-axis from month 0 (January 2008) to month 35 (December 2010).
families and providers for medication or symptom management, making secure messaging a valuable tool. In contrast, the specialties of pediatric genetics, development, and neonatology, which had lower volumes of clinic visits, may involve fewer interactions with patients and family, with little ongoing interaction after establishing a diagnosis. Some variation in adoption of secure messaging across specialties also may be due to individual differences in group practices at VUMC. Barriers to adoption of secure messaging that have been described for adult populations in the past have included providers’ workload concerns, clinical communication preferences, and clinical adoption inertia resulting from the information overload in a clinical environment that is already highly computerized.\textsuperscript{25} The reasons for the differences in usage of patient portal messaging by the pediatric primary care and subspecialty populations are not evident from our usage data alone. Our ongoing research is exploring the content of portal messages across specialties, which may yield further insight into these differences. Future research using qualitative methods such as interviews or focus groups with patients and physicians may elucidate the reasons for differences in usage.
Prior work has shown a complex relationship between the implementation of messaging and effects on the number of traditional clinic visits. Some studies reported declines in the number of traditional clinic visits after messaging implementation,\textsuperscript{10,11,26} suggesting that clinical care may be offset; others have observed no change or increases in office visits after messaging is implemented.\textsuperscript{27,28} Although we were not able to obtain data about the baseline number of clinic visits, across specialties, the number of clinic visits per month did not change significantly over the study period after the portal was implemented.

There are important considerations uniquely relevant to use of patient portals and secure messaging in pediatrics. Adolescents' and parents' legal rights to access patient records are not standardized and vary between states. MHAV requires parents to register to access their child’s accounts, which enabled us to contrast usage between patients, delegates, and surrogates. We found that, as expected, most of those messaging about children were surrogates (97%), with the rest being the small number of delegates who had been given access to their record. However, adolescents sent their own messages 18% of the time. Of all messages sent during the study, 18% were sent about adult patients, an observation due to the continued care of patients over the age of 18 by pediatric specialists, usually for congenital disorders or diagnoses common during childhood. Of those who messaged pediatric providers on behalf of adults, 96% were the adults themselves, 2% were surrogates, and 2% were delegates.

This study has several limitations. First, it was conducted at a single large academic medical center with a locally developed patient portal with specific features and attributes that may limit the generalizability of the findings to other institutions.\textsuperscript{21} Second, VUMC has approached pediatric accounts like other major children’s hospitals with policies that focus on preserving parental and guardian rights over those of adolescents\textsuperscript{21,22} (i.e., the “family engagement” model). As such, parents have access to all of their child’s health data and control access rights for their children. In contrast, the University of Florida implemented an adolescent patient portal with very limited access to adolescent patient health data by parents or guardians, also known as the confidentiality model.\textsuperscript{29} This approach was designed to comply with known adolescent care best practices as well as state laws that protect confidentiality of teenage patients. In this study, although the rate of portal and messaging use by adolescent patients themselves was high, our policies that allow ongoing parental access for adolescent patients may have limited adolescent use, especially for sensitive primary care issues such as birth control and sexually transmitted infections. In addition, it’s possible that some of the adolescents or adults who sent messages themselves were actually caregivers who were logged into the patient’s account. However, VUMC discourages this practice by requiring surrogate account use for young children and then keeping the surrogate accounts separate from the patient accounts when patients turn 13.

Our study is limited in that MHAV does not store complete sociodemographic information for all delegates and surrogates, and thus, our analysis included only the characteristics of the patient about whom the message was sent. Thus, we cannot explore whether there were age- or race-based disparities in usage of the caregivers. The focus of this work was messaging use across pediatric specialties, as age and racial disparities in portal usage have been explored elsewhere.\textsuperscript{30,31} In addition, this paper describes data from 2008 to 2010, and both healthcare institutions and consumers have had substantial experience with patient portals since that time. Thus, contemporary usage patterns, which may be influenced by the Affordable Care Act and Meaningful Use incentives and penalties, may vary. We selected this time period to focus on the usage of a portal immediately after implementation of accounts for pediatric patients and their caregivers. Thus, our results may inform other institutions that are at the early stages of pediatric portal adoption. Our research group is currently examining long-term trends in usage of the portal across specialties.

In this study, we only explored use of secure messaging, not looking at other functions, such as access of health education topics or access of selected portions of the EHR. This decision was made because messages are sent to baskets associated with a certain specialty, but it would have been difficult to determine the specialties associated with use of all other functions. We also assumed that the specialty associated with the initial message within each thread was the most appropriate specialty for the entire thread of messages, not accounting for potential transfers to other clinical specialties. We did not examine message content to determine what types of care or other services were provided through these messages, although this topic is the focus of ongoing research. This study did also not look at other forms of outpatient interaction beyond messaging and clinic visits, namely, telephone calls and non-
secure emails. At VUMC, telephone calls are not systematically recorded, preventing quantification of call volumes; email interaction with patients is strongly discouraged. Finally, in our analysis, the GEE modeling approach allowed us to cluster records of message threads associated with the same patient, but we were unable to cluster encounters by patient. Therefore unaccounted correlations for interactions involving the same patient might affect the estimated standard errors. However, given the large sample size and high level of significance in the observed p-values, our findings are unlikely to be affected.

Conclusions

This study is one of the first to analyze use of secure messaging in a patient portal for pediatric patients across clinical subspecialties. After widespread deployment of pediatric accounts at our children’s hospital, most specialties experienced rapid growth in adoption of secure messaging. In contrast to studies of portal use for adult patients, we found that pediatric subspecialties demonstrated greater growth in messaging use as a form of outpatient interaction compared to primary care. Our research may inform institutions that are at the early stages of patient portal adoption or deployment of pediatric accounts. As different stages of MU unfold across the country and pediatric practices adopt patient portals and secure messaging, providers can expect to see rapid increase in the usage of messaging as a form of outpatient interaction, not only in primary care but also across pediatric subspecialties. In adopting patient portals at a children’s hospital, adolescents require unique considerations. Our study revealed enthusiastic adoption by adolescent patients across clinical specialties with use of patient-provider messaging by both adolescents and their parents. When implementing portal messaging for the pediatric population, institutions must take care not to violate state privacy laws and protect the privacy of adolescents. Additional research is needed to examine the types of information and care delivered through patient portal messages in pediatric specialties.

Abstract

An important aspect of post-marketing drug surveillance involves identifying potential side-effects utilizing adverse drug event (ADE) reporting systems and/or Electronic Health Records. These data are noisy, necessitating identified drug/ADE associations be manually reviewed – a human-intensive process that scales poorly with large numbers of possibly dangerous associations and rapid growth of biomedical literature. Recent work has employed Literature Based Discovery methods that exploit implicit relationships between biomedical entities within the literature to estimate the plausibility of drug/ADE connections. We extend this work by evaluating machine learning classifiers applied to high-dimensional vector representations of relationships extracted from the literature as a means to identify substantiated drug/ADE connections. Using a curated reference standard, we show applying classifiers to such representations improves performance (+≈37%AUC) over previous approaches. These trained systems reproduce outcomes of the manual literature review process used to create the reference standard, but further research is required to establish their generalizability.

Introduction

In 2007, the Institute of Medicine estimated that 1.5 million preventable adverse drug events (ADEs) occur each year in the United States¹. One report in JAMA indicated that ADEs are the most common nonsurgical adverse events that occur in hospitals,² and another meta-analysis indicated that ADEs were between the fourth and sixth leading cause of patient mortality³. Additionally, 25 drug products were removed from market due to safety issues over the last decade, highlighted by high-profile cases such as Vioxx (rofecoxib)⁴, which was removed from market on account of increased risk of potentially fatal cardiovascular side effects. The seriousness and prevalence of post-marketing ADEs is a motivation for modern pharmacovigilance systems – systems that actively monitor adverse event reports and clinical records for the emergence of yet undetected associations between drugs and side effects. A key challenge to this process, however, is determining whether there is sufficiently compelling evidence to support the belief that an observed drug/side-effect relationship is plausibly causal⁵. In order to make this assessment, information from a variety of data sources, including randomized clinical trials, observational studies, and spontaneous ADE reporting systems, is integrated by subject matter experts⁵. This process is extremely time- and resource-intensive, and doesn’t scale well to the vast and growing amount of such data. Though there has been a considerable amount of methodological research focused on the problem of signal detection – the selective identification of meaningful drug/ADE associations using statistical methods – an urgent need exists for informatics methods to support the process of critical clinical review to establish the plausibility of such associations once identified⁶.

In this paper, we evaluate a novel approach to this problem by applying machine learning methods to vector representations of implicit relationship patterns that connect a given drug/ADE pair in the literature. We call this approach "Classification-by-Analogy", as classification is thought to occur on the basis of the alignment between the relational structures connecting pairs of entities - a defining characteristic of analogical reasoning⁷. Our hypothesis is that the structure (rather than just the content) of the relations that connect pairs of entities in the literature can serve as a meaningful basis for categorization of the nature of the relationship between them. As an initial case study, we set out to determine whether a drug/ADE pair has a plausibly causal relationship substantiated in the literature, as determined by expert review.

Background

In the field of Literature-based Discovery (LBD), relationships extracted from the literature are used to establish the plausibility of an observed or hypothetical relationship (known as “closed discovery”)⁸-¹⁰. The main idea is that two concepts (such as a drug and disease) that are not connected directly in the literature, may be connected implicitly by relations involving other concepts (for example a drug might inhibit a gene associated with a disease). Though originally intended to assess potentially therapeutic relationships¹⁰, this approach can also be applied to drug/ADE
relationships\textsuperscript{11,12}. Several systems have been deployed in an effort to automate LBD analyses, many of which operate on a co-occurrence based approach\textsuperscript{13-16}. In this paradigm, co-occurrence of concepts or terms are taken as indications of relationship between concepts of interest. In general, these methods do not consider the nature of a particular relationship, even if assertions that specify it occur in the text. These linking words are of particular interest in LBD methods, however, as they can add additional information to constrain the search space of intermediate concepts. Natural language processing systems such as SemRep have been developed to extract these relational assertions from the biomedical literature\textsuperscript{17}. SemRep preserves relational assertions by extracting concept-predicate-concept triplets – such as (ibuprofen-TREATS-pain) – which have been used effectively for LBD in a number of applications\textsuperscript{15,18}. As noted by LBD’s originator, Don Swanson, however, exhaustive exploration of every implicit relationship occurring between concepts is unlikely to be computationally tractable\textsuperscript{19}, motivating the development of methods that operate on reduced-dimensional approximations of the relationship matrix between concept pairs\textsuperscript{19,20}. In one approach, concept-predicate-concept triplets form the basis for a vector representation scheme, Predication-based Semantic Indexing (PSI)\textsuperscript{19,21}, that encodes concepts and their relational connections (or predicates) in a hyper-dimensional semantic vector space. These PSI encodings can be used to query the relationships between concepts by using an approximate form of reasoning in which the potentially intractable task of exploring large numbers of implicit relationships is converted to the computationally convenient task of comparing the similarity between semantic concept vector representations\textsuperscript{21}. Although PSI represents concepts as vector encodings in a high-dimensional vector space similar to those of neural embedding approaches (e.g. word2vec\textsuperscript{22}), these encodings are derived differently. Neural word embeddings are derived directly from natural language using a neural network optimized to predict the context of a given term (or vice versa). In contrast, PSI representations are derived from semantic predications by explicitly encoding the nature of the relationships between concepts using compositional operators.

PSI accomplishes encoding and query functions by leveraging reversible vector transformations provided by a family of representational approaches: Vector Symbolic Architectures (VSAs)\textsuperscript{23-25}. The vector transformations are algebraic operations, and can be characterized as follows: a bundling operation (+), which adds (or superposes) vectors to generate a vector product that is similar to its component vectors; and binding (\(\odot\)), which results in a vector that is dissimilar from its component vectors and is functionally analogous to multiplication. These vector transformations are reversible by subtraction of component vectors and release (\(\odot\)) of the binding operation respectively, and vary in technical implementation between VSAs. In our work, we employ the Binary Spatter Code (BSC) as the VSA, which uses high- (or “hyper-”) dimensional binary vectors with dimensionality on the order of 1,000s as a representational unit\textsuperscript{26}. On account of the statistical properties of high-dimensional space, large numbers of such vectors can be generated stochastically – by randomly assigning a one or zero in each dimension with equal probability – with a high probability of their being far apart in space. This means these vectors are exceedingly unlikely to be confused with one another, despite their being distorted during the superposition process: large numbers of such random vectors can be superposed before their signal is lost. The BSC’s bundling transformation takes a majority rule vote between component vectors (ones are assigned to dimensions with more ones than zeros, and ties are broken at random), and employs Pairwise Exclusive OR (XOR) to bind and release (since XOR is its own inverse). These operations provide the basis for training in PSI. The semantic vector for a concept is generated by superposing the bound product of the random vectors for the predicate and argument of each predicate it occurs in. For example, the predication “ibuprofen-TREATS-pain” would be encoded into the semantic vector for the concept “ibuprofen” by superposing the bound product of the random vectors for “TREATS” and “pain”. In symbols, where \(S(\text{concept})\) is the semantic vector for a concept, and \(E(\text{concept/PREDICATE})\) is the elemental (or random) vector for a concept or a predicate, \(S(\text{ibuprofen}) \equiv E(\text{TREATS}) \odot E(\text{pain})\). A consequence of this encoding process is that when applied to two semantic vectors, the release operator reveals the two-predicate path (if any) that connects them:

\[
\begin{align*}
\text{If} & \quad S(\text{ibuprofen}) & \equiv & \quad E(\text{TREATS}) \odot E(\text{pain}) \\
\text{and} & \quad S(\text{arthritis}) & \equiv & \quad E(\text{CAUSES}) \odot E(\text{pain}) \\
\text{then} & \quad S(\text{ibuprofen}) \odot S(\text{arthritis}) & = & \quad E(\text{TREATS}) \odot E(\text{pain}) \odot (E(\text{CAUSES}) \odot E(\text{pain})) \\
& & = & \quad E(\text{TREATS}) \odot E(\text{pain}) \odot E(\text{pain}) \odot E(\text{CAUSES}) \\
& & = & \quad E(\text{TREATS}) \odot E(\text{CAUSES})
\end{align*}
\]

1941
For example, in the PSI semantic space for the current work, the nearest-neighboring bound products of predicate pairs to the vector product $S(\text{valdecoxib}) \otimes S(\text{gastrointestinal_hemorrhage})$ are shown in Table 1. Importantly, these pathways contain only bridging relationship information (structure), and not the bridging concepts themselves (content).

Once inferred, these predicate-based (or reasoning) pathways can be used to direct a search through the space for other concepts that relate to a third concept in a manner similar to the relationship between the cue concept pair—a process referred to as Discovery-by-Analogy ($DbA^2$), as the reasoning employed follows the pattern: “what is to myocardial infarction as valdecoxib is to gastrointestinal hemorrhage”. We have previously applied this methodology to estimate the plausibility of drug/ADE relationships, using a procedure that restricts the search to a small number of two- and three-predicate pathways (termed “discovery patterns”) inferred from known therapeutic or drug/ADE relationships.

In this paper, we take previous PSI approaches a step further: rather than inferring and applying discrete reasoning pathways from known examples (the “discovery patterns”), we evaluate the utility of applying machine-learning methods to the vector products of semantic PSI representations directly. As these vector products represent patterns of relationships (predicates), we call this approach Classification-by-Analogy ($CbA$). Our hypothesis is that this will lead to improved performance in a classification task, as the distribution of reasoning pathways between pairs of concepts, rather than the strength of relatedness across a set of discrete pathways, is considered.

By way of novelty, these models have not yet been utilized as a representational framework for machine learning in the biomedical domain, aside from in the context of $DbA$, so the literature provides little guidance as to which algorithms might be best applied to them. For the current analyses, we chose to utilize k-Nearest Neighbors ($kNN$), a support vector machine ($SVM$), and a logistic regression ($LR$) model. $kNN$ is a nonparametric classifier that functions in simple deployments by taking a majority vote amongst the closest $k$-neighbors to an unknown data point. Since VSAs generate a vector space populated by vectors in such a way that similar vectors co-localize to a similar geometric region, we anticipated that $kNN$ would provide reasonable performance. SVMs are parametric models that learn a dividing hyperplane defined by a subset of the data (so-called support vectors) in high dimensional spaces to classify examples occurring on either side. As one previous example exists of an SVM applied to vector symbolic representations with success on a text categorization task, an SVM with similar parameters was chosen. Finally, $LR$ was chosen due to both its popularity and its simplicity in defining a classifying hyperplane as a function of coefficients on the input data alone (i.e., it does not learn the hyperplane as a function of support vectors). Cost functions differ between SVMs and $LR$, and they differ slightly in their handling of regularization despite sharing the same hyperparameter, $C$, a term to encourage sparsity.

Labeled data are required input for these supervised machine learning algorithms. In pharmacovigilance, such labeled data has historically been difficult to acquire, as it requires the very human-intensive process that makes pharmacovigilance itself a costly expenditure. The Observational Medical Outcomes Partnership (OMOP) research initiative endeavored to meet this data need, and produced a drug/side-effect database to facilitate methodological research for drug safety surveillance. This manually curated reference set consists of 165 positive

and 234 negative test cases. Each test case is a drug-ADE pair, and each drug is one of 181 unique drugs in the set, including NSAIDs, beta-blockers, ACE inhibitors, antidepressants, antibiotics, and more. The four side-effects chosen – acute myocardial infarction, acute renal failure, acute liver failure, and gastrointestinal bleeding – are four of the most significant ADEs for a risk identification system. Together, these combinations provide a widely used methodological evaluation set and the current benchmark in PV.

Methods

To facilitate our research, we utilized the semantic predications extracted from the literature by SemRep housed in the Semantic Medline Database (SemMedDB) version 2.2 database and the 2012 MetaMapped Medline Baseline (MBB) for PSI and co-occurrence approaches respectively. The SemMedDB extractions were generated by SemRep version 1.5. The MMB was derived from 20,494,848 citations up to November 2011, and contains 399,701 distinct concepts, while SemMedDBv2.2 was derived from 22,252,812 citations up to March 2013, and contains 63,795,467 predications spanning 58 predicates and 257,350 distinct concepts. These versions are identical to those used in the previously published analyses, and were chosen to facilitate methodological comparison. As in previous work, negative predications, such as drug DOES NOT TREAT side-effect, were excluded, comprising only 1.2% of the total predications.

Of the OMOP data set, we utilized 164 positive and 230 negative test cases. For our analysis, we did not use test cases for the drugs darunavir and sitagliptin, as they did not occur in the vector representation stores used for the analyses. The four side-effects in the OMOP set can be defined by a list of International Classification of Diseases (ICD) 9 codes, and so we expanded the list of terms encompassing each ADE to all of its ICD-9 codes and sub-codes. Table 2 represents some of the expanded query terms used for myocardial infarction. Drug names were not expanded, and were queried in all cases as named in the OMOP reference set except for niacin, which was translated to nicotinic acid.

Table 2. Example expanded terms for myocardial infarction.

As our co-occurrence approach, we employed reflective random indexing (RRI) which considers both direct co-occurrence and indirect relatedness (between terms co-occurring with the same other terms). RRI was implemented using the Semantic Vectors package version 3.7 with 32,000 dimensional binary vectors in accordance with the BSC. Briefly, document vectors are built by superposing the elemental vectors for each distinct concept that occurs in each document in the MMB, using a log entropy weighting metric (which reduces the effect of high-frequency terms across and within documents). Semantic concept vectors – i.e. S(concept) – are then built by superposing the document vectors that the given concept occurs in. These semantic vectors are then rank ordered based on (1 – the normalized Hamming distance), a similarity measure, between drugs and (expanded) ADEs in the reference set. To expand each ADE into a query that reflected the sum of its ICD-9 codes, we superposed the available vector representations of expanded list terms reflecting the given condition.

For both producing results as in previous PSI analyses using discrete pathways (i.e. DbA) and for our classification analysis, we utilized vector stores from previous analyses, whereby 32,000 dimensional binary vectors were generated consistent with the BSC using Semantic Vectors version 3.711. A maximum frequency threshold of 1M terms was used to prune uninformative high-level concepts, and negative predications were removed as mentioned above. In order to further mitigate the effect of highly frequent, uninformative terms, superposition of bound products were weighted by predicate frequency multiplied by the sum of the inverse document frequency of the predicate and bound concept such that (using ibuprofen as an example):

\[ S(\text{ibuprofen}) \leftarrow E(\text{TREATS}) \otimes E(\text{pain}) \cdot f_{\text{TREATS}} \cdot (idf_{\text{TREATS}}+idf_{\text{pain}}) \]

where \( f_{\text{TREATS}} = \log(1+\text{occurrences of prediction ibuprofen-TREATS-pain}) \)

\( idf_{\text{TREATS}} = \log(\text{number of total predications} / \text{number of predications containing TREATS}) \)

\( idf_{\text{pain}} = \log(\text{number of total predications} / \text{number of predications containing pain}) \)

</tbody>
</table>

Additionally, ADE terms were expanded as in RRI for DbA and CbA. For each drug/ADE pair in the reference set, the semantic vectors for the respective drug and ADE are then released as shown above (Table 1), giving us the abstract pathway vector representation for that pair. This vector is then projected into a subspace composed of two predicate discrete reasoning pathways (Table 3) and rank ordered by magnitude to generate DbA results, and passed as input to the machine learning algorithms in our CbA work. Only double predicate pathways were utilized for DbA to facilitate a fair comparison with CbA (in previous work, triple-predicate pathways were also considered).

With our goal to classify these vectors according to ground truth relationship, we labeled the vectors representing each drug/ADE pair relationship with the OMOP ground truth state (Figure 1) for input into machine learning algorithms.

---

All machine learning development and deployment was done in the Python programming language version 3.5 using the scikit-learn package. The specific Python deployment was from Continuum Analytics Anaconda platform, version 2.5, and a development environment was created using the conda command line utility packaged with Anaconda specifically for the purpose of these analyses and to ease reproducibility. This environment file, along with saved data arrays, code files used, and additional information on software versions utilized, are available upon request.

Within scikit-learn, we utilized the LibLinear library through the scikit-learn.LinearSVC() front end; for k-Nearest Neighbors (kNN) we utilized the scikit-learn.kNN() front end; and for LR we utilized the LibLinear library through the scikit-learn.LogisticRegression() front end. Hyperparameters for the SVM (the regularization C parameter), for LR (C parameter) and for kNN (the k number of neighbors) were chosen using cross-validation grid search functionality built into the scikit learn package (scikit-learn.GridSearchCV). For the SVM and LR, an L1 penalty parameter was chosen to enforce sparsity in the learned model. ROC AUC curves for SVM and LR models were generated by passing the results of the decision function, which calculates the distance from the dividing hyperplane.
of the classifier for each example in the case of the SVM, as the rank ordering. Additionally, Stratified 5-Fold cross-
validation was used to generate the mean ROC AUC curve by averaging each fold’s performance on a held out test
set. Learning curves were generated for the F1 metric by varying the number of training examples and the
dimensions of the data. Test data was never utilized in the training phase of any supervised machine learning
approach in an attempt to mitigate over-fitting. All plotting was done using the matplotlib package in Python.

Results

A comparison of kNN performance results with 5, 10, and 15 nearest neighbors are reported below in Table 4. kNN
typically performed best with $k=5$ in our analysis. For comparison, see F1 scores in Figure 4.

Table 4. kNN precision, recall, and F1 scores reported with two times the standard deviation across cross-
validation runs in error per number of k neighbors used.

A summary of the ROC results between DbA, RRI, and SVM and LR models both utilizing a C of 1, including
AUCs, can be found in Figure 2. All variants of CbA outperformed DbA (+≈37% over 0.68 AUC) and RRI (+≈48%
over 0.63 AUC) models, with AUCs around 0.93-0.94. Additional context for these results can be found in the
learning curves presented in Figure 4.

For C=1, SVM coefficient vectors contained approximately 300/32000 nonzero weights when trained, with similar
levels of nonzero weights in LR models. Coherence of nonzero features, including sign and strength of weight, is
shown in Figure 3. These nonzero features are distributed across the coefficient vectors for these models. There are
approximately 70% shared nonzero positions between them.

Figure 2. ROC Curves for tested models. AUCs are listed +/- two times the standard deviation (across cross-validation runs).
LR and SVM models both have one hundred percent accuracy on training sets when trained with full dimensional vectors with $C=1$. Cross-validation performance is consistently above 0.80 when considering an F1 scoring metric with even a small portion of the training data set and significantly diminished input vector dimensions.

**Figure 3.** Coherence among LR and SVM models. Negative weights are colored in white, zero values colored in grey, and positive values colored in black. In either case, the 32k weights - one for each dimension of input data - are reshaped into a 200x160 matrix for visualization. Nonzero elements are distributed across the weight vectors. Contrast adjusted for visibility.

LR and SVM models both have one hundred percent accuracy on training sets when trained with full dimensional vectors with $C=1$. Cross-validation performance is consistently above 0.80 when considering an F1 scoring metric with even a small portion of the training data set and significantly diminished input vector dimensions.

**Figure 4.** The effect that truncating dimensions (a) and limiting training samples (b) has on cross-validation performance of CbA parametric methods, as measured by an F1 metric.

**Discussion**

To our knowledge, these results represent the first evaluation of classification based on vector representations of abstract relational structures. kNN performance indicates that relational neighborhood as defined by abstract predicate pathways is of value for this task. Although we believe that performance metrics indicate the LR and SVM models are over-fitting, the strong cross-validation performance implies remarkable self-consistency in the representations of the literature for the OMOP reference set. Additionally, LR and SVM models both have striking
coefficient vector homology. Since the OMOP set derived its positive examples using automated NLP methods to extract drug reactions from package inserts as the first pass, and since negative examples were likewise selected as those that did not show up in drug packaging inserts, Tisdale evidence, and had nonexistent or only negative linkings to the ADE in question in the literature during manual review, it is possible that their selection criterion generated a reference set that is internally coherent amongst examples of each class. While more work needs to be done to assess generalizability, presented results indicate that there exists a self-consistent structure to the OMOP reference set as represented here that provides CbA approaches sufficient information to make accurate classifications on it.

The machine learning algorithms we chose are particularly simple and incorporate no prior information; we anticipate the incorporation of priors will improve performance and likely lend to more generalizable models. Unsurprisingly, it also seems that the models would be well served with additional examples, as evidenced by the learning curves. Such examples would ideally introduce more variance, and trained models would be less prone to over-fitting. Experimentation with additional weighting strategies within the representation itself may also be warranted, as the weighting procedures can influence which predicate pathways are encoded more influentially.

In addition to only being characterized in the context of a single data set, our study has other limitations worth mentioning. First, we didn’t attempt to optimize any statistical weighting metrics or other PSI parameters in the development of this work. Second, we didn’t systematically evaluate how performance changes cross different initializations of the random vectors, opting instead for pseudo-random instantiation per [33]. Additionally, work is presented in comparison to similar approaches that operate on literature information exclusively; other studies have been published on the data set utilizing different methods and data, including observational data34,35, which is not considered here.

One major benefit of the DbA approach, and one current limitation to CbAs, is clearly defined interpretability. For DbA, confidence scores are generated based on vector-subspace similarity, and the subspace is constructed from elected double predicate pathways. If something has high similarity to the subspace, then the interpretation is that it has high similarity to those predicate pathways which make up the subspace. In our CbA approaches, it is difficult to directly map nonzero coefficients to interpretable pathways or features. Since a fully distributed representation encodes information across vectors, individual features are primarily important in their context of other features. The primary challenge we see facing this work is in mapping learned nonzero parameters from these classifiers back to more interpretable predicate pathways, and to the literature sources that plausibly link these entities themselves. In this same vein, it is likely that more information than just common relations are being utilized by classification algorithms as presented here. The vector space, as a function of its structured encoding scheme, likely incorporates common object information as well when comparing our derived relational representations. For example, in comparing drugs A and B that inhibit the same target C, A\(\bowtie\)C would be similar to B\(\bowtie\)C, and is functionally similar to a direct object comparison in that context (i.e. similarity(A\(\bowtie\)C, B\(\bowtie\)C) = similarity(A,B)). The information used in this case is not exclusively relational, though relational information plays a role (A inhibits y, A causes C; B inhibits Y therefore B may cause C). Further research is needed to identify the extent to which these different sorts of information contribute toward classifier performance.

Conclusion

Each model accurately predicted across a variety of drugs and four ADEs, learning only one set of parameters to distinguish between plausibly causal as defined by the OMOP set and not, substantiating that the representation itself is a meaningful basis for classification tasks. Our original hypothesis that the basis of the relational structure between pairs of biomedical entities could provide the necessary information for categorization of higher level relational status was substantiated by our results on the OMOP reference set.

Abstract

Parkinson’s Disease (PD), a prevalent problem, especially for the aged populations, is a progressive but non-fatal nervous system disorder. PD patients have special motor as well as non-motor symptoms over time. There are several limitations in the study of PD such as unavailability of data, proper diagnosis and treatment methods. These limitations significantly reduce the quality of PD patient life quality, either directly or indirectly. PD also imposes great financial burdens to PD patients and their family. This project aims to analyze the most common reasons for PD patient hospitalization, review complications that occur during inpatient stays, and measure the costs associated with PD patient characteristics. Using the HCUP NIS data, comprehensive data analysis has been performed. The results are customized visualized using Tableau and other software systems. The preliminary findings sheds light into how to improve the life quality of PD patients.

Parkinson’s disease, Data Analytics, Hospitalization utilization and cost, Tableau, HCUP NIS database

1. Introduction

Parkinson’s disease (PD) is a slowly progressive, chronic but non-fatal neurological movement disorder or disorder of the brain. It is the second most common neurodegenerative disease in US. It is reported that there is an average of 0.3\% of PD prevalence throughout the entire population as estimated by the individual studies based on the projection of economic burden of PD\textsuperscript{1}. Previous study also showed there was about approximately 2\% and 5\% increase rate in the number of patients identified with PD over age 65 and over 85, respectively. In addition, the overall prevalence and global economic burden of PD in World’s top 10 densely populated nations has been investigated and it is estimated that the PD occurrence rate will be double by 2030.\textsuperscript{2}

Although the actual cause of PD remains unclear, it has been seen that the symptoms of PD is associated with the deficiency of Dopamine, a chemical in the brain. There is no explicit tests to diagnose PD. Thus, the disease is diagnosed only based on the patient’s report and the combination of exhibited symptoms. Confirmed PD is typically treated with the combinations of medications and exercises. Medicines can improve the symptoms to some extent, but the care and management is very challenging and costly for the patients and their healthcare providers.

The major symptoms of PD disease is characterized by a collection of motor as well as non-motor symptoms, which is the results from dopaminergic neuron degeneration.\textsuperscript{1,3} The major PD motor symptoms is clustered into an acronym called TRAP: Tremor, Rigidity, Akinesia or Bradykinesia and Postural instability. The non-motor symptoms include mood disorders, sleep disorders, depression, anxiety and decreased motivation etc. These symptoms have a huge influence to the potential adverse effects on health-related life quality of PD patients. The severity of such symptoms indicates the progression of the disease, which resulting in a higher costs of medical treatments for hospitalization and care coordination.

The major objectives of this study are to perform data analytics, to highlight the most common reasons for PD patient hospitalization, to determine hospitalization costs, and to measure the co-morbidities associated with this disease. The long term goal of this study is to lessen the symptoms of PD and hence, improve the quality of life of the patients by lowering the hospitalization costs and inpatient hospital stays.

2. Materials and Methods

2.1 Data Source:

A retrospective analysis was performed using the Healthcare Cost and Utilization Project's (HCUP) Nationwide Inpatient Sample (NIS)\textsuperscript{4} data for the year 2012. The Agency for Healthcare Research and Quality (AHRQ) sponsors
the HCUP databases that are specifically designed to determine and identify patterns in hospital utilization and cost across the United States. The HCUP-NIS database is the largest inpatient database available in the US, which represents a sample of non-federal US community hospitals. Just in 2012, there are 1,049 hospitals from 46 states in US participated in NIS projects. More than 7 million records of hospital stays were reported by these hospitals. It is estimated that the sampling includes over 95 percent of discharges from the hospitals participated in NIS. The estimated samples were weighted in order to minimize the margin of error and to reflect all 50 states across the US. The large sample size of the database enabled us to analyze rare conditions, uncommon treatments and special patient populations.

To protect the privacy of individual patients, physicians, and hospitals, the state and hospital identifiers are de-identified. There are many clinical and non-clinical hospitalization data elements recorded in the HCUP NIS database. Sample non-clinical information are patient demographic information, payment related information, hospital characteristics (such as region, census division, and location), and total charges. Sample clinical related information include principal and secondary diagnosis and procedure (includes both ICD-9 and CCS codes), discharge status and Length of stay.

2.2. Variables of Interest:

At first, based on the ICD-9-CM diagnosis codes, the individuals who were primarily diagnosed as PD patients at the time of admission had been identified. In HCUP databases, more than 14,000 ICD-9-CM diagnosis codes and 3,900 procedure codes had been mentioned which were further classified and clustered into lesser number of clinically appropriate categories by the AHRQ's Clinical Classification Software (CCS). This enabled the database to capture a large population of relatively similar conditions into a single group by making the information more useful for performing statistical analyses and developing reports. PD patients were identified using CCS diagnosis code as 79.

One of the dependent or outcome variable of interest was the total hospitalization cost resulting from the entire hospital stay. The total hospital charges counted all the expenses for services provided to the patients excluding physician or professional fees.

For the analysis, among the predictor variables, the primary and secondary disease conditions and procedures and length of the hospital stays were important. The preliminary diagnoses had been identified at the time of admission whereas the comorbidities or the secondary disease conditions were recorded throughout the entire hospital stay. The similar manner has been followed for the determination of the primary and secondary procedures. The length of stay was the time period from the admission to the discharge of latest hospital stay of each patient.

2.3. Approaches:

Retrospective analysis was performed over the HCUP-NIS database focusing on the determination of the hospital utilization cost for PD patients. Descriptive statistics were used to summarize the results. The mean and standard deviation was used to explain the continuous variables. On the other hand, the categorical variables were shown in percentage values.

Statistical approaches have been used to determine the correlation of clinical features including diagnosis, current medical conditions and costs. For the Univariate analysis, the two major characteristics of the variable analyzed were the distribution and the central tendency.

Data were analyzed using R language and Tableau software. The Tableau software provides a great user interface and visualization tools for the analytical results.

3. Results & Findings

Extensive analysis were performed for the 2439 PD patient hospitalization records. The preliminary results are presented below.

3.1 Demographics:

Age Distribution: The patients were distributed according to their age group as shown in the (Figure 1). The result shows that a total of more than 99% of patients were in the range of 50 to 90 age group where approximately 26%, 34% and 25% patients were in 61-70, 71-80, and 81-90 age groups, respectively. Although, in earlier studies, there is no significant association has been found between the aging process and the acceleration of the disease, still it is a debatable fact whether the aging influences the progression of the disease or not.
Figure 1. The distribution of PD patients by the age group.

Patients across the census division: The data is geographically divided into 9 divisions from 4 regions. Figure 2 below shows all the states in each of the 4 US Census Bureau Regions and 9 divisions. The states highlighted in grey color do not participate in HCUP.

Figure 2. The map depicting the 9 census divisions and 4 regions in US.
Figure 3. The percentage of PD patients across the census division and the region in US.

For the four geographical divisions, the Middle Atlantic division in the Northeast Region contributes to the highest number of PD patient sample (20% of total 2439 patients) whereas the New England division from the same region contributes to the lowest number of PD patient sample (5% of total 2439 patients) as described by the (Figure 2). Next to the Middle Atlantic division, the South Atlantic division from South region, East North Central division from Midwest region and Pacific division from the West region contributes to the more number of inpatient samples.

3.2. Diagnosis Related Group (DRGs):

DRG is a system of classification that has been developed with the intent to identify the presence of complications or comorbidities and to replace "cost based" reimbursement that had been used up to that point by the hospitals. In contrast, according to the literature by Muller et al.\textsuperscript{12} published in 2010, a significant decrease in the reimbursement of treatment costs has been noticed in spite of the presence of increased operation risk and medical conditions that in turn results in an increased economic burden for the PD patients.

The DRGs, identified for the PD patients, included craniotomy and endovascular intracranial procedures, spinal procedures, extracranial procedures, peripheral/ cranial nervous system procedures and degenerative nervous system disorders. The DRGs also indicated the severity of the disease as it has identified the patients with or without minor or major complications and co-morbidities.

The top 6 DRGs having the percentage of the total number of PD patients in each group is shown in (Figure 4). The description of these DRGs are -

- Degenerative Nervous System Disorders W/O MCC (57),
- Craniotomy & Endovascular Intracranial Procedures W/O CC/MCC (27),
- Degenerative Nervous System Disorders W MCC (56),
- Cranio W Major Dev Impl/Acute Complex CNS PDX W/O MCC (24),
- Craniotomy & Endovascular Intracranial Procedures W CC (26)
- Periph/Cranial Nerve & Other Nerv Syst Proc W/O CC/MCC (42)

where W CC, W MCC, W/O MCC and W/O CC/MCC corresponds to With Complications or Co-morbidities, With Major Complications or Co-morbidities, Without Major Complications or Co-morbidities, Without Complications or Co-morbidities/ Major Complications or Co-morbidities respectively.
3.3. Frequently Used Procedures:

The study has identified total top 11 primary procedures that has been frequently used for the PD patients. The Figure 5 shows 10 primary procedures having percentage frequency in between 0.5% to 2% and excludes the procedure with ICD-9 code as 293 having the highest frequency of 20%. The Table 1 listed the top 10 primary procedures based on
their average cost per day. Considering both the Figure 5 and Table 1, the study found it interesting that the procedures having higher average cost per day has been frequently used for the PD patients. This analysis has also listed 3 interesting procedures based on their cost and usage frequency:

1) The procedure Imp/repl brain stim lead (ICD code 293): It having the highest frequency, is used for 20% of the total patients. The description of the procedure is known as Implantation or replacement of intracranial neurostimulator lead(s). This is applied to the implantation, insertion, placement, or replacement of intracranial brain pacemaker [neuropacemaker], depth electrodes, foramen ovale electrodes and intracranial electrostimulator.

2) Implantation or replacement of peripheral neurostimulator lead(s) (ICD code 492): This procedure having the highest average cost per day is also used frequently for the patients.

3) The cranial implantation or replacement of neurostimulator pulse generator (ICD code 120): It is a procedure which is also found in the top 10 list, and is followed along with the above procedure (ICD code 293).

Figure 6. The length of hospital stays for PD patients
3.4 Length of Patient Stay:

The average length of stay for the top 10 primary procedures was approximately 4.8 days, with a range of 1-16 days. Qualitatively, the PD patients treated with the procedure called percutaneous endoscopic gastronomy had the longest stays whereas the patients treated with insertion of catheter had the shortest stays as described by the Figure 6.

3.5. Average cost per procedure:

The study calculated the average cost for each of the primary procedures. The below diagram shows the plots for top 15 primary procedures and each boxplot represented one primary procedure as shown in Figure 7. The plots were sorted based on the mean value of cost per day in an ascending order.

The average cost for all the top 10 procedure was approximately $28400 (range ~ 9000-65000) with the standard deviation as approximately $12800 (range ~ 660-30450). The below table (Table 1) shows the average cost and standard deviation for the top 10 primary procedures.

![Figure 7. The average hospitalization cost for top 15 frequent procedures](image-url)
When the study compared the procedures by taking average cost, average length of stay and frequency into consideration, it has identified the below procedures for which the average cost, length of stay and the frequency was higher as described by the (Figure 8) -

- Imp/repl brain pulse gen (120)
- Imp/repl brain stim lead (293)
- Imp/repl peri stim lead (492)
- Percu endosc gastrostomy (4311)

### 4. Discussion:

This analysis of population-based hospital discharge data from patients with PD reveals variations in hospital costs by patient demographic characteristics. Average hospital cost was significantly higher for hospitalizations. Several important observations were generated. A major component of the overall economic burden of healthcare is the initial cost. The study identified the procedures, having higher cost and length of stay, was related to the Deep Brain Stimulation (DBS) which is an important treatment option for PD patients experiencing dyskinesia and motor complications. Literature related to DBS showed that the most common reasons for prolonged hospitalization after DBS are mental status changes and cerebral hemorrhage.\(^{13,14}\)

Although the study illustrated the large economic burden of PD in terms of medical costs, still it couldn’t able to demonstrate the true burden of the disease. The presence of comorbidities and its treatment procedures had been significantly reduced the quality of life for people with PD and their family members. It has been further projected that the pressure of such chronic conditions will substantially increase in next few years with the increase of size of the aged populations.\(^{15,16}\) Such projections demonstrate the need for the innovation of old techniques and identification of new treatment procedures including vigorous exercises in order to prevent or delay the onset of the disease; hence, increasing the quality of life for the PD patients.

The present study had several limitations common to administrative databases. It was susceptible to errors for categorizing patients and calculating costs. The hospital charges analysis does not constitute the hospital-specific
differences in charge practices. There may be variation in cost-to-charge ratio (CCR) by patient population and by individual hospital departments that could have resulted in errors in calculating costs. Thus, it is difficult to develop comprehensive framework of current payment models focusing on cost structure on PD patients because up-to-the minute charge data are not available, and charge practices may be lost in the heterogeneity of hospital type.

However, based on these data, a predictive model of cost can be built in future so that the model can be additionally utilized in the cost management debate and the creation of data-driven policies. This can fuel further studies in the field and provide elements for the design of prospective investigations.

5. Conclusion

This study has successfully identified the most common reasons for hospitalization in PD, determined costs associated with nationwide hospitalizations of individuals with PD and measured the co-morbidities associated with the disease using the nationwide discharge sample data across the US. Future work, incorporating the development of a prediction model of hospitalization utilization cost can fuel the further studies in the field of healthcare.

Medication Harmony: A Framework to Save Time, Improve Accuracy and Increase Patient Activation

Frank Pandolfe MD,1,2 Bradley H Crotty MD MPH,1,2 and Charles Safran MD MS1,2

1Division of Clinical Informatics, Beth Israel Deaconess Medical Center, Boston, MA
2Harvard Medical School, Boston, MA

Abstract

Incompletely reconciled medication lists contribute to prescribing errors and adverse drug events. Providers expend time and effort at every point of patient contact attempting to curate a best possible medication list, and yet often the list is incomplete or inaccurate. We propose a framework that builds upon the existing infrastructure of a health information exchange (HIE), centralizes data and encourages patient activation. The solution is a constantly accessible, singular, patient-adjudicated medication list that incorporates useful information and features into the list itself. We aim to decrease medication errors across transitions of care, increase awareness of potential drug-drug interactions, improve patient knowledge and self-efficacy regarding medications, decrease polypharmacy, improve prescribing safety and ultimately decrease cost to the health-care system.

Introduction

Patients receive prescriptions from multiple clinicians and often use more than one pharmacy. They may take over-the-counter (OTC) medications and herbal supplements. For patients and clinicians alike, constant reconciliation of a medication list has been a Sisyphean task. Discrepancies and inaccuracies among medication lists are linked to errors in prescribing and self-administration. Clinicians often settle for a list that is “good enough,” yet contains numerous errors. These errors translate into adverse drug events (ADEs) and often result in increased morbidity, mortality, hospital readmission, and increased health-care-related cost1-4. In the United States, the cost of ADEs is estimated at $76.6 billion in the ambulatory setting alone5.

Numerous studies have assessed how to decrease ADEs, and hospital readmission rates6-11. Some form of intervention to obtain the “best possible medication history” over typical care has repeatedly shown to decrease error rates on the medication list. Research to date has primarily focused on improving the accuracy of a singular medication list and decreasing ADEs. Thus far, however, there has not been much consideration to the amount of institutional infrastructure and person-time needed to complete such tasks and how often the task must be repeated.

Some studies have suggested cost-benefit by paying pharmacists to reconcile the best possible medication history upon hospital admission, a process that can take more than 30 minutes per patient12. Broader system changes include creating leadership positions, changes in workflow, management teams, “reconciliation champions”, interdisciplinary teams, encouragement from those who are “less than enthusiastic” to participate, and other daunting barriers to implementation13,14.

Currently, the “gold standard” of obtaining the best possible medication history involves a pharmacist compiling patient history, obtaining patient and office medication lists, pharmacy data, and discharge summaries upon admission. Approaching discharge, the pharmacist reviews changes in medications, describes indications and reviews discontinued medications15,16. Post discharge, the pharmacist contacts the patient again to resolve any unanswered questions. Many institutions are not yet current with these best practices or have limited pharmacy staff to complete such tasks. The process of medication reconciliation is then delegated to nurses or physicians who often do not have time or resources to ensure a high-degree of accuracy. Although this workflow is effective for a single hospitalization, it is a laborious task that must be repeated at every transition of care and does not address the issue of creating multiple out-of-date medication lists.

Medication managers through mobile applications and institution-based systems currently exist, however, under fractured infrastructure17-19. A hurdle for federation is the siloing of information in institution-specific systems (Figure 1). These systems fail to communicate with one another and patients are often responsible for the input of all
medications by hand. Even with interoperability and communication among systems, keeping multiple lists synchronized remains challenging.

**Figure 1.** Current structure of the outpatient medication list

Although an approach such as “Blue Button” allows patients read-only access to their own information, a user must be actively engaged and obtain separate log-in information and credentials at each institution they receive care. Additionally, patients do not have the ability to easily modify the data provided by “Blue Button”. A consolidated, shared, patient- and physician-modifiable view of a medication list hasn’t been successfully implemented.

To achieve provider buy-in we need to overcome the tremendous time and effort needed to keep an accurate medication list. We must increase patient activation, and where appropriate, family members, by offering them utility in keeping a list. For most patients, the list represents an array of unpronounceable names of various colored pills that he blindly takes. We must incorporate common-language, actionable information while minimizing patient effort for information loading and updating of their medications.

**Envisioning a Solution**

A solution should allow patients, providers, institutions and pharmacies to eliminate disparities among a medication list that is used across various environments. It must be:

- Widely visible while protecting patient privacy
- Modifiable by patients, caregivers, and practitioners, and family members where appropriate
- Institution agnostic
- Able to easily fit into the current framework of medication reconciliation so that minimal disruption in workflow is caused.

The solution must also encourage patient activation and aid in comprehension. Therefore, it should:

- Easily capture OTC medications
- Pre-populate the list to avoid confusion and fatigue
- Provide knowledge regarding drug information, including pill images
- Alert for potential interactions

A benefit to such a solution is a faster and more accurate medication reconciliation process thus reducing ADEs from inadvertent prescribing errors.
Using the HIE to centralize the medication list and establish a “single source of truth”

Practically speaking, a dedicated, stand-alone database and accompanying application to act as a medication manager must be implemented. For many locations, a HIE is established to help share data among various providers. As a hospital or a physician office registers its EHR as a provider on a HIE, so too will the medication manager. By doing so, it will be able to interact with other “trusted” systems on the network. Its job will be to maintain a database of an individual’s medications by gathering information from other institutions that have recorded medications (Figure 2). Linking the medication manager into the HIE enables a dedicated provider of medication information. Furthermore, providers such as PCPs, specialists, hospitals and nursing homes will have access and the ability to update the list.

Under the proposed solution, a patient would register for this service via a web site or a smart-device application. Identity would be verified and the user authenticated. Exchange of health information over a HIE requires patients to accept the terms and conditions of their local HIE. For example, Massachusetts has an opt-in policy for patients. Consent is possible online and one can opt-out at any time. This process can be accomplished within the medication manager app itself.

![Figure 2. Centralized Medication Manager](image)

**Interoperability**

To be viable, the solution must be able to fit within current workflow situations. Although difficult to imagine within our current EHR landscape, effort is currently underway towards interoperability. We must be forward thinking and design for such a future. By using the same infrastructure an EHR uses to pull information from a Surescripts® Medication History data source, the EHR would also be able to pull information from the medication manager. In addition, as an EHR is able to send an e-prescription to a pharmacy, it would also be able to send a message to the medication manager. The medication manager would have the capability to consume HL7-NCPDP SCRIPT e-prescriptions, the National Council for Prescription Drug Programs standard for transmission of...
prescription information\textsuperscript{22-27} to update information. In the future, it could also run as a SMART application\textsuperscript{28} utilized as a web-app, mobile device-app or trusted service within an EHR.

**Data federation and reconciliation**

Once verified, medication information would be federated from available sources (Figure 3). Pre-population of data can be accomplished by gathering data from inpatient and outpatient visits via EHR generated Consolidated-Clinical Document Architecture (C-CDA) documents. Pharmacy data can be gathered from Surescripts data. It is possible that at some point in the future, pharmacies would be willing to expose patient fill information onto the HIE as well, providing an additional data source.

Once the data is collected, a matching algorithm would be applied to find overlaps and eliminate duplicates\textsuperscript{29}. Patients would have the ability to verify and change any of the listed medications. In addition, the patient would be able to add other prescribed medications not appearing on any lists (i.e. from providers not participating in the HIE or older, yet still active, medications). Over-the-counter medications, less commonly captured by traditional methods, can be added via bar-code scan, text-matching input or optical character recognition (OCR) software.

Updating the medication list can occur at transitions of care, patient-provider interactions, or at any time by the patient. Primary users of this system will be providers who will rely on it to maintain an accurate list of medications that can be shared and updated by other providers; health-care institutions, who will use it to more easily reconcile medications during points of transition; and patients who will be able to add, delete, modify and verify OTC and prescribed medications. Each time a patient or provider logs in, a query will be performed and if information more recent than the last time of reconciliation is discovered, it will be presented for reconciliation. This way, every time the list is accessed, a pro-active and pre-population approach to reconciliation is taken. Doing so, will increase accuracy and fidelity of the medication list in addition to preventing fatigue from demanding that the list be created from scratch. The combination of these services will make it easier for patients to have a list that reflects the true medications that they are taking.

*Figure 3. List federation and reconciliation*
Encouraging patient engagement; using an interactive interface that provides information

Patients are left to their own devices to maintain a medication list. Either they write out a list (which is often out of date and lacks vital information such as dose and frequency), use a list printed from their PCP office (often containing cross-outs, corrections, omissions and out of date information), bring a bag of pills, or rely on their memory. Such solutions typically don’t provide access to other useful information such as images of medications, indications, drug class, or potential interactions. Apps that focus on adherence typically require that the patient hand enter all medications. These applications are vendor specific, and although it may be able to print or show a list to others, there is not a standardized way to integrate that information across platforms. For the elderly or medically complex patient who may be on multiple prescription and over-the-counter medications, the full medication list may not be captured sheerly due to the initial time investment needed to complete the process.

Using government resources, such as RxNorm, MedlinePlus, and RxImage provided by the National Library of Medicine, a well-designed medication manager can provide services such as brand and generic name, dose, frequency, images of the medications, common indications, convenient links for more detailed drug information, and an interaction checker. The combination of these services will aid in patient-education in addition to recognizing possible unintentional polypharmacy. In addition, the medication manager will provide an opportunity for dialogue regarding differences in the way that medications are prescribed and taken. Discontinued medications can be moved to a separate list keeping track of prior medications (Figure 4).

![Figure 4. Patient view of current medications](image)

**Time and safety benefits**

When a patient presents to the hospital or doctor’s office, providers attempt to fulfill the Joint Commission’s requirement to “maintain and communicate accurate patient medication information”, and thus undertake the process of formulating the best possible medication history. As mentioned, this is time-consuming, and non-scalable job that includes collecting lists from various sources. In addition, errors are common and often result in ADEs. Under the proposed solution, these lists would be instantly and electronically obtained and compared. (Figure 3) The job of formulating an accurate medication list is simplified to resolving discrepancies among the lists.
On admission, a decision regarding whether to stop, continue or modify each medication is made. The proposed system would not be involved with medication management during an inpatient stay. On discharge, the admission list is compared to the inpatient list and the discharge medication list is formulated. As described above, the discharge medication list would be available to the centralized medication manager either via an e-prescription or C-CDA document and accessible by outpatient providers and the patient, decreasing confusion regarding an accurate discharge medication list. Available drug class information and interactions help ensure safer prescribing habits. Additionally, since all providers will be referencing the same list, prescribing errors secondary to ignorance of other medications the patient is on should be decreased.

**Barriers**

No comprehensive solution for solving the problem of the multiple inaccurate outpatient medication lists exits at this time. It is an important problem to tackle, and clearly a difficult one. We acknowledge that the implementation of this framework will require cooperation among several groups, however, we must look towards designing a solution to battle the inefficiency and lack of scalability that is today’s normal. The result of our current system is wasted time reconciling patient lists in addition to the high cost of ADEs. Convincing patients to remain diligent in keeping an up-to-date list is difficult. Physicians are typically slow to adopt new technology and are resistant to tools that ask them to check more boxes. Secure storage and sharing of electronic information is a challenging task. HIEs are local and an organized network to connect them must be considered. Finally, one must demonstrate that cost savings is worth the expenditure of implementation. Each problem deserves attention and must also be considered together when designing a comprehensive solution.

**Medication Harmony**

The triple aim of medication reconciliation is: reasonable time to reconcile, high level of accuracy, and improved patient activation. Instead of each patient and provider struggling to maintain an individual copy of a medication list, the list will be shared among providers and audited by providers and the patient himself. Increased coordination, safety, and education afforded by the centralized list will clearly have the greatest benefit for the patient who verifies and modifies the medication list. However, within the proposed solution, it is important to recognize that active patient involvement is not necessary for maintaining a medication list. Even without active patient involvement, centralization among physicians, hospitals, and pharmacies should be sufficient for obtaining a reasonable proxy to the medication list. In addition, providers can be assured that changes made during a provider-patient interaction will permeate to all other providers. Therefore, instead of each provider having a partial medication list that is often inaccurate, each provider will be able to view the same federated list and can change and prescribe medications more safely. The expectation is that if the task is not overwhelming to the provider, he will be more willing to ensure the accuracy of the list. Finally, a centralized system aids the institutions and individuals attempting to reconcile medications at every transition of care. The process of reconciliation requires significant time and resources. It is a process that is repeated often and at every outpatient visit or transition of care. Tremendous efficiency gains will be realized by implementing the above framework.

**Conclusions**

“You’ve got to be very careful if you don’t know where you are going, because you might not get there.”
- Yogi Berra

Research identifying medication management problems and solutions supporting such a framework has thus far been considered individually. Patients are willing and able to interact with electronic medication tools to manage their health. Medication lists are currently being stored electronically and can be accessed by trusted sources via an HIE. Considerable time and effort is made reconciling the medication list at each transition of care. Inaccuracies in the medication list result in ADEs causing poor patient outcomes and increased cost. We believe that the momentum of the health care system flows towards interoperability, the sharing of data, and the promise of decreased cost. Our lab has started development of this idea into an existing project involving elder care management.

A comprehensive solution involves:
- Providing a pre-populated list with easily accessed and actionable information for patients
- Patients and providers working off the same list
Simplifying and saving time during the process of medication reconciliation  
Encouraging legislation allowing for easier transmission of medical information over trusted networks  
Continued maturity of the FHIR standard and the opening of APIs by EHR vendors  
Financial incentives that continue to emphasize decreasing hospital readmission rates and preventable events

We must utilize the trusted network provided by a HIE and automate the federation of information from multiple sources into a central database. Most importantly, by allowing the patient access to the same list used by providers, patient input into the list will more accurately reflect the daily medications actually taken and allow safer prescribing practices. Imagine a future where patients, doctors, hospitals and pharmacies have easy access to a complete and accurate medication list. We have the potential to drastically reduce adverse drug events both inside and outside the walls of a healthcare setting and should strive to accomplish such goals.

Use of a Patient Portal During Hospital Admissions to Surgical Services

Jamie R. Robinson, M.D., Sharon E. Davis, M.Stat., Robert M. Cronin M.D., M.S., and Gretchen P. Jackson, M.D., Ph.D.
Vanderbilt University Medical Center, Nashville, TN

Abstract

Patient portal research has focused on medical outpatient settings, with little known about portal use during hospitalizations or by surgical patients. We measured portal adoption among patients admitted to surgical services over two years. Surgical services managed 37,025 admissions of 31,310 unique patients. One-fourth of admissions (9,362, 25.3%) involved patients registered for the portal. Registration rates were highest for admissions to laparoscopic/gastrointestinal (55%) and oncology/endocrine (50%) services. Portal use occurred during 1,486 surgical admissions, 4% of all and 16% of those registered at admission. Inpatient portal use was associated with patients who were white, male, and had longer lengths of stay ($p < 0.01$). Viewing health record data and secure messaging were the most commonly used functions, accessed in 4,836 (72.9%) and 1,626 (24.5%) user sessions. Without specific encouragement, hospitalized surgical patients are using our patient portal. The surgical inpatient setting may provide opportunities for patient engagement using patient portals.

Introduction

Patient portals are web-based applications that enable patients to view portions of their electronic health record (EHR) and interact with their healthcare providers. The United States government defines a patient portal as “a secure online website that gives patients convenient 24-hour access to personal health information from anywhere with an Internet connection.” The data within a portal is typically managed by a healthcare institution and allows patients to have access to personal health information, including recent doctor visits, discharge summaries, medications, immunizations, allergies, and laboratory results. More advanced portals enable patients to schedule appointments, message their providers, and sometimes maintain personal health records. Increasingly, health care systems offer portals to their patients, and consumers adopt them quickly. Hospitals are motivated to provide patient portals by financial incentives created by the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 and Meaningful Use criteria. Consumers are also demanding such technology and transparency from their health care providers.

The majority of research about patient portals has been performed in the primary care or medical specialty settings with a paucity of research focusing on acute care specialties, such as surgery, or acute care settings, such as the hospital. Two recent systematic reviews of over 100 studies on the effectiveness of patient portals revealed only three studies exploring portal use outside of primary care or medical specialties. Our prior research demonstrated that after broad deployment of a patient portal across clinical specialties, surgeons were the second most frequent specialty to use patient-provider messaging. Further, messaging adoption by surgical patients and providers grew rapidly across surgical subspecialties. As healthcare organizations increasingly deploy patient portals across clinical specialties to meet Meaningful Use objectives, we anticipate the use of patient portals by the understudied acute care population to continue to grow.

Many trials investigating patient portals involve outpatient management of chronic diseases, but very little is known regarding patient use of patient portals while in the hospital for an acute illness or after surgery. Masterson et al have described their development of a personalized inpatient portal to improve patient engagement while in the hospital, but results are not yet reported. Very small studies have assessed the efficacy of providing patients with tablet computers for specific encouragement of portal use during inpatient stay, showing patients utilized and appreciated the ability to view their health information. At Brigham and Women’s Hospital, a web-based patient-centered tool kit offering many common patient portal functions was implemented and evaluated in the medical intensive care unit and oncology unit settings. Studies of this system have shown encouraging trends for the adoption and sustained usage of such technologies in the acute care setting. Although the functions commonly offered by patient portals meet important needs of hospitalized patients, there has been a reluctance to encourage portal usage by hospitalized patients. Many patient portals have policies that would discourage inpatient usage, such
as specific delays for availability of test results or several business day expectations for answering of secure messages. Nonetheless, healthcare consumers often find innovative ways to use health information technologies. To address existing gaps in the literature about the use of patient portals by surgical patients in acute care settings, we sought to characterize the adoption and use of a patient portal by patients admitted to surgical services at a large academic medical center.

Methods

Study Setting
This study was conducted at Vanderbilt University Medical Center (VUMC), a private, non-profit, academic institution in Nashville, Tennessee, which provides primary and regional referral care to adults and children. VUMC encompasses Vanderbilt University Hospital (VUH) and Vanderbilt Children’s Hospital (VCH), with over 900 inpatient beds and 50,000 inpatient admissions per year.

Patient Portal
VUMC launched the My Health At Vanderbilt (MHAV) patient portal in 2005, with implementation across the clinical enterprise completed in 2007. After initial implementation, a physician champion introduced MHAV to providers, and technical support staff was available to patients, physicians, and staff as the portal was introduced in individual clinical units. MHAV was promoted to patients through flyers posted in outpatient clinics. This process was repeated, beginning in adult primary care, and then extending to adult and pediatric specialties. Programs did not promote MHAV use in the inpatient setting until 2014, when a link to the MHAV was made available through interactive television in the hospital rooms of VUH.

All patients who receive medical care at VUMC may register for access to MHAV. MHAV users may authorize another individual, termed a delegate, to access their MHAV account on their behalf. Our policies for MHAV accounts for pediatric patients are similar to those developed for other major children’s hospitals. For patients under 13 years of age, parents or guardians (called surrogates) may access MHAV account on behalf of their child. Adolescents 13 years of age and older may have their own, parent-controlled MHAV accounts. MHAV provides access to selected portions of the medical record, appointment scheduling, account and bill management, targeted health education materials, and secure messaging with healthcare providers. MHAV is now a well-established patient portal, with over 327,000 registered users and over 300,000 logins per month by 50,000 unique users. MHAV is directly linked to the VUMC EHR, StarPanel, and thus, content is continually updated. MHAV allows access to selected health information from the EHR, including clinical visit summaries, laboratory results, and medication lists. Some information is immediately available and other sensitive content is only viewable after short delays to allow for physician review and management. MHAV messages are managed by clinical groups based on provider preferences. Some providers directly answer all patient-initiated messages, and others have messages triaged by administrative and clinical staff members, any of whom may respond. Tailored educational materials are available within MHAV based on patient problems and medication lists. Specific policies and procedures developed to enhance patient and provider adoption are published elsewhere.

Study Population
We examined all admissions to surgical services at VUMC and all use of the MHAV patient portal by patients admitted by a surgical service or their delegates or surrogates between January 1, 2012 and December 31, 2013. This time period was chosen after a rise in anecdotal reporting of inpatient MHAV usage and prior to the promotion of portal registration and usage through interactive television in the hospital. We sought to examine inpatient portal access in the absence of specific programs to promote such usage.

Measures
For each admission during the study period, we recorded patient age, sex, and race, as well as admitting service, International Classification of Disease (ICD-9) admission diagnosis code, and length of stay. We categorized admitting services using 21 surgical specialties reflecting the departmental organization at VUMC: cardiac, thoracic, otolaryngology, emergency general, general, gastrointestinal/laparoscopic, liver transplant, neurosurgery, oncology/endocrinology, oral/maxillofacial, orthopedic, pediatric, pediatric trauma, pediatric urology, plastic, renal transplant, spinal, trauma, burn, urology, and vascular. MHAV users include VUMC patients who have registered for MHAV, delegates, and surrogates. For each admission, we considered the patient registered with MHAV if they had a portal account by the time of discharge. MHAV use during a hospital admission was defined as any MHAV
activity through the admitted patient’s or any affiliated delegate/surrogate accounts occurring between the date/time of admission and the date/time of discharge. We determined the total number of inpatient MHAV user sessions across user types. For each session, we classified the type of portal function utilized as account management, appointments, education materials, laboratory test results, messaging, or other.

Analysis
We calculated the total number of inpatient admissions to each surgical service, as well as the number of these surgical patients who were registered for MHAV either before or during their admission. We also calculated the number of these patients who specifically registered for MHAV during inpatient stay. We constructed descriptive distributions and summary statistics of MHAV registration and use status across patient demographics and admission characteristics. Continuous variables were summarized with medians and inter-quartile ranges. Categorical variables were summarized as counts and frequencies. We modeled inpatient use among admissions of registered patients using a logistic model controlling for month of admission, race, sex, age at admission, length of stay, and admitting service. Standard errors were adjusted to account for correlation among multiple admissions for the same patient. All analyses were conducted in R version 3.0.1.

Results
During the study period, VUMC surgical services managed 37,025 admissions of 31,310 unique patients. Demographics of the unique patients admitted to a surgical service listed in Table 1.

Table 1. Demographic and clinical characteristics of unique patients admitted to a surgical service at VUMC 2012-2013. Counts and percentages or median and IQR.

**MHAV Registration Status**

Of the 37,025 admissions during the study period, 9,362 (25.3%) involved patients registered for MHAV and 7,549 (24.1%) unique patients were registered for MHAV during at least one admission in the study period. In 194 admissions, the patient registered for MHAV during an inpatient stay rather than enrolling in MHAV prior to the admission. The MHAV registration rate was higher at VUH than VCH, with 27.0% of unique patients admitted to VUH having a portal account compared to 8.8% among unique patients admitted to VCH.

Table 2 presents the demographics for all patients admitted to a surgical service compared to those registered for MHAV. Patients registered for MHAV differed from the entire patient cohort on each demographic characteristic, both overall and within each hospital ($p < 0.01$) with the exception of sex among patients admitted to VCH ($p = 0.29$). White and Asian/Pacific Islander patients were more likely to have a MHAV account than were Black, Native American/Alaskan, and other/unreported race patients. Overall, patients in their 50s and 60s were most likely to be registered for MHAV. Among patients admitted to VUH, female patients were more likely to be registered for MHAV compared to male patients (33.3% vs. 22.3%, respectively).

The number and proportion of patients registered for MHAV by surgical admitting service are presented in Table 3. At the adult hospital, VUH, 8,851 of 31,448 (28.1%) admissions to surgical services involved patients registered for MHAV compared to 511 of 5,577 surgical admissions (9.2%) at VCH. The surgical services with the highest rate of MHAV registration were adult gastrointestinal/laparoscopic (54.5%) and adult oncology/endocrinology (49.6%). The surgical
services with the lowest rates of MHAV registration were pediatric trauma (1.2%) and burn (1.8%).

Inpatient Use of MHAV

Portal usage occurred during 1,486 surgical admissions (4% of all admissions and 16% of registered user admissions) involving 1,270 unique patients. 6,634 portal user sessions occurred during surgical inpatient admissions. For admissions during which MHAV was accessed, the median number of MHAV sessions was 2 (IQR 1-4); however, during some admissions, patients accessed MHAV more than 20 times, with a few users accessing MHAV over 80 times during admission. Normalizing by length of stay, the median number of MHAV sessions per inpatient day was 2.0 (IQR 1.0-3.1) among admissions with MHAV use.

In unadjusted tests among admissions involving MHAV registered patients, admissions with inpatient portal use differed from those without portal use in terms of length of stay, race, sex, and admitting service (p < 0.01), but did not differ on patient age. These findings were observed overall and within VUH admissions only. Among admissions to VCH, admissions with portal use were longer than admissions without use (median LOS 5 vs. 3 days; p < 0.01).

Adjusting for patient demographics and admission characteristics, white race, male sex, increased length of hospital stay, and admitting service were associated with inpatient portal use (p < 0.01). Figure 1 demonstrates the odds ratios (OR) for inpatient portal use based on demographics and admission service. Black patients were significantly less likely than white patients to use the portal or have MHAV accessed on their behalf during hospitalization (OR 0.53, 95% CI 0.39-0.71). Male patients were more likely to use the portal or have MHAV accessed on their behalf during hospitalization than female patients (OR 1.33, 95% CI 1.17-1.52). Compared to general surgery admissions, admissions to the liver transplant service were at 76% higher odds of portal use (OR 1.76, 95% CI 1.19-2.62). Admissions to the liver transplant service were also more likely to use the portal than those to neurological, plastic,
gastrointestinal/laparoscopic, otolaryngology, and orthopedic surgery services. Otolaryngology (OR 0.69, 95% CI 0.48-0.98), gastrointestinal/laparoscopic (OR 0.57, 95% CI 0.41-0.80), and orthopedic surgery (OR 0.73, 95% CI 0.56-0.94) admissions showed a decreased likelihood of portal use compared to general surgery admissions.

Among admissions with inpatient use of MHAV, the portal was accessed through the patient’s account in 92.7% of admissions, through a delegate account in 2.6% of admissions, and through a surrogate account in 5.5% of admissions (see Table 4). Although patients utilized a variety of portal functions, viewing health record data (i.e. laboratory results, medication lists, or clinical documents) and secure patient-provider messaging were the most common, accessed in 4,836 (72.9%) and 1,626 (24.5%) of total inpatient user sessions, respectively (see Table 4).

Tables 5 and 6 describe the most prevalent ICD-9 diagnosis codes for all admissions and admissions with inpatient use of the patient portal to VUH (adults) and VCH (pediatrics), respectively. The three most frequent diagnoses among adult patients who utilized the portal while hospitalized were postoperative infection, morbid obesity, and intestinal obstruction. In contrast, the 3 most frequent diagnoses among pediatric patients who used the portal while inpatient were scoliosis and kyphoscoliosis, esophageal reflux, and hypertrophy of tonsils with adenoids.
was liver transplantation, potentially due to frequent laboratory monitoring and clinical complexity of patients.

Discussion

This study documents modest and somewhat unexpected usage of a patient portal by hospitalized surgical patients; it is one of the first studies to report inpatient portal adoption outside of a specific program or technology designed for the hospital setting. Without promotion for use in the inpatient setting, 4% of all admitted surgical patients and 16% of patients registered for the portal utilized the portal while in the hospital. With a known lack of research about technologies to engage patients in the inpatient setting, this study suggests that existing technologies such as patient portals may have a role in meeting the needs of hospitalized patients and their families.

Our study showed that patient portals were more likely to be used during hospitalization for patients who were white, male, and had extended lengths of stay. Outpatient studies of patient portals have shown similar disparities with decreased use by minorities, especially African Americans. In contrast to our findings, prior studies suggest that portal use is fairly similar between women and men, with most studies demonstrating slightly higher registration rates and usage by women. Of note, we cannot determine from usage logs whether the portal was actually used personally by the patient, or rather another individual using the patient’s login information.

In our study, the services with the most registered portal users included those with significant pre-operative relationships, including gastrointestinal and laparoscopic (including a large majority of bariatric surgery patients) and oncology and endocrine surgery. ICD-9 diagnosis codes for adults registered for the portal aligned with the service designations, with the most common diagnoses being prostate cancer and morbid obesity. Interestingly, the most frequent ICD-9 code of adult patients using the portal while inpatient was post-operative infection, suggesting patients with a complication may be more likely to utilize the portal to view personal health information and contact providers. The only service that showed portal usage increased over that of general surgery in hospitalized patients was liver transplantation, potentially due to frequent laboratory monitoring and clinical complexity of patients.
Prior research has shown encouraging adoption of similar technologies during hospitalization, but usually in the context of a specific research program in which registration was encouraged and usage was supported by training. Wilcox and colleagues piloted a customized inpatient personal health record in cardiothoracic surgery patients and found medication tracking tools to be an effective means to increase inpatient engagement. Burke reported enthusiastic adoption of a web-based multimedia EHR for patients with congenital cardiac disease and their parents with a 93% adoption rate and 67% of use occurring during hospitalization. Notably, this study was conducted in families with children undergoing surgical repair of congenital cardiac abnormalities, who likely have long-standing relationships with their surgeons. O’Leary and colleagues showed that patient use of a portal designed specifically with inpatient information including team members, medication lists, and daily agendas on tablet computers within a general medical service unit could improve the ability of patients to identify physicians and roles by over 25%. In contrast to prior work focused on technologies developed for inpatient setting, our study demonstrated substantial use of a patient portal designed for the outpatient setting, by patients who were hospitalized and their caregivers, without specific encouragement or training, and in the presence of policies that might discourage inpatient use.

There are many potential benefits to using a patient portal during inpatient admissions. First and foremost, even minor surgeries are considered major life events for most patients and families, and they offer “teachable moments” when otherwise unengaged individuals might consider making important healthcare changes. Introducing patient portals during hospitalizations may provide tools for patients and families to learn about health problems and engage in their care. Furthermore, hospital team members, including physicians, residents, and nursing staff are highly dynamic, and many hospitalized patients are unable to identify their physicians. Hospitalized patients frequently have multiple active conditions, tests, and procedures, with acute illness and its associated stress making it difficult for patients and families to retain information provided on daily rounds or at discharge. Others have shown that patients and caregivers desire access to the daily plan of care and team member roles, often not present in patient portals. Patient portals can allow patients to review their health data, schedule and view post-operative appointments, and communicate with providers. In the inpatient setting, hospital staff can provide training and support to assist patients and their families with registration and navigation of portal functions, giving them the knowledge and experience needed to promote ongoing engagement. Use and familiarity with the portal prior to discharge may increase the portal usage on an outpatient basis. For example, patients may feel more comfortable communicating problems or concerns post-operatively through secure messaging after using it as an inpatient.

Such changes could have a significant impact on surgical workflow. Some patients who undergo certain operations may not require a face-to-face follow up, and provider-patient messaging could be utilized to ensure the patient is recovering as expected post-operatively. A pilot study at our institution has shown that over three-fourths of patients undergoing elective general surgery procedures were satisfied with online follow up, and post-operative complications were not missed by online visits. Portal follow-up can potentially prevent patients from travelling long distances or missing work or school for unnecessary face-to-face clinic visits. This approach also benefits providers as follow-up appointments are typically included within the global payment period.

This study has important limitations. The design is retrospective, and the research was done at single large academic medical center with a locally-developed patient portal. The findings may not apply to other clinical settings or portal implementations, and therefore may not be generalizable to all hospitals. However, our portal functions and many of the MHAV procedures and policies are similar to those reported by others. One main difference is that MHAV was broadly deployed across clinical specialties soon after implementation, and our findings represent those of an established portal in use across the clinical enterprise for over 5 years. We have not assessed factors that may contribute to adoption and usage of the portal, such as encouragement by specific providers or teams. Further, we do not know the platform on which the portal was used by patients, the clinical context in which the portal was accessed, or other measures of usability or satisfaction, which would further inform the interpretation of our usage data. These questions are the subject of our ongoing research projects.

**Conclusions**

This study demonstrates modest use of a patient portal by hospitalized surgical patients without specific encouragement. Disparities in portal adoption among minority patients may occur in the inpatient setting. Although designed for the outpatient setting, patient portals may have a role in meeting consumer health information needs and engaging surgical patients both during and after hospitalizations. The perioperative period may offer a uniquely teachable time in which to engage patients and families in their care, and using a portal during hospitalization could...
support online postoperative follow up, which can benefit both patients and providers. Additional research is needed to determine the best ways to leverage patient portals during inpatient admissions to improve care.

Abstract:

With online social platforms gaining popularity as venues of behavior change, it is important to understand the ways in which these platforms facilitate peer interactions. In this paper, we characterize temporal trends in user communication through mapping of theoretically-linked semantic content. We used qualitative coding and automated text analysis to assign theoretical techniques to peer interactions in an online community for smoking cessation, subsequently facilitating temporal visualization of the observed techniques. Results indicate manifestation of several behavior change techniques such as ‘feedback and monitoring’ and ‘rewards’. Automated methods yielded reasonable results (F-measure=0.77). Temporal trends among relapers revealed reduction in communication after a relapse event. This social withdrawal may be attributed to failure guilt after the relapse. Results indicate significant change in thematic categories such as ‘social support’, ‘natural consequences’, and ‘comparison of outcomes’ pre and post relapse. Implications for development of behavioral support technologies that promote long-term abstinence are discussed.

Introduction and Background:

According to CDC statistics of 2015, chronic diseases – such as hypertension, stroke, cancer and diabetes, are responsible for 7 of 10 deaths every year in the United States and treating people with chronic diseases accounts for 86% of all healthcare costs [1]. These chronic conditions are often caused by health-related behaviors such as tobacco smoking, which is “the leading cause of preventable disease and death in the United States, resulting in approximately 480,000 premature deaths and more than $300 billion in direct health care expenditures and productivity losses each year” [2]. Health promotion campaigns emphasize the need to create behavior change avenues through theoretically designed interventions to help people modify this risky health behavior and stay abstinent. Current trends show that online social communities are gaining popularity as behavior modification venues as users of these platforms reach out to their peers and experts for support and guidance irrespective of geographical and demographic boundaries [3]. End-users of these virtual support groups (patients or population at large) have expressed that they trust and rely on the information in social media, and even base their decisions on this information [4]. In addition, using social media peer interactions for behavior analysis has great potential because (a) unlike conventional survey-based or controlled laboratory studies, content on social media is spontaneous and unprompted [3], and (b) electronically captured communication is amenable to large scale text analysis thereby scaling up traditional socio-behavioral analytical methods to social media platforms in the digital era.

Previous research in this field has focused on analysis of the structural characteristics of the online communities [5], development of theory-guided interventions [6], and validation of social support in online communities for behavior change and chronic illness management [7]. Recent studies on social media analysis for smoking cessation have suggested new methodological advances for enhancing user engagement through content-mediated network modeling of peer interactions [8, 9]. Methods of distributional semantics, which learn the relatedness between terms from large electronic text collections, have been used in conjunction with social influence models to characterize content-specific communication patterns underlying behavior change in smoking cessation [10]. Such automated text analysis methods have been used for large scale analysis of content on social networking sites [11-13]. Latent Semantic Analysis (LSA) [14] has been used in conjunction with machine learning techniques to annotate large amount of health information on social media [15-17]. However, computational overhead may pose a problem while using LSA. More scalable distributional semantic methods such as Reflective Random Indexing (RRI) [18] can also learn semantic relatedness from text corpora, including meaningful relations between terms that do not occur together. Semantic space models have been developed to represent text characterizing a specific user’s temporal transitions in online communities [19-21]. Further development of automated methods that enable understanding of individual and network level trends may
provide insight into social influence mechanisms in the context of sustained behavior change. Once analyzed, messages exchanged between users provide a semantic context for their health-related behavior. We posit that the relationship between this semantic context, behavior change events, and user engagement levels can be understood by modeling user communication over time.

Advances in text analytics can enable us to characterize temporal trends in semantic context underlying peer interactions [21-23]. While the overarching goals of our work are to develop informatics-driven methods to develop resource optimized analytics that account for granularity and scalability, and inform the design of consumer-facing digital health platforms for sustained user engagement and long term behavior change, the specific methodological objectives of this paper are three-fold: (a) to employ a behavior change taxonomy for annotation of peer interactions in QuitNet, an online community for smoking cessation, (b) to utilize automated text analysis to scale the results of qualitative analysis to a large dataset, and (c) to visualize peer interactions in QuitNet and characterize user semantics over time, and across smoking and abstinence behaviors.

Materials and Methods:

QuitNet is one of the first online social networks for health behavior change and has been in continuous existence for the past 16 years [24]. Forum interactions were the primary mode of communication and each forum message has a message id, a thread id (the thread in which the message was exchanged), a sender id and recipient id. For the purpose of this study, we considered two subsets of QuitNet data: 16,492 forum messages exchanged between March-April 2007 (we refer to this as “Dataset 1” from now on) and 65,910 forum messages exchanged from January -December 2014 (we refer to this as “Dataset 2” from now on). Overall, there are 82,402 messages and 2,354 unique users who have exchanged messages during these two time periods. The research reported in this manuscript has been reviewed and exempted by the Institutional Review Board at the University of Texas Health Science Center at Houston.

![Figure 1. Methodological outline: Qualitative-Automated-Temporal Analysis](image)

Figure 1. Methodological outline: Qualitative-Automated-Temporal Analysis

Qualitative coding, automated text analysis, and temporal visualization were integrated to conduct the study described in this paper. Figure1 represents the overall methodological details of the study. The first step in this study was the qualitative analysis, guided by an established behavior change taxonomy [25]. 1000 randomly selected messages from the QuitNet Dataset 1 were manually coded into 16 themes to characterize 93 theory-linked behavior change techniques outlined in the taxonomy. In order to validate the generalizability of thematic categorization, scalability of automated methods, and observed semantic shifts before and after relapse in temporal models, we extended our analysis to Dataset 2. The qualitative codes assigned to the subset of 1000 messages in Dataset 1 were then used to annotate the rest of messages in Dataset 1 and entire Dataset 2 using methods from distributional semantics as described in the next section. We then utilized temporal modeling to visualize changes in semantic context over these two time periods (2007 and 2014). On account of its clinical importance, temporal modeling was focused on relapse behavior (self-reported change from ex-smoker to active smoker) during the study period.
**Qualitative methods:**
We selected 1000 messages randomly from the Dataset 1 using a random number generator. Each of these messages was coded into thematic categories by two coders independently to ensure objectivity in the coding process. The themes to which each of the messages was assigned were obtained from the taxonomy of behavior change techniques, which was developed by a large panel of behavior change experts [25]. This taxonomy has 16 thematic categories drawn together from multiple behavior change theories [26] such as Social Change Theory, Social Cognitive Theory, the Health Belief Model, and the Integrative Model of Factors Influencing Smoking. As suggested by Michie at al., the messages were coded to appropriate themes that were explicitly linked to the target behavior (in our case smoking) and target population (QuitNet users). As evident from the sample messages and thematic definitions, a single message may be assigned to multiple taxonomy themes. The definition of each theme and the subcategories of each theme can be found in [25].

**Automated Analysis:**
Methods from distributional semantics in conjunction with a machine learning classifier were used as part of this approach. Incorporation of background semantic information facilitates derivation of meaningful interpretations of QuitNet vector representations, on account of their short and terse textual features [10, 27, 28]. To this end, we used the distributional information from the Touchstone Applied Science Associated (TASA) corpus [29] to provide sufficient semantic context. The TASA is a collection of 44,700 articles that contain 10 million words of unmarked high-school level English text on arts, health, home economics, industrial arts, science, social studies and business. We applied RRI, a variant of Random Indexing which was developed to recognize meaningful relationships between terms without requiring they co-occur directly. This method was applied using Semantic Vectors, an open source package for applying distributional semantics [30]. A stopword list was used in this process [31]. This list contains words that are frequently used in texts but offer little semantic context. We used a dimensionality of 500, with minimum term frequency of 10, maximum term frequency of 15000 and a ‘logentropy’ termweight. We applied RRI to the TASA corpus to obtain *TASA term vectors* - representation of terms in the TASA Corpus. We generated *TASA based QuitNet message vectors* by generating vector representations for each QuitNet message as the sum of the TASA term vectors of the terms it contains, with subsequent normalization. Similarly, we obtained *QuitNet term vectors* by adding the QuitNet message vectors for each term occurring in QuitNet. This step leads to meaningful vector representations for terms that occur in QuitNet, but not in TASA, such as neologisms developed by the community. Finally, we derived a second message vector for each QuitNet message by adding the QuitNet term vectors for the terms it contains, and normalizing the resultant vector to generate *QuitNet message vectors*. This procedure is illustrated in Figure 2.

![Figure 2: Vector generation sequence](image)

From the QuitNet message vectors thus obtained, essential features were selected and extracted for machine learning techniques using the open source Weka package [32]. Each of these vector’s 500 features was considered as individual attributes for the machine learning classification. Each of the themes was considered as a target for classification. Multi label classification was achieved by constructing individual binary classifiers for each theme. The classifier we used for this purpose was the J48 tree which is an improved version of the C4.5 tree [33, 34]. The classifier was trained using ten-fold cross-validation on the QuitNet message vectors representing the training set (manually coded 1000 messages). The trained J48 model was then used to classify QuitNet message vector representations of the entire sets.
of messages Datasets 1 and 2. A random sample of 100 of these messages was used to test for reliability and accuracy of the machine coded messages. These messages were then coded manually by two independent coders and compared with the machine coding results to assess reliability measures. The inter-rater reliability for the machine versus the manual coding was calculated using Cohen’s Kappa measure.

Temporal Modeling:
The communication pattern underlying peer interactions was modeled as a function of time by analyzing the proportion of messages that were categorized as belonging to each thematic category of the BCT taxonomy. The annotated messages from the automated analysis were used for this purpose. A specific category of QuitNet users, ‘relapsers’ (status change from ex-smoker to active smoker as self-reported by the users during study period) was considered for detailed temporal analysis, to characterize the frequency and thematic attributes of communication before and after relapse. The period of time modeled was the period of study (Mar-Apr 2007 & Jan-Dec 2014), i.e, the relapse was used an event marker and the entire set of messages exchanged by a given user before and after their relapse event in the study time period was taken into consideration.

Results and Discussion:
Over 72% users who exchanged messages during the study period were female, and the average age of the users at the time of registration was 45.

Qualitative analysis:
From the manual coding of the 1000 messages, the results indicated that ‘feedback and monitoring’ was the most commonly found theme. The second and third most frequently communicated themes were ‘natural consequences’ and ‘social support’ respectively. The Cohen’s kappa measure between the two coders for the 1000 messages was 0.74. Most differences were related to coding of a single message into multiple themes and were all resolved by discussions. Messages which had users taking “pledges” to not smoke on that day were classified into ‘goals and planning’. Messages where users mention how much time and money they have saved by quitting were classified into the categories ‘feedback and monitoring’ and ‘comparison of outcomes’. QuitNet users also have traditions like “bonfire” where each user virtually throws unused cigarettes into the fire. They spell out the number of cigarettes they are throwing into the fire, thereby, monitoring their own progress. Table 1 shows sample messages for each thematic category. Since communication on social media is unprompted and uninhibited, QuitNet users discuss several extraneous aspects that are not specifically related to smoking. These messages were classified as ‘miscellaneous’ and not considered for further analysis since the taxonomy specifically focuses on target behavior, which in our case is smoking. However, it is important to note that these miscellaneous communications can aid in formation of social bonds, trust, and peer respect which are vital to long-term sustenance of user engagement in these online platforms. In addition, we observed that certain themes did not have ample representation. For instance, the theme ‘associations’, ‘regulation’ and ‘antecedents’ had only four samples out of the 1000 messages. In summary, the mapping of messages to the taxonomy of theoretically-linked behavior change techniques helped us understand if and how such techniques manifest in online platforms that promote health behavior changes. Describing the current landscape of behavioral techniques that manifest spontaneously in peer interactions could help us design better technology platforms that facilitate user interactions resembling other behavior change techniques, to enable users stay quit. For example, content recommendations to QuitNet users providing advice to peers about novel stress management strategies, would integrate ‘shaping knowledge’ techniques from the taxonomy of behavior change.

Automated Analysis:
The F-measures, precision and recall metrics for the cross validation of the machine learning technique J48 tree were 0.77, 0.79 and 0.77 respectively. The F-measures were calculated as an average of the individual binary classifiers using RRI vectors as attributes for the machine learning algorithm. The reliability measure between rater 1 and the automated classification system is 0.71, rater 2 and the system is 0.736. Therefore, the average system-rater agreement 0.72 approached inter-rater agreement of 0.74. A detailed characterization of thematic distribution over the years 2007 and 2014 as obtained using the automated classification system is shown in Figure 3. Although the users under consideration in these two time periods may not be the same, focusing on proportions of messages across themes over two different timelines gave us an overview of temporal patterns underlying thematic content of QuitNet user interactions.

\[
\text{Percentage of messages in a specific theme in a given year} = \frac{\text{(Number of messages in that theme in that year)}}{\text{Total number of messages in that given year}} \times 100

</tbody>
</table>

The themes ‘feedback and monitoring’ and ‘comparison of outcomes’ were the most commonly used themes among QuitNet users in the years 2007 and 2014. The theme ‘comparison of outcomes’ has increased in proportion by 22% from 2007 to 2014. This could be attributed to the traditions within QuitNet community such as virtual bonfires where users account for unsmoked cigarettes and discuss consequent benefits with respect to quality of life. The increase in proportion of messages in this theme indicates that the users were aware of the outcomes of the behavior change (both positive and negative), which in turn could have motivated them to remain abstinent. The other theme which has increased in proportions of messages are the ‘reward and threat’, where the increase is 15%. Over the years, QuitNet
users began each of their messages by congratulating the recipient for their quit, which seems to be another new tradition, thus increasing content in this theme. The theme with most dip in percentage of messages were ‘comparison of behavior’ by 9.31%. Although the traditions on QuitNet were the same between the two years, huge reduction in the proportion indicates that number of users participating in the traditions may have reduced. The messages contributing to this theme are those in which users symbolically give their hand to others as a form of support and pledge not to smoke for the day. The messages in the themes ‘feedback and monitoring’, ‘natural consequences’ and ‘goals and planning’ have decreased by around 1%. Messages in which users account for unsmoked cigarettes and discuss the subsequent benefits in terms of quality of life were classified under “self-monitoring”. The proportions of messages in the theme ‘social support’ has reduced by 7.72%. The proportion of messages in this theme was low overall in comparison to other themes across both years. This is not consistent with the results of the previous work done [10] and can be construed as a coding artifact of using the behavior change taxonomy.

Figure 3. Distribution of messages across each theme after automated analysis over the years 2007 and 2014

Overall, this method has enabled visualization of the change in QuitNet users’ communication across time. In summary, machine-learning techniques (to assign categories) in conjunction with distributional models (to provide additional semantic information not available in the content of short social media messages) have facilitated the extension of manually-coded thematic mapping to a large dataset with reasonable accuracy and reliability measures. This task would otherwise be prohibitively labor and resource intensive. Applying distributional semantic techniques such as RRI, to the content on social media has revealed implicit relationships between the messages without dramatically increasing computational overhead.

Temporal Modeling:
For the purpose of temporal modeling across active smoking and abstinence behavioral states, we chose to focus on QuitNet users who relapsed during the study period. Figure 4 portrays the change in percentage of messages before and after relapse.

For a specific theme:

\[
\text{Percentage of messages before relapse} = \left( \frac{\text{Number of messages before relapse in a specific theme in a given year}}{\text{Total number of messages in the theme in that year}} \right) \times 100
\]

\[
\text{Percentage of messages after relapse} = \left( \frac{\text{Number of messages after relapse in a specific theme in a given year}}{\text{Total number of messages in the theme in that year}} \right) \times 100
\]

The percentage difference between message frequency before and after relapse across all themes in the year 2007 was 80%, indicating an overall drop in frequency of communication. This pattern can also be seen in 2014 with a drop of 60% in proportion of messages before relapse and after relapse across all themes. The drop in percentage of messages before and after relapse in the year 2007 was 75% in the categories ‘goals and planning’ and ‘feedback and monitoring’, 66.6% for ‘Social Support’, ‘comparison of behavior’ and ‘comparison of outcomes’, 38.5% for ‘natural consequences’, 71% for ‘miscellaneous’ and 100% for ‘reward and threat’ and ‘self-belief’. The pattern of communication among relapers in the year 2014 was similar to the year 2007. The difference in proportion of
messages before and after relapse in the year 2014 is 70% in the category ‘goals and planning’, 80% in ‘feedback and monitoring’, 70% in ‘social support’, 60% for the categories ‘comparison of behavior’ and ‘comparison of outcomes’, 50% for the theme ‘natural consequences’, 95% for ‘miscellaneous’, 75% in ‘rewards and threat’. Most frequently found themes embedded in communication of relapsing QuitNet users in 2007 belonged to the category ‘feedback and monitoring’ both before and after the relapse event. The theme that had the most significant reduction in number of messages before and after relapse, in the year 2007, was ‘rewards and threat’. Most QuitNet messages which fell under this category are congratulatory in nature for the efforts of the users. Thus, it is coherent that number of messages in this thematic category have reduced. In 2014, the categories most prominent in users’ messages before the event of their relapse, were ‘feedback and monitoring’ and messages that were in the ‘miscellaneous’ category (no relation to smoking cessation in particular). Whereas, the theme that had a huge fall in message count after relapse event in 2014, was ‘miscellaneous’ category. The messages in ‘miscellaneous’ category in QuitNet were related to postings on addictions other than smoking and everyday generic experiences of one’s daily life. Examples of such messages were “my hd has gone out to get a dog”, “Quit drinking without AA! From XXX on 4/9/2014 2:00:48 PM”.

Figure 4. Pattern of communication of relapsing users before and after the event of their relapse

Both in 2007 and 2014, the message count in the thematic category ‘self-belief’ have remained low in comparison to count in other themes, before and after relapse. In 2014, specifically, message count in this theme had remained at 0% before and after relapse. Existing literature of behavior change suggest that users displayed lower self-belief when they were closer to a relapse episode and lower self-belief has been found to be an indicator for relapse [35]. It can also be seen that the number of messages in the category ‘social support’ have also reduced in both years, before and after relapse. The reduction in ‘social support’-related messages after relapse may be attributed to the messages coded under other themes due to explicit discussions of ideas related to quit rebound and coping with failure. Although these messages offered moral support implicitly, they were categorized to ‘shaping knowledge’ and/or ‘natural consequences’ according to the taxonomy of behavior change theories. The overall drop in frequency of communication across both years, has indicated that users tend to communicate less after their relapse. Conversely, when a user quiets down it could indicate that they may relapse. Literature suggests that after relapse, users tend to be affected by guilt and shame, consequently tend to become reclusive [36], which can be observed from the pattern of communication of users over time. Again, the attitude of guilt and shame among relapsers after a relapse event is re-affirmed by the significant drop in messages in the ‘feedback and monitoring’ category. The users may not want others to revisit the event of their relapse unless they cope with their failure. The reduction in message count in the category ‘comparison of behavior’ may also be attributable to the shame that relapers experience after quitting. Overall low presence of the theme ‘goals and planning’ after a relapse event could suggest that the relapers may not be ready to set immediate quit goals [37].

When the post-relapse activity of users was represented as a percentage of the pre-relapse activity, the results revealed interesting insights into specific theoretical techniques embedded in the messages exchanged by the relapers before
and after relapse. In the year 2007, techniques such as ‘goals and planning’ and ‘feedback and monitoring’ were retained in 14.3% messages exchanged post-relapse as compared to pre-relapse. The retention observed was highest in the themes ‘natural consequences’ at 44.4%, followed by ‘comparison of behavior’, ‘comparison of outcomes’ and ‘social support’ at 20%. Themes such as ‘reward and threat’ and ‘self-belief’ had the lowest retention in messages post-relapse. In the year 2014, themes that were retained in the messages post relapse were highest in ‘natural consequences’ at 33.3%, followed by ‘comparison of behavior’ and ‘comparison of outcomes’ at 25%. The messages in ‘Miscellaneous’ category were retained in 2.7% of the messages and was the lowest post-relapse retention in the year 2014.

In summary, understanding semantics and behavior change techniques before and after relapse has provided us with insights into the specific content that users might be interested in and can benefit from, at points in time corresponding to changes in behavioral states within a smoking cessation episode. Such information is essential to design targeted user-content and interactions to enhance the efficacy of existing health promotion platforms such as QuitNet. The information on the users’ low self-efficacy and their attitude towards recovery is evident from analyzing the semantic content. The reduced communication indicating guilt and shame has been observed from the reduced frequency of interaction and also from the semantic content attributes.

**Limitations and Future Work:**

The BCT taxonomy used in this study specifically targets the identification of theoretically driven techniques that target a particular health behavior, in our case abstinence from smoking. However, applying the BCT taxonomy to analyze user-generated content and peer interactions in QuitNet like online platforms may result in omission of important social interactions that, though not recognized as techniques of behavior change, foster trust, bonding, and nurturing of the community. These aspects are ancillary to smoking cessation, yet are important mediators of behavior change in social platforms. Therefore, if it is to be used to annotate such data, the taxonomy should be extended to incorporate these interpersonal interactions – particularly as these may include community-initiated traditions that the users have developed over years of collective effort toward change in behavior. These are best captured through inductive coding techniques such as grounded theory. Our previous and ongoing work employs these techniques to capture emergent nature of user communication within QuitNet [26, 27, 38]. Certain themes did not have adequate representation during qualitative coding, so could not be considered for automated analysis on account of a lack of training cases. Other methods of representation learning (e.g. word embeddings [39]), machine learning involving deep neural networks [40]) may enhance the ability of our methods to generalize from small numbers of training examples. We have used data from two different years 2007 and 2014 to validate the generalizability of thematic categorization, scalability of automated methods, and observed semantic shifts before and after relapse in temporal models. In our future work, we will extend the study to incorporate additional datasets to examine continuous temporal trends. Such analysis will help us to identify semantic content that is predictive of behavior change, and vice versa. Relapse is an important behavioral phenomenon from a clinical perspective. Characterization of the temporal and social dimensions of relapse may permit proactive identification of relapsing users, with subsequent personalization of interventions to meet the associated user needs and behavioral targets. Understanding other user behavioral states beyond relapers (e.g. active smokers, successful quitters) is equally important to help us distinguish specific communication characteristics underlying peer interactions based on smoking status.

**Conclusion:**

This study focuses on using peer-to-peer communication in an online community to understand the implications for data-driven health promotion. The major contributions of this study are as follows:

- This study uses a taxonomy of behavior change techniques to annotate peer communications in a health-related online community for smoking cessation. This offers an insight into the theoretical roots and related techniques embedded in QuitNet user communication.
- The automated analysis methods were used to extend the annotation from a set of 1000 manually coded messages to a large data set of about 84,204 messages. Use of distributional information that captures implicit meanings associated with peer interactions has provided us with better understanding of semantic context within terse social media interactions.
- The temporal modeling of QuitNet peer interactions has focused on understanding the semantic context surrounding a user’s communication across multiple behavioral points surrounding an event of relapse.
semantic context offers insights into users’ needs and triggers, which may be used for effective design of interventions appropriate to a particular stage of behavior change.

Annotating peer-to-peer communication to relate it to established theories of behavior change provides a bridge between these empirical data and scientific understanding of the mediators of behavior change. To our knowledge, this is the first effort to use the taxonomy of behavior change techniques (version 1 with 16 themes) to evaluate the construct of social media as a venue for behavior change. The application of the taxonomy for evaluation has revealed the theoretical manifestations underlying QuitNet user interactions that are primarily user-driven rather than expert-guided. Such findings can help us design better computer-mediated support technologies that nudge and prompt users to exchange theory-guided messages with embedded behavior change techniques. Distributional semantics in conjunction with machine learning, reduces human effort in dealing with large corpus of social media data making it amenable for large scale temporal modeling. Longitudinal trends in communication help us understand the traits of the user groups (classified based on their smoking behavior) that can help us customize the support infrastructure on social platforms for just-in-time guidance to sustain long term behavior change efforts. Indicators of relapse and understanding of user attitudes before and after relapse are essential to provide tailored assistance at the point in time when it is most relevant to the users of QuitNet like behavior change technologies in the digital era.

A Social Network Analysis of Cancer Provider Collaboration

Bryan D. Steitz1, Mia A. Levy, M.D., Ph.D.1,2
Vanderbilt University Medical Center, 1Department of Biomedical Informatics, 2Department of Medicine, Division of Hematology and Oncology, Nashville, TN

Abstract
Cancer treatment often consists of multiple therapeutic modalities delivered by specialists. As changing reimbursement paradigms move towards quality outcomes and bundled payments, extensive care coordination between healthcare providers is imperative. We developed an approach to quantify care coordination relationships among providers treating breast cancer patients at the Vanderbilt University Medical Center. Our cohort of 1285 providers treated 3924 breast cancer patients, and had 1758 unique provider-provider relationships. Providers treating stage III breast cancer patients had the highest ratio of providers to patients, indicating a more tightly connected network than providers treating stage I or II patients. Network analysis can provide quantitative approaches to understanding the relationships of multi-specialty providers and may inform approaches to measuring the impact of care coordination on outcomes.

Introduction
Cancer prevalence is growing, with nearly 1.7 million new cases expected in 2016. Breast cancer is the second most common form of cancer, with nearly 250000 new cases expected in 2016. Cancer management is complex, requiring multiple treatment modalities across diverse settings, managed by many healthcare providers who must coordinate care over time. Care coordination is a multidimensional concept involving the integration of care across all providers and settings. Coordination involves information sharing among the patient, clinicians, and care providers to ensure effective communication of accurate information. A previous study by Smith and colleagues found that cancer patients see an average of 32 physicians over the course of their treatment. Without appropriate coordination among these providers, patients can experience treatment delays, poorer outcomes, and inevitably higher costs.

Cancer care coordination has received attention as an approach to deliver high-value care. With cancer treatment complexity growing, the cost of cancer is projected to reach nearly $158 billion by 2020. A study by Ekwueme and colleagues estimated that many Medicaid breast cancer patients incurred over $5700 in direct monthly costs while receiving their treatment. Similarly, Pollack and colleagues found that patients who received care from a connected network of physicians had lower care costs than patients who visited providers with a less connected network. As reimbursement paradigms shift to a value-based model focusing on quality outcomes and bundled payments, extensive care coordination among specialists is imperative.

Analyzing provider relationships as a social network, or network of interactions between providers, is one methodology used to evaluate coordination and collaboration. In one study, researchers observed a survival advantage in stage III colon cancer patients when medical oncologists and surgical oncologists shared at least three patients. However, to evaluate adequately the significance of tightly coordinated networks of providers on cancer patient outcomes, we must first devise methods to describe and measure the connectedness of provider networks. In this study, we evaluate the network defined by collaborations between providers treating stage I through stage III breast cancer patients. We employ a network analysis methodology to quantify the collaboration between providers treating stage I through stage III breast cancer patients. We define provider collaboration as the number of breast cancer patients shared between two providers.

Methods
This study was conducted at the Vanderbilt-Ingram Cancer Center (VICC) at Vanderbilt University Medical Center (VUMC), an academic health care center in central Tennessee and a major referral center for the Southeastern United States. We collected data on breast cancer patients who met criteria for inclusion in the VUMC tumor registry; those who had been diagnosed or had received all or part of their first course of treatment at VUMC. Data in the VUMC tumor registry follows the North American Association of Central Cancer Registries data standards and dictionary schema. The Vanderbilt University Institutional Review Board approved this study (Protocol 130957).
**Study Population**

Patients with stage I, stage II, or stage III breast cancer diagnosed between January 1, 2000 and December 31, 2014 were included in the cohort. Data on patient demographics, diagnosis characteristics, and treating provider characteristics were extracted from the VUMC Tumor Registry. Demographic data included patient race, sex, ethnicity, and age at diagnosis. Diagnosis-related data included date of initial cancer diagnosis, summary of cancer treatments, date of each treatment, and cancer stage. Provider characteristic data included name, national provider identifier (NPI), and facility associated with each treatment for each patient.

**Provider Specialty Identification**

We used the provider characteristics from our initial data extraction to create a list of all providers and their respective NPI and treatment location (Figure 1). We downloaded the January 2016 NPI registry file\(^{13}\) and imported it into a PostgreSQL\(^{4}\) database. The NPI registry is a national database of medical provider identifiers. We chose to use the NPI registry to obtain provider information to ensure the accuracy of provider specialties, which was not as well represented in the tumor registry data. For each provider in our dataset without a listed NPI, we queried the NPI registry by provider name and location and recorded each match. Queries yielding duplicate name possibilities for the given location were recorded for manual review. Providers without any matches were separately recorded for manual review to account for potential data entry errors.

To validate all pre-populated NPI numbers, we queried the NPI registry. Each NPI number without a successfully matched name was flagged for manual review. For each provider flagged for review, we manually queried the NPI registry for a match. We reviewed each query result for potential matches. Each successfully matched provider was recorded in our dataset. Providers without clear matches, such as individuals with the same name at the same location were indicated as having an unknown NPI number. We excluded providers without an NPI number for subsequent specialty identification.

We queried the NPI registry to extract specialty codes for each provider. In cases where providers had more than one medical license, we extracted codes associated with their current state. The extracted specialty codes were translated into specialty names using the Centers for Medicare and Medicaid Services taxonomy definitions\(^{15}\). We manually reviewed the list of provider specialties to determine larger, more general, specialty categories for network creation. Providers categorized as medical oncologists, radiation oncologists, or surgical oncologists were included for network representation due to their relevance in breast cancer treatment. Provider specialties composing the medical oncology, radiation oncology, and surgical oncology categories are shown in Table 1.

Network Representation

We created social networks, or networks of relationships between physicians, to identify collaboration patterns among medical oncologists, radiation oncologists, and surgical oncologists. Each of the social networks consists of nodes, or circles on the graph, and edges, or lines between nodes. Nodes represent providers associated with the care of a patient. Edges represent a relationship between two providers defined by the fact that they share in the care of an individual patient. In typical network diagrams, node circle size and edge line thickness in a network diagram may be modulated to represent the magnitude of what they represent. In this study, the size of each node represents the total number of patients treated by the provider and the thickness of each edge represents the total number of patients shared between two providers. Nodes are color coded by provider specialty to understand inter-specialty relationships.

To create networks, we combined the lists of patients and providers to create a table of unique patient-provider pairs. Providers associated with each patient were combined into provider-provider relationships such that each provider associated with a patient was paired with every other provider associated with that patient. The resulting provider-provider relationships were reduced to the set of unique relationships and a count of the occurrences of that relationship determined the respective thickness or weight of the edge between two providers.

Network Visualization

We created two types of network visualizations: 1) a large, interconnected, network of all medical oncologists, radiation oncologists, and surgical oncologists who treated patients in our cohort, and 2) individual provider networks for top volume providers in each specialty. We used the igraph package within R 3.2.0 to create and visualize the networks. Network layouts were determined using the graphopt, force-directed, algorithm.

Network Analysis

For each network, we calculated the number of patients and providers included in the graph, and the number of relationships between providers. Node and edge sizes were summarized with means, medians, and interquartile ranges. We analyzed the relationship between the number of patients and number of providers in each network to normalize the relative collaboration between providers. We also calculated provider influence within each of the networks by measuring the percentage of patients seen by each of the providers. By evaluating each node’s color within the network, we can identify provider significance within a particular specialty and collaboration between specialties within the context of all providers.

We also created individual provider networks to evaluate collaboration patterns between individual providers. To determine potential referral patterns, we analyzed provider relationships across specialties. We similarly analyzed inter-specialty relationships. Finally, we compared intra-institution and inter-institution collaborations between providers.

Results

Our data included 3924 breast cancer patients with stage I-III disease who received treatment from at least one VUMC-affiliated provider between January 1, 2000 and December 31, 2014, and who had a medical oncologist, radiation oncologist, or surgical oncologist documented in the VUMC tumor registry. Table 2 presents the number of patients who had zero, one, two, three, or more VUMC-affiliated surgical oncologists, medical oncologists, and
radiation oncologists recorded in the tumor registry. On average, patients in the VUMC tumor registry had 2.17 (range 1 to 6) VUMC-affiliated providers listed with a median of 2 providers. Some (7%) patients in the tumor registry were only diagnosed at VUMC and never received treatment there.

**Table 2**: Number of VUMC-Affiliated Providers Treating Each Patient. Percentage representations under each specialty designate the percentage of total patients receiving treatment from a provider of that specialty.

Figure 2 visualizes the cancer provider collaboration network for surgical oncologists, medical oncologists and radiation oncologists treating the 3924 stage I-III breast cancer patients. The entire network consists of 409 providers with 1758 unique provider-to-provider collaborations. Network statistics for each of the stages are shown in Table 3. More providers (276) treat stage II patients, and have more provider-provider collaborations (885) than either of the other stages. Across each of the stages, medical oncology has the highest number of providers with 166 total medical oncologists. Radiation oncology is the least abundant specialty with 92 total radiation oncologists. The provider network for stage III breast cancer patients has the largest provider-patient ratio with 0.31 patients per provider, whereas the respective networks for stage I and stage II patients have ratios of 0.12 and 0.20. One radiation oncologist dominates the network, treating over half of the patients who receive that treatment (Table 4). The second largest volume radiation oncologist treats only 9.5% of the patients. The top medical oncologist and surgical oncologist treat 21.4% and 21.5% of patients respectively.

**Figure 2**: Cancer Provider Collaboration Network. Each node (circle) represents a unique provider in the network. The color of the node represents the type of cancer specialist: surgical oncology (black), medical oncology (white), and radiation oncology (grey). The size of the node represents the relative number of patients treated by each provider. Edges (lines) between nodes in the network represent provider-provider relationships created when two providers care for the same patient. The weight (thickness) of the edge represents the number of patients shared between two providers. In this network, 409 providers treated 3924 breast cancer patients diagnosed with stage I-III disease between 2000 and 2014. This network contains 1758 unique provider-to-provider relationships with an average of 3.7 (range 1 to 212) patients per provider-provider relationship.

Across the entire network, only 6% (25) of the providers are affiliated with VUMC. Provider-provider collaborations including one VUMC-affiliated provider account for 80.5% of the total collaborations in the network. Similarly, 9% of the collaborations are between two VUMC-affiliated providers. The collaborations between two VUMC-affiliated providers account for 55.5% of the total edge weights. Among VUMC-affiliated providers, an average of 74% (range 51.2%, 100.0%) of the weighted edges are with another VUMC-affiliated provider (Table 5). The majority (60.4%) of collaborations between two VUMC-affiliated providers share more than three patients, while only 4.1% of collaborations between non-VUMC-affiliated providers share more than three patients. Similarly, 21% of collaborations between two VUMC-affiliated providers share one patient, while 85.7% of non-VUMC-affiliated providers share one patient.

Figure 3 shows individual provider networks for the highest volume cancer provider in each specialty. Summary statistics are presented in Table 6. The top medical oncologist treating 723 patients has the most collaborators, with 159 unique provider-provider relationships. The top radiation oncologist and surgical oncologist have 140 and 131 provider-provider relationships respectively.

Over 28% of provider-provider relationships for both the top medical oncologist and top surgical oncologist are intra-specialty. 21.3% of the top radiation oncologist’s provider-provider relationships are intra-specialty. The top surgical oncologist shares the most patients within the same specialty, accounting for 8% of the total number of shared patients. The top surgical oncologist and radiation oncologist respectively share 5.5% and 3.8% of patients within the same specialty.

The top radiation oncologist shared four or more patients in one quarter (24.8%) of the provider-provider relationships. Four or more patients were shared in 16.7% of the top radiation oncologist’s intra-specialty relationships. The top surgical oncologist and medical oncologist shared four or more patients in 18.9% and 13.8% of relationships respectively. Four or more patients were shared in 8.1% of the top surgical oncologist’s intra-specialty relationships and 4.4% of the top medical oncologist’s intra-specialty relationships.

Discussion

We have developed a methodology to visualize and quantify cancer provider collaboration networks using tumor registry data for breast cancer patients. Using simple network graph statistics, we are able to quantify the degree of connectedness of a group of specialists providing multi-disciplinary therapy for a specific patient population. Multiple studies have employed social network methodologies to quantify collaborative relationships. A previous study by Bridewell et al. demonstrated the effectiveness of social network analysis in quantifying institutional boundaries between neighboring organizations\textsuperscript{19}. Social network analysis of collaborative relationships has also been applied to non-clinical healthcare domains. Studies by Malin, Carly, and Long et al. have each applied network centrality measures to analyze relationships in scientific communities\textsuperscript{20, 21}. Similarly, Hether et al. used social network analysis to evaluate user interactions on prenatal support websites\textsuperscript{22}.

Our methodology offers a scalable approach to analyze cancer provider collaboration networks. The scalable approach is supported by our use of data from the VUMC tumor registry, which stores data within NAACR guidelines. Data format consistency, between cancer types and other external registries, allows us to extend our methodology to evaluate differences in provider collaboration networks across cancer diagnosis. To normalize network statistics across different networks, we used the ratio of providers to patients and the ratio of provider edges to patients across each stage. The ratio of providers to patients allowed us to measure the relative size of each network. The ratio of provider edges to patients allows us to measure the network’s relative density. Both networks normalize for the relative number of patients. Other common network statistics, such as density and connectivity, failed to normalize population differences across networks.

Our scalable approach is not without limitations. Our data was based on the tumor registry’s knowledge of providers involved in the patient’s care, and may not reflect all cancer providers who cared for each patient. The VUMC tumor registry has received awards for their abstraction process. Less complete tumor registries could limit the generalizability of this approach to other institutions. We could also improve our methodology by adding additional data sources. Bridewell et al. refined their network analysis by incorporating treatment and billing data extracted from electronic health records\textsuperscript{19}. Other studies\textsuperscript{3} have used data from the SEER-Medicare database\textsuperscript{23}, which links tumor registry data to Medicare claims data providing a more complete picture of all of the providers treating Medicare patients.

Furthermore, our study is limited by the fact that it provides a static view of an inherently dynamic system of provider-provider relationships that change over time. Our network analysis contains provider-provider relationships spanning 14 years during which time some providers joined and others departed our institution or the geographical region, thus changing the dynamic of their referral patterns. Dynamic network analysis has previously been used in other domains to study changes in social interactions over time\textsuperscript{24, 25}. Future work will incorporate dynamic network analysis techniques to address network temporality.

Our results indicate that the majority (55 percent) of provider-provider collaborations occur between VUMC affiliated providers. We also found that 74 percent of each VUMC affiliated provider’s interactions are with another VUMC provider. Similar to our results, Bridewell et al. observed strong institutional ties between providers at an academic medical center\textsuperscript{19}. Our results also indicated that 68 percent of the provider-provider relationships

1993
share only one patient, while 13 percent share four or more patients. Similarly, providers shared an average of 3.7 patients with a median of one patient. A study of collaboration between surgical oncologists and medical oncologists treating stage III colon cancer patients in the SEER-Medicare database by Hussain et al. found that nearly three quarters of providers share at least two patients, with a median of three shared patients. However, among relationships between two VUMC providers, we found that nearly 79 percent of the provider-provider collaborations share at least two patients, with 60 percent of relationships sharing more than three patients. These results indicate strong collaboration within VUMC, with many individual collaborations between external providers, which may be related to geographically distanced patients visiting VUMC to receive part of their care, but receiving much of their daily care closer to home. The study by Hussian et al. also correlated a survival advantage with surgical oncologists and medical oncologists who share more patients. Our future work will focus on evaluating the correlation between the number of patients shared between providers and clinical outcomes including patient survival and other process outcomes.

To our knowledge, this study is one of the first to evaluate individual specialist networks. To normalize each individual provider networks by the relative number of patients, we measured the ratio of unique edges to patients for each provider. Our results indicate that the top radiation oncologist has the lowest ratio with 0.16 unique edges per patient, while the top medical oncologist has the highest ratio with 0.22 unique edges per patient. The low ratio for the top radiation oncologist indicates a high level of collaboration between fewer providers; potentially due sharing many patients with other VUMC affiliated specialists. We hypothesize the medical oncologist’s larger ratio is due to geographically distanced patients receiving much of their day-to-day care from providers closer to home.

Within the diagnosis of breast cancer, we were able to identify differences in provider collaboration networks for a sub-population of stage III breast cancer patients. Stage III breast cancer has a higher risk of recurrence and is more often treated with pre-surgical or post-surgical adjuvant chemotherapy than stage I or II breast cancer. The intensity of treatment and coordination with surgical plan management requires a closer collaboration between surgical and medical oncologists. We hypothesized that stage III cancer provider collaboration would be more closely connected than stage I or II provider networks. We observed that stage III breast cancer patients had the highest provider-patient ratio and provider-edge-patient ratio compared to stage I and II. These higher ratios indicate that providers are sharing more patients and are more closely connected than other stages, confirming our hypothesis.

**Conclusion**

Cancer treatment often consists of multiple treatment modalities, managed by many care providers. While improved care coordination has been identified as a way to save costs and deliver high value care, few methods exist to quantify the relationships between multi-specialty providers. We employed a network analysis approach to evaluate the collaborations between surgical oncologists, medical oncologists, and radiation oncologists treating stage I – III breast cancer patients. Not surprisingly, we found that intra-institutional relationships were stronger than inter-institutional relationships. We also found that as cancer stage increases, the ratio of providers to patients increases to better coordinate more complex care. Network analysis can provide quantitative approaches to understanding the provider relationships between specialties and may inform approaches to better understand the impacts of care coordination on patient care.

Baby Steps Text: Feasibility Study of an SMS-Based Tool for Tracking Children’s Developmental Progress

Hyewon Suh, MS, John R. Porter, MS, Robert Racadio, MS,
Yi-Chen Sung, MS, Julie A. Kientz, PhD

1University of Washington, Seattle, WA

Abstract

To help reach populations of children without consistent Internet access or medical care, we designed and implemented Baby Steps Text, an automated text message-based screening tool. We conducted preliminary user research via storyboarding and prototyping with target populations and then developed a fully functional system. In a one-month deployment study, we evaluated the feasibility of Baby Steps Text with fourteen families. During a one-month study, 13 out of 14 participants were able to learn and use the response structure (yielding 2.88% error rate) and complete a child development screener entirely via text messages. All post-study survey respondents agreed Baby Steps Text was understandable and easy to use, which was also confirmed through post-study interviews. Some survey respondents expressed liking Baby Steps Text because it was easy, quick, convenient to use, and delivered helpful, timely information. Our initial deployment study shows text messaging is a feasible tool for supporting parents in tracking and monitoring their child’s development.

1. Introduction

Approximately 1 in 6 children between the ages of 3 and 18 in the United States are diagnosed with developmental disorders, such as autism, ADHD, or anxiety disorders. It is known that the earlier these disorders can be diagnosed, the sooner early interventions can start, resulting in better outcomes for these children. Unfortunately, approximately half of children who eventually receive diagnoses of developmental disorders are not identified until they reach kindergarten in the United States, with lower-income populations being missed at a higher rate. Tracking and regular screening of child development is the key to early detection of many types of developmental disabilities. Developmental screening involves regular checks for developmental milestones at up to 22 different intervals across a child’s first 5 years of life. Milestone screening includes age-based questions such as “does your baby turn her head towards a loud noise?” and “can your child climb stairs?” Because these activities take place in daily life outside of traditional clinical settings, parents’ and caregivers’ reports for the early signs of developmental delay are the most reliable way to track them. Therefore, it is important to engage, inform, educate, and empower parents to track and assess their child’s development in an easy way in order to make monitoring more accurate and meaningful. Unfortunately, 5 years is a long time to keep parents engaged consistently. In addition, parents without access to developmental screening often have difficulties in monitoring because they may not be aware of what to watch for. Pediatricians provide parents milestone questionnaires to complete at Well Child Visits (regularly scheduled checkups in the U.S). However, given Well Child Visits are months to up to a year apart depending on the child’s age, it is not the timeliest solution. In addition, many resource-constrained populations, such as low-income or immigrant families, lack the insurance to cover Well Child Visits, and frequent moves or language barriers make it difficult to access information about normal child development.

The ubiquity and penetration of mobile phones presents an opportunity, particularly in under-resourced health ecosystems, via SMS (Short Message Service), a low-cost communication channel that is supported on even the most basic of mobile phones. Between 2000 and 2012, the number of mobile phones in use worldwide grew from fewer than 1 billion to around 6 billion. In the United States, 91% of adults own a cell phone as of 2013. This widespread distribution of mobile phones across diverse populations may solve one of the most difficult problems in public health domain – barriers to access. Thus, mHealth (mobile health) can make it possible to inform caregivers and let them collect and share relevant data at any time, allowing more rapid convergence to optimal treatment.

To attempt to reach more underserved populations with child developmental screening, we have developed Baby Steps Text, a tool that prompts parents to track and review developmental milestone data and connect them to resources using only text messages. Baby Steps Text is a completely automated, personalized, and self-contained two-way communication system that also works seamlessly with a larger set of tools that have been developed as part of a developmental screening ecosystem (including a web portal and Twitter-based tools). Baby Steps Text provides a way to understand how we can include resource-constrained populations who may not yet have constant Internet access or sophisticated smartphones. This paper presents the design, development, and feasibility study of the Baby Steps Text system. Our research brings SMS-based mHealth interventions to a new domain (childhood developmental
screening) and helps expand knowledge about how parent-generated health data can be collected in a simple but thoughtful way, thus expanding the reach of its benefits.

2. Related work

2.1. Domains of SMS-based mHealth

Using mobile phones to support health interventions has a number of advantages over other technologies. The biggest advantages of using mobile phones for supporting public health are that they are personal, connected, relatively inexpensive, and always with people. Current evidence suggests that SMS-based mHealth supports the following four health domains: 1) **Disease Management & Treatment Adherence**: Use of text messaging to reinforce treatment (e.g. HIV/AIDS\(^6\), \(^{40}\), diabetes\(^{14},^{24}\), asthma\(^{38},^{42}\), smoking cessation treatment\(^{15},^{37}\), weight loss\(^{34}\), mental illness\(^9\), and medication adherence\(^{29}\); 2) **Health Information Delivery and Behavior Change**: Text messaging as an inexpensive tool for behavior change and the delivery of health information (e.g. educating about pregnancy and newborns\(^{10},^{31}\), vaccination\(^{41}\), youth sexual health\(^{29}\), weight management\(^{16}\), and encouraging physical activity\(^{12}\)); 3) **Patient-Provider Communication**: Use of mobile phone as a communication channel between patients and providers (e.g. clinic appointment reminders\(^5,^{27}\) and communication with visually impaired patients about health information\(^{22}\)); 4) **Early Detection & Screening**: Screening for early detection of disease (e.g. cervical cancer screening\(^{26}\), and breast self exams\(^{26}\)). However, despite advantages of SMS in delivering information at the appropriate time, use of SMS for screening purpose has not been as well-explored as much as other areas. Baby Steps Text fits into this domain most closely, and addresses a new area within it for children’s developmental screening.

2.2. One-way vs. Two-way SMS Communication

One-way SMS communication is similar to mass media in that it “pushes” information to subscribers’ phones by using messages tailored to personal needs. A large body of SMS-based research has typically been designed this way. This includes simple reminder programs such as reminding clinic appointments and other systems such as sending health promotion and dietary and disease management information. In one-way SMS systems, the subscriber is more of a passive recipient rather than an active user. In order to solve this problem, some projects used two-way communication in their communication message design. For users, the interactive nature of two-way communication may require greater effort and generate greater interest\(^{19}\). While some projects support a fully natural way of communication by having a humans responding to questions and concerns sent by users\(^2\), other projects support fully automated communication by requiring users to follow a specific structure to enable automated parsing by the system\(^{1,^{32}}\). Recently, Perrier et al.\(^{55}\) deployed a hybrid two-way communication where the system sends out bulk messages to its users automatically, and a human behind the scenes takes care of user replies.

2.3. Technology Design for Infant and Children’s Health

Researchers in the human-computer interaction community have sought to design technologies in support of children’s health. These areas have primarily been focused on general studies on the opportunities for design of technologies for children’s health, technologies for use of parents and doctors, and technology to be used by children themselves. For general studies of opportunities, Kientz et al. conducted a formative study on the opportunities for the design of developmental tracking systems\(^{21}\), and then later conducted an in-depth evaluation of the opportunities for supporting parent-pediatrician interaction\(^{33}\). Jeong et al. studied parents with the purpose of providing insights for the design of technology for tracking general health data about children\(^8\).

This prior formative work has informed a number of systems designed to support parents in tracking their children’s health. The original Baby Steps system\(^2\) was a software application to track developmental progress, with follow on work expanding it to using Twitter\(^39\). Baby Steps Text seeks to build upon this previous literature by exploring a new delivery mechanism for developmental screening. Additional designs for helping parents monitor their children’s health include ENSURE\(^2\), which help parents track daily health data such as meal intake and diapering, and Fitbaby\(^17\), which helps parents of premature infants track their child’s physical exercises and overall wellbeing. Both ENSURE and Fitbaby focus on general health observations and are not intended for screening, as is the goal of Baby Steps Text.

3. User-Centered Design Process

One of the primary goals for the overall Baby Steps project was to identify ways to reach underserved families for developmental screening. We conducted a user-centered design approach that formed the basis for the final design of Baby Steps Text, which we describe in the following section (see Figure 1) to engage with key members of this initiative to explore the use of technology in helping to reach underserved populations in collaboration with Washington State’s Department of Health. We focused specifically on Latino populations in our state, as they represent a large percentage of underserved populations and experience a number of challenges that may affect other underserved populations, such as access to health insurance, access to mobile technology, and cultural and language barriers\(^3\). However, the intended users of Baby Steps Text are broader than just this specific population.
3.1. User Research

To get a broader perspective on our target population, we conducted semi-structured interviews with five stakeholders, including one Latino parent of a child with a developmental disability, two health care providers, and two Latino community health advocates. The interviews aimed to understand how parents engage in healthcare for their child and participate in developmental screenings and how health information is communicated. The research team members also visited a Latina health fair located in a predominantly working class Latino neighborhood in Seattle. The health fair was organized by a Latino-focused community health center, attended by Latina women, their families, and community leaders. We administered short surveys to 15 mothers and asked questions related to technology use, the number of children in their family, and their language use.

From the interviews, we learned that Latino households are commonly multi-generational—consisting of children, their parents, and their grandparents—and the responsibility of caring for children is shared with members of the extended community. When asked to describe the technologies that members of the Latino community would most likely have access to, the most common answer was the mobile phone with basic capabilities. They suggested that home computers or home Internet access would not be common, but families might use computers in public venues, such as at the library. Findings from the survey supported several findings from the interviews. In particular, mobile phone use was prevalent (93% of respondents), as was text messaging (87%). Only 6 participants (40%) used their phone to access the Internet and only two (13%) downloaded applications, which meant an entirely text message-based system would have broader reach than a mobile website or app, as home computer and Internet access were not as prevalent (60% and 53% respectively). Two mothers (13%) also mentioned they did not use services like mobile Internet or Facebook, but that their spouses did. We learned from the providers and health advocates that they serve a community that varies widely on literacy skills. The Latina fair survey confirmed these numbers, with the majority of participants preferring Spanish, but nearly half also having English proficiency.

To summarize our preliminary user research, we developed a set of 9 personas representing stakeholders of the potential system, including three different family caregiver types, community members, healthcare providers, and advocates in the state (see Figure 2 for an example persona). These personas were used during the ideation and design process to ensure the needs of stakeholders were represented in the design of the tools.

Figure 2. Left: Persona for a parent of a child with special needs. Right: Spanish-language Storyboard of Baby Steps

3.2. Ideation & Prototyping

The research team conducted a design ideation brainstorming session and generated 63 unique ideas for potential technologies to reach Latino families in the state with developmental screening. We kept copies of the personas present during the brainstorming to ensure designs were grounded in the needs of the stakeholders. From there, we narrowed design ideas into the most promising and feasible three ideas for which we developed storyboards in both English and Spanish suitable for user feedback (Figure 2). The three ideas included text messaging, a website, and a public kiosk. We also developed high-fidelity interactive prototypes of a public kiosk and a website using the Axure prototyping software.
tool (http://axure.com) and a Wizard-of-Oz prototype of the text messaging tool using Google Voice to send messages to participants’ phones and a detailed script of messages.

3.3. Evaluation
We reviewed the storyboards and prototypes with stakeholders, including advocates and families attending the Latina health fair. When reviewing the storyboards with potential users, the text messaging-based system seemed to be the most promising approach for the furthest reach. Stakeholders and parents all responded positively to a text-messaging based system, as long as the costs were kept low. Participants were unsure if they would use or have consistent access to a public kiosk, and though a website would be helpful and provide a richer experience, the lack of a home computer or data plans on their phones limited potential access. After deciding to move forward with the text messaging design, we iterated on the design and wording of the Baby Steps Text system through initial Wizard-of-Oz usability studies with 10 parent participants. We had two researchers simulate the experience of using Baby Steps Text for the participant. Participants used their own mobile phones to send and receive text messages to the researcher playing the part of the “wizard,” who used the Google Voice interface on a laptop, along with a script (see Figure 3), to quickly customize responses for the users during testing. We had a total of 12 tasks that covered all aspects of the system, including registering, responding to several milestone questions, receiving a report, requesting help, and stopping the service. Participants had a printed sheet with each task, and a study coordinator guided them through the process while the “wizard” read and responded to the system. Participants offered suggestions on improving the content and process for receiving and responding to text messages. In particular, our original design for the progress report only included the number of questions answered and no real information about how the child was progressing in each category. We thus added more information about the child’s progress and added information about what to do if the child’s result in any given category of development was “More evaluation needed.” The registration component was also confusing, as we required the child’s name, birthdate, and gender to be separated by spaces. We found participants could easily remember the “y” “s” and “n” responses after a few milestone prompts and thus only needed simple instructions rather than the full instructions with each message.

Task 3: Responding to Milestone Questions
Participant task: You will soon receive a message with a question about your child. When you receive the message, respond to it based on your child’s experience using the instructions.
Wizard response: Send message: “Can NAME drink water, juice, or formula from a cup while you hold it? (Reply Y for “yes,” S for “sometimes,” N for “not yet”)”
If response is anything but Y, S, or N, reply back with:
○ Reply to ?’s with “Y” for yes, “S” for sometimes, or “N” for not yet. New msg sent after you reply. Txt “stop” to cancel. Txt “report” for NAME’s progress.

Task 11: Requesting a Report
Participant task: Request a progress report on how many milestones your child has completed so far.
Wizard response: Expect to receive the word “report” from parent. Send back:
NAME’s Progress, Number of milestones completed:
Personal-Social – 34
Gross Motor – 23
Fine Motor – 22
Communication – 40
Problem Solving – 22

Figure 3. Example script for “Wizard” in Wizard-of-Oz prototype for two of the twelve tasks. Wizard instructions are in italics and BOLD CAPS indicate parts customized by the Wizard for the user’s child.

4. Baby Steps Text Design & Implementation
Based on the results of our initial studies, we finalized a fully functional version of Baby Steps Text that would be suitable for a deployment study. The milestone question content used in Baby Steps was inspired by the Ages and Stages Questionnaire. In this section, we describe the design features of the messaging system.

4.1. Personalized Milestone Questions
Several previous studies also have shown the benefits of individually tailored messages that are personalized for the user. Because each message is sent to an individual, we can personalize the content of the messages. Using information from enrollment such as child birthdate, name, and gender, Baby Steps Text can send age appropriate messages and can include the child’s name and gender-specific pronouns (unlike paper-based screeners), conveying a feeling of personal attention cost-effectively. To automate this process, we used placeholders such as %n% and %s% for words that needed tailoring and replaced those via an automated script. Overall, Baby Steps Text consists of 660 distinct milestone questions that are tailored for each child and delivered based on age. Our system differs from many other SMS-based approaches in that all milestone questions are personalized to increase user engagement and is entirely automated to run without behind-the-scenes human effort.

4.2. Simplified Response Structure
There are four response options to milestone questions: ‘Yes,’ ‘Sometimes,’ ‘Not Yet,’ and ‘Revisit’ (all case-insensitive) to skip to the next question and respond to it later. To reduce typing, parents could also use first letter of each response type (e.g., Y for ‘Yes’ and R for ‘Revisit’) (see Figure 4). If the caregiver has multiple children registered with Baby Steps Text, they need to also include their child’s name. Beyond these required elements, caregivers can add free text in their response (e.g., “Yes, Tommy can drink milk from a cup!”) like a natural text conversation, which does not interfere with the system’s automated parsing mechanism. We wanted to repeat instructions for using “Y” “S” and “N” with each milestone prompt to remind participants, but even after shortening, some questions were too long to include the full instructions within the 160-character limit. Thus, for shorter milestone questions, we included the full instructions (“reply ‘Y’ for “Yes”, ‘S’ for “Sometimes”, or “N” for “Not Yet”) whereas for longer questions, we used a simplified instruction (reply ‘Y’, ‘S’, or ‘N’). When we shortened the screener content, we made the longest message a maximum of 130 characters to ensure we had at least 30 characters remaining for the simplest instructions.

4.3. Progress Report
If parents text “Report” to Baby Steps, we generate a child’s progress report based on parents’ responses to individual questions (e.g., whether they are developing on schedule or if they should get in touch with their provider for additional assessment). To fit the progress report into a single text message, we used three simple reporting levels (“On track,” “Let’s watch,” and “More evaluation needed”) for each development category (e.g., Communication, Fine Motor, Gross Motor, Problem Solving, Personal & Social). We aimed to carefully convey progress to reduce unnecessary caregiver anxiety by working on the exact wording with experts a local non-profit organization that provides a free statewide program for family health that serves many low-income families and also runs a toll free parent help hotline to connect parents to early intervention services. If a parent requests a progress report before they answer half of the questions, we provide a message to answer more questions first. If they answer more than half but not all 30 questions, we send an additional message that the progress report they receive may not be an accurate reflection of their child’s development until all questions are completed. If a child is not ‘On Track’ in any development categories based on

![Figure 4. Example of Baby Steps Text syntax usage. Gray (left) indicates messages sent by Baby Steps and green (right) indicates messages sent by caregiver.](image-url)
parents’ responses, we provide the toll free hotline number for the non-profit mentioned above in a message following the progress report so that parents have contact points for questions or concerns about child.

4.4. Intervals of Screening Questions
Because our user research indicated that mobile phone plans used by lower income families may vary and be limited (e.g., pay-per-use plans), we had to find ways to deliver complete screening questionnaires within a certain timeframe so that those screening questions are still valid to the child’s age. We originally intended to send one screening question per day to avoid information overload, but due to this finding, we designed Baby Steps Text to send the next question immediately after they respond to one because it signals that 1) they are active on mobile texting, and 2) they are able to send and receive messages at the current moment. If the parent does not respond to a question within 48 hours, we resend the same question again.

4.5. Supporting Multiple Caregiver Engagement
Child development happens in daily life, and it is not always one parent who observes when their child hits certain milestones. In our user research, we found that often family members shared child-raising responsibility with aunts, uncles, and grandparents, with not every member of the family having consistent access to mobile phones. To coordinate tracking child development across multiple caregivers, we allowed our system to register multiple users’ phones. The same question is sent to all caregivers’ mobile phones, and if one answers a question, the others receive a message saying “[name of other caregiver] answered [response type]” (e.g., “Juan answered yes”) and all will receive the next milestone question to answer. This allows all caregivers follow their child’s development and coordinate responses.

4.6. System Implementation
Baby Steps Text is a custom-built Python application and associated MySQL database, which uses the Twilio cloud communications platform (https://twilio.com) for SMS and MMS handling. Incoming messages sent by users to our phone number are received by Twilio, which then relays the data to our system via HTTP request to be parsed for keywords. Similarly, by sending HTTP requests to Twilio, we can send both SMS and MMS messages to our users programmatically. When our system receives an incoming message, the content is parsed to determine if it is a milestone response or another of our recognized keywords (REPORT, START, STOP, HELP); responses are stored in the relevant child's database entry and sends an appropriate error message to any message that does not fit into the response structure. Outgoing messages are sent in two distinct scenarios. When a user answers a milestone question, the next question is sent immediately. They can also be sent via a daily check (handled by a cron job on the server), which determines on a child-by-child basis if it is time to either send the first question of a new milestone set (if the child has entered a new age range) or resend the last outgoing message (if 48 hours have elapsed without a response).

5. Feasibility Study
In Winter 2015, we conducted a month-long deployment study with 14 participants to test the feasibility and usability of Baby Steps Text. This study included collecting usage logs and qualitative data from pre- and post-study surveys. The study was reviewed and approved as minimal risk research by our university’s human subjects board.

5.1. Participants
Although we did not exclude participants based on income, we aimed to recruit resource-constrained families in our study through the waiting room of local pediatric clinic that serves a high number of underserved, low-income, and immigrant families. Because our current prototype only has English-based questions, we required participants to have basic English literacy. The clinic receptionist introduced eligible parents of children under five years old to our study at check-in and directed them to the researcher in the waiting room to enroll in the study. We recruited 14 participants from a variety of backgrounds and none of feasibility study participants participated in any of our preliminary user studies. The participants were caregivers (M:2, F:12) of at least one child under 5 (Table 1). We aimed to recruit a balance of genders, but in all but three cases (two fathers and one aunt), it was the mother who checked in at the clinic. The majority were aged between 33 and 40 years old (n=8), and the total children in the household varied from zero (aunt) to seven. All owned smartphones and were active text users. Half were single and half were married. Child participant ages ranged from 4 months to 60 months. One participant (P11) used Baby Steps Text with two children.

5.2. Study Procedure
Participants received instructions, signed a consent form, and completed a pre-study survey on family demographics, current mobile phone use, and parenting experience. We also provided a one-page instruction sheet that explained how to use the system. We then registered them with Baby Steps Text, and participants started receiving screening milestone questions. After the first visit, the research team did not interact with participants until one month had passed. After one month, we mailed an exit package that included a study completion brief, compensation, and a post-study survey with a self-addressed, pre-stamped return envelop. Participants received $20 for their study participation.
6. Results

6.1. Baby Steps Text Usage

Among the 14 parent participants, one (P2) withdrew from the study in the early stage by replying “STOP.” The remaining 13 participants successfully used text messages to track their child’s development and completed the study. Over their one-month-long participation, Baby Steps sent 557 messages and received 520 SMS messages in response from participants. On average, each participant who completed the study received 42.3 messages (SD = 18.6) and sent 39.4 messages in response (SD=19.7). The high standard deviation is due to three participants whose child transitioned from one milestone question set age range to another during the course of study (therefore answering 60 questions) and among them, one participant used Baby Steps Text for two children and responded to 90 questions. Four participants (P1, P5, P6, P8) responded to all 30 milestone questions almost in one sitting (Table 2). We did not see a completion rate difference between the two strategies (e.g., responding to all at once vs. periodically).

6.2. Use of Baby Steps Text Syntax

For Baby Steps Text to recognize and store user responses in the database automatically, we required participants to use one of the four response options. We provided an instruction sheet when participants enrolled in our study and continuously included these instructions within the question message itself. As a result, 505 of the 520 user messages were correctly formatted, yielding a very low error rate of 2.88%, and participants were able to self-correct errors early due to an automated response that informed them of syntax errors. About 15% of the text message responses used shortened response types such as Y/S/N, but there was no particular pattern as many participants used both full and

and $10 each for the pre- and post-study survey completion (post-study survey had to be mailed back). Five participants (two were survey respondents and three were not) also participated in the post-study interview to provide us richer feedback. As a token of appreciation, participants received $20 at their sign up to cover any texting fees incurred using Baby Steps Text.

Table 2: Overall text activity by 14 participants. The rightmost cell shows a sparkline plot of the month-long timeline of texting activity. (*P2 withdrew from the study.)
shortened responses interchangeably. Although we included the “Revisit” feature on the instruction sheet, it was not included as a response type in question messages, and thus no participants used this feature during the study. One post-study survey respondent mentioned she did not know about the option but would appreciate having it.

6.3. Participants’ Experience with Baby Steps Text
Six out of the thirteen participants completed and mailed back the post-study paper survey. Meanwhile, five participants participated in a phone interview to share their experience (see Table 1). Although the survey response rate was low, this is not unexpected for mail-in surveys with lower-income populations. All survey and interview participants agreed that milestone questions asked by Baby Steps Text were understandable and the system was easy to use, respectively scoring 4 and 4.3 where 5 is strongly agree. They also agreed the total number of milestone questions (30 per 2-6 months age range) asked was appropriate, which we could also confirmed from interviews. However, P9 was not as satisfied with receiving one message immediately after the other: “the constant stream of texts on the 1st day was a little overwhelming.” This may be due to not clearly explaining they could take time between questions and they would receive reminder messages after 48 hours, which some participants appreciated – “At times I forget to answer and it would hit me up again to make sure I answer them. (P4)” When asked about message frequency, survey respondents were mixed. Half (n=3) preferred to receive the next question immediately and answer in one sitting, and the other half preferred to receive questions periodically. However, most of the interview participants (4 out of 5) preferred to receive questions one after another, as P6 said, “I think that was really cool that you can keep going and don’t need to wait a while for the next question” and P4 also noted, “even though it’s first annoying, I think you should keep them one after the other. My schedule is hectic and if it’s periodic, I am not going to think about it as much.” In their interviews, P4 and P7 mentioned that although milestone pictures were helpful, they had to make space for them because their phone’s storage was full. P7 also noted shortcomings of milestone questions – “There are some didn’t apply because – the ones with stairs, we don’t have stairs. So I couldn’t really answer. Some of them didn’t apply. So I answered ‘no’” For the open-ended survey question about what they liked, P3 and P9 reported that it was easy, quick, and convenient. Several also liked receiving useful information that can be helpful to their child in timely manner (P5, P9, P10). P10 noted, “I really enjoyed participating in this study. I think the texting format is really great and unique. It’s nice to receive personalized texts and not have to go to the Internet to look things up!”

6.4. Continued Usage After Study Completion
The exit package explained to participants that they could choose to continue using Baby Steps Text beyond the study. P10 finished the 60-month milestone questionnaire during our study, which was the last questionnaire of Baby Steps Text system, thus there was no more milestone questions to send. None of the remaining twelve participants who completed the study explicitly opted out of Baby Steps Text. Nine out of 12 participants were still responding to milestone prompts three months study completion, where we received an additional 385 messages from participants. Due to a software glitch, we were not able to send messages longer than 3 months. However, this is promising in that participants found our system engaging and worth using outside of study compensation.

7. Discussion
7.1. Recommended Changes to Baby Steps Text Design
1) More Detailed Progress Report: To fit the progress report into a single text message, we had to make it brief. Although the report design worked well in usability testing, when we provided real data to participants, they were not as satisfied with minimal data. P3 noted that, “I felt the report was too high level and vague. Didn’t tell me much of anything.” To reflect this feedback, the next version of Baby Steps Text will convey more information on interpreting each item by allowing parent to text “more” after a report to receive explanations about each developmental category, what the child’s result means, and what actions they can do beyond calling the family health hotline. For users with Internet access, providing a link to a web-based report with more detail could be useful, as others have done.

2) Providing Ideas for Activities to Encourage Development: To support parents in encouraging development beyond tracking, we plan to implement an opt-in feature where the system sends a message asking if they want to receive ideas for activities they can do to encourage development with their child. If yes, the system would send age-appropriate items automatically (e.g., “Activity Idea: Put dry rice inside an empty bottle to encourage shaking and turning behaviors”). Because activities are suggestions rather than screening, no response would be required.

3) Sentimental Records along with Developmental Records: Previous research indicates that tracking sentimental childhood records, such as memories and “firsts and favorites,” along with development can increase parent engagement. We plan to expand Baby Steps Text to make keeping sentimental records as easy as sharing photos and videos of their child. The new version will allow parents to text memories via SMS or send photos and videos via MMS with the keyword “memory” to the system. Parents who have access to the Internet can view their records on a companion website alongside developmental reports for a complete picture of their child’s life.
7.2. General Implications for Text-Based mHealth
From our study, we found that extra keywords explained only on the instruction sheet (REVISIT, REPORT, HELP, etc.) were rarely used, except for one “HELP” and one “STOP” message. We had to ask participants to use the REPORT feature in the post-study survey to get their feedback on that feature. Therefore, we recommend to make all information inclusive in outgoing messages. Another suggestion is to allow adjustment of message frequency based on user preference if possible (immediately vs. periodically). System designers may also consider adding non-text features, such as web links or photos, to extend capabilities for users with Internet access to read detailed explanations that might help understanding or features that improve engagement (e.g., online photo albums). Future studies will explore these features and how technology interventions might “gracefully degrade” based on financial constraints. Next, shortening an already validated screening tool (e.g., ASQ) to 160 characters was necessary for the tool to function, but may have broken its validity. As using SMS (160-character limit) for health interventions becomes more common, we encourage creators of screening questionnaires to consider making questions fit within 140 characters or less to accommodate these constraints and to allow for additional characters for any instructions. Finally, communicating the results of a screener entirely via text message could create unnecessary anxiety [4] if done without including actionable information (such as calling a hotline) or without acknowledging the user’s feelings. Careful testing of wording in the results with potential users can help mitigate the potential for anxiety. Finally, our Wizard-of-Oz prototype was very useful in identifying problems with the messaging and syntax and required no technical skill to implement, as the only components were the scripts and the use of Google Voice. We suggest designers consider adopting this method for designing SMS-based applications.

7.3. Limitations & Future Work
Due to 160-character limit of SMS, we needed to shorten a validated screening tool and thus the validity of content needs to be reevaluated. We also did not follow up with the family health hotline to determine if any of the participants called to request access to services for early intervention, and only tested an English-language version of the tool. In the next iteration of Baby Steps Text, we plan to use a shorter validated screening tool that fits within character constraints (http://theswwy.org) and provide support in Spanish. Also, as this was an initial feasibility study, participants used Baby Steps for a brief period and we do not have sufficient data to tell how our system impacts parents in a long term (e.g. how it changes parental efficacy, their knowledge on child development, etc.) Therefore, we plan to conduct a longer study to answer questions about long-term engagement, identify ways to combine developmental tracking with sentimental record-keeping, and compare it to other approaches to technology-based developmental screening.

8. Conclusion
The primary objective of this study was to design and evaluate the feasibility of using SMS for childhood developmental screening. We presented our design process and implementation details for Baby Steps Text, an automated text messaging system to collect and screen child development using everyday technology available to resource-constrained populations. Our initial month-long deployment study shows that text messaging is a feasible tool for supporting parents in monitoring and screening their child. Continued use of our system beyond the study participation also indicates that the approach is promising in encouraging parent engagement.

Evaluating a Novel Summary Visualization for Clinical Trial Reports: A Usability Study

Maurine Tong, BS, William Hsu, PhD, Ricky K. Taira, PhD
University of California Los Angeles, Los Angeles, CA

Abstract
Contributions of clinical trials are captured in published reports that are unstructured and often require extensive manual review to gain a deeper understanding of the study itself. Our goal is to increase comprehension and decrease the time necessary to understand these reports through the use of visualization tools. In this paper, we specify and evaluate the visualization of a previously developed representation as well as gain insight from user input for further development. The usability experiment consisted of a two-arm study with users either having or not having access to the visualization. A user questionnaire was used to measure time spent and accuracy in comprehension; intuitiveness and reproducibility of the visualization; and preferences. We found that having the visualization required on average 28.1% less time (25.8 min vs. 35.8 min, p=0.01) while maintaining similar accuracy (73.7% vs. 67.0%). Users were then asked to create their own visualizations, with their visualizations averaging 86.1% similar to the gold standard. All participants either preferred the visualization over the status quo or preferred both equally. These results demonstrate that novel visualizations for trial reports could provide time savings and achieve similar accuracy as reviewing the paper itself. Understanding the strength and quality of clinical trials can be alleviated with a visualization that makes content explicit.

Introduction
Information within clinical trial reports can help inform clinical guidelines and support evidence-based medicine (EBM). Accurate interpretation of these results is important to characterize the quality and strength of a given clinical trial study. However, this information is difficult to assess, one reason is that its representation is free-text with numerical data scattered in tables, figures, and embedded in the text. A significant amount of effort is needed to identify and interpret information scattered throughout published reports, requiring the clinicians' and researchers' to organize this information mentally. This further complicates tasks such as assessing the strength of similar trials or comparing trials with conflicting results. The overarching goal of this work is to evaluate a visualization that links scattered data of a clinical trial together to better assess and understand its contributions.

The medical community is striving towards a structured representation to facilitate the deeper understanding of contributions from clinical trials. One attempt at standardizing the type of information within clinical trial reports is the Consolidated Standards of Reporting Trials (CONSORT), which comprises a checklist of essential items that should be included in reports of clinical trials and a diagram for documenting the flow of participants through a trial. CONSORT is a starting point to help investigators and others write or appraise trial reports, but its purpose is to promote good reporting, with no particular emphasis on appraising trial reports. Since CONSORT's founding, groups have worked on defining, structuring and standardizing information related to clinical trials. RCT Schema captures concepts related to a trial's design, basic intervention description, execution, administration, and results. These data structures create classes for specific types of information, with a standardized way to fill in classes and attributes. While structuring of data has been done mainly for the purpose of patient recruitment, few efforts have attempted to develop a representation for capturing the context of information for further interpretation. Clinical Research Eligibility Criteria Extraction and Representation (EliXR) addresses the disconnect in ambiguous eligibility criteria and clinical data results through developing a framework for eligibility criteria text. Our effort attempts to capture a wider spectrum of information and reported statistics necessary to perform quality assessment, relationships to piece information together, and a method for interactively presenting a published report to facilitate the user’s understanding of the study.

We have been developing a data model, which abstracts various types of information presented in clinical trial literature and connects these pieces together, and a visualization that allows target users (e.g., translational researchers, research students) to better interpret this information. We hypothesize that this representation and its visualization can facilitate understanding and analysis of clinical trial studies. In this paper, we specify a representation to classify information presented in clinical trial reports. We evaluate the visualization and report its performance, measured on a set of non-small cell lung cancer (NSCLC) clinical trial reports.
Methods

A usability study was performed to assess the benefit of using a standard visualization to understand the contents of a clinical trial report. In particular, we were interested in determining how well the visualization assists a researcher with understanding the published report's content, its ease of use, whether its presentation is intuitive to navigate and comprehend, and user preferences. Various aspects of the representation and visualization have been previously demonstrated\textsuperscript{10}, including methods for representing experimental flow\textsuperscript{11} and statistical analysis\textsuperscript{12}. In this paper, we briefly describe the representation model and the visualization. Results of the usability study were based on a comparison of interpreting information using the status quo published report versus the visualization.

The Representational Model

A representational model has been developed to store information presented in a published report. The first goal of this structured representation is to capture the essential elements related to recruitment, steps of the experiment, the data collection process, the data, the analyses, and the conclusions in a logical and consistent manner. The second goal is to provide context for observational data or reported statistics.

The model is functionally divided into purpose, methodology with raw data as a subgroup of methodology, statistical methods, and interpretations. These sections parallel the structure of a clinical trial report. Under the purpose section, the model captures the overall goal of the clinical trial with a free-text statement. The methodology section of the model contains a process model of nodes with a list of relevant variables, attributes, and values. Table 1 shows typical examples from a NSCLC clinical trial report\textsuperscript{13}.

Table 1. Example excerpts from clinical trial report\textsuperscript{13}.

The process model serves three purposes: (1) it documents the recruitment process using a flow chart to represent eligibility criteria, (2) demonstrates randomization by branching of nodes from one to many nodes, with each node representing a subpopulation, and (3) captures the overall study flow using nodes to represent specific types of experimental procedures. Typical types of nodes include general population, population sampling pool, decision boxes, recruitment criteria, control and intervention population, methods, and observation points. Each node is associated with a list of relevant variables, attributes, and values within a spreadsheet structure corresponding to the raw data stated in the published report. Together, the process model and linked spreadsheet allow fragmented knowledge pre-
sented in free-text, figures, and tables, to be placed in the context of the entire clinical trial "experiment." The statistical methods section of the model collects information from the text and displays it in a consistent manner with references back to the nodes of the process model and data elements from the spreadsheet. Each statistical method includes inputs from the spreadsheet, outputs as a measure of statistical significance, and a statement of significance. The interpretations section of the model captures the contributions of the clinical trial as stated by the published report.

The Visualization

The visualization assists with viewing and interacting with the contents of the representation from each clinical trial report. The visualization is divided into four panels following the structure of the model: (1) purpose of the trial, (2) process model and data grid, (3) list of statistical methods with variables compared and results, and (4) interpretations. The purpose of the trial and the endpoints are listed at the top of the visualization in free-text. The recruitment process and methodology are below. At the bottom are the interpretations summarizing the contributions of the published report listed in free-text (Figure 1).

The process of a clinical trial study is displayed as a timeline of events performed over the course of the entire study. In this example, the study population is recruited using three separate types of criteria: tumor status, presence of prior chemotherapy, and other clinical criteria. The study population is then randomized into three groups, control, low dose, and high dose; and each group undergoes a set of protocols. Note that the control receives no drug intervention as shown by a lack of yellow boxes in the control row (Figure 2).

Figure 2. Flow chart of events.

Directly below the diagramming interface, the methodology, raw data, and results can be viewed as a data grid. The variables appear on the left side, with one variable per row. Thus, the rows give an inventory of variables that are mentioned in the clinical trial study. The columns of the data grid correspond to different nodes in the process model. Any numerical data generated is placed along the same row as the variable and is beneath its corresponding event. Thus, each cell in the data grid is associated with an event node from the flow diagram and variable and the cell itself corresponds to the specifications or characterization of a variable for an experimental procedure of a group of patients for which the node refers to in the flow chart. A cell can show (1) summary statistics, and (2) all the patient values for a given variable, if available (Figure 3). We are working towards the customization of visualizing the data from individual cells. We are also developing methods to derive useful information from the data within related cells (e.g., points in Kaplan-Meier diagram where curves cross).

Figure 3. (Left) Example of data stored within a cell. Data is sorted by population and organized as individual data or population statistics. (Right) Graph generated by data. In this example, a Kaplan-Meier graph is drawn.

The panel for statistical methods provides a visual inventory of all the tests performed. Each test is listed with its corresponding inputs from the data grid, the test statistic, output statistics such as a p-value, and a statement of significance.
significance (Figure 4). For the purpose of the usability study, participants were presented with a mockup of the visualization in Microsoft Visio for each published report created; the final version is being implemented as an interactive application using Java.

Figure 4. Statistical method visualization. Inputs include experimental arm name, sample size, and variable. This is followed the statistical test within the box. Outputs include a quantitative measure of statistical significance, and a statistical statement.

Overview of Usability Study

The usability study had three objectives: (1) test the ease of interpretation and time saved against the status quo (i.e., the published report), (2) test the intuitiveness of the visualization through reproducibility of the visualization, and (3) elicit preferences from a targeted user group.

Paper cohort: Clinical trials were randomly chosen based on a PubMed search using the keywords "EGFR", "lung cancer", "non-small cell lung cancer", and "clinical trial" (Table 2). The search yielded 38 published reports which were different from the set of reports used to develop the original visualization. For the initial scope of this study, we randomly selected three papers that met the criteria of being a clinical trial about NSCLC involving EGFR mutations to assess time spent and accuracy. The fourth report was used for the study on reproducibility.

Participant recruitment: The participants were students with familiarity in biostatistics and informatics. In this usability study, students served as a proxy for potential users (i.e., biostatisticians and clinician researchers). The study for time spent and accuracy, and for eliciting preferences had 11 participants, and the study for reproducibility had 6 participants. All participants were asked in a pre-questionnaire about the length and fluency of their experience with clinical trial reports, non-small cell lung cancer, and statistics.

Task definition to assess time spent and accuracy: For the first objective, the participants used the visualization to answer questions demonstrating their comprehension of the clinical trial and recorded the time required to answer each question. Questions were divided into two types: comprehension to assess whether the individual is able to synthesize evidence from the published report, and information retrieval (IR) to focus on locating specific pieces of evidence in the report. Comprehension questions were developed based on reporting guideline requirements5, and
asked readers to interpret the objective and claims made in the published report. For example, one comprehension question asked: "The trial states 'This large prospective biomarker study found that patients with activating EGFR mutations derive the greatest PFS benefit from erlotinib maintenance therapy.' Describe the method, numerical data, and analyses for this statement." IR questions focused on locating key information as adapted from applicable CONSORT requirements. IR questions include reporting the eligibility criteria, locating the experimental arms, summarizing the methodology, and identifying the results of statistical tests. Questions of both types were presented using multiple choice, fill-in-the-blank, and short answer. All questions were reviewed by a biostatistician who was not involved in the development of the system to reduce bias in word-choice and to ensure conformance to standard guidelines and terminology. The gold standard was created by a domain expert who was given an open amount of time. Tasks were timed and graded for accuracy by determining the percentage of questions answered correctly.

**Study design to assess time spent and accuracy:** A two-arm randomized trial design was used with 11 participants and 3 clinical trial studies. The presentation of the trial was randomized for each participant and each participant reviewed clinical trial 1, 2 and 3 (Table 2). For each clinical trial, participants were randomized into the visualization study arm or the status quo study arm. In either study arm: (1) participants filled out paperwork (consent form, pre-test questionnaire) and received a tutorial on how to interpret the visualization based on two example questions; then (2) participants completed the usability sessions either with the status quo or visualization; finally (3) participants answered a post-questionnaire about the visualization (Figure 5).

**Task definition to assess reproducibility:** For the second objective, the participants were asked to generate a section of the visualization (i.e., the experimental flow) using a provided set of guidelines and a tutorial. Reproducibility was assessed through percent match of elements, nodes and variables. Elements are annotations given to a node, and can include sample size and time points. Nodes are used to label processes for recruiting a sample population and intervention processes. Variables describe and characterize a node. Example variables include randomization methods, baseline experimental procedures, and survival assessment methods. Tasks were compared with a gold standard created by a domain expert who was given an open amount of time.

**Task definition to assess user preferences:** A post-questionnaire was given to assess the affinity and usefulness of the visualization to gather impressions on the adequacy of its contents and to provide feedback on design, interface, and suggestions for additional functionalities. Participants answered questions using a Likert scale from one to ten, ten being very satisfied and very usable.

**Statistical Methods**

The participants used the status quo or the visualization to answer questions demonstrating their comprehension of the clinical trial and recorded the time required to answer the questions. The dependent measures of this usability study included time spent, measured in minutes; and accuracy, measured as the percentage of questions answered correctly. A weighted accuracy, combining time and accuracy, was calculated to place more emphasis on high accuracy scores that were obtained in a shorter amount of time. Descriptive statistics were computed for all measures.

\[
Weighted\ Accuracy = \frac{1}{Time} \cdot Accuracy
\]

Overall time spent and accuracy was determined by averaging over all values in each condition. Groups were conditioned on having either the status quo paper representation or the visualization. A pilot study was used to estimate the amount of time and accuracy for each task that was considered reasonable. A power calculation was performed to determine the appropriate sample size for the combination of participants and clinical trials needed. With an estimated time difference of 10 minutes (30 minutes vs. 40 minutes) and standard deviation of 8 minutes, a sample size of 12...
per group would yield an 83% power with 5% significance level. With an estimated accuracy difference of 15% (70% vs. 85%) and standard deviation 17%, a sample size of 12 per group would yield an 80% power with 5% significance level. Hence, a sample size of at least 24 is needed, meaning at least 8 participants each reading 3 clinical trial reports. This is satisfied by the number of participants enrolled. A 2-sided student’s t-test was used to compare (1) accuracy, (2) time spent, and (3) weighted accuracy using the visualization vs. using the status quo method.

Results

Participant Characteristics: Eleven student participants were involved in the study for time spent and accuracy, and for eliciting preferences; and six additional student participants were involved in the study for reproducibility. Participants ranged in experience from one to five years participated. All participants have read a clinical trial report before and took on average 80 minutes to read it completely. General participant characteristics are presented in Table 3.

Table 3. Characteristics of Participants. For confidence, scale values are 1 = not confident and 10 = very confident. For courses, values indicate number of college/graduate level courses.

Time spent and accuracy: In this usability study, time spent and accuracy was measured using self-reported completion time, and percent questions answered correctly. Non-significant differences were found in both time and accuracy between the visualization condition and the status quo condition for each clinical trial study (Table 4). The point estimate of report #2 was shown to have decreased accuracy as compared with report #1 and #2. The accuracy can be affected due to an increase in complexity of the study design and greater amount of content for both the visualization and status quo method. The accuracy for comprehension question and for IR questions were separated for exploratory analyses. The mean accuracy for comprehension questions within one reports suggests a difference between the visualization condition and the status quo condition, favoring the visualization (data not shown). This suggests that using the visualization can increase comprehension. This trend within reports are currently being studied in an attempt to significantly increase accuracy in the visualization.

Overall accuracy was similar between the visualization and status quo, however, participants with the visualization had on average a quicker overall time than participants with the status quo (visualization 25.8 ± 10.10 minutes vs. status quo 35.8 ± 9.94 minutes; p<0.01). This suggests that information is easier to locate in a visualization than in the status quo. While the visualization provided similar accuracy, the tradeoff is a significant times savings when compared to the status quo alone. The weighted accuracy results further demonstrated that participants with the visualization had a combined quicker time and increased accuracy than participants with the status quo (visualization 3.39 ± 1.66 vs. status quo 2.10 ± 0.87, range=0.71 to 7.00, p<0.008).

Reproducibility: Compared with the gold standard, the visualizations created by the six participants with limited training were 86.1% similar to the gold standard with a standard error of 6.45%. Dissimilarity was due to incomplete
visualizations as opposed to visualizations that differ fundamentally in structure. Out of all errors, 32% of the dissimilarity was due to neglecting to fill in available time points; 24% was neglecting to put in baseline experimental procedures; 12% was neglecting to fill in survival assessments time points; 12% was neglecting to put in events that can change the sample size, such as drop outs; and 20% was due to neglecting to fill in sample sizes for populations. The reasons for error and the high similarity score shows that our representation is logical and easy to understand for the participants in our usability study.

Preferences: All eleven participants preferred the visualization to the status quo, or preferred both the report and the visualization. No one preferred the status quo to the visualization. Participants rated the usefulness on average as 8.0 (7.1-8.9, where 10 is completely essential), and the satisfaction of the visualization at the current state as 7.8 (6.7-8.9, where 10 is completely satisfied). The likelihood of participants using the visualization again is reported on average as 87.2% with a standard error of 10.7%. Additional comments mentioned participants appreciated the clean and well-formatted visualization, but wanted more context, such as information covered in the introduction and discussion. Participants suggested additional development and/or functionality, such as having a summary box to better navigate a visualization that contains too many details and including the ability to distinguish significant findings visually. In general, participants found the visualization to be a good overview that assisted in understanding the clinical trial study.

Discussion

Understanding the strength and quality of clinical trials is a critical step in providing better healthcare to medical practice. Our previously developed visualization places essential information in context with a process model. A user can navigate through nodes to identify the population involved, its sample size, the procedures performed, and data that result. Because the visualization can help summarize essential elements and connect relevant elements together, it can be valuable for biostatisticians and research clinicians, who routinely access information from within clinical trial reports, and are considered our potential users. With any system, it is critical to examine usability issues pertaining to people of varying backgrounds in academia successfully accessing information needed within clinical trial reports. The goal of this study was to determine whether our previously designed visualization could be used to increase time saved and accuracy as compare to the current method, while maintaining an easy to understand format.

The results of the usability study were consistent with our intuition. We found that having the visualization required on average 28.1% less time (25.8 min vs. 35.8 min; p=0.01) while maintaining similar accuracy. These findings did not appear to be affected by participants’ varying levels of familiarity with the statistics, clinical domain (i.e., non-small cell lung cancer) and clinical trial procedures. This suggests that having essential information placed in context of the entire experiment helps users cognitively critique and apply contributions of clinical trials on a deeper level in a more timely fashion. This enables informatics tools to query information to be used for meta-analysis and probabilistic disease modeling and assist with the difficult task of assessing the quality and usefulness of each trial. The results of the reproducibility study showed that visualizations were on average 86.1% similar to the gold standard when produced by participants. This suggests that the proposed visualization is easy to understand and apply, and logically represents essential elements in a clinical trial study. This paper presents an attempt at identifying a standardized view that follows from intuition given that users have formal training in informatics.

While all participants favored the visualization over the current method, questionnaires revealed that much work is needed to improve the satisfaction and usability of the visualization. One solution to avoid bias of a less completely documented clinical trial study is to use the visualization to supplement an individual’s understanding gained from reading the status quo published report. While the study design proposed in this paper assigns participants to either the status quo or the visualization condition, in actuality, the two conditions are not mutually exclusive. This suggests that the combination of having a visualization to reference while reading the status quo published report can further help to save time and increase accuracy. One of the next steps include extending the evaluation to potential users. While the results from this study were gathered on students serving as surrogates, preliminary interviews with potential users show promise. In an unstructured interview, one biostatistics professor anecdotally noted that she liked the hybrid process model-spreadsheet for contextualizing observations and statistics.

We recognize one limitation is the current reporting of clinical trial studies, which may contain missing information. Because the visualization is designed to present the same information as the status quo, missing information can negatively affect the user satisfaction rating. Another limitation is related to the design of the task questionnaires. Because no standard list of questions exist to test comprehension of clinical trials, we tailored questions from standard reporting guidelines to determine the types of information necessary for comprehension. The final list of questions was confirmed by domain experts to determine if answering questions display understanding. We also need to address
the limitation of self-reporting (e.g., timing), which may be inaccurate. Another limitation includes the recruitment of participants and the selection of baseline assessment measures in the pre-questionnaire analysis. Participants were students that served as proxy for potential users. Classes provided a quantitative way to rank students, however, the assessment may not be accurate for non-traditional students who gained experiences outside of classes or have a time-lapse of many years between graduate and undergraduate courses. One more limitation relates to the issue with questionnaires based on the Likert scale. While Likert scales can pinpoint problem areas, they are unable to give information on the nature of the identified problem.

Conclusion

The current research addresses the usefulness of the visualization and tests its efficacy in understanding clinical trials in a timely manner. Our results suggest that the application can decrease time without sacrificing accuracy, the visualization is reproducible across multiple users, and the system is generally accepted in a targeted user group. With the abundance of clinical trial research, further work is necessary to translate the published report into a concise and informative visualization containing the same information but with more functionality. The logical structure of the results of clinical trial reports will allow computers to better assess the quality and strength of trials, extract important statistics, and assist in comparison of trials.

Acknowledgements

This work is supported by the NIH grant number LM011333. We thank James Sayre, PhD., and Grace Hyun Kim, PhD., for their helpful discussions and constructive criticisms. We also thank our domain experts, our pilot study participants, and all our usability study participants.

Abstract
This study presents a qualitative content analysis of nurses’ satisfaction and issues with current electronic health record (EHR) systems, as reflected in one of the largest international surveys of nursing informatics. Study participants from 45 countries (n=469) ranked their satisfaction with the current state of nursing functionality in EHRs as relatively low. Two-thirds of the participants (n=283) provided disconcerting comments when explaining their low satisfaction rankings. More than one half of the comments identified issues at the system level (e.g., poor system usability; non-integrated systems and poor interoperability; lack of standards; and limited functionality/missing components), followed by user–task issues (e.g., failure of systems to meet nursing clinical needs; non nursing-specific systems) and environment issues (e.g., low prevalence of EHRs; lack of user training). The study results call for the attention of international stakeholders (educators, managers, policy makers) to improve the current issues with EHRs from a nursing perspective.

Introduction
The benefits of converting from paper-based systems to electronic health records (EHRs) are being advocated for in various nations around the globe, leading for a push for healthcare professionals, including nurses, to adopt EHRs. In 2012, the EHR adoption rates were relatively high and those numbers grew in the last few years, for example: Sweden and Germany adoption rate was over 80%, the United States (U.S.) 69%, France 67%, Canada 56%, and Switzerland 41%¹.

An increased awareness of the importance of usability and other system issues have accompanied the increased adoption of EHRs by healthcare providers². A systematic review of empirical studies of EHRs identified the potential benefits of this technology in supporting patient care and clinical documentation³. However, reaping these benefits require addressing challenges related to implementation, adoption, and satisfaction of EHRs. The careful consideration of sociotechnical contexts and links between the clinicians, patients, and technology should be taken into account during the EHR development and implementation processes⁴. Barriers to EHR adoption included cumbersome system functionalities, lack of interoperability, and hardware issues in a study examining the use of EHR in community settings in the U.S.⁴. This study highlighted the impact of usability on nurses’ workflow, satisfaction, efficiency, and adoption of the EHR, as well as the importance of considering the interaction between system functionality, usability, and clinician workflow. The far reaching
negative effects of poor system usability are exemplified by the call for solutions to poorly designed EHRs by the American Medical Association in 2014. This resulted from physicians’ frustration and dissatisfaction with EHR usability and increasingly negative perceptions of EHRs since 2010. Nurses have expressed similar dissatisfaction with EHRs related to the system’s poor fit with clinical workflow, disruptions to productivity, and negative impacts on nurse-patient communication. In one survey of 13,650 nurses in the U.S. in 2014, 92% expressed dissatisfaction with EHRs, 85% noted that they struggled with continually flawed systems, and 67% reported using workarounds to avoid the unresolved flaws of EHR systems. Beyond causing frustration and being time-consuming for clinicians, poor EHR usability may also result in adverse events, medical errors, and other unintended negative consequences. Clearly, the usability of EHRs has important implications for patient safety and quality of care.

While the impact of EHR implementation on nursing is increasingly recognised, the complexities of how the technology is adopted in clinical nursing practice remains poorly understood. Nevertheless, nurses are still called upon to be key drivers towards the move from paper-based to electronic systems. Furthermore, nurses’ participation in decision-making, development, and evaluation of EHR development and implementation is being increasingly emphasized. Although nurses represent approximately one-third of hospital employees and nursing is one of the largest EHR user groups, nurses’ perceptions of EHRs are rarely surveyed and remain largely unknown. For example, only two out of 346 identified usability studies of healthcare information technology conducted between 2003 to 2009 examined systems use by nurses. A specific examination of usability issues related to nurses’ use of EHRs is warranted as the usability issues faced by nurses may differ from the issues faced by other healthcare professions.

The International Medical Informatics Association–Nursing Informatics Special Interest Group (IMIA-NISIG) Students Working Group members aimed to fill this gap in health information technology research by conducting an international survey of the state of nursing informatics. Our survey solicited responses from participants from 45 countries on various health informatics topics, one of which was the respondents’ perceptions of the usability of EHR systems. In this paper, we present the results of two survey questions related to respondents’ level of satisfaction with, and comments relating to, the current state of EHRs used by nurses.

Methods

Survey creation and distribution

This study had a cross-sectional survey design with online data collection. The questionnaire was developed based on current nursing informatics literature that explored current and future trends in nursing informatics. The questionnaire was iteratively developed, revised, and edited by the members of the IMIA-NI students working group. The group also shared the questionnaire with several international nursing informatics experts within the IMIA-NISIG leadership. Experts were defined as individuals with multiple publications that examined general informatics trends. Based on several rounds of expert recommendations, comments, and feedback, the group revised the questionnaire until a final version was developed. The online survey version used Google forms and was pilot-tested to assure its adequate functionality before the international distribution.

The study received a supportive ethical statement (Institutional Review Board exempt approval) from the University of Turku (Finland), where it was coordinated. The questionnaire was translated from English into six languages (Arabic, Korean, Portuguese, Spanish, Mandarin and Swedish). Each translation was conducted by a native speaking nurse with a background in informatics. The translation was validated by at least two other native speaking nursing informatics professionals and revised until the final version for distribution was generated. Responses to the open ended questions collected with the different translated versions of the survey were translated back to English for analysis. The translations were conducted by the nurses who translated the original survey questions and each translated response was validated for accuracy by one or two additional native language speakers fluent in English. Data were collected in August - October 2015. The following inclusion criteria were outlined in the survey invitation: any nurse (or other allied health professional) with experience in nursing informatics either in clinical practice or academia was eligible to participate. These groups were targeted in an effort to obtain a comprehensive overview of current trends in academia, as well as to explore issues with EHRs identified by clinicians. We used snowball sampling strategy to reach as many international respondents as possible. The IMIA-NISIG student working group’s members were invited to collaborate on the study and distribute a cover letter and the links to the survey to their networks. Eighteen students from fourteen countries actively participated in distributing the survey through their professional networks. These included global and local health informatics associations (e.g., IMIA, AMIA, etc.), clinical settings (hospitals and outpatient settings), and academic institutions.

The survey consisted of 24 questions with both structured and open-ended response options. Eight of the questions were focused on demographics (i.e., professional background; highest degree received; clinical or academic position; years of
informatics experience; and country and city) and eighteen questions pertained to the current or future state of nursing informatics.

To date, results of two survey questions related to current and future trends in nursing informatics have been presented in two published papers. This paper focuses on the two questions that related to respondents’ satisfaction with the current state of EHRs used by nurses. The two questions were: 1) Are you satisfied with the current state of nursing computerized documentation (in electronic health records) in your country/hospital?; and 2) If you are not satisfied with the current state of nursing computerized documentation (in electronic health records) in your country/hospital, please provide a few reasons. Responses to question one were collected using sliding Likert scale ranging from 1 to 10, where 1 indicated the lowest level of satisfaction and 10 the highest level. Responses to question two were open ended without a text length limitation.

**Conceptual framework:** A Stratified View of Health Information Technology usability evaluation (SV-HIT) was used as a conceptual framework to guide the qualitative analysis in this study. SV-HIT was created as a result of a review of 319 articles that evaluated health information technology used by clinicians. The model has 3 levels, as illustrated in Figure 1.

**Level 1- User-Task Issues:** Targets system specifications to understand any issues with user–task interactions during the system development. This level focuses on several key questions, including “How can an information technology system be used to support the needs/tasks?” and “What are the user needs?”; **Level 2- System Issues:** Targets task performance to assess systems and human–computer interaction, user–task–system or system–task interactions. The key questions are: “Does the information system work for the task?” and “What is the quality, speed, accuracy, and completeness of user -system interaction performance?”; **Level 3- Environment Issues:** Incorporates environmental factors to identify work processes and system impact in a real clinical setting. Key questions include: “What are the organizational, user and other factors affecting system use?” and “How does the system impact healthcare?”

**Quantitative analysis:** First, the general sample demographic and the professional characteristics were summarized. Then, respondents’ characteristics were compared between those who provided comments on issues with EHR versus those who did not, using standard statistical tests (Chi-square/exact Fisher test or t-test).

**Qualitative analysis:** Open-ended questions were independently analysed by two authors experienced with qualitative data analysis (CR and MT). Thematic analysis, a qualitative descriptive approach for identifying, analysing and reporting themes within data, was used to analyse the responses. First, each response was examined independently by the two authors and one or more themes for each response were suggested. Data were collated in an Excel spreadsheet. For example, the response, “The current EHR systems are cumbersome, not intuitive, and require too much clicking,” was classified as related to “Poor usability”. After an initial categorization of all the responses, the authors discussed the themes that emerged and consolidated them into eight major themes and an additional Other category. Each author then went back to the original responses and revised the themes for each of the responses. The themes for each response were then merged and the two authors achieved consensus on the themes for each response. Finally, each theme was mapped to one of the 3 SV-HIT levels (task- user/ system/ or environmental issues). For example, Poor usability theme was mapped to the System issues level whereas Lack of support at the hospital or policy levels theme was mapped to Environmental issues level. The results were shared with two additional authors for validation. The summary statistics and description of the major themes that emerged are presented in this paper. As illustrated in Figure 1, the three different levels have some degree of overlap. This was evident in our work where some themes that emerged were inter-related. For example, the Limited system functionality theme (System issues level) was related to the Systems failing to meet nursing clinical needs theme (User-task level), and vice versa.

Results

A total of 469 respondents (the sample for this paper) answered the question regarding their satisfaction with EHRs used by nurses. Table 1 presents the sample characteristics. Most of the participants were nurses (89%). The rest were other healthcare professionals, including health informaticians, pharmacists, biomedical engineers, etc. Most of the participants had at least a Master’s degree and more than five years of experience in informatics. Slightly more than one-third (36.2%) of the participants had formal training in informatics. When the question was relevant, most of the participants indicated that they occupied a middle management position or higher and/or held an academic rank of teacher or professor.

* Indicates p-value levels <.05 in bivariate comparisons (chi-square/exact Fisher test or t-test) of characteristics between participants who commented on the issues with nursing electronic health records vs. those who did not comment.

** Indicates p-value levels <.001 in bivariate comparisons (chi-square/exact Fisher test or t-test) of characteristics between participants who commented on the issues with nursing electronic health records vs. those who did not comment.

The respondents’ satisfaction with the current state of EHRs

The average satisfaction with the current state of EHRs used by nurses was 4.5 (SD= 2.3) on a scale from 1 (not at all satisfied) to 10 (very satisfied). Some geographic regions (and countries) were represented by a small number of respondents (e.g. from the African countries or Eastern Mediterranean region). We also conducted an association analysis between the respondents’ levels of EHR satisfaction and background characteristics (e.g., level of education, academic & clinical positions, etc.) but did not identify significant associations, thus, these results are not presented here.

The reported issues with the current state of EHRs used by nurses

Two out of three study participants (n= 283, response rate 60.3%) answered question two and provided comments regarding issues with the current state of EHR used by nurses. Table 1 presents a comparison between participants who provided...
comments versus those who did not. Participants who responded to question two had significantly (p<.001, t = 9.1, df = 467) lower scores (mean=3.7, SD= 2.3) for satisfaction with the current state of EHR used for nursing than non-respondents (mean=5.6, SD= 2.2). Overall, participants who commented on the issues with EHR had significantly higher levels of education (e.g., 30.9% of those who commented had PhD vs. 12.4% of non-respondents); had more years of informatics experience; were more likely to be formally trained in informatics; had higher levels of either clinical or academic positions; and were more likely be from the Europe or the Americas Would Health Organizations (WHO) regions, and not the Western Pacific region.

Nine themes were identified in the answers to question two, and each response was mapped to an average of two themes. Each theme was mapped to one of the SV-HIT levels. Overall, 562 concerns were identified in the 283 comments. The most commonly reported concerns were associated with system issues (54.5%), followed by user-task issues (27.5%) and environment issues (18%). Figure 2 presents the distribution of the concerns by SV-HIT levels and Table 2 presents the summary of concern levels, themes and examples of participant quotes.

### User-task issues

**Systems fail to meet nursing clinical needs**: Almost one-third of the respondents (28.6%) indicated that the systems did not meet their clinical needs. One common concern was the inability of the information systems to capture the patient story in either a narrative or structured format. An example comment was, “Too cookie cutter, does not allow for a narrative format, and does not capture the patient story [U.S.]”. Several respondents suggested that further work is needed to improve the utility of the EHR for clinical nursing. For example, “We need to develop better tools that are patient-centered and tell the patient story in ways that are easy and intuitive for healthcare providers to use [U.S.]”.

**Systems are not nursing specific**: Several respondents (16.3%) suggested that information systems do not work well for capturing, storing, and presenting nursing knowledge. Respondents indicated that some of the electronic systems were developed for billing or regulatory reporting needs, thus their usefulness for nursing is limited. For example, respondents suggested that, “Nursing documentation is driven by accreditation & regulatory needs rather than by what actually makes a difference to the patients/families/populations [U.S.]” and “The development of nursing information system is not based on nursing needs, but for the management of hospital expenses [China]”.

Overall, many respondents felt that the current information systems are not capable of reflecting and supporting key aspects of nursing practice. For example, “Systems do not adequately reflect nursing practice, especially the critical thinking and the processing of data and information to knowledge [U.S.]”. In addition, respondents reported that nursing clinical decision support tools were very uncommon. The respondents indicated that, “Current system does not include decision support that is valuable to nurses [U.S.]”.

### System issues

**Poor system usability**: Usability is defined as how easy it is for users to accurately and efficiently accomplish a task while using a system. In our survey, system usability was the most reported concern with almost one-third of the respondents (31.1%) identifying multiple usability issues. The existing systems were referred to as time-consuming and slow, requiring

---

**Figure 2**: Distribution of concerns reported about nursing electronic health records by level*

* Percentage of issues reflect the individual concern level out of total concerns reported, e.g., 127 user-task issues/ 562 total concerns = 27.5%.
too many key strokes to record simple information, and presenting multiple unnecessary screens that interrupt clinical thinking. Multiple respondents experienced issues with poor interface design and challenges with identifying and working with interdisciplinary documentation. Other respondents expressed that documentation is a burden and is often duplicative and hard to track chronologically. Some of the responses included, “The system is not friendly, need to open multiple screens to record information, very slow, and impractical [Brazil]” and “Time consuming, duplicate documentation, lack of discrete data, poor design, too many keystrokes, and nuisance alerts [U.S.]”.

Non-integrated systems and poor interoperability: About a quarter (23.7%) of the respondents indicated that either the systems, or the data that is collected in them, is not integrated with clinical workflows. Some of the common concerns included issues with multiple systems that were difficult to integrate. For example, “Many ‘silos’ and standalone solutions [Sweden]”, “Absence of integrated clinical database [Argentina]” and “Information is spread across many different systems [Belgium]”. One respondent noted that because they use multiple systems in their clinical practice, “Same information is documented in different areas so one ends up double, triple, and even quadruple documenting the same information [U.S.]”.

Lack of interoperability was an additional major concern for survey respondents. Many participants indicated that they require more connected systems to be able to see the patient data across care continuum and collaborate with other professions. For example, “The current systems are not sharing the pertinent information across care areas, such as homecare and acute care, there is also no sharing of information across provinces [Canada]”. Respondents felt that lack of information sharing prevents them from achieving optimal outcomes for their patients. For example, “For care coordination and achievement of the Triple Aim, need more health information exchanges between community - acute - primary care [U.S.]”.

Lack of standards & standardization: Another area of concern reported by some respondents (13.8%) was the lack of use of documentation standards and insufficient system standardization. Several respondents wished to see nursing terminologies implemented to standardize documentation and care quality assessments. For example, “Little comparison of the effect of clinical practice on patient outcomes - no clear way to compare since there is no standardization of terms, [Philippines]” and “Nursing needs to go further and use standardized languages to measure the effectiveness of interventions [Brazil]”. Several nursing terminologies were suggested to resolve the existing issues, such as the International Classification for Nursing Practice (ICNP®). Also, there were a few suggestions regarding the development of guidelines to promote interoperability and system standardization.

Limited functionality/missing components: About one-fifth of the respondents (20.5%) reported that their EHRs lacked at least one key functionality. For example, some suggested that there is not enough coverage for specific content areas, such as pediatric nursing, homecare, or care management. Some other missing areas, mentioned earlier in the paper, included a lack of nursing clinical decision support and inability to re-use nursing data that was already collected for epidemiology and other applied clinical or research processes.

Environment issues

Low prevalence of EHR systems: One-tenth of the respondents (10.6%) indicated that their environments (countries, or a specific health setting) did not implement EHRs comprehensively. For example, “Unfortunately 95% of nursing records are manual records [Venezuela]”; “Few electronic records are being used [South Africa]”; and “Still using paper based systems for nursing documentation with minimal electronic records [Australia]”. Other respondents indicated that their settings, such as homecare, do not have EHRs. A few respondents commented on the differences between regions within countries. For example, “Nursing EHR are only utilized in tertiary private hospitals. Public hospitals in most of the country, especially in provinces, still use paper documentation [Philippines]”.

Lack of users training: Some respondents (7.4 %) identified that insufficient user training prevents full use of EHR system capabilities. A few respondents believed that the generation gap between younger and older nurses requires different levels of training.

Other: Less frequent issues raised by the respondents were grouped as Other. One of the prevalent themes in this category was the lack of EHR support at organizational or policy level. For example, “Policy makers don’t even realize EHR importance so no one is taking any initiatives in this regard [Pakistan]” and “Nursing Councils should motivate Indian Nurses in using EHR [India]”. Others observed a lack of centralized initiatives regarding EHR adoption and/or development. For example, “No national policy to encourage hospitals to develop electronic nursing records [Taiwan]”.

2021
Discussion

Respondents assigned relatively low rankings regarding their satisfaction with the current state of EHRs used by nurses. Two thirds of the respondents specified their concerns with the current systems in their responses to the open ended question. Participants who provided comments to question number two, had lower EHR satisfaction scores, higher levels of education, more years of informatics experience, had higher level professional positions (in clinical practice and academia) and were more likely be from Europe or the Americas WHO regions than participants who did not provide comments. It is possible that more experienced and more educated participants were more likely to respond since they have experienced more EHR issues during their careers.

The literature review identified only a few studies that focused on evaluation of nurses’ use of HIT, and these studies tended to focus on one particular system domain such as usability21-22. Other interdisciplinary studies, mostly focused on medicine, identified similar trends with user perceptions of EHRs21-22. This study revealed low user satisfaction with EHRs that nurses use. More than half of the concerns were at the system issues level of the SV-HIT model, followed by user-task issues and environment issues. These results warrant further examination and potentially, are a call for the attention of international stakeholders (educators, managers, policy makers) to begin to improve the current issues with EHRs used by nurses. In practice, addressing system issues will rely on organizational supports to include end-users in the process of design, purchase, upgrade, and implementation decisions.

Specific user-task issues were identified that affected the ability of information system to support the nurse’s work. First, respondents reported that systems fail to meet nursing clinical needs, such as telling the patient story. The lack of EHRs' ability to tell the patient story is an emerging concern in the healthcare literature regarding system usability23. Respondents also suggested that neither strict structured formats (e.g., check-lists) nor free text documentation (e.g., narrative descriptions) help with clinical decision making. Rather, they hinder a comprehensive understanding of the impact of nursing on patient outcomes. This finding reflects a long-standing discussion regarding how much of the documentation in EHRs should be structured when compared to free text24. One possible solution to this is using automated extraction of important data from free text using natural language processing25. More research on the best balance between narrative and structured documentation to meet nursing clinical needs is needed. Another concerning theme was that EHRs are not nursing specific. Respondents felt that systems were developed either for other disciplines (e.g., medicine) or to meet billing and/or regulatory requirements. Although some literature exists on creating nursing-specific EHRs24, more research and practical recommendations are critically needed.

System issues were the most reported concern about the current EHR systems. In congruence with other studies on the topic21, 22, 27, 28, survey respondents believed that EHR systems suffer from poor usability, e.g., systems are time-consuming, slow, require too many key-strokes and overall burdensome. The survey results also confirmed the well-documented lack of systems interoperability29 and the absence of adoption of nursing terminologies30. Systems lacked key functionality for nursing, with the largest concern being nursing clinical decision support systems. Although some examples of successfully developed and implemented nursing clinical decision support systems exist31, our findings call for more development and application of these systems in clinical practice.

Respondents, mostly from developing countries, indicated that they only have few EHR systems in place. As the trend of EHR adoption increases internationally, driven by local legislations and other reasons, we expect this to change sometime in the next decade. Other environmental level issues included insufficient user training and a lack of EHR implementation support by management and/or policy makers. These issues are also supported by other U.S. and international studies30. In general, there is a need to educate nursing students, practicing nurses, faculty, nurse executives, and the inter-professional care disciplines on key aspects of nursing informatics. There are some existing approaches to increase education and awareness that can help address this issue32-33.

Limitations: Our study has several limitations. First, the generalizability of our survey results is limited due to small number of respondents from certain countries/geographic regions (e.g. from the African countries or Eastern Mediterranean region) and an overrepresentation of nurses with higher professional positions/academic degrees who answered the open ended question (question two). The snowball sampling approach was also limited by the reach of our respective networks and only reached certain organizations and practitioners while others were not included. Our respondents were informaticians and thus were more likely to identify system concerns compared to nurses without an informatics specialization. Further, only a fraction of the survey respondents identified specific issues, such as a lack of documentation standards (13.8%); it is possible that the remainder of participants may have been satisfied with the state of standard terminologies in their EHRs. Finally, respondents who answered the open ended question had a lower mean EHR satisfaction score and were mostly from Europe and North and South America, with fewer responses from Asia and Pacific.
Learning from these limitations, we are currently planning a follow-up study to explore EHR-related international concerns in more detail.

Conclusions

This study focused on nurses’ satisfaction and issues with EHRs. It is one of the largest studies of international trends in nursing informatics. Respondents from 45 countries ranked their satisfaction with the current state of EHRs relatively low. Two-thirds of more educated and more experienced study participants, mostly from the Europe or the Americas WHO regions, provided disconcerting comments explaining their low EHR rankings. More than one-half of the comments identified issues at the system level (e.g., poor system usability; lack of integrated systems and poor interoperability; lack of standards & standardization; and limited functionality/missing components), followed by user–task issues (e.g., systems fail to meet nursing clinical needs; and systems are not nursing specific) and environment issues (e.g., low prevalence of EHR systems; and lack of user's training). Although the study sampling and analytical approaches have limitations, the results call for the attention of international stakeholders (educators, managers, policy makers) to begin to improve the current issues with EHRs used by nurses.

Abstract

Introduction: Implementations of electronic health records (EHR) have been met with mixed outcome reviews. Complaints about these systems have led to many attempts to have useful measures of end-user satisfaction. However, most user satisfaction assessments do not focus on high-level reasoning, despite the complaints of many physicians. Our study attempts to identify some of these determinants.

Method: We developed a user satisfaction survey instrument, based on pre-identified and important clinical and non-clinical clinician tasks. We surveyed a sample of in-patient physicians and focused on using exploratory factor analyses to identify underlying high-level cognitive tasks. We used the results to create unique, orthogonal variables representative of latent structure predictive of user satisfaction.

Results: Our findings identified 3 latent high-level tasks that were associated with end-user satisfaction: a) High-level clinical reasoning b) Communicate/coordinate care and c) Follow the rules/compliance.

Conclusion: We were able to successfully identify latent variables associated with satisfaction. Identification of communicability and high-level clinical reasoning as important factors determining user satisfaction can lead to development and design of more usable electronic health records with higher user satisfaction.

Introduction

Healthcare institutions have been increasingly implementing electronic health records (EHR) over the last decade. These systems are very expensive and have mixed reviews. Despite many positive outcomes, clinicians continue to complain about difficulties with usability, lack of cognitive support or failures to match workflow in design. EHRs that provide cognitive support should be expected to match the users’ task-based mental processes such as perception, memory, reasoning and behaviour.

The degree to which systems fail to support clinical reasoning, interrupt complex thought processes and increase (rather than decrease) cognitive load have been cited as a major source of dissatisfaction. Studies show that irrelevant display clutter can negatively affect the clinicians’ ability to perform tasks and lead to clinicians missing critical information. Studies show that irrelevant display clutter can negatively affect the clinicians’ ability to perform tasks and lead to clinicians missing critical information.

User satisfaction is a combination of the ease of use and the degree to which the system supports work and is useful. In this paper, we are focusing on how well the system supports user’s perceived performance of high-level reasoning tasks. We created and validated an instrument based on high-level reasoning tasks as one way to explore underlying mental representations.

Background

Dissatisfaction with EHR Design

EHR systems with poor designs significantly increase the mental workload of a clinician while performing high-level cognitive tasks thereby reducing user satisfaction, increasing frustration, and causing ineffective work-arounds. Such poorly designed systems can also affect patient safety. A 2009 report by National Research Council of deployed EHRs studied how health information technology (HIT) is used in 8 different medical centers and noted that none provided the much needed cognitive support to clinicians, i.e. the high-level reasoning and decision.
making capacity that spans several low-level transactional tasks like ordering and prescribing. As per the report, IT applications are largely designed to automate simple clinical actions or business processes. These narrow task-specific automation systems that make up the majority of today’s health care IT provide little cognitive support to clinicians. For example, as Stead and Linn noted:

“Today, clinicians spend a great deal of time and energy searching and sifting through raw data about patients and trying to integrate these data with their general medical knowledge to form relevant mental abstractions and associations relevant to the patient’s situation. Such sifting effort forces clinicians to devote precious cognitive resources to the details of data and make it more likely that they will overlook some important higher-level consideration.”

This refrain is common amongst clinicians, but the exact nature of these higher-level “considerations” is not clear. Although EHR adoption has been steadily increasing, in part due to federal incentives, research suggests that the design and implementation of EHRs do not align with the cognitive and/or workflow requirements and preferences of physicians.

Prior research on identifying the cognitive tasks involved in healthcare delivery has come from a variety of traditions. Ethnographic studies assessing user’s needs in a clinical environment lists behavior actions, but often they do not make sense clinically and cognitively. For example, Tang, Jaworski and Fellencer, et al. (1996) observed 38 clinicians across several sites and found 5 types of activities: reading, writing, talking, and assessing the patient. Although accurate, these kinds of descriptions of activity types do not translate to understanding cognitive processing goals.

Complexity in health-care decision-making arises out of a multitude of factors, including sicker patients, general increase in the prevalence of chronic disease, and the increased emphasis on team care. The delivery of high-quality health care to patients increasingly involves multiple clinicians – primary care physicians, specialists, nurses, technicians and others – all of whom are required to deliver effective coordinated care. Each clinician has specific, limited interactions with the patient and thus a somewhat different view resulting in increased fragmentation or compartmentalized into silos of facts and disconnected symptoms. Although ONC (Office of the National Coordinator for Health IT) encourages the use of EHRs across the continuum of care, problems in continuity of care continue.

A qualitative study conducted by AHRQ on clinician’s recommendations for improving clinical communication and patient safety, found that HIT and organization of EHR information were the most frequent safety solutions recommended by clinicians to address problems in clinician-to-clinician communication. Moreover, clinicians envisioned EHRs to become the desired “one source of truth” for a patient’s medical information. How this source of truth is organized, accessed and displayed remains problematic.

**Mental Representations of Tasks**

Authors in information systems research examining "task-technology fit" (TTF) also focus on task definition. TTF was proposed early by Goodhue and others and expanded by Ammenworth and Lee with the goal of examining the degree to which a system helps to support user’s tasks. The premise is that satisfaction (and use) is derived from a good match between the tasks and the technology. Some of this work examined the impact of data representation on task performance and found performance dropped rapidly when data representation did not reflect cognitive processing. Some of this work focused on dimensions of tasks and not the cognitive representation of behavior.

In this paper, we approach defining clinical tasks based on the Theory of Action Identification. Assessing the clinician’s high-level cognitive actions or tasks require exploring the mental representation of action. According to Action Identification Theory, behavior is controlled by hierarchical representations that are a group of associated neurons and pathways that include behaviors, schemas, and goals. Specific movements involved in an action, such as typing or searching or scrolling are at the “bottom.” The higher-level component of the representation includes the goals, intentions and associated values. A core principle is that expert behavior is controlled and cued at the highest levels possible. In other words, when physicians start to investigate the best treatment for a cancer or they initiate a plan for helping the patient control their diabetes, they are not really engaged in typing, sifting, sorting and scrolling or even in looking for Hemoglobin A1C trends over time. They are actually looking to see if the treatment protocols are working. That high-level action identification is supported by a myriad of smaller information representations and physical actions. The other key aspect of this theory is that behavior that is functioning at the highest level of its representation is more fluid, uses less cognitive resources and is more satisfying. Think about what happens to an expert musician when you ask them to think about where to put their fingers. They may become
distracted and lose focus. Similarly, high-level reasoning actions are also interrupted when they cannot “flow” due to an increase in the difficulty of actually performing the task.

The high-level identities of many clinical tasks have not been made explicit. As a result, designing EHR to support those tasks is difficult. In addition, evaluating the success of systems to support those tasks remains indirect and is often limited to simple usability testing. General usability metrics often neglect high-level reasoning tasks or activities and do not discriminate between high-level reasoning difficulties and those difficulties associated with the interface itself.

**Objectives**

In this study, our goal was to explore the characteristics of high-level tasks by generating task-based questions for a survey from prior work (observations, interviews, and surveys) and validating the instrument using factor analysis to determine latent task structures. If the factor analysis revealed a clustering of items together that reflected the tasks, then we would have established one form of validation. We used exploratory factor analysis, an analytic technique used for examining latent structures in a set of items. The ultimate goal is to develop a method of measuring user satisfaction that addresses high-level reasoning tasks and provides useful directions for design of an effective EHR.

**Method**

**Design:** The study was conducted in 3 phases. First, we identified an initial set of 51 questions addressing clinician tasks from prior literature and our own work. The top most frequent and important questions were preserved after pilot testing and were used to build the final survey instrument. The final survey was conducted among practicing clinicians across all levels of service in multiple specialities. Second, an exploratory factor analysis of the survey results was conducted. Finally, scales were created using tests of Cronbach’s alpha reliability and evaluation of item loadings on derived factors. The aggregate ratings of those scales were used to predict the overall judgment of how well the system supported work performance. Specific details are outlined in results.

**Setting and Sample**

The University of Utah Institutional Review Board approved this study. Data collection was conducted at a large, >500-bed academic hospital located in Salt Lake City, Utah. We identified and targeted 189 residents, fellows and attendings who were currently posted at the University of Utah hospitals or the Huntsman Cancer Institute and were using EPIC EHR for their in-patient care. We used direct approach, email public link to the survey or email personal link to contact the targeted participants for the survey. All email links were created using the REDCap survey tool.

Residents were the targeted participants were approached during one month, in December 2015, 18 months following EPIC implementation.

For purposes of statistical analysis service domains were broadly categorized into “Medical Specialties” which includes: Internal Medicine, Anesthesiology, Physical Medicine and Rehab, Psychiatry, Neurology, Pediatrics, Cardiology, Gastroenterology, Rheumatology and Family Medicine, and “Surgical Specialties” which includes: General Surgery, Cardiovascular Surgery, Obstetrics & Gynecology, Neuro Surgery, Plastic Surgery, Orthopedics and Urology.

**Phase I: Item Selection and Evaluation**

An initial set of 51 tasks were created based on our prior research and information needs as well as from the general recommended areas of concern noted by Stead and Linn. This report highlighted 7 information sensitive domains identified in Institute of Medicine’s vision for 21st century healthcare: a) integrate patient information from various sources, b) integrate evidence base with daily practice, c) developing tools for portfolio management of patients at an individual and population level, d) rapid integration of new knowledge into a ‘learning’ health system, e) extending care (treatment and monitoring) beyond hospitals through better communication and technology, thereby empowering patients in the decision making process more effectively. The items were all identified as tasks that clinicians needed to accomplish during the course of their work. We designed the questions to be about at the same level of abstraction and to reflect general domains of work, e.g. patient assessment, diagnosis, teamwork.

The items were extensively pilot-tested and then rated by 8 physicians as to their frequency/importance on a 1 (Very Low) to 5 (Very High) scale. The final set of questions included those that were rated in the top 50%. (n=21).
The final survey questionnaire had 3 parts. The first part included demographic questions about the participant including name, department affiliation and level year. For the second part, clinicians were asked to respond to the question “While caring for hospitalized patients, how well does Epic help you to…” The responses were captured in a Likert scale ranging from 1 (very poorly) to 5 (very well). The third part consisted of a free text comment box, where the user was asked to add any additional comments he/she had. The questions used in the survey instrument are listed in Table 2.

Phase II: Validation of Factor Structure and Variable Creation

Factor analysis has long been used in the social sciences to assess for underlying latent structure in perceptions and mental variables which cannot be measured directly (e.g., intelligence). Multiple methods have been devised for determining these factors (latent variables), all of which center on determining the pattern of correlations between variables. A pattern of correlations amongst the questions may reveal clusters that suggest those questions are measuring the same construct. Inspection of the resultant patterns of correlations (factors) provide evidence of a latent structure. We conducted an exploratory factor analysis using a correlation matrix with varimax rotation. Recommendations for the sample size varies with some recommending as low as 5 participants per question and as many as 10 or more. Our analysis showed each common factor was over-determined with at least 5 measured variables representing each common factor. As few as 3-4 measured variables per common factor can reduce the required sample size to approximately 100, which is consistent with our sample size.

Items loading on the same factor with a loading value of greater than 0.5 and not loading greater than 4.0 on another factor were combined (summed and averaged) to create 3 new variables (or scales). The reliability of these new variables were assessed using Cronbach’s alpha with an acceptability criteria of greater than 0.80.

Phase III. Predictive Validity Assessment

The 3 newly defined variables were then regressed on the rating of overall efficiency to validate their association with performance using linear regression.

Results

Study population

Of the 189 targeted clinicians (residents, fellows, and attendings) who were working in the system at the time, 47.6% (n=90) participated in the survey. The distribution of respondents by level and domain are presented in Table 1 below. Two participants did not disclose their service category (department) and one participant did not disclose the level year of service.

**Level of service**

Participant sample for this study included clinicians from post graduate year 1 to post graduate year 7, fellows and attending physicians. Total user satisfaction score was calculated for all the participants and were categorized based on the year of service. Average satisfaction score for each level of service was calculated by dividing the total score of all participants in each level year by the product of total number of participants in each level year and the number of questions answered (Figure 1).
Factor Analysis

An exploratory factor analysis using the correlation matrix was conducted using varimax rotation. The number of factors was constrained to 3 based on inspection of the scree plot showing 1 factor with a large eigenvalue (amount of variance) and 2 smaller factors (which we preserved for theoretical reasons). There were 4 factors with eigenvalues above 1.0; however the lowest one explained only 5.26% of the variance with an eigenvalue of only 1.04 so it was excluded. Eigenvalues are a measure of how much of the observed variables’ variance is explained by the factor. The initial eigenvalues show that the first factor explained 48.85% of the variance, the second factor 6.75% of the variance, the third factor 6.11% of the variance and the fourth factor 5.26% of the variance (see Table 3). Any factor with an eigenvalue ≥ 1 explains more variance than a single observed variable and is the minimal acceptable level to be included as a factor. The first 3 factors explained 62% of the variance.

Table 4 displays the items and their associated factor loadings. The questions related to each of the 3 factors were examined and the factors were identified as: 1) High-level clinical reasoning (i.e.: complex thinking about patient information, such as linking meds and labs); 2) Communication /coordination (i.e.: those items associated with shared responsibility of care, including communicating with team or the primary care physician (PCP)); and 3) Following the rules / compliance (i.e.: following billing rules/ following clinical guidelines). These labels are descriptive of the underlying construct. Two questions did not show a strong association (above 0.5) with any factors (questions 6 and 7).

Scale Construction

Composite scores were created for each of the 3 factors by summing the items highlighted in Table 4. Higher scores indicate higher satisfaction. Reliability was tested for each item. All were acceptable as measured by Cronbach’s alpha (see Table 5).

Regression and Predictive Validity

The 3 constructed variables, communication/coordination, compliance/follow the rules and high-level clinical reasoning were regressed on the rating of overall efficiency using forward entry. The overall model was significant (R=0.54; p=0.00) with communication entering in first with the largest component and high-level clinical reasoning entered on the second step producing a significant R2 change (R=0.59; p=0.04). Compliance (follow the rules) was not significant after the other 2 variables were included in the model.
**Discussion**

Our exploratory factor analysis successfully explained 62% of the overall variance in the items and 3 latent high-level cognitive tasks were validated with the factor structure. These can be thought of as latent variables referring to overarching “groups” of actions. They also illustrate how clinicians are trying to use the EHR to accomplish their work and identify high-level intentions for action in the clinical environment.

The overall means across these 3 variables were not meaningfully different, although they correlated significantly. All were in the middle of the scale (around 3.5) indicating mid-level of satisfaction. The validity of the constructs were also supported by the regression results with communication/coordination and high-level reasoning explaining most of the variance in overall satisfaction.

Current user satisfaction studies focus on specific functionalities and technical attributes of the system rather than a deep understanding of the cognitive processes that influence the end-users’ usage of the system. Specific models like the Technology Acceptance Model (TAM) suggests user perceptions of ease of use and usefulness as major determinants of user satisfaction. Additionally, Delone and McLean information system success model suggests other determinants of user satisfaction like user characteristics, a) system usefulness and b) service quality. None of these address satisfaction regarding the ability of the system to support high-level cognitive work. A popular usability measurement instrument, System Usability Scale (SUS), is a 10 question survey instrument which focuses on the user perception of a system’s usability and learnability metrics. However there is very little information that can be inferred from the SUS regarding the system’s ability to support high-level cognitive tasks, communicability or compliance with regulations.

Our research strongly suggests that user satisfaction is determined by factors well beyond those suggested by the above models. We identified 3 high-level tasks factors: a) ability to communicate/coordinate care between teams, b) ability to conduct cognitive tasks and c) ability to abide by the rules, as independent determinants that significantly influence the end-user satisfaction with our EHR system. Our findings validate the common clinician complaints about the lack of support to carry out cognitive tasks and collaborate between teams observed in previous research. Amongst the 3 high-level task factors, we found that communication/coordination had the strongest relationship with overall efficiency leading to highest perceived user satisfaction.

These findings suggest that the ability of EHRs to support these high-level tasks could be one crucial factor in determining overall user satisfaction. However, we may not have identified all of the attributes related to high-level action identities. Different contexts would likely be associated with more variety in the specific high-level tasks in which clinicians are engaged as well as the amount of non-EHR support. This pattern would explain why a system may be well received by users within one context, but rejected in another. As clinicians’ tasks vary from one setting to another, system vendors and system optimizers should modify their current approach and try to understand this dynamism and optimize the system accordingly.

**Implications for Providing Cognitive Support**

Clinicians’ cognitive resources are limited, and therefore any task which forces them to divert their attention away from patient care to data acquisition and interpretation should be avoided. Functionalities that support coordination, communication, shared views and negotiated responsibilities might be more important than realized. In addition, systems should be able to provide a holistic picture of the data in a complete patient context and its relevance to the situation at hand. Having this holistic picture can significantly reduce the cognitive effort required while conducting high-level tasks.

**Clinical Implications**

Our study shows that ability to communicate and coordinate between various clinical teams with relative ease and efficiency is associated with significantly higher user satisfaction amongst clinicians. As healthcare evolves from an individual doctor – patient relationship to a multidisciplinary team-based approach, the functionality of electronic health records to support collaboration between the teams proves to be crucial in a successful EHR implementation. Another important factor that determines user satisfaction was found to be the ability of the system to support high-level cognitive tasks conducted by the clinicians. These findings should prompt EHR vendors to undertake further system modifications to support these functionalities. It would also encourage clinical informaticians to undertake system optimization projects where they could study the various cognitive tasks within different contexts, and to implement practical solutions.
**Limitations**

The sample size to support a factor analysis was only minimally acceptable. The use of one variable assessing overall satisfaction might limit reliability. Finally, the study was conducted at only one site, which may impact generalizability. Even so, this study was intended to be exploratory and involved a newly-developed instrument which can be used and further validated by others.

**Conclusion**

Our research significantly increases our understanding of the determinants of end-user satisfaction with electronic health record (EHR) systems. We find that measuring a system’s ability to carry out high-level tasks has a much higher influence on end-user satisfaction than currently measured determinants. These findings could be adopted by system vendors as well as system optimizers in the future to create effective and efficient electronic health records that generate true value to the end-user.

Learning Effective Treatment Pathways for Type-2 Diabetes from a clinical data warehouse

Rohit Vashisht, PhD1, Ken Jung, PhD1, Nigam Shah, MBBS, PHD1

1Center for Biomedical Informatics Research, Stanford University School of Medicine, Stanford, CA, United States

Abstract

Treatment guidelines for management of type-2 diabetes mellitus (T2DM) are controversial because existing evidence from randomized clinical trials do not address many important clinical questions. Data from Electronic Medical Records (EMRs) has been used to profile first line therapy choices, but this work did not elucidate the factors underlying deviations from current treatment guidelines and the relative efficacy of different treatment options. We have used data from the Stanford Hospital to attempt to address these issues. Clinical features associated with the initial choice of treatment were effectively re-discovered using a machine learning approach. In addition, the efficacies of first and second line treatments were evaluated using Cox proportional hazard models for control of Hemoglobin A1c. Factors such as acute kidney disorder and liver disorder were predictive of first line therapy choices. Sitagliptin was the most effective second-line therapy, and as effective as metformin as a first line therapy.

Keywords: Type-2 Diabetes, Learning Health Systems, Treatment Pathways, Second-line treatment options

Introduction

Type 2 diabetes mellitus (T2DM) affects an estimated 29.1 million people in the United States [1]. Its global prevalence is projected to reach 440 million adults by the end of 2030 [2]. Current treatment guidelines, which are derived from a few randomized controlled trials [3-6], recommend the use of metformin as first line mono-therapy [7]. However, when metformin exhibits adverse effects or fails to control diabetes, the second line therapy must be chosen, and there is little consensus on how to choose a second line therapy; with the American Diabetes Association recommending sulfonylureas, meglitinide, pioglitazone or dipeptidyl peptidase 4 inhibitor (DPP4) as second-line agent [8], and the American Association of Clinical Endocrinologists recommending alpha-glucose inhibitors, DPP4 inhibitors and GLP-1 agonist [9]. Given the availability of myriad treatment options for second-line therapy, the problem of selecting an optimal second-line agent requires urgent attention.

In contrast, knowledge captured during routine clinical care in Electronic Medical Records (EMRs) has ushered in a new era of learning health systems that can provide evidence for medical decision-making beyond that from formal clinical studies [10]. Initiatives such as the Patient-Centered Research Institute (pcornet.org), Observational Health Data Science & Informatics program (OHDSI) (ohdsi.org) and the Green Button [11] exemplify early efforts towards building learning health-care systems. In one recent study, analysis of data by the Observational Health Data Science and Informatics initiative revealed significant diversity in the choice of first line therapy for T2DM [12]. Harnessing data from 11 databases that collate 250 million records into a unified common data model, the study found that metformin was the predominant initial choice of therapy but that other choices were also common. Substantial heterogeneity in the prescription of second-line agents was also noted, highlighting a gap in available clinical guidelines for management of T2DM. Important clinical questions such as the factors that determine the initial choices of treatment, and the effectiveness as well as the optimal choice for second-line therapy were not addressed.

In pursuit of these goals, we set out to perform a systematic analysis of treatment-pathways in T2DM using data collated in Stanford’s clinical data warehouse[13]. We recapitulate previous work regarding variation in the choice of first line therapy, and find clinical factors that are predictive of the first line therapy choice that are consistent with biomedical knowledge of adverse effects associated with metformin. Finally, we
demonstrate the feasibility of assessing the relative efficacy of different choices of second line therapy in controlling HbA1c. We find that sitagliptin appears to be as effective as metformin as a first line therapy, and is considerably better than other options as a second line therapy. At present, our analysis is limited to data from Stanford Hospital, and is an example of a research study that can be extended to any site that has adopted the OHDSI common data model.

Methods
Data Source
The electronic medical records of 2.1 million patients were obtained from the Stanford Clinical Data Warehouse under an approved IRB protocol [13]. Patient satisfying the following creation were selected for our study cohort. The index date of each patient was defined as the date of the first prescription of any of the drugs considered in this study following at least one mention of a T2DM ICD9 code. Patient were required to have at least 90 days of data prior to their index date. Patients were also required to have at least one HbA1c measurement following their index date to be included in the analysis of treatment pathway efficacy.

Practice-Based Treatment Pathways
Our approach extracts sequences of drug prescriptions from the EMR, reflecting treatment decisions made in actual clinical practice. We call such sequences “practice based treatment pathways”, and they are the basis of our analysis of factors influencing the choice of initial treatment as well as the relative effectiveness of different treatment options. First, we construct a cohort of diabetic patients using criteria described above and summarized in Figure 1a. Treatment pathways were constructed by following the medication trajectory of patient from their respective index dates.

Our analysis was focused on two types of treatment pathways. First, in order to focus on the factors influencing the choice of first line therapies and their efficacy, we considered treatment pathways consisting of a single drug. Second, we considered treatment pathways in which the second prescription was different from that of first, with the first prescription lasting at least 30 days. Current guidelines suggest intensifying therapy after two months of the initial therapy if the desired HbA1c goals are not met [9]. At present we restricted our analysis to have required a minimum gap of at least 30 days before the prescription of next drug, which can be relaxed in future analysis. The treatment pathways with a second prescription were used to evaluate the efficacy of second line treatments.

Table – 1 Drugs considered in this study.

Clinical Factors Associated with Initial Choice of Therapy
Clinical factors associated with the choice of initial therapy were found by fitting logistic regression models with an L1 regularization, using drug and disease codes prior to the patient’s index time to predict the choice of first line therapy. This analysis was done using the glmnet package in R [14].

Efficacy of Practice-Based Treatment Pathways
The relative efficacy of pairs of treatment pathways were assessed using Cox proportional hazard models adjusted for age and gender. Patients on a specific treatment pathway were considered only if they had a follow up lab value reporting HbA1c profile after the index date. Since the number of HbA1c measurements...
following their index date differed among patients, we considered only the first lab value after the index date. Four levels of HbA1c (6.5%, 7%, 7.5% and 8%) were selected as target thresholds for clinically relevant “control” of HbA1c. For a given target threshold, the time to event was defined as the time at which the first measured HbA1c after the index time was below the threshold. Patients were considered censored if their first reported HbA1c measurement was above the threshold. The hazard ratios and 95% confidence intervals were then computed using cox regression, adjusting for both age and gender of patient.

Results

Practice-Based Treatment-Pathways
The cohort consisted of 6121 patients; most were between 40 to 80 years of age. The gender distribution of patients was observed approximately even, with 2989 females and 3132 male. The ethnicity of the cohort was varied, with Asian (n = 1277), White (n = 2517), Native Hawaiian/other Pacific Islander (n = 168), Black/African American native (n = 357) and American Indian (n = 19) patients, and 1783 patients with unknown ethnicity.

![Figure 1](image)

Figure 1 a) Criteria for cohort construction, b) distribution of patients based on their initial prescription and c) distribution of patients with metformin as initial prescription followed by another drug.

Treatment-pathways were constructed by following the medication trajectory of each patient starting from their respective index dates. Figure 1b illustrates the distribution of first line therapy choices. As expected,
metformin was the predominant first line therapy. However, other drugs such as glipizide, glyburide, pioglitazone and sitagliptin were also used as first line therapies, recapitulating the findings of the OHDSI study. Figure 1c illustrates the distribution of patients who were prescribed metformin as their first prescription but were then prescribed other drugs over a period of time reflecting the choices of second-line treatments. Overall, the trends of initial prescription pattern were consistent with the earlier analysis by OHDSI [12].

Clinical Factors Associated with Choice of First Line Therapy
We searched for clinical factors that are able to explain the choice of first line therapy by fitting L1 regularized logistic regression models [15] to predict first line therapy choices based on the drug and disease codes occurring in the medical record prior to the index time for each patient. Due to the small number of patients in most treatment pathways, this analysis was carried out only for two pairs of initial drug choices: metformin versus glipizide, and metformin versus pioglitazone. Identified factors for each of these treatment pathways are shown in Table 2 below.

Table 2 Clinical factors predictive of initial choice of therapy. The listed factors are all predictive of the use of glipizide or pioglitazone instead of metformin as first line therapy.

Factors identified in the first comparison, metformin vs glipizide, are consistent with prior knowledge about adverse events associated with metformin. For instance, the choice of glipizide as first line therapy was associated with manifestations of chronic kidney diseases and liver disorders. This is consistent with earlier observations that metformin may induce severe lactic acidosis, which can impair kidney function [16] and thus would be avoided in patients with kidney disease. Another interesting factor is use of the antibiotic cefepime. Earlier investigations suggest a possible drug-drug interaction between cefepime and metformin resulting in reduced efficacy of metformin [17]. On the other hand the factors such as “cirrhosis of liver without mention of alcohol” were predictive of metformin use, consistent with studies showing that metformin is beneficial to diabetes patients with cirrhosis [18].

Similarly, factors associated with initial choice of metformin vs pioglitazone are also broadly consistent with prior biomedical knowledge. For instance, “coronary atherosclerosis of native coronary artery” was predictive of first line use of pioglitazone, consistent with work suggesting that pioglitazone may protect against adverse cardiac events in patients with impaired glucose tolerance [19]. Altogether the identified factors suggest that deviations from the recommended use of metformin as first line treatment for T2DM are largely driven by comorbidities and concerns about adverse events.

Efficacy of Treatment Pathways
The efficacy of pairs of contrasting treatment pathways were assessed by fitting Cox proportional hazard models against the outcome of lowered HbA1c levels (Figure 3). These models compare the rates of outcomes of interest over time in two contrasting groups. We compared five pairs of treatment-pathways. The first three are alternative first line therapy choices (metformin vs glipizide, metformin vs pioglitazone, and metformin vs sitagliptin), while the last two reflect second line treatment choices after metformin (metformin to glipizide vs metformin to pioglitazone, and metformin to pioglitazone vs metformin to sitagliptin). For each of these pairs of treatment-pathways, we computed Cox proportional hazard ratios adjusted for age and gender against a series of outcomes reflecting different levels of HbA1c control – 6.5%, 7.0%, 7.5% and 8.0%. A hazard ratio greater than one means that the treatment pathway highlighted in red text is more effective than the reference treatment pathway (in black text).

As expected, metformin as a first line therapy appeared to be quite efficient in lowering HbA1c compared to glipizide and pioglitazone (Figures 3a and b). Metformin as a first line therapy also showed no significant reduction in the HbA1c profiles in comparison to sitagliptin (Figure 3c), suggesting sitagliptin might be a useful initial therapy controlling the HbA1c profiles to desired levels in situations where metformin is contraindicated due to comorbidities.
The comparisons of treatment pathways with a second line drug suggest that both pioglitazone and sitagliptin are superior to glipizide when added on following metformin, and that sitagliptin is more effective than pioglitazone (Figure 3d and e). If these results hold in other datasets, they suggest that sitagliptin should be considered over glipizide and pioglitazone as second line treatment.

**Discussion**

The choice of second-line treatment for T2DM is not evidence-based due the lack of randomized controlled trials assessing their relative efficacy. Treatment pathways for T2DM derived from observational data in EMRs have been used to elucidate what actually happens in routine clinical practice. We have shown that further analysis of such treatment pathways can also provide insight into why alternative treatment pathways are taken, as well as their relative efficacy. Consistent with work from OHDSI, we found that there was considerable variation from current guidelines in choosing the first line treatment. We then took the next step and identified clinical factors underlying the choice of first line therapy. These factors are consistent with known adverse effects of metformin, as well as comorbidities. Furthermore, analysis of the comparative effectiveness of different treatment pathways suggest that sitagliptin may be as effective as metformin as a first line therapy, and could be an effective choice as second line therapy in cases where monotherapy with metformin fails.

The present analysis is based only on data from Stanford Hospital, which is limited in its population coverage and hence can introduce biases that limit the generalizability of our findings. Furthermore, the strict inclusion criteria regarding pre- and post-index time history result in a relatively small cohort that renders matching on co-morbidities and other patient features before fitting the hazard model problematic. Thus, our results may also exhibit bias due to confounding. It is thus important to replicate this study across multiple sites and in larger cohorts to build generalizable recommendations.

Our initial analysis can be scaled up within the OHDSI research community. Expanding the scale of our work to include data from many different sites may provide further insights into the practice of diabetes management, complement the design of comprehensive clinical trials and help fulfill the goals of learning health-care systems.

**Conclusion**

We have demonstrated the use of observational data from EMRs to address outstanding problems in the management of T2DM that lack evidence from RCTs. These problems include the factors underlying deviations from current guideline recommendations on first line therapies and the relative efficacy of both first and second line therapies. Our approach is easily scalable to incorporate data from any site that has adopted the OHDSI common data model.

Melinda – A custom search engine that provides access to locally-developed content using the HL7 Infobutton standard

Yik-Ki J. Wan, BS1, Catherine J. Staes, BSN, MPH, PhD1,

1Department of Biomedical Informatics, University of Utah,
Salt Lake City, Utah, USA

Abstract

Healthcare organizations use care pathways to standardize care, but once developed, adoption rates often remain low. One challenge for usage concerns clinicians' difficulty in accessing guidance when it is most needed. Although the HL7 ‘Infobutton Standard’ allows clinicians easier access to external references, access to locally-developed resources often requires clinicians to deviate from their normal electronic health record (EHR) workflow to use another application. To address this gap between internal and external resources, we reviewed the literature and existing practices at the University of Utah Health Care. We identify the requirements to meet the needs of a healthcare enterprise and clinicians, describe the design and development of a prototype to aggregate both internal and external resources from within or outside the EHR, and evaluated strengths and limitations of the prototype. The system is functional but not implemented in a live EHR environment. We suggest next steps and enhancements.

Background and Significance

Among industrial nations, the US ranks highest in health care costs and last in quality, efficiency and patient outcomes. In a recent White House report, the US President attributed these inefficiencies to the lack of coordination of care, over-treatment, and the failure to adhere to best practices. For example, one study shows that 53% of patients who have undergone cataract surgery still received unnecessary preoperative testing even though guidelines recommending against such testing were published 20 years ago. To address these problems, healthcare organizations began developing care pathways to standardize best practices. However, difficulties with accessing these care pathways at the point of care impede adoption. Therefore, organizations use a variety of knowledge management solutions for delivering resources and guidelines, ranging from storing static documents in a shared network location, customizing off-the-shelf products (such as Microsoft SharePoint), configuring internal wiki pages, and developing custom mobile applications. While these approaches are better than the archaic paper-in binder approach, none allow users to access documents from within electronic medical records where care pathways and support for clinical decision-making are needed most.

The difficulty of retrieving relevant clinical guidance at the point of care is a well-documented problem. To address this problem, the HL7 Context-Aware Information Retrieval (e.g., Infobutton) Standard was adopted as a Meaningful Use Requirement. The standard specifies the usage of controlled terminologies, and query and reply formats. Using a service-oriented architecture, the basic workflow is as follows: 1) a standardized query is submitted as a knowledge request to the Infobutton Manager; 2) the Infobutton Manager interprets the clinical context within the request and matches against available resource profiles; 3) once matched, the Infobutton Manager replies with the Uniform Resource Locator (URL) to any matched resources (see top section of Figure 1). Depending on the receiving application, the user may be presented with the resources' URL or the content fully rendered. Although Infobutton is designed to be flexible for local adoption, most accessible resources are developed externally and published by third-party content providers. Local content is not accessible through Infobutton until a resource context profile is defined by indexing with standard terminology. OpenInfobutton, an open-sourced implementation of the Infobutton standard, includes a Librarian Infobutton Tailoring Environment (LITE) to ease the creation of context profiles.

Information retrieval problem at UUHC

University of Utah Health Care (UUHC) is an academic, regional healthcare system. UUHC consists of both inpatient hospitals and outpatient clinics serving patients in Utah and surrounding areas. Since 2014, Epic has been the electronic health record (EHR) in the inpatient and outpatient settings. The Epic system includes an Infobutton solution called ClinKB. OpenInfobutton serves as the Infobutton Manager for Epic's Infobutton requests. Users can initiate an Infobutton query by clicking an icon next to a discrete patient data field such as a diagnosis, lab result, or...
medication. The query is then submitted to the OpenInfobutton. OpenInfobutton then aggregates and returns resources from third-party content providers such as UpToDate, Micromedex and Karma. Like most Infobutton implementations, accessing an Infobutton requires that a provider first be signed into Epic, search for a patient's record, find the relevant discrete data with an Infobutton icon, and then click on the icon to query for the references. To date, content developed locally is not part of the result set. For locally developed content, UUHC uses Microsoft's SharePoint, which also serves as a collaboration space for all workforce teams (see Figure 1). Naturally, searches in SharePoint only return locally developed content.

![Figure 1. Current UUHC Information access paths for internal and external resources](image)

Many approaches have been tried to meet the information needs at the point of care. Early on, static documents were compiled into physical binders and distributed to each nursing unit within the medical facilities. Access and updates proved to be cumbersome. A less physically-bound approach was implemented by adding static links to the EMR's toolbar menu. However, the number of searchable links became unmanageable as the number of documents grew, and the linked guidance became outdated. Another approach used links within Epic to redirect users to SharePoint. While this method did allow providers to search for local content, the search results often included clinically less relevant documents. Another approach was adding resource links to Best Practice Alerts (BPA) within Epic. This approach meant resources were only accessible after providers have performed specific steps that triggered the BPA. Often decisions were already made and alerts were ignored.

Using Infobutton to access care pathways poses another challenge. Since Infobutton is designed to serve relevant resources within clinical contexts, many resources are only available after the provider has established a clinical context by making some clinical decisions. Conversely, care pathway documents often are needed before decisions are made. One organization added a search box to their Infobutton result page for their providers to find resources beyond the scope of the established context. They have found that providers used this search box more than half the time. Their finding demonstrated that the need for a more flexible search was greater than expected. Similarly, at UUHC, even with the availability of Infobutton and SharePoint, providers still have difficulty accessing institutional guidelines and content. A new approach is needed to leverage the relevance of Infobutton search results while providing the flexibility of free searches for both internal and external content.

**Objective**

Our long-term goal is to utilize the Infobutton standard and provide users access to both local and external content at the point of care even before the establishment of a patient's context. Our specific objectives for the work described in this paper were to a) define major requirements to provide users more flexible access, b) design and develop a prototype solution, and c) evaluate strengths and limitations of the prototype and propose next steps for evaluation and development.

**Define major requirements**
During 2015, a team of informatics graduate students collaborated with a multidisciplinary team of clinicians and IT hospital operations staff responsible for the EHR and enterprise-wide document control. The team focused on the challenge of implementing care pathways and communicating recommended guidance. After performing user testing of clinical alerts associated with the care pathway guidance, the team reviewed the literature and started to document requirements particularly focused on making information available at the point of care. The team reviewed the current knowledge workflow within the organization and determined that a custom solution may meet that need. After several meetings with stakeholders responsible for document control, quality control, and clinical care, the following major requirements were identified:

**Functional requirements**

- **Providers should be able to access care pathways within EHR:** Since providers began using Infobutton to access references, the solution should allow providers access to locally-developed care pathway documents using Infobutton. Infobutton access makes it easier for providers to search for these documents.

- **Providers should be able to generate custom Infobutton queries at the point of care:** The effectiveness of Infobutton depends on the precision of the resource context profiles. However, because the context is defined with high specificity, the reference often can only be accessed after a matching context is established. Of course, generalizing the context profile would return more results, but it would also decrease precision. Instead of generalizing the context profiles, the solution should enable the user to customize the query.

- **Providers should be able to search resources by free-text:** One of the difficulties in formulating Infobutton queries is using relevant controlled terminologies. Free-text search shifts the burden of term selection from the user to the system. The solution should allow providers to perform free-text searches.

- **Providers should be able to access both internal and external resources from a single tool:** Outside of Infobutton, UUHC providers use SharePoint to search for internal documents. For external references, providers must remember the appropriate content provider's website. Since this multi-portal approach has been a hurdle in care pathway implementation, the solution should search and aggregate both internal and external content, forming a single point of access.

- **Providers should be able to access the tool from anywhere:** Allowing access to reference materials independent of an EHR is important. In fact, most medical reference content brokers include searches on their websites or mobile applications. Conversely, searching for resources indexed within Infobutton requires multiple logins to access the organization's EHR through a secure network. Separating protected health information from openly available references allows searches from any Internet-enabled device and may lead to wider dissemination of best practices. Therefore, the solution should be accessible from inside and outside of the EHR.

**User Interface design requirements**

An effective search engine should be simple to use, provide useful feedback and display accurate results with meaningful metadata to help users select the most relevant results. With these goals in mind, we identified the following user interface (UI) related requirements:

- **The UI should be fast, simple and easy to use:** Ideally, users should be able to use it without explicit instruction. The layout of the website should direct users to the entry point of the workflow. The user interface should be responsive, intuitive and fast in returning results.

- **The solution should provide meaningful feedback:** The current appearance of the Infobutton icon does not indicate if a locally developed resource exists. Anecdotally, some users hesitate to use Infobutton because it may detract from their workflow without gaining any useful information. An effective search engine should provide feedback even before the query is issued. Since providers and the institution may consider internal content to be more relevant, the solution should give an indication if the query will return any local content.

- **The system should provide customizable autocomplete ranking for more relevant results:** Autocomplete had been the most used Google Search feature. The selection of the search term that affects the accuracy of search results is heavily influenced by the entry's ranking. With the promotion of a certain autocomplete suggestion, UUHC would be able to deliver relevant resources more accurately.
Prototype development

To build within the Infobutton ecosystem, two parallel efforts were required: 1) identify resources requested by clinicians in a primary care setting that are stored in a location accessible by URL, and then index the resources' URLs using LITE and creating their resource profiles; and 2) develop a custom search engine to initiate an Infobutton knowledge request and present the resulting URLs of the resources.

Identify and index resources using Librarian Infobutton Tailoring Environment (LITE)

Resources were selected two ways. We included four care pathway diagrams recently developed by UUHC clinicians for knee pain, concussion, and seizures. We also included 14 resources selected by a lead pharmacist and a nurse manager in a UUHC community clinic. These resources were accessible by URL and included because they were either frequently used or desired to be accessible. Most of the sample resources identified (n=16) currently reside in UUHC's internal SharePoint server. Two are external resources (Table 1).

</table>

The resources represented an array of references requested by clinicians working in outpatient primary care settings. Ten of the resources were care pathways and clinical guidelines that could be used to guide clinicians in treatment planning. Four resources were patient education materials that could be used in various contexts. Two documents addressed specific clinical tasks (i.e., blood pressure measurement and IV line care) that may be useful as a reference for interns and students outside of a single patient’s context. Two additional documents related to
medication administration and guidance that may be useful before a physician places an order. Currently, the 16
resources that reside in SharePoint can only be accessed by URLs after user authentication has been established, and
after searching the site for the resource.

Independently, two informatics graduate students assigned standardized codes that should be used to index the
resources in LITE according to the HL7 specification, including for example SNOMED CT codes for the main
search criteria and other code systems for the performer, encounter, and task context properties. The students had
access to the specification and experience with clinical-related controlled terminologies through their informatics
course work. The codes were then reviewed by an informatics research faculty member (author CS) with extensive
experience in controlled terminologies, followed by discussions with the two students to reconcile differences. After
the list of codes was finalized, the two students created context profiles for each resource using LITE. Note that
LITE has functionality that allows the user to select the major concept heading for the "MainSearchCriteria"
element, and will then populate additional MainSearchCriteria with the children of the major concept heading based
on hierarchies in SNOMED CT. For those resources that were not related to a particular disease process (such as the
Patient Complaint Process Form), the "MainSearchCriteria" element was left unpopulated.

Design and Develop the Prototype

The design of the custom search engine was based upon service oriented architecture and consisted of three parts:

1. A front end application allowed for user input and submitted the input to the server for suggestions.
2. A backend server received user input, queried the database, and replied with appropriate suggestions.
3. A custom database contained all the available resource titles and controlled terminologies for suggestions.

The prototype was named Melinda. Its focus was to help a user easily formulate an Infobutton request using an
autocomplete function and submit the request to the Infobutton Manager. Figure 2 illustrates the system's
components and their interactions with the Infobutton Manager. The front-end user interface was developed using
Angular. Django was chosen as a web framework for the backend server because of its ease of in prototyping. A
SQLite database contained the resource titles and the set of standardized terms and associated codes used for
matching by Melinda. Melinda is hosted by Heroku as www.Melinda.tech

![Figure 2. Proposed Design of Infobutton Search Engine Information Process](image)

The terms used for user-input matching came from two sources. First, we downloaded the "CORE Problem List
Subset of SNOMED CT" from the National Library of Medicine UMLS Terminology Services and loaded the
6,166 concepts into the matching table. We selected this source because the complete list of terms in SNOMED CT
is too large and many terms would not be relevant. This subset of most used terms to represent clinical problems
seemed sufficient to seed the system for the prototype. Second, we used a new service recently-developed for our
use in the OpenInfobutton Manager that allowed Melinda to directly access and download the standard codes
assigned for the MainSearchCriteria in the resource profiles. We loaded these codes into the matching table as well.
Therefore, each row in the matching table contained the term, the code, and the Object Identifier (OID) for the corresponding code system.

The matching process has three major steps. Step 1: As a user starts typing in the text box, the front-end application takes the user’s input and submits the input for matching. Step 2: The server matches the input against the terms in the matching table as well as the titles of the indexed resources. The matching is done by tokenizing the user’s input into list of words and matching them with the terms in the matching table. Step 3: The server replies with suggestions consisting of terms and/or resource titles. The replies with terms include the code and code system required for an Infobutton request. The replies with resource titles include the resource URLs for direct Ajax calls. The suggestion ranking is customizable in Melinda’s database, allowing an enterprise to prioritize internal versus external resources. Any entry that is associated with locally-developed content is displayed with an icon as shown in Figure 3.

![Figure 3](image)

**Figure 3.** Melinda’s user interface as user first types in the text box

The response process has several steps depending on the user’s selection. If the user selects a term from a standard terminology, Melinda will build an Infobutton request with the associated code and submit the request to the Infobutton Manager. Then, Melinda parses the resulting JSON object from the reply, sorts the URLs by the source of the content, and displays the results. In contrast, if the user selects a resource title, Melinda extracts the URL and displays the link directly to the user, bypassing the Infobutton request-reply workflow altogether. The results are displayed to the user organized by the source of the resource. The order of the sources in the display is a customizable feature. For each result entry, the title, URL and last update date are displayed as shown in Figure 4.

![Figure 4](image)

**Figure 4.** Melinda’s display of results, showing the metadata including title, URL, and last update date
Strengths and Limitations of the current prototype

Strengths

- Users have a single point of access for both internal and external content: Once internal content was indexed within the Infobutton Manager, relevant (i.e., matching) internal resources were included in the Infobutton reply along with relevant external resources in a single page. Users were able to access both internal and external resources from a single application.

- Users can perform search outside the current patient context: With Melinda, clinicians now can perform any searches without the need to first establishing a patient context.

- Users can perform custom searches at the point of care: Melinda's autocomplete suggestions allows providers the flexibility to search any resource, even those that were without MainSearchCriteria populated in their profiles. This added flexibility allows content authors to define the resource profiles as precisely (or as generally) as needed without hindering access to a resource.

- Users can access Melinda anywhere: Since Infobutton context profiles were accessible publicly, and Melinda was hosted on a public domain, the query result was accessible to anyone without the burden of logins. Moreover, Melinda can detect device display size and provide navigation layout appropriate for small mobile devices, tablets, or full desktop display. Screenshots of the interface rendered on a mobile device are shown in Figure 5.

- Finer control of information distribution for the organization: Melinda's autocomplete suggestion and result rankings are both customizable. The sorting order allows UUHC to sort most relevant and targeted information to the top, thus allowing providers easier access to common organization-specific resources. Furthermore, many accreditation programs, such as ISO9001, require healthcare organizations to establish a policy update and access procedures. This approach may be part of such an established system.

- Better user experience: The three principles of effective search engine design guided Melinda's UI development. For simplicity, the single search box design was chosen to minimize confusion and distraction. Second, since locally-developed guidelines were more likely to be considered than external resources, the suggestion list's special icon allows users to see which searches would return locally-developed content before the search was performed. Finally, the title, URL and updated date and time associated with the resources help the user determine the relevancy of the result.

Limitations

- Possible user confusion if similar terms from different coding system return different resources: To ensure adequate matches, system administrators may include terminologies with overlapping domains of clinical content. As a consequence, users may be presented with a set of similar terms that return different resources when used in a query. For example, if terms from SNOMED CT and ICD-10 were loaded into the matching
table and a user inputs "knee pain", both "Knee Pain (findings)" from SNOMED CT and "Pain in unspecified knee" from ICD10 would be presented. Depending upon the MainSearchCriteria indexed in the resource profiles, each term may return different results.

- **Lack of full integration into EHR:** Currently, the prototype was only a proof of concept. While it was functional, the lack of full integration with Epic means access to the tool remains isolated from Epic. Within Epic, access to care pathways continues to be Infobutton icons or the dedicated link to SharePoint. The theorized benefits of custom search by Melinda within the EHR can only be realized after UUHC Epic's ClinckKB environment is configured to direct requests to Melinda.

- **Limited context tailoring:** Separating the Infobutton queries from protected health information introduced one major drawback: the user now must re-establish the context manually for Infobutton. When forming the request, even though Melinda could search by the most used Infobutton resources criteria (i.e. mainSearchCriteria), the absence of other contextual information may diminish the relevance of the search results. Soliciting for these additional parameters would require additional user input which the current simple UI design does not yet accommodate.

- **Lack of free-text search:** The quality of Infobutton queries rests on the use of standard terminologies, particularly a standard codes' Universally Unique Identifiers (UUIDs). To this end, Melinda supplied standard terms (with associated codes) for the user to select. In turn, Melinda converted the term to its corresponding UUID to make a request. In essence, the search box is not a true free-text search box but an expanded picklist. This approach limits the flexibility of free text searches, a feature commonly used by other external content providers. Future enhancements could address this need.

Even with these limitations, adding Melinda to the Infobutton framework may expand the power of Infobutton to other clinical decision support solutions. Melinda met many of the initially-identified requirements (Table 2).

**Future work**

**Evaluation**

The usability and functionality of Melinda needs to be evaluated more formally. First, Neilson' usability heuristic criteria should be applied to evaluate Melinda's usability before provider end user feedback. After most of the usability defects and issues are addressed, we should then perform user studies with five to 10 providers who
represent the target audience for this application. For example, the user study should include physicians, pharmacists, and nurses in the outpatient primary care setting during the first phase of testing. These evaluations will provide input for enhancements and guide further evaluation plans before Melinda can be implemented in a production setting. Once Melinda can be implemented in a production environment, on-going monitoring should be carried out to assess usage, satisfaction, system response times, and the relevance (i.e., predictive value positive) of terms presented to the user based on selections made by the user. Ongoing feedback may be solicited with the use of a simple feedback button.

**Enhancements**

The following future enhancements can be built upon the current framework:

- **More context awareness:** The Infobutton Standard allows for use of other context information that Melinda is currently not gathering. With additional context information, the system may be able to learn to map frequent user input to the appropriate standard terminology (e.g., ‘K’ for Potassium level). Of course, such features will require a machine learning middleware and an efficient user interface with a feedback loop.

- **Encapsulate Melinda into a web service:** Minor customization of Melinda could convert the web page to a web service that passes Infobutton requests along to Infobutton Manager. As a web service, Melinda could also replace the current Infobutton responder page and unify the interface between Infobutton icon access and search page access. As a web service, Melinda could integrate more fully and easily with an EHR.

- **Security:** While the resources at UUHC were protected behind SharePoint's user authentication, the indexes and metadata could be accessible without user authentication, allowing open access to Melinda. If security were needed, single sign-on technology, such as LDAP or OAuth might be beneficial to free the user from having to remember yet another secure identity.

- **Individual accounts:** The framework design could also be leveraged as a mobile app. If user accounts were implemented, a mobile app might be built to include advanced features such as push notification and user feedback. Melinda could query a provider's schedule and calendar to present needed resources as a custom reading list based on chief complaints of patients upcoming in their clinic. User's interaction tracking for dynamic page ranking may be added as a well.

**Conclusion**

We identified key requirements for a system to support the clinician’s needs to access clinical guidelines that were developed internally and externally both from within and outside an individual patient’s clinical record (i.e., both with and with clinical context). A prototype was developed to demonstrate the feasibility and to study further the system and user requirements for full implementation. While the benefits may seem promising, the limitations we uncovered would need to be addressed in future development. This research addresses a major gap in the current strategy for accessing relevant and updated information important for clinical care.

**Acknowledgment**

We thank Guilherme Del Fiol for providing insight and expertise about the use of Infobutton and access to LITE, Bruce Bray for providing insight into the clinical setting workflow, Andrew Iskander for developing a web service that allowed Melinda to query Infobutton Context Profiles, Bret Heale and Stacey Slager for creating the resource profiles, and UUHC Value Driven Care Team for selecting the sample reference resources.

Term Coverage of Dietary Supplements Ingredients in Product Labels

Yefeng Wang¹, Terrence J. Adam, RPh, MD, PhD¹,², Rui Zhang, PhD¹,³

¹Institute for Health Informatics; ²College of Pharmacy; and ³Department of Surgery; University of Minnesota, Minneapolis, MN

Abstract

As the clinical application and consumption of dietary supplements has grown, their side effects and possible interactions with prescribed medications has become a serious issue. Information extraction of dietary supplement related information is a critical need to support dietary supplement research. However, there currently is not an existing terminology for dietary supplements, placing a barrier for informatics research in this field. The terms related to dietary supplement ingredients should be collected and normalized before a terminology can be established to facilitate convenient search on safety information and control possible adverse effects of dietary supplements. In this study, the Dietary Supplement Label Database (DSLD) was chosen as the data source from which the ingredient information was extracted and normalized. The distribution based on the product type and the ingredient type of the dietary supplements were analyzed. The ingredient terms were then mapped to the existing terminologies, including UMLS, RxNorm and NDF-RT by using MetaMap and RxMix. The large gap between existing terminologies and ingredients were found: only 14.67%, 19.65%, and 12.88% of ingredient terms were covered by UMLS, RxNorm and NDF-RT, respectively.

Introduction

According to the National Health and Nutrition Examination Survey (NHANES) 2003-2006, 53% of U.S. adults took at least one dietary supplement, most of which were multivitamin and multi-mineral supplements. Recently, the National Health Statistics Reports indicated that about 40% of Americans use some form of complementary and alternative medicine (CAM) and that non-vitamin/non-mineral dietary supplements were still the most commonly used complementary and alternative health approach. The prevalence of supplement use was estimated to be 69% in 2011 when occasional and seasonal use was taken into account.

Dietary supplements are typically used to complement conventional medicine with the goal of achieving better healthcare outcomes; however, dietary supplements were found to result in 23,000 emergency room visits yearly in the U.S. according to the study conducted by Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention (CDC). Moreover, one out of four people taking a prescription medicine also uses an herbal supplement, increasing the possibility of drug-supplement interactions (DSIs). For example, warfarin can interact with supplements such as Panax ginseng and Gingko biloba, which can lead to severe adverse effects such as spontaneous postoperative bleeding. In particular, supplements are increasingly used by patients diagnosed with cancer to help strengthen their immune system and ease the side effects of treatments. Unfortunately, our ability to identify adverse effects from herb and dietary supplements and their reactions with conventional Western medications are currently limited and the reports on such interactions occur infrequently in clinical practice. Therefore, it is necessary to gather information on the ingredients in these supplements to facilitate medication safety efforts.

New drugs are typically tested for their efficacy and toxicity before market approval. However, U.S. Food and Drug Administration (FDA) regulates dietary supplements differently from conventional food and drugs under a separate regulation called Dietary Supplement Health and Education Act of 1994 (DSHEA). DSHEA requires appropriate labeling of dietary supplements. These labels contain rich information such as suggested use, ingredients, product indication, target population, and other necessary safety precautions. In particular, the dietary supplement labeling guideline requires all dietary ingredients to be listed on the label, and the synonyms for the dietary ingredients can be used. Such information provides a great resource to analyze the ingredients of dietary supplements from the perspective of terminology.

To support effective mining of product labels information for DSIs and supplements adverse effects studies, it is vital to understand the representation of supplements and ingredients in dietary supplement labels as well as the coverage of standard biomedical terminologies for supplements and their ingredients. One possible reason for the lack of
extensive studies on DSIs is an absence of a standard and accepted terminology for dietary supplements. In a recent study comparing terms with different resources, we found that none of five major online databases covered all supplement terms\(^8\). Another prior study also evaluated the supplement term coverage in both medication lists and clinical notes in the electronic health record (EHR)\(^9\). To the best of our knowledge, the investigation of supplement term representation and coverage on dietary supplement labels is limited and deserves further investigation. In this study, we sought to evaluate terminology coverage of data elements in supplement product labels by cross-validating online supplement databases with EHR patient data. We also sought to investigate the adequacy of standard terminologies for representing supplements, especially their product ingredients, based on existing product labels.

**Methods**

We extracted supplement product information and their ingredients from the Dietary Supplement Label Databases (DSLD), and then normalized and formed a comprehensive list of ingredients followed by mapping them to standard terminology, including UMLS, RxNorm, and NDF-RT. The term coverage in these terminologies was investigated. In our assessment, we compared the term overlap among three resources, including supplement labels, online resources, and the EHR medication list. We first introduce DSLD, MetaMap, and RxMix which are used in this study, followed by the details of methods.

**DSLD**

The DSLD is created by the National Institutes of Health (NIH) Office of Dietary Supplement (ODS) and U.S. National Library of Medicine (NLM). The database collects full label contents from dietary supplement products including both currently available products as well as products which are no longer on the market in the U.S., as well as those consumed by National Health and Nutrition Examination Survey (NHANES) participants. Each product in DSLD provides four types of label information: product information (including serving information, product type, supplement form, target groups), dietary supplement facts (e.g., usage, ingredients), label statement (e.g., FDA statement, precautions, and suggested use), and contact information.

**Unified Medical Language system (UMLS) and MetaMap**

UMLS is a repository that integrates over 100 medical vocabularies and provides a unified platform which can be used to develop or enhance applications. Metathesaurus, as one of the three main components in the UMLS, contains over 2 million terms and codes from many different vocabularies such as Systematized Nomenclature of Medicine - Clinical Terms (SNOMED CT), Current Procedural Terminology (CPT), Logical Observation Identifiers Names and Codes (LOINC), etc. Each concept in the Metathesaurus has a Concept Unique Identifier (CUI), which can be used to map to various dictionaries and compare data from different sources. For this paper, UMLS was used to normalize data from different sources (i.e., supplement ingredients).

To map the biomedical texts to the UMLS Metathesaurus, the NLM developed and maintains a natural language processing tool, called MetaMap, which lexically and syntactically analyzes texts and provides a list of mapping concept candidates. We used MetaMap to find the matched UMLS concepts in Metathesaurus. The versions of MetaMap and UMLS Metathesaurus used in this study are 2016 and 2015AB, respectively.

**RxNorm, NDF-RT, and RxMix**

RxNorm provides a standardized nomenclature of clinical drugs by integrating 12 drug vocabularies\(^10\). RxNorm contains names not only for prescription drugs but many over-the-counter drugs on the U.S. market. RxNorm provides the ability to normalize the drug names along with drug dosage, generic name, chemical components, and dosage forms to support the communications between different systems. The version of RxNorm used in this article is “04-Jan-2016”.

National Drug File - Reference Terminology (NDF-RT) is developed by the U.S. Department of Veterans Affairs, Veteran Health Administration. It is used to represent drug characteristics such as ingredients, chemical structure, and additional information about their molecular interactions and kinetics\(^11\). The version of NDF-RT used in this article is “2016.01.04”.

RxMix is a web application integrating various functions from the RxNorm and NDF-RT application program interfaces (APIs) to allow users to create their own workflow to conduct a certain task, such as finding drug class from a drug name\(^12\). In this paper, RxMix was used to map terms to RxNorm and NDF-RT concepts.
Extracting and analyzing product information from DSLD

Step 1: Downloading the data from DSLD. For each supplement in DSLD, the data containing the abovementioned label information are presented in four separate comma-separated values (CSV) files that are available for download. DSLD consists of 45,455 up-to-date records, downloaded through batch processing by Python according to the unique DSLD identifier of each supplement.

Step 2: Extracting the product information of the supplements. The information pertaining to the product name and the product type can be found in the Product Information. DSLD used the LanguaL™ system for the classification of the supplements since LanguaL™ is an “automated method for describing, capturing and retrieving data about food” 13. In total, 12 categories (e.g., single vitamin and single mineral supplement) were applied to label more than 45,000 dietary supplements. It is noteworthy that no generic names for these supplements can be found in the database, and the manufacturers have come up with their unique nomenclature for these mixtures. Therefore, the most useful information in terms of terminology in the product information label is the LanguaL™ supplement type. LanguaL™ assigns the letter “A” to all dietary supplements and a four-digit code following the letter for further classification. The supplement types for each supplement were extracted and the distribution of the supplements in each type was then analyzed.

Normalizing and analyzing supplement ingredient list

Since no generic names could be found for the supplements in DSLD, more emphasis were put on scrutinizing the ingredients of each supplement. Here, we describe how to extract, normalize and analyze ingredients for each supplement.

Step 1: Extracting ingredient names and ingredient types. The information pertaining to the ingredient names and ingredient types was further extracted from Dietary Supplement Facts. Therefore, it is straightforward to iterate through the items in each dietary supplement facts file and extract the relevant information. The number of ingredients in each supplement was also recorded. Then the information were categorized into 20 different types (e.g., vitamin and amino acids) which appeared in the data. Among these, two categories of ingredients (i.e., default and header) were excluded in this study as these types of ingredients are not specifically classified in the database. There are 60,005 items that are belong to this class that was named “default”. The “header” type of ingredients is used to organize the presentation structure of dietary supplement facts on the label, while the information itself does not contain any useful information about the ingredients.

Step 2: Normalizing the ingredient information. After extracting the ingredient raw data, it was discovered that further data cleaning is required before any terminology mapping could be done. We removed information including comment in parentheses, brackets and braces, HTML marker residue from webpage sources left in the CSV files during the transfer process, non-alphanumeric characters and various duplicates for a single ingredient type with regular expression filters. It was found that the different formulations of the same ingredients contributed to the majority of redundant information. For example, the ingredient acai has multiple duplicates in the record: acai extract, acai powder, acai freeze-dried powder, acai concentrate, acai juice, etc. The word “extract”, “powder”, “concentrate” does not contribute to efficient mapping. To eliminate all these duplicates, a keyword list with formulations (e.g., extract, powder, concentrate) was manually summarized and used to preprocess these ingredient list using additional mapping steps. The list of original and normalized ingredients and the Python source code are available at: https://github.com/Schneitzer/Term-Coverage-of-Dietary-Supplements-in-Product-Labels.

Step 3: Analyzing the ingredient information. After normalizing the ingredient information, a list of unique terms and their ingredient types were generated. The normalizing efficiency can also be deduced by comparing the number of items in each set before normalizing and after normalizing.

Mapping ingredient terms to existing terminologies

After normalizing the ingredient data, seven subsets were chosen without loss of generality, i.e., amino acids, animal part or source, botanical, chemical, enzyme, hormone, and vitamin, for mapping.

Step 1: Mapping the list of normalized ingredients to UMLS using MetaMap. The mapping result contains a matching score according to the accuracy of mapping could be measured. A score of 1000 represents a perfect match, while lower scores indicates a partial match. It is possible that a certain ingredient could be mapped to multiple keywords, which will obfuscate its clinical significance due to a partial match. Therefore, only mappings with 1000 matching score were further analyzed in this study.
Step 2: Filtering the list of ingredient information according to the semantic types. The UMLS semantic types of the exact matched concepts were examined as some of those concepts may not refer to dietary supplements. For example, the concept “beta carotene” has two exact match in UMLS Metathesaurus, but only one of them refers to “organic chemical, pharmacologic substance, and vitamin”; the other maps to “Beta carotene Measurement”, which is a laboratory procedure. In addition, although the ingredient information has been preprocessed and normalized, there are still items that may contain long phrases that may produce false positives. Therefore, only a certain subset of semantic types (e.g., “Enzyme, organic chemical”) that are closely related to dietary supplements were manually chosen to filter out the mapping noise.

Step 3: Mapping the list of normalized ingredients from each ingredient type to RxNorm and NDF-RT using RxMix\textsuperscript{12}. The normalized lists were directly uploaded to RxMix workflow for mapping. Two function, \texttt{RxNorm:findRxcuiByString} (with normalized string match parameter selected) and \texttt{NDF-RT:findConceptsByName}, were applied to find the unique concept identifiers in RxNorm and NDF-RT terminologies.

Evaluating ingredient term coverage of terminologies

After the ingredient information was mapped to UMLS, RxNorm and NDF-RT terminologies, the unique concepts were collected although many ingredient terms can be mapped to the same concept although we normalized the ingredients terms described above. The number and percentage of the unique mapped concepts in each terminology were calculated to indicate the unique terms of the ingredient information of DSLD that can be mapped to all the databases included in this research.

Results

Extraction of supplement list from DSLD

All 45,455 supplements from DSLD databases were extracted and classified by 12 LanguaL\textsuperscript{TM} product types. Number and percentage of each product type were shown in Table 1.

Table 1. The supplement representation in DSLD; number, percentages and LanguaL\textsuperscript{TM} product type.

</table>

About 36% of supplements were classified as “dietary supplement – combination/other”. According to the LanguaL\textsuperscript{TM} code, “dietary supplement – combination/other” is a subcategory of “dietary supplement – combination” where 16,531 dietary supplements are included under this category. Among these, 16,522 dietary supplements were classified as “combination/other” subcategory and the remaining 9 products were classified in the “combination” category. We combined these two product types and listed them as one type in the table. However, this is not the only overlap found in this classification system. For herbal and botanical supplements with vitamin or mineral, they could either appear in the “dietary supplement – herbal or botanical” or “botanical supplement with vitamin/mineral” listed in Table 1 since the second category does not specifically exclude the supplements that contain vitamin or mineral. A graphic
presentation of the distribution of each type is shown in Figure 1.

**Normalizing and analyzing ingredient list**

Before normalizing the ingredient information, the distribution of the number of ingredients in each supplement is shown in Figure 1. It can be seen that the histogram peaks at 13,004 for one ingredient, implying about 30% of the supplements have one dietary ingredient. The distribution is also very long-tailed. The 25th percentile, the median, the 75th percentile and the mean for the number of ingredients are 1, 5, 12, and 9.6, respectively. Among 45,455 dietary supplements in the DSLD database, 1,091 items (2.4%) included more than 50 ingredients on their supplement labels, which were not shown in Figure 1.

![Figure 1](image-url)

**Figure 1.** Distribution of the number of ingredients present in the supplements listed in DSLD. Due to the long tail of the data, 1,091 supplement (2.4%) containing more than 50 ingredients were not shown in Figure 1.

These ingredients are classified into 20 categories. The only irrelevant category listed in the database is the “header” category, which only serves the purpose of organizing the dietary ingredient facts, and thus will not be discussed
further. The normalized results for the other 19 categories were shown in Table 2. The “Before Normalization” column lists the number of items extracted from the dietary ingredient fact sheets of all the supplement products in the DSLD, while the “After Normalization” column lists the number of unique items remaining after normalization. Each category was slimmed down by 81.6% to 99.5%, which facilitates faster cross-referencing among different databases.

**Evaluation of supplements term coverage**

The mapping coverage across different terminologies is described in Table 3. The UMLS column presents the number of CUIs mapped by MetaMap. As the mapping process returns explicit semantic types, the quantity of matching CUIs is affected by relevant semantic types as those are not related to dietary supplements were filtered out. But for RxNorm and NDF-RT, the mapping was performed by RxMix that does not output explicit semantic types. RxNorm assigns a unique concept id (RxCUI) for each individual product, making it possible that RxNorm generate more matches than the UMLS.

The mapping coverage across different resources (e.g., online resources, and EHR medication lists) was also compared. As shown in Figure 2, the DSLD database has more unique terms than online resources and the medication list. However, the mapping percentages of UMLS and RxNorm terminologies to the unique terms of DSLD are much lower than the MedList and online database. The NDF-RT terminology produced similar mapping percentage. It is noteworthy that these ingredient categories are not orthogonal. The unique concepts in one category might overlap with the ones in another category; therefore, the final mapping percentage is slightly lower after removing the duplicates.
Table 3. The number of unique concepts mapped into each terminology by the respective ingredient category.

Figure 2. Distribution of the number of matched concepts among different resources (DSLD, medication list, and online databases) in UMLS, RxNorm, and NDF-RT terminologies. The percentage of unique terms that have been mapped to each different resource was shown above the corresponding bar.
Although most of the ingredients can be exactly or partially mapped to the UMLS, there is still a portion of ingredients that cannot be mapped to any terminology. Some examples are given in Table 4. Most of these non-mapping results are due to misspelling or errors which occurred during the transfer from physical labels to digital data; instances where the ingredients are simply names created by manufacturer can also lead to a non-mapping result; for botanical ingredients, the name of the ingredients might be coming from another language (e.g., Chinese) that is not in the terminologies; and for chemical ingredients, some nomenclature of organic compounds are not included in the terminologies.

Discussion

Due to the known and potential adverse effects on patient safety, DSIs and supplement side effects have attracted a lot of attention due to potential patient risk. Many researchers have found DSIs through pharmacological experiments; however, they usually focus on a small set of supplements or drugs. To largely explore such DSIs from a variety of resources, standardized terminology of supplements is necessary. We have evaluated the terminology coverage among online resources and medication lists in EHR data. Supplement labels contain rich information, including product information and especially complete lists of their ingredients, which are the main components interacting with drugs. Thus a study on the coverage of terminology concerning the supplement ingredients by standard terminologies such as UMLS, RxNorm, and NDF-RT needs to be investigated.

A relatively unique problem for supplements as opposed to comparable over-the-counter and prescription medications is the large numbers of ingredients noted in Figure 2. The use of multiple active agents is fairly infrequent in prescription medications. It shows up more frequently with over-the-counter medications, but it is rare to include more than 3 or 4 components in a product. The supplement data indicate a very large number of ingredients, which may be challenging to practical management of supplement content in secondary document sources such as EHRs. Standardization of ingredient terms is vital for information extraction and information retrieval of dietary supplement in many resources, including both structured data and free texts. Standardization can also promote the accurate use of higher level generic or trade names to represent known ingredient combinations whenever it is feasible. The example of multiple vitamins is a typical case where in the medical record only the multivitamin is noted, since it is known to contain a typical set of usual vitamins. Effective terminology and mappings to higher level names such as the trade name of supplement products can make clinical documentation and research much easier to manage.

The low sensitivity of mapping may also due to the fact that the normalization is unable to cover all possible variations of the ingredients. The rule-based regular expression filters cannot eliminate all possible typos, affixes and duplicates for the ingredients. For example, “copper” and “Cu” were treated as two distinct concepts, but they actually refers to the same concept, which is the copper element. On the other hand, only exact matches were taken into account when mapping the UMLS concept, thus yielding a relatively lower number of mapped concepts. All of these factors contribute to lower mapping sensitivity. Another observation is that RxNorm mapped more ingredient terms in DSLD and medication lists than the UMLS Metathesaurus, which is an anomaly as RxNorm contains more detailed information than UMLS Metathesaurus. For example, there are two distinct RxCUIs that correspond to glycine (1311532 (glycine hydrochloride) and 4919 (glycine)). While MetaMap specifies the semantic type for each CUI, RxMix does not reveal the semantic type difference between the different CUIs, thus making the mapping percentage higher for RxNorm. This could cause further complications as these RxCUIs would be consequently applied in RxMix to find corresponding NUIs. More detailed information is required to eliminate all the one-to-many mappings in order to derive more accurate term coverage for dietary supplements.
This study has certain limitations. We only evaluated the term coverage in a limited number of terminologies, and only considered the exact matches, which may ignore some related concepts from UMLS. This study lays the foundation for additional examination of current drug terminologies and the improved understanding of current dietary supplements. Without terminology examination, further steps such as information extraction would be very challenging. Our future study will investigate how to better represent dietary supplements using existing resources and terminologies to enhance dietary supplement research.

Conclusion

In conclusion, we extracted the product information and the dietary ingredients of all the supplements listed in DSLD. While generic names for the supplements in this database were not available, the dietary ingredient facts became the source of data for analysis of term coverage. The distribution of dietary supplements according to the product types and the ingredient types was derived. The ingredient terms have been mapped to concepts in three different terminologies including UMLS, RxNorm and NDF-RT, to evaluate the ingredient term coverage with the aid of MetaMap and RxMix. It has been observed that the RxNorm provides the best coverage (19.65%).

Abstract

Resolving word ambiguity in clinical text is critical for many natural language processing applications. Effective word sense disambiguation (WSD) systems rely on training a machine learning based classifier with abundant clinical text that is accurately annotated, the creation of which can be costly and time-consuming. We describe a double-loop interactive machine learning process, named ReQ-ReC (ReQuery-ReClassify), and demonstrate its effectiveness on multiple evaluation corpora. Using ReQ-ReC, a human expert first uses her domain knowledge to include sense-specific contextual words into the ReQuery loops and searches for instances relevant to the senses. Then, in the ReClassify loops, the expert only annotates the most ambiguous instances found by the current WSD model. Even with machine-generated queries only, the framework is comparable with or faster than current active learning methods in building WSD models. The process can be further accelerated when human experts use their domain knowledge to guide the search process.

Introduction

Clinical documents contain many ambiguous terms, the meanings of which can only be determined in the context. For example, the word “malaria” appearing in a clinician note may refer to the disease or the vaccine for the disease; the abbreviation “AB” may mean “abortion,” “blood group in ABO system,” “influenza type A, type B,” or “arterial blood,” depending on the context. Assigning the appropriate meaning (a.k.a., sense) to an ambiguous word, based on hints provided in the surrounding text, is referred to as the task of word sense disambiguation (WSD).\textsuperscript{1,2} WSD is a critical step towards building effective clinical natural language processing (NLP) applications, such as named entity extraction\textsuperscript{3,4} and computer-assisted coding.\textsuperscript{5,6}

Among different approaches to inferring word senses in clinical text, supervised machine learning has shown very promising performance.\textsuperscript{7,8} Supervised machine learning methods typically build a classifier for each ambiguous word, which is trained on instances of these words in real context with their senses annotated, usually by human experts with required domain knowledge. To train an accurate WSD model, a large number of such annotated instances are needed,\textsuperscript{9} the curation of which can be costly as every instance has to be manually reviewed by domain experts. Many methods have been explored in the past to reduce this annotation cost.\textsuperscript{10-14} Among them, active learning, by inviting human experts to directly participate in the machine learning process, has proven to be an effective approach. The premise of active learning is its ability to reduce the number of judgment calls that human experts need to make while achieving the same results as having a fully annotated corpus, thus significantly reducing the amount of human labeling needed.\textsuperscript{14} As such, how to select the most informative instances to present to human experts to annotate is the key to success for the family of active learning based methods.

Existing active learning methods use different strategies to select the most informative instances for annotation.\textsuperscript{15} For example, some select the instance with the least confident prediction or the instance with competing label assignments. However, these strategies suffer from the “cold-start” problem: a number of precisely annotated examples for every sense are usually required to kick off the classifier. Further, a classical active learning procedure does not fully utilize the domain knowledge of human experts. For example, practicing physicians frequently write or read ambiguous words in their notes without any difficulties in conveying or understanding their meaning. They are able to do so largely because of the surrounding context of the ambiguous words; e.g., when AB is used as shorthand for “blood group in ABO system,” physicians know that it commonly appears as “blood type AB,” “AB positive,” or “AB negative.” These contextual words are strong indicators of the sense of an ambiguous word, which is invaluable to a WSD model but remains largely untapped by existing active learning methods.
In this paper, we demonstrate a method that capitalizes on human experts’ domain knowledge to improve the performance of interactive machine learning. We apply a framework that we recently developed, referred to as ReQ-ReC (ReQuery-ReClassify), to the problem of word sense disambiguation in clinical text. Originally designed for high-recall microblog and literature search, ReQ-ReC features a double-loop interactive search and classification procedure that effectively leverages the domain knowledge of human experts. In an outer loop (ReQuery) of the procedure, an expert searches and labels the instances of an ambiguous word along with sense-specific contextual words. Then, a ReQ-ReC system helps the expert compose additional search queries by suggesting other potentially useful contextual words. In an inner loop (ReClassify), the framework requests the expert to annotate the most informative instances selected from those retrieved by all previous queries and then use the results to update the classifier accordingly. An expert can flexibly switch between these two “teaching strategies.” (1) to generate initial examples of a particular sense by launching a keyword search, and (2) to provide fine-grained clarification by labeling the instances selected by the system. Empirical experiments on three different clinical corpora show that this framework is more effective in building accurate WSD models than current active learning methods, even if the expert solely relies on system suggested keywords.

Method

A. The ReQ-ReC Framework

A.1. Sample scenario

To illustrate how ReQ-ReC works, let us consider the following scenario. Suppose we have a set of clinical text snippets (e.g. sentences) all containing the word “AB,” which means either “blood group in ABO system” or “influenza type A, type B.” Our task is to assign the actual sense to each instance. Based on the domain knowledge, a human expert would know that if “AB” co-occurs with the phrase “blood type,” then it likely means “blood group in ABO system;” if it co-occurs with the word “influenza,” then it likely means “influenza type A, type B.” Naturally, the expert would use keywords “blood type AB” to retrieve a set of instances from the text corpus and label them as “blood group in ABO system;” she or he would then search for “influenza AB” and label the retrieved instances accordingly (Figure 1a). These context-sense pairs are used as an initial corpus to warm-start the first round of WSD model learning. The learned model will then be applied to predicting unlabeled instances and ask the expert to further clarify a few boundary cases, e.g. “Labs include influenza AB swab and blood typing.” (Figure 1b). Determining the senses of these boundary cases would allow the model to capture the nuances in language use and quickly improve model accuracy. Later on, the expert may switch between searching for instances and labeling instances. After a few iterations, the expert may start to realize that in phrases such as “AB positive,” “AB” also means “blood group in ABO system.” Through a new search, she or he can quickly label another batch of instances of “AB positive,” which further improves the WSD model (Figure 1c).

Figure 1. An illustrative example of the searching and labeling process of the ambiguous abbreviation “AB.”

From this sample scenario several observations can be made. First, keyword search is a natural interface for domain experts to retrieve cases of ambiguous usage of words and to provide high-yielding, targeted annotation. This process can significantly reduce annotation cost, as human experts are only asked to label instances that are most informative to train the WSD model, while avoiding the need of labeling all instances in a corpus, most of which contribute little to improving the model performance. Additionally, search also benefits the learning algorithm: it provides a warm start in generating an initial model, and subsequent searches further refine the model by covering
other potential senses of an ambiguous word or additional contextual words. Second, while classifying individual instances retrieved by keyword search is necessary for training the model, it is only able to produce a simplistic model, similar to rules. The ReQ-ReC framework therefore asks domain experts to also clarify boundary cases, which informs the model on how to weigh the nuances of language use in clinical text for better sense disambiguation. After being re-trained on these cases, the model becomes more robust and more accurate. In addition, answering these clarification questions might also inspire the human expert to come up with new search queries covering other potential senses of an ambiguous word or additional contextual words that might have not been thought about. Therefore, the two stages – keyword search and active classification – can be used iteratively to inform each other.

A.II. Anatomy of the ReQ-ReC framework

Generalizing from the above example, the double-loop procedure of the ReQ-ReC is illustrated in Figure 2. The procedure operates on an inverted index of the documents so that all keywords, including the ambiguous words and the contextual words, are searchable. The procedure maintains a set of search queries, a pool of retrieved instances, and a WSD model. To start, a human expert first uses her domain knowledge to compose a search query for each known sense, and then the system retrieves an initial set of contexts using the search function. The inner-loop kicks in there, in which the system iteratively presents a small number of instances selected from the current pool of retrieved instances to the expert and asks her/him to assign senses. The WSD model is consequently updated based on the accumulated annotations by the expert, which is then used to reclassify the pool of instances. After a few iterations of the inner-loop, the WSD model’s predictions stabilize on the currently unlabeled instances. At this point, the outer-loop of the system will kick in to recommend new search queries for each sense (the requery process), aiming to retrieve more diverse instances with additional contextual words. These new search queries will be presented to the human expert for review and for further modification. Then, the system will retrieve a new set of instances using the new queries and add them to the existing pool of retrieved instances. After this requery process, the system will start a new inner-loop and continue to update the WSD model. The learning process ends when the expert is satisfied with the predictions made by the WSD model on those unlabeled instances in the newly retrieved pool.

Figure 2. The ReQ-ReC framework.

The framework consists of the following key computational components.

1) Search. The framework uses a standard, Google-like search interface to retrieve instances containing ambiguous words. It can either leverage an existing clinical text search engine or build a just-in-time index over an unlabeled corpus while search is being performed. The search engine’s ranking function can use any retrieval models that take the input of a keyword query and outputs a certain number of instances from the index (using a vector space model,
a boolean retrieval model, or a language modeling approach). After each search, the retrieved instances will be added to a pool, which becomes the basis of the next step, instance selection.

2) Instance selection. In every iteration of the inner-loop, the framework selects a small number (e.g. 5) of unlabeled instances from the current pool of retrieved instances and asks the expert to assign senses. At the beginning of the double-loop procedure, the framework can simply return the top instances ranked by the search engine’s retrieval model. With more and more instances being labeled by the human expert, the system will leverage this knowledge to update the WSD classifier and use active learning strategies to select the next instances for labeling.

3) WSD classification. Given an accumulated set of labeled instances, the WSD classification component learns or updates a multiclass classifier (such as a random forest or a support vector machine) and reclassifies the pool of retrieved instances.

4) Query expansion. When the classifier appears to be achieving a stable prediction on the pool of retrieved instances, the system proceeds to expand the pool in order to cover more contexts in which a sense may appear. This is done through constructing a new query for each sense and retrieving a new set of instances from the target corpus. Query expansion can be done using different methods, such as the Rocchio’s method or semantic term matching. The human expert may either approve this query, edit it, or compose one by her own.

ReQ-ReC is a general framework and each of the key components above can be instantiated in many different ways. In the following subsection, we describe specific implementations of each component.

A.III. Instantiating the ReQ-ReC framework

1) Search. In our current research implementation of the ReQ-ReC framework, we use the Lucene Package to build a search index for each ambiguous word. Instances are tokenized with Lucene’s StandardAnalyzer. To preserve the original form of ambiguous words (“nursing,” “exercises”) and negations (“no,” “without”), we do not perform stemming or stopword removal. We use the Dirichlet prior retrieval function with the parameter \( \mu \) set to 2000, a typical setup in information retrieval literature.

2) WSD classifier. We use logistic regression with linear kernel for WSD classification, implemented by the LIBLINEAR package. If an ambiguous word has two senses, we build a binary classifier; otherwise we build a one-versus-rest multiclass classifier. Logistic regression classifiers output well-calibrated probability predictions \( p(y|x; \theta) \) for each sense \( y \) and each instance \( x \), which will be used by active learning algorithms (\( \theta \) is the classification model parameter). We use presence/absence of the all unigrams appeared in the instance as features. For the L2-regularization hyperparameter \( \mathcal{C} \), we set it to 1.0 across all ambiguous words. This setting is comparable to previous reported studies.

3) Instance selection. In the inner-loop, there are multiple possible methods for selecting the next instance for labeling:

   a) Random Sampling. The algorithm simply selects an instance from the unlabeled pool uniformly at random.

   b) Least Confidence. The algorithm selects the instance \( x \) with the least predicted probability \( p(y^*|x; \theta) \), where \( y^* = \arg\max_y p(y|x; \theta) \) is the most probable sense. Intuitively, the model has little confidence in predicting the sense of instance \( x \) as \( y^* \), therefore it is most uncertain about the sense of \( x \). In this case, expert advice would be needed.

   c) Margin. The algorithm selects the instance \( x \) with the least predicted \( p(y_1|x; \theta) - p(y_2|x; \theta) \), where \( y_1 \) and \( y_2 \) are the most and second most probable senses. Intuitively, the model may not be able to determine if \( y_1 \) or \( y_2 \) is the appropriate sense, therefore it needs further clarification from the human expert.

   d) Entropy. The algorithm selects the instance \( x \) with the highest prediction entropy. High entropy means that the current WSD model considers any sense assignment as almost equally probable. Expert advice is thus needed to resolve the confusion.

In our implementation, we use the margin based active learning strategy to select instances. Note that all four methods can be launched without the search component, which in effect reduces the ReQ-ReC into a classical active learning system. In the evaluation experiments reported in this paper, these methods will be used as baselines for comparison.
4) Query expansion. In the outer-loop, a new query can either be automatically generated by the system and reviewed and improved by human experts, or be composed manually. In this study, we consider the following two extreme strategies: (a) the system automatically generates a new query based on the current status of the WSD model with no human input; and (b) the human expert composes new queries solely based on her or his domain knowledge. These two strategies represent the “worst” scenario and a “desirable” scenario of ReQ-ReC. We use the Rocchio’s method to automatically generate the next query \( q_y \) for every sense \( y \).\(^{18}\) The basic premise of Rocchio’s method is to learn a new query vector that is related to sense \( y \) and far away from other senses.

In fact, we hope that the new query \( q_y \) will not be too close to the known contexts in which sense \( y \) may appear. This would allow the framework to suggest to human experts other contexts of the sense that might not have been thought of. To achieve this goal, we use the “diverse” method developed for high-recall retrieval,\(^{17}\) which generates a new query that balances its relevance to the sense and the amount of diverse information it introduces to the current pool of instances. In the rest of the paper, this strategy is referred to as “machine-generated” queries or the “worst case” of ReQ-ReC.

We also simulate the scenario where human experts use domain knowledge to include contextual words into search queries. To do this, we rank all the contextual words, words appearing in at least one instance of the ambiguous word, by the information gain, i.e. the reduction of uncertainty on the sense of the ambiguous word after seeing a contextual word.\(^{24}\) Top-ranked contextual words are considered as informative and used as search queries to warm-start the initial model learning. In our experiment, the simulated expert guides the first 6 queries using the top 30 contextual words.\(^{†}\) As a simulation of domain knowledge, information gain is computed based on the entire set of labeled instances. Note that information gain is only a crude measure for selecting informative contextual words; human experts can do better with their domain knowledge. This simulation would result in an underestimate of the true performance of ReQ-ReC. We denote this scenario as ReQ-ReC with “simulated expert” queries.

B. Evaluation Methodology

B.I. Evaluation corpora

In this study, we used three biomedical corpora to evaluate the performance of the ReQ-ReC framework.

The MSH corpus contains MEDLINE abstracts automatically annotated using MeSH indexing terms.\(^{8}\) Originally, it has 203 ambiguous words, including 106 abbreviations, 88 words, and 9 terms that are a combination of abbreviations and words. Following previous work,\(^{14}\) we only included ambiguous words that have more than 100 instances so we have sufficient data for training and evaluation. This results in 198 ambiguous words.

The UMN corpus contains 75 ambiguous abbreviations in clinical notes collected by the Fairview Health Services affiliated with the University of Minnesota.\(^{25}\) 500 instances for each abbreviation were randomly sampled from a total of 604,944 clinical notes. Each instance is a paragraph in which the abbreviation appeared. In this study, we excluded unsure and misused senses in training and evaluation.

The VUH corpus contains 25 ambiguous abbreviations that appeared in admission notes at the Vanderbilt University Hospital.\(^{26}\) Similar to the MSH corpus, we only retained 24 abbreviations that have more than 100 instances. Each instance is a sentence in which the abbreviation appeared.

The statistics of the three corpora are summarized in Table 1. We can see that the MSH corpus has the richest context in an instance and the least skewed distribution of senses for an ambiguous word. Because our main goal in this study was to compare the effectiveness of different learning algorithms, we did not further tune the context window size for each corpus.

B.II. Metrics

In this study, we used learning curves to evaluate the cost-benefit performance of different learning algorithms. A learning curve plots the learning performance against the effort required in training the learning algorithm. In our case, learning performance is measured by classification accuracy on a test corpus and effort is measured by the number of instances labeled by human experts. For each ambiguous word, we divided its data into an unlabeled set and a test set. When a learning algorithm is executed over the unlabeled set, a label is revealed only if the learning algorithm asks for it. As more labels are accumulated, the WSD model is continuously updated and its accuracy continuously evaluated on the test set, producing a learning curve. To reduce variation of the curve due to differences between the unlabeled set and the test set, we ran a 10-fold cross validation: 9 folds of the data are used as the unlabeled set and 1 fold used as the test set. The learning curve of the algorithm on the particular ambiguous word is produced by averaging the 10 curves. The aggregated learning curve of the algorithm is obtained by averaging the curves on all ambiguous words in an evaluation corpus.

To cope with the cold start problem of active learning algorithms, we randomly sampled one instance from each sense as the initial training set. To facilitate comparison, we used the same initial training set for random sampling and ReQ-ReC. The batch size of instance labeling was set to 1 for all learning algorithms, so that we could monitor the performance improvement by every increment in the training sample.

To summarize the performance of different learning algorithms using a composite score, we also generated a global ALC (Area under Learning Curve) for each algorithm on each evaluation corpus. This measurement was adopted in the 2010 active learning challenge. The global ALC score was normalized by the area under the best achievable learning curve (constant 1.0 accuracy over all points).

Results

We evaluated six interactive WSD algorithms (one trained on randomly sampled instances, three trained using active learning methods, and two using the worst case and the simulated expert case of ReQ-ReQ) on three biomedical text corpora (MSH, UMN, and VUH).

Table 2 shows the global ALC scores for each learning algorithm on different evaluation corpora. ReQ-ReC with simulated expert queries consistently outperforms all other methods on all three corpora. On the MSH and VUH corpora, even the worst case of ReQ-ReC achieves higher ALC scores than all existing active-learning algorithms. On the UMN corpus, the worst case of ReQ-ReC is slightly outperformed by the margin active learning algorithm. Compared to other active learning methods, the worst case of ReQ-ReC has the highest ALC scores for 164 out of 297 words across three corpora (55.22%) (129/198 in MSH, 20/75 in UMN, and 15/24 in VUH). With simulated expert queries, ReQ-ReC has the highest ALC scores for 206 out of 297 words across the three corpora (69.36%) (156/198 in MSH, 35/75 in UMN, and 15/24 in VUH).

Figure 3, 4, and 5 shows the aggregated learning curves of all algorithms on three evaluation corpora, respectively. Results on the MSH corpus present the clearest patterns: the two ReQ-ReC methods learn faster than other algorithms, especially in the beginning stage (first 30 labels). The learning curves of three active learning algorithms are almost identical and much higher than that of random sampling, as previously reported. To achieve 90% accuracy, the best active learning algorithm requires 26 labels on average, while ReQ-ReC with simulated expert queries requires only 17 labels, saving 35% labeling effort.
Patterns on the other two corpora are less significant, due to highly skewed sense distributions. In general, ReQ-ReC with simulated expert queries still achieves the best learning curve than other methods, but with a smaller margin, followed by an active learning algorithm on the UMN corpus and by the worst case of ReQ-ReC on the VUH corpus. Surprisingly, on the VUH corpus, random sampling learns faster than active learning methods at the very beginning. The benefit of active learning kicks in after 20 labels.

Discussion

The goal of inviting human experts into the machine learning process is to achieve large performance gains with relatively small labeling effort. An active learning process tries to select the next instance such that it brings in as large amount of fresh information as possible for the model to learn from, therefore giving rise to large gains. When asking for the next label, an active learner prefers to ask those instances that represent an unexplored subpopulation and/or instances whose labels the current model is still uncertain about. In contrast, a passive learner randomly picks the next instance from the unlabeled set, regardless of whether it overlaps with a previously labeled one, or whether the model can accurately guess its label, neither of which make the best use of the labeling effort.

WSD model learning benefits considerably from expert queries as a warm start. When the first few queries are informative contextual words, they construct a pool of representative instances. The initial WSD model learned on this representative pool inherits the domain knowledge from the search queries. Human experts can do even better than the simulated expert in composing these queries. Even when the queries are machine-generated, the query expansion procedure also picks up potentially informative contextual words. On the other hand, active learning methods select instances from the entire corpus rather than a representative pool. In the initial learning stage, models are usually poor and their predictions are unreliable. Thus the “uncertain” instances selected by such predictions may not benefit the learning as much as the representative ones. As the model becomes more robust in the later learning stage, the clarification questions raised by active learning will make more sense and labeling these instances can better improve the model.

Different characteristics of text documents affect learning process. In biomedical papers that are formally written (the MSH corpus), an ambiguous abbreviation often appears with its full form for clarification purposes, e.g. “high-risk (HR)” and “heart rate (HR).” The co-occurrence of the abbreviation with its full form greatly makes it easier for both the annotation process and the WSD model. In contrast, an ambiguous abbreviation in clinical notes (the UMN and VUH corpora) is almost never expanded to its full form as abbreviations are typically used to save the time of input. A clinical abbreviation can have many senses that are used in many different contexts. As a result, the annotation process for clinical abbreviations requires extensive search and labeling. Compared to active learning, the ReQ-Rec framework can better assist human experts in building clinical WSD models.

When an ambiguous word has many senses, the sense distribution is often highly skewed: one or two major senses cover more than 90% use cases, while many other senses are rarely used. As we can see in Table 1, word senses of the two clinical corpora are highly skewed (for more than 4 senses, a majority guess has above 70% accuracy).
Skewed sense distribution presents challenge to machine learning. Without abundant labeled instances, it is difficult to learn a WSD model that accurately identifies a rare sense. The classification model will bias towards predicting the major senses and hurt the recall of the rare sense, which becomes an issue for high-stake events such as a rare disease. A straightforward way to cope with the rare sense learning problem is to harvest and label more data for the rare class, for which the first step is to search using contextual words. ReQ-ReC, originally designed for high-recall information retrieval, can be useful in searching for more rare senses.

This study has several limitations. First, in this study we assume the senses of an ambiguous word are known upfront and one instance is already available for each sense, which is a standard setup in the active learning literature. In reality human expert may have knowledge of some but not all of the senses; it is more natural to discover senses on the fly. Second, instead of using the simple bag-of-unigram features, we can use more elaborate features for WSD, e.g. part-of-speech tags, medical concepts (extracted by MetaMap), and word embedding. This could further improve the WSD performance. Third, the framework is only evaluated through simulated experiments and is not evaluated with real users.

Conclusion

In this paper, we describe a novel interactive machine learning framework that leverages interactive search and classification to rapidly build models for word sense disambiguation in clinical text. With this framework, human experts first use keyword search to retrieve relevant contexts in which an ambiguous word may appear to enable targeted, high-yielding annotation. This interactive active learning process, capitalizing on human experts’ domain knowledge, could therefore significantly reduce the annotation cost by avoiding the need to have a fully annotated corpus. Experiments using multiple biomedical text corpora show that the framework delivers comparable or even better performance than current active learning methods, even if human wisdom is not used to aid in the search process (i.e., all search queries are automatically generated by the algorithm). In future work, we will conduct more evaluation studies to assess the performance of the framework using real-world scenarios and real human experts.

Abstract

Social determinants of health play an important role in diagnosis, prevention, health outcomes, and quality of life. The objective of this study was to examine existing standards, vocabularies, and terminologies for items related to Residence, Living Situation, and Living Conditions and to synthesize them into model representations. Sources were identified through literature and keyword searches, and an examination of commonly used resources. Each source was systematically analyzed by two reviewers, mapped to topic area(s), and further mapped to a model representation. A total of 27 sources were identified and reviewed. Seven of the sources had no items, i.e. concepts, elements, or values, related to the three topic areas while SNOMED-CT had the most items at 436 followed by the US Census at 174. While none of the identified sources encompassed a complete representation for documenting the three topic areas, their synthesis together results overall in more comprehensive representations.

Introduction

Social and individual behavioral factors play an important role in diagnosis, prevention, health outcomes, and quality of life.1, 2 As defined by the World Health Organization, “social determinants of health are the conditions in which people are born, grow, live, work, and age”.3 Social determinants of health (SDOH) can cause illness, exacerbate chronic illness, but can also prevent disease and improve health. When considered broadly, SDOH includes behavioral components, such as alcohol, drug, and tobacco use; diet; and physical and environmental factors that may influence an individual’s health such as living conditions, social support, occupation and its associated exposures, and physical activities. These factors contribute to mortality as well as account for being a dominant causal mechanism for many types of disease.4–8

With respect to SDOH related to Residence, Living Situation, and Living Conditions, insecurity related to housing, for example, has been associated with poor health among children,9 barriers related to access to health care,10 and the need for chronic disease management.11 Living situation, residence, and physical living conditions all have been shown to have significant impact on a patient’s health outcomes.12, 13 Since SDOH have a significant impact on patient health as risk factors, they should be considered when assessing and prescribing interventions and can serve to influence provider recommendations. For example, if a patient requires a weekly treatment at a distant location, lives in a residential facility, and relies on public transportation, then a weekly treatment plan may not be realistic without additional support, and the patient could become non-compliant. Or, if the patient is homeless, then a treatment plan that requires the use of a refrigerated antibiotic is most likely not a feasible option.

While much work has been done to demonstrate the deleterious effect of behaviors such as alcohol and tobacco use on health outcomes,14 many other social determinants particularly around physical and environmental factors have not been investigated as thoroughly or linked as deliberately to health outcomes. Housing, for example, has been studied with respect to the impact of homelessness on various conditions and housing related exposures.15–24 However, little work has been done around examining the health affects of housing density or with whom the patient lives.25 In a number of cases, the benefits of housing interventions including different types supportive housing have been demonstrated on physical and mental health.26–32 Moreover, knowledge regarding the patient’s physical living space, who the patient lives with, and living conditions would be of benefit clinicians and other stakeholders in providing patient-centered and more appropriate care and services.33

Electronic health record (EHR) systems provide an unprecedented opportunity to collect and analyze patient data at the point of care and for improving our understanding of disease and healthcare outcomes with secondary use of this data. If leveraged fully, SDOH data may be collected at the point of care within these systems and then re-used. For
instance, SDOH can be analyzed along with clinical data to more fully evaluate patient outcomes, generate evidence-based care guidelines, and identify patients who may benefit from special services or interventions or those who may be at higher risk for preventable events. Despite the opportunity of EHRs, standard terminologies and well-designed discrete data collection tools for social history have not been widely developed and incorporated to different EHR systems. In most cases, SDOH documentation may be entered as structured data or unstructured text (e.g., in clinical notes or free-text data collection fields). This leaves a large gap in the data that can be used to enhance patient care as well as facilitate population health research to further the study of SDOH impact to health. The development of standard representations for SDOH information and ultimately optimized data collection tools will ultimately facilitate analytics, clinical decision support, and re-use and interoperability of this information.

To start bridging this gap, work to define and harmonize SDOH standards for inclusion in the EHR has been done,\textsuperscript{34, 35} including recent National Academy of Medicine (NAM; formerly Institute of Medicine) reports recommending social and behavioral domains and measures for EHRs for inclusion in Stage 3 Meaningful Use requirements.\textsuperscript{35} Some work (Chen et al and Melton et al) \textsuperscript{36, 37} has also been done to model social history from clinical notes and public health surveys including residence and living situation. The goal of this study is to expand upon these previous model representations for Residence, Living Situation, and Living Conditions through synthesis of a collection of interface terminologies, standards/specifications, documentation guidelines, and measures/surveys, evaluate the coherence of documentation, and ultimately contribute to a preliminary model representation that will be used to inform design and development of data collection tools in the EHR for these topic areas.\textsuperscript{38}

**Methods**

The topic areas of Residence, Living Situation, and Living Conditions examined in this study are defined and summarized from a literature search in Table 1. This study was performed in three phases: (1) identifying sources potentially containing references to at least one of the three topic areas; (2) analyzing each data source for specific items related to each topic area; and, (3) synthesizing items into comprehensive representations for each of the three target topic areas. For the purpose of this analysis, all references found were weighted equally whether they were a concept, survey question, element, or member of a value list and termed as “items”.

**Table 1: Definitions and sentence/statement examples for target SDOH topic areas.**

Qualifying sources were identified via literature and Internet searches using search terms that included: “<EHR or EMR> documentation”, “social documentation <standards or terminology>”, “social worker documentation <standards or terminology>”, “physical therapy documentation <standards or terminology>”, “occupational therapy documentation <standards or terminology>”, “social determinants documentation”, “<EHR or EMR> residence”, “<EHR or EMR> living situation”, and “<EHR or EMR> living conditions”. Additional sources were suggested by subject matter experts, and professional organization websites for physical therapy, occupational therapy, and social work were examined and also searched using the above list of terms. A source was included in the final set if it contained references to or specific items related to one or more of the three topic areas of Residence, Living Situation, or Living Conditions.

Each of the identified sources were grouped into one of four categories: (1) Interface Terminology, (2) Standards/Specifications/Coding Terminology, Vocabulary, (3) Documentation Guideline, and (4) Measures/Surveys. These categories were partly based upon the sources own definition, as well as the type and function of the source, i.e. how it is used in health IT and patient care. Each individual source was examined to identify specific items related
to each of the three broad topic areas of Residence, Living Situation, or Living Conditions. The source search was limited to assessment-related items and excluded interventional references. Those sources that were available electronically were searched systematically using the provided search tools, such as the IHTSDO SNOMED-CT browser or the standard search mechanisms provided by each source. Sources available in book or paper form were searched manually. The initial list of search terms used was derived from the literature search. The list was further iteratively refined as sources were examined. The final list of search terms used included: “home”, “house”, “housing”, “residence”, “live”, “living”, “lives”, “people”, “mold”, “insect”, “rodent”, “water”, “heat”, “social”, and “density”. All sources were reexamined and searched by two reviewers using this final complete list of search terms. Any discrepancies between the primary and secondary review were subsequently evaluated and the final list of items was amended accordingly to compile a final comprehensive list by consensus. In cases where a source contained items from another standard or terminology source, the duplicates were excluded from the data set in the final analysis.

Each item identified from within each source was then mapped to one of the three topic areas of Residence, Living Situation, and Living Conditions. Each item was then further analyzed and then mapped to specific element axes and values from a previously defined model resulting in an enhanced and more comprehensive model for Residence, Living Situation, and Living Conditions. Element axes and values were added to the previous model representation or expanded on to accommodate findings from this review.

Results

A total of 27 data sources were identified as potentially having applicable items for one or more of the three topic areas. Of the 27 sources, seven sources were excluded during the initial analysis due to lack of detail or specificity. Those included the Meaningful Use Stage 2 Requirements and the EHR Certification Requirements, which did not include specific items directly related to the target topic areas for this study. The Nursing Management Minimum Data Set also did not contain relevant items. The Centers for Medicare Social Work Documentation Guidelines (MSWDG) and the Medicare Rehabilitation Documentation Requirements (MRDR) did contain references to the target topics areas; however, these sources were very high level and did not provide sufficiently detailed information appropriate for this work. Lastly, the Nursing Interventions Classification (NIC) and Uniform Terminology for Occupational Therapy contained items related to interventions and patient activity and not assessments, therefore these two sources were excluded from the final analysis. Secondary review of the 27 sources confirmed these results.

The remaining 20 sources contained applicable items for one or more of the three topic areas. Nineteen of the 20 sources contained some references to Residence totaling 643 items not including the United State Board on Geographic Names, which in itself contained millions of items for national and international named geographic locations (Table 2). SNOMED-CT had the highest number of items related to Residence at 265, followed by the US Census at 160, and third was HL7 at 58 items. Fifteen of the 20 sources contained items related to Living Situation totaling 96 items, the highest being again SNOMED-CT with 62 items, followed by openEHR with 7 items, and the US Census with 6 items. Lastly, 11 of the 20 sources had references to Living Conditions totaling 197 items. The source with the most references to Living Conditions was once again SNOMED-CT with 109 items followed by the Health Indicators Warehouse with 24 items and lastly NANDA-I with 19 items.

Identified items were further manually evaluated and classified using the previously published model representations as a foundation (Table 3). Logical groupings of items were derived and individual items were mapped to an existing element axis or new elements axes were added to accommodate findings related specifically to the three topic areas. The most prevalent mapping was to Residence Detail with 13 sources containing items, and the second most prevalent was Residence Type, which was found in 12 of the 20 sources. Nine sources had items mapping to Living Situation Detail, 9 sources had items mapping to Living Conditions Detail, and 7 had items mapping to Living Condition Type. Of the 20 sources, PhenX Toolkit, openEHR and the US Census had the broadest coverage of elements and values.

Model representations were developed from the mappings. The model representation for Residence uniquely contains items to describe the physical dwelling type, such as “House”, “Apartment”, or “Group Home” as well as details about that physical dwelling including presence and number stairs, and other safety items such as railings. There are also items to collect data about age of the residence, residence build time point as well as geographic location. The model representation for Living Situation includes more detail around Subject since this topic area is related to whom the patient is living with as well as Living situation Detail. Lastly, the model representation for Living Conditions includes an entity to document Living Conditions Type, which refers to the type of hazard such as “mold”, “insects”, or “animals” as well as Living Conditions Detail, which includes details about the Living Conditions Type or more general information about Living Conditions such as “Control environmental pests” (Figure 1).
Table 2: Sources and item counts (*USBGN contains all national and international geographic location names.

**Figure 1:** Preliminary Enhanced Model Representations of Residence, Living Situation, and Living Conditions.
Discussion

While SDOH represent important considerations in the provision of patient care and are also becoming more important in population health management, a number of important gaps in their use continue to exist. Currently, SDOH are not consistently or well-documented in the EHR, particularly the three topic areas on which this work is focused: Residence, Living Situation, and Living Conditions. By working towards synthesis of existing sources to derive enhanced models, we are starting to bridge this gap. Ultimately, the enhanced model representations could be used to inform the design and development of associated EHR documentation tools. To that end, our focus was to err on comprehensiveness in collecting assessment items associated with these topic areas rather than provided or resulting outcomes of those interventions.

A preliminary search for data sources in the form of interface terminologies, standards, specifications, coding terminologies, vocabularies, documentation guidelines, measures, and surveys yielded 27 possible sources that potentially contained items related to the three topic areas. While some sources were eliminated, collating the remaining 20 was highly informative. While no single source was completely comprehensive for all three topic areas, there was overall coverage to support an enhanced model representation. The most broadly comprehensive source was SNOMED-CT, which contained the highest number of relevant items overall, as well as ranking first for the highest number of items for each of the three individual topic areas. The US Census survey ranked second for total items as well as second for Residence (Table 2).

Collectively, the final set of 20 sources were very diverse in specificity primarily because they had distinct but different purposes and uses. For example, OMAHA, NIC, NOC, NANDA-I, and CCC are intended to assist in nursing documentation whereas HL7 is a standard intended for broader data exchange and the US Census and the OASIS are intended to collect data for population surveillance. Lastly, the US Board on Geographic Names was an outlier as it contained millions of very specific items for named geographic locations including city, state, county, country, as well as landmarks and bodies of water. This source could be helpful in standardizing how we model and record geographic locations. As a result of this variability in use and purpose, some sources contained high level, broad concepts, while others contained very specific items and very lengthy, detailed value lists. This diversity presented a challenge in the harmonization phase of the project. For example, SNOMED-CT lists “Housing, local environment and transport finding” with a diverse value list that includes residence types such as “apartment” and “mobile home” as well as living conditions such as “Lives in damp conditions” and “Presence of lead-based paint” while HL7 listed a specific item “primaryResidenceSetting PrimaryResidence” that has an extensive value list associated with it that contained types of physical dwellings. In many cases the lack of specificity caused an item to be counted in more than one topic area. One example of this was found in the Open EHR source that had an item “Description of the home environment”. This could include a description of any of the three topic areas and was counted as such in the final analysis. Ultimately, due to the variability in specificity of the items the data sources, in the final analysis and harmonization, all references to the three topic areas were weighted equally as items whether they were high level broad concepts, questions, elements, or individual values within a value list. This allowed for equal comparison and categorization of the items into the model representation.

Analysis of the final 20 data sources demonstrated that the topic areas of Residence, Living Situation, and Living Conditions are being included in those sources with Residence being most prevalent, specifically Residence Detail (details about the physical structure of the dwelling including safety features) and Residence Type (type of physical dwelling such as house, apartment, group home, nursing home). References to Living Situation were not very detailed. Many of the sources included some indication of whom the patient was living with but the value lists were very non-specific including values such as “family” or “partner/spouse”. Items related to Living Conditions were mostly related to water, sewage, electricity, and heat availability with some references to sanitation specifically insects or rodents. Present, but much less prevalent, were references related to subject other than patient, as were references to temporality, certainty, quantity, and negation, i.e. the absence of an item or condition. Despite these unique challenges, the analysis of these sources, generated 934 items that were ultimately mapped to model elements resulting in enhanced model representations for the three topic areas.

The contributions of this work represent a step towards further informing biomedical standards for the representation of social determinants of health, specifically Residence, Living Situation, and Living Conditions. Next steps will be to further enhance this model representation and ultimately inform the design of EHR data collection tools through the incorporation of EHR unstructured and semi-structured text classifications. One unexpected challenge this work was the complexity of the sources and the difficulty in categorizing them into logical groupings. In future work it may be of interest to examine and develop standard definitions for these types of sources.
Conclusions

While this is a compilation and harmonization of a unique and diverse set of sources, overall, the diversity of the data sources contributed to a broader more detailed model than in previous work. Our results demonstrate that there are many sources that are currently being used to inform data collection with regards to Residence, Living Situation, and Living Conditions. While none of the sources were completely comprehensive, once harmonized they served to inform a more detailed model representation for the three topic areas that can be used towards developing more comprehensive data collection tools in the EHR.

Abstract

\textbf{Purpose:} Clinical decision support tools provide recommendations based on decision rules. A fundamental challenge regarding decision rule-sharing involves inadequate expression using standard terminology. We aimed to evaluate the coverage of three standard terminologies for mapping imaging-related decision rules.

\textbf{Methods:} 50 decision rules, randomly selected from an existing library, were mapped to Systemized Nomenclature of Medicine (SNOMED CT), Radiology Lexicon (RadLex) and International Classification of Disease (ICD-10-CM). Decision rule attributes and values were mapped to unique concepts, obtaining the best possible coverage with the fewest concepts. Manual and automated mapping using Clinical Text Analysis and Knowledge Extraction System (cTAKES) were performed.

\textbf{Results:} Using manual mapping, SNOMED CT provided the greatest concept coverage (83%), compared to RadLex (36%) and ICD-10-CM (8%) (p<0.0001). Combined mapping had 86% concept coverage. Automated mapping achieved 85% mapping coverage vs. 94% with manual mapping (p<0.001).

\textbf{Conclusion:} Although some gaps remain, standard terminologies provide ample coverage for mapping imaging-related evidence.

Introduction

Clinical decision support (CDS) integrated with a computerized physician order entry (CPOE) system can improve workflow efficiency, increase guideline adherence, and reduce the rate of inappropriate imaging in certain outpatient and Emergency Department (ED) settings(1-4). To improve quality of care and reduce waste, the Affordable Care Act was implemented to encourage CDS adoption(1, 5). Additionally, under the Protecting Access to Medicare Act of 2014, health care providers will be required to consult specified appropriate use criteria using a qualified CDS system when ordering advanced imaging for Medicare patients(6).

CDS decision rules are often derived from professional society guidelines, published evidence, and local best practices and are generally described in free text(7). For CDS decision rules to be shareable, they need to be machine interpretable and available in standard representation(8). Recently, a repository of diagnostic imaging decision rules has been developed, which also includes systematic grading of recommendations(7). Although these decision rules are available in semi-structured format, the terminology is not in standard format and limits shareability. Leveraging existing medical terminologies could potentially offer a solution to standardizing concepts within decision rules. In addition, automated approaches for mapping to standard terminologies could enable large scale mapping of decision rules from various CDS systems.

Three terminologies have been utilized previously to retrieve critical imaging findings in radiology - Systemized Nomenclature of Medicine (SNOMED CT), Radiology Lexicon (RadLex) and the International Classification of Diseases, 9\textsuperscript{th} edition (ICD-9-CM)(9). For this study, the newer edition, ICD-10-CM is used. A brief description of these three terminologies follows.

\textbf{SNOMED CT}
SNOMED CT contains more than 311,000 concepts. SNOMED CT is an extensive clinical terminology that was formed by the merger, expansion, and restructuring of SNOMED RT® (Reference Terminology) and the United Kingdom National Health Service Clinical Terms. It is the most comprehensive clinical vocabulary available in English(10).

RadLex

RadLex is developed by the Radiological Society of North America in recognition of limited coverage of radiological concepts by other lexicons(11). RadLex provides a standardized method for indexing radiological concepts in a variety of settings. RadLex consists of approximately 12,000 individual concepts(12).

ICD-10-CM

ICD-10-CM is a clinical modification of the World Health Organization’s ICD-10, which consists of a diagnostic system. ICD-10-CM includes the level of detail needed for morbidity classification and diagnostic specificity. As with ICD-9-CM, ICD-10-CM is maintained by the National Center for Health Statistics. It has more than 68,000 codes, compared to approximately 13,000 in ICD-9-CM(13).

Therefore, the primary goal of this study was to evaluate the coverage of SNOMED CT, RadLex and ICD-10-CM for mapping imaging-related decision rules. As a secondary goal, we assessed automated mapping using Clinical Text Analysis and Knowledge Extraction System (cTAKES), a natural language processing (NLP) tool.

Methods

Source of Decision Rules

This study was exempt from Institutional Review Board review. Imaging-related decision rules were randomly selected from among those in an existing publicly available library of evidence(7). The library currently contains 411 annotated and graded decision rules, derived from practice guidelines and studies published between 1995 and 2014. Specifically, 50 decision rules were selected for this study from five sources – two professional society guidelines (American College of Radiology [ACR] and American College of Physicians [ACP]), local best practice from two healthcare organizations (Ottawa Civic Hospital and Brigham and Women’s Hospital) and a clinical study (Wells Criteria for pulmonary embolism evaluation).

Each decision rule consists of 20 attributes, of which 6 attributes contain values with clinical content that can be expressed using standardized medical terminology. We selected these attributes’ corresponding values for mapping: “imaging modality”, “contrast”, “body region”, diagnosis/symptom”, “clinical logic (if)” and “clinical logic (then)”.

An example of clinical logic – If (Chronic headache) AND (No new features) AND (Normal neurologic examination), THEN MRI of the head without contrast – is included in Figure 1. The other attributes that were not suitable for mapping included names of graders, guideline publishers (e.g. ACR), dates of publications, citations and evidence grades. Full decision rules are publicly available on the library website(14). The list of the 50 rules is included in the supplemental file.

Generating Unique Attribute Values

A total of 300 attribute values were derived from the 50 decision rules (6 attribute values per decision rule). Repeated attribute values were only analyzed once. In addition, stop words, and commonly occurring English words (e.g., with) were removed(15). Attribute values comprised of solely stop words (e.g., “without”) were removed entirely, while those containing partially stop words had only the stop words removed (Figure 1). A total of 75 unique attribute values were generated.
Figure 1. Flow chart of Methods

Manual Mapping

The National Cancer Institute (NCI) Metathesaurus Term Browser, which includes SNOMED CT, RadLex and ICD-10-CM(16), was used to map each unique attribute value to each terminology. To maintain consistency, the “Exact Match” option in the NCI browser was used to search each terminology. We used the UMLS build 2015AB,
which contains SNOMED CT (version, 2013_09_01), Radlex (version, 3_10), and ICD10_2010. Evaluation of match type and computation of coverage are described in the subsequent subsections.

a. Generating unique concepts – A concept is defined as “the fundamental unit of meaning of terms ... and contains all atoms from any source that express that meaning in any way.”(17) If a phrase contains only one word (e.g., Head), then the concept is equivalent to the phrase. If a phrase contains more than one word (e.g., Chronic Headache), then the concept is determined by prioritizing pre-coordinated terms over post-coordinated terms. For example, if the attribute value “chronic headache” results in a simple match (“chronic headache” to “chronic headache”) or a partial match (chronic headache” to “chronic ache”) from any one of the three medical terminologies during mapping, then “chronic headache” would be a concept. Otherwise, “chronic” and “headache” would be two separate concepts that make up the attribute value “chronic headache”. By this definition, any concept with more than one word could be partially matched, while concepts with one word may or may not match. This ensures mapping attribute values to the least number of concepts.

b. Calculating concept coverage – Concept coverage is calculated for each of the three terminologies by calculating the percentage of matched concepts using a single terminology over all concepts from the attribute values. For example, concept coverage for SNOMED CT is defined as the number of unique matched concepts (simple or partial match) using SNOMED CT alone, over the number of existing concepts derived from all attribute values.

c. Categorizing match types – Using methods described by Aronson(18), when mapping attribute value, one of the following could result: “simple match”, “complex match”, “partial match” or “no match”. A simple match results when the concept value is identical to the attribute value (e.g., “pulmonary embolism” to “pulmonary embolism”). A complex match results when individual terms in an attribute value have a simple match to more than one concept, but the entire attribute value does not have a simple match (e.g., “acute ankle injury” to “acute” and “ankle injury”). A partial match results when at least one word of either the mapped result or the attribute value does not participate in the mapping process (“hereditary nonpolyposis colorectal cancer” to “hereditary nonpolyposis colon cancer”), and a no match results when no concept in the attribute value was successfully mapped. All three terminologies were utilized to calculate the highest possible number of matched concepts.

d. Calculating mapping coverage – Further using methods described by Aronson, assuming the attribute value has X words, in which X0 words (X0 ≤ X) participated in the mapping process, and corresponding mapped result has Y words, in which Y0 words (Y0 ≤ Y) participated in the mapping process, the mapping coverage is defined as: 
\[
\frac{2}{3} \left(\frac{Y_0}{Y}\right) + \frac{1}{3} \left(\frac{X_0}{X}\right).
\]
For example, for the attribute value “(Chronic headache) AND (No new features) AND (Normal neurologic examination)” (Fig. 1), there are 7 words in total (“No” is a stop words thus removed). Of the 7 words, “feature” was not matched, while all other words had simple matches. Therefore, X = 7, X0 = 6, Y = 6, Y0 = 6, leading to a mapping coverage of: 
\[
\frac{2}{3} \left(\frac{6}{6}\right) + \frac{1}{3} \left(\frac{6}{7}\right) = \frac{20}{21}.
\]
Abbreviations were un-abbreviated (e.g., MRI would count as three words). Under this definition, simple and complex matches would automatically have a mapping coverage of 1, partial match with a mapping coverage between 0 and 1, while no match would have a mapping coverage of 0. The average mapping coverage is the mean mapping coverage of all 75 attribute values.

Automated Mapping

cTAKES version 3.01(19) was used with YTEX (part of the cTAKES Apache Project) to perform automated mapping. cTAKES was customized with RadLex, the latest releases of the SNOMED CT vocabulary files and ICD-10-CM using the NCI-supported knowledge representation languages, resource description framework (RDF) and the MetamorphoSys’ sub-setting utility, a customization tool provided by the Unified Medical Language System (UMLS) to customize and add source vocabularies to UMLS(20). Custom components were developed to allow cTAKES to take its input from a structured data source and write its output to the YTEX defined schema. cTAKES was applied to all 75 unique attribute values, and the output included concept unique identifiers (CUIs) from the three terminologies(21).

Categorizing match types and calculating mapping coverage were performed similar to manual mapping. We also prioritized pre-coordinated results over post-coordinated results. For example, cTAKES maps “pulmonary embolism”
to the concept “pulmonary embolism” and two other concepts, “pulmonary” and “embolism”. In this case, we would disregard “pulmonary” and “embolism”, and would only consider the simple match result “pulmonary embolism.”

**Data Analysis**

We calculated the concept coverage of SNOMED CT, RadLex and ICD-10-CM individually for all existing concepts, and assessed concept coverage for all three terminologies combined. We used McNemar paired test to compare concept coverage between the three terminologies. We further computed the average mapping coverage for all attribute values resulting from automated mapping, and compared this to the average mapping coverage when we performed manual mapping using paired t-test. A p-value of <0.05 was considered significant.

**Results**

A total of 75 unique attribute values and 220 unique concepts were generated from the randomly selected 50 pieces of evidence.

**Concept Coverage for SNOMED CT, RadLex and ICD-10-CM**

Of the 220 concepts, SNOMED CT provided coverage of 182 concepts, an 83% concept coverage (181/219) rate, significantly greater than RadLex with a 36% concept coverage (79/220, p<0.0001), and ICD-10-CM with an 8% concept coverage (18/220, p<0.0001). When combining all three terminologies, the concept coverage was 86% (190/220). The 8 concepts in addition to the 182 concepts covered by SNOMED CT were contributed by RadLex (Table 1). The unmapped concepts are listed in Table 2.

**Match Categorization and Mapping Coverage: Automated vs. Manual Mapping**

For automated mapping using cTAKES, there were 19 simple matches (25%), 5 complex matches (7%), 49 partial matches (65%), and 2 no matches (3%). For manual mapping, there were 20 simple matches (27%), 34 complex matches (45%), 21 partial matches (28%) and 0 no match (0%). The mapping coverages for manual and automated mapping were 94% and 85%, respectively (p<0.001)

**Discussion**

CDS aids clinicians in decision making, thus reducing medical errors and cost, and promoting more effective care(22). Despite this, most healthcare institutions have limited CDS capabilities(23, 24). One key reason for limited adoption is the predominant use of non-standard approaches to implementing CDS that are often specific to an implementation setting(23, 25, 26). As a result, CDS capabilities developed at one institution may not be easily
transferred to other health care institutions, or even to other types of CDS applications within the same institution(23, 27).

At its core, CDS represents clinical knowledge in a detailed, machine-interpretable format. Machine-interpretable representation, while challenging, is necessary because narrative clinical guidelines often lack the detail and algorithmic specificity required for execution(28). One promising approach to promote CDS capabilities is the availability of machine-interpretable knowledge resources, which can be leveraged across multiple care settings(23, 29-32). However, this approach requires overcoming the heterogeneity that often exists across institutions with regard to patient data and knowledge representation(33). Thus, the adoption of a robust CDS system is critically dependent upon the development and adoption of standards that encompass these facets of CDS delivery.

Various standard terminologies that can represent CDS content are already well-developed(34). Thus, the challenge lies with the fact that multiple terminologies are in concurrent use and the unavailability of content represented using these standard terminologies. As a result, a CDS resource designed for use in one setting may not be readily applicable in another setting. When we assessed concept coverage of SNOMED CT, RadLex and ICD-10-CM, SNOMED CT provided the highest concept coverage at 82.6%. With well over 300,000 concepts, even though not imaging-specific, SNOMED CT provided significantly more coverage than RadLex (35.6%), a radiology-specific lexicon with approximately 13,000 concepts and ICD-10-CM, a terminology primarily for diagnoses and billing with about 68,000 concepts. Although SNOMED CT was able to capture most of the concepts, RadLex presented 8 additional concepts, some of which were specific to radiology (e.g., colonography).

The list of unmapped words (Table 2) covers mostly common English words (e.g., obvious), specific clinical concepts (e.g., hemodynamic), and proper names (e.g., Ottawa). One way to decrease the number of unmapped words is the use of a dynamic suggestion drop down menu when converting narrative clinical guidelines to a structured format. For example, if SNOMED CT is incorporated during the authoring tool when converting guideline recommendations, using synonyms of the unmapped words may prompt authors to use concepts that can be mapped to SNOMED CT.

For the match types of attribute values, manual and automated mapping resulted in similar simple matches, while the majority of attribute values that were mapped as complex matches were mapped as partial matches under automated mapping. The average mapping coverage for manual mapping was significantly higher than that of automated mapping. This result is not surprising as complete matches, defined by combining simple and complex matches (72% in manual mapping; 32% in automated mapping) have a coverage of 100%. Therefore, mapping manually is capable of achieving significantly higher coverage compared to using cTAKES. Some reasons why cTAKES did not have a complete match include deficiency in mapping of abbreviations (e.g., MRCP), adjectives/modifiers (e.g., missing “chronic” in “chronic headache”), and occasionally, incorrect matches (e.g., “without risk factors or neurologic deficit” was mapped to “malnutrition”).

Limitations
This study focused primarily on terminologies that can represent imaging-related guideline knowledge and may not generalize to guidelines in other disciplines. Second, manual effort was required to filter out redundant mapping results from cTAKES. This may have resulted in greater mapping coverage, compared to fully automated mapping. Lastly, while our study addresses the coverage of the three terminologies, it does not taking into consideration the importance of certain words or phrases during the mapping process.

Conclusion
Standard terminologies, such as SNOMED CT, RadLex and ICD-10-CM, provide ample coverage for mapping imaging-related guideline knowledge. Among the three terminologies, SNOMED CT provides the highest amount of coverage. Efforts are underway to further reduce gaps in coverage and increase availability of guideline knowledge, expressed using standard terminologies.

Factors Contributing to Dropping-out in an Online Health Community: Static and Longitudinal Analyses

Shaodian Zhang, Noémie Elhadad, PhD
Biomedical Informatics, Columbia University, New York, NY

Abstract

Dropping-out, which refers to when an individual abandons an intervention, is common in Internet-based studies as well as in online health communities. Community facilitators and health researchers are interested in this phenomenon because it usually indicates dissatisfaction towards the community and/or its failure to deliver expected benefits. In this study, we propose a method to identify dropout members from a large public online breast cancer community. We then study quantitatively what longitudinal factors of participation are correlated with dropping-out. Our experimental results suggest that dropout members discuss diagnosis- and treatment-related topics more than other topics. Furthermore, in the time before withdrawing from the community, dropout members tend to initiate more discussions but do not receive adequate response from the other members. We also discuss implications of our results and challenges in dropout-member identification. This study contributes to further understanding community participation and opens up a number of future research questions.

Introduction

Internet and mobile technologies, especially newly emerging social networking applications, are revolutionizing how patients exchange information and social support with care providers, family members/friends, and other patients. Traditionally, patients with life-threatening conditions receive most of the information about their disease from their care providers. While providers tend to focus on the clinical impact of the disease and might ignore the impact of the disease on a patient’s emotional wellbeing and daily life, support groups and more recently online health communities (OHCs), act as a complementary source of support for patients. Previous research suggested that peer patients are able to appreciate each other’s conditions better than health providers, family members and friends, and to exchange necessary emotional support and practical advice of daily health management. Recent years have witnessed increasing popularities of OHCs, with a wide range of formats ranging from discussion forums, to Facebook groups, to dedicated communities like Patientslikeme. Critical to studying OHCs’ impact on their members is characterizing and understanding the patterns of participation in a community. Researchers have studied whether users actively participate or lurk, as well as when they decide to withdraw from the community permanently. Lurking—the phenomenon of users browsing the content but not actively participating in discussions—has been shown to correlate with lower perceived social support and diminished emotional benefits when compared to active participation in a community. Dropping-out—i.e., stopping participation or leaving an intervention, such as an online community, altogether—when examined across members indicates the level of activity in an OHC. For instance, Eysenbach and colleagues reported that the phenomenon of attrition (or dropout) is particularly common in online-based interventions, with more than 90% of study subjects quitting throughout Internet-based studies. In the case of OHCs, understanding factors associated with dropping-out might help identify opportunities for more targeted support of members, and more generally identify for which members participation in an OHC is beneficial and for which it is not. Wang and colleagues examined how type of information received affect users’ choices between staying and leaving, and suggested that informational support is positively correlated with dropping-out while emotional support is positively correlated with staying active in the community. Zhang suggested that information and small group interactions, like emotions, also play a key role in retaining users. Sadeque and colleagues proposed a supervised model to predict dropping-out, and found that factors like time since last activity were predictive. To date, however, it is still unclear which other factors of individual members are moderating dropping-out from online health communities, such as topic of discussions, users’ sentiment expressions, and interactions among users.

Previously we carried out longitudinal analysis of members’ posting history in an online health community to explore how participation affects members’ sentiment, and how different factors impact sentiment change through time.
found that members show an increasingly positive sentiment at the early phases of participation, and that later changes may be correlated with different variables like age and cancer stage. In this study we carry out a series of static and longitudinal analyses, which take topic of discussions, sentiment, and user interactions as variables of interest. We explore if and how these factors correlate with members’ decisions of dropping-out. Because there is no explicit marker for any participant to convey they dropped out of the community, we explore different approaches to determining that a member dropped out. To explore factors in context of dropping-out, we leverage established machine-learning-based methods for sentiment analysis and topic classification of a given member’s posts. We hypothesize that dropout members discuss more disease-specific topics, express more negative sentiments, and interact with other members less actively than the members who stay active in the community. Furthermore, we hypothesize that characteristics of dropping-out can be detected by investigating patterns of changes of these factors.

Methods

The basic workflow of our analysis is as follows. First, we identify members that have dropped out from the community, i.e., members who had history of active participation in community, but have been inactive for a certain amount of time. We collect a set of variables for each members throughout their history of participation in the community. We compare distributions of each variables between dropout members and other members. The longitudinal analyses focus on dropout members to investigate if any patterns of changes of variables exist before they drop out the community, with respect to their sentiment expressions, topics of discussions, and interactions with other members.

Data set

The data set we relied on is from the publicly available discussion board of breastcancer.org, one of the most popular online breast cancer communities. The discussion board is organized in several forums, each with threads and posts. At the time of data collection (January 2015), the dataset consisted of 3,282,008 posts in 121,474 threads, published by 57,424 community members. We extracted post content, public available meta-data like author ID and author name, as well as post signatures including user profiles of self-reported demographics, diagnosis and treatment histories.

Identifying dropout members

Identifying which members in a public community dropped out is not a trivial task. In practice, it is impossible to determine with absolute certainty a dropout member from a public community solely based on changes of posting activity, since an inactive user can always return to the community and resume participation. Moreover, in many communities, like our community of interest in this study, there is no publicly available information about members and their login patterns; and as such the only available information relates to their posting activity. Thus, a member could withdraw from posting content, but still act as a lurker.

To identify the cohort of dropout members for our study, we explored different heuristics. We defined a user in the breast cancer forum as a dropout member, if she has posted more than \( n \) times in the community (i.e. had some history of posting activity), but has been inactive for at least \( t \) years at the time of data collection. The first cut-off is to ensure that users we identify are users who participated in the community discussion meaningfully, instead of one-time information seekers or users who just chimed in a limited number of discussions without real information or support exchanges with other members. The second threshold is to exclude members that may return to the community in the near future, as we assume that users who have been inactive for longer time are less likely to return.

In this particular study, \( n \) and \( t \) were experimentally set as 10 posts and 3 years. As such, for the remaining part of this paper, dropout members refer to those who have posted more than 10 times in the community, and whose most recent post was before January 2012 (three years before January 2015).

Longitudinal analysis of dropout members

Three specific variables were studied to examine if they are correlated with dropout: topic of discussion, interaction with other members, and sentiment expression. These three variables are important building blocks of OHC content and member characteristics, and have been investigated in a wide range of previous studies.

Our research hypotheses are as follows:

</table>

1. Dropout members are more likely to discuss certain topics such as cancer treatments and their side effects, and show certain patterns in topic transitions, before they drop out. These topics and topic transitions may indicate end of cancer treatment journeys, which are usually followed by participation withdrawal.

2. Dropout members receive inadequate social support from other members. They ask questions and seek support more often than other members, but receive less responses. These may indicate lower levels of social support reception leading to decreased sense of belonging, a phenomenon known to be vital to self-perceived effectiveness of community usage.\(^{30}\)

3. Dropout members express more negative sentiment in general, or in their final stage of participation, which indicates a declining level of satisfaction towards community participation.

**Dropout and topics.** To investigate whether topics of discussions correlate with dropping-out, topics of posts must be identified. In this study, topics of posts were identified using a supervised machine-learning tool based on convolutional neural networks (CNN).\(^{31}\) The tool was trained on an annotated data set consisting of 9,016 posts, which was sampled from the same data set used in this study. Eleven topics were considered, which are relevant to describing the information needs of the breast cancer community members. The topics range from disease diagnosis, treatment, to more personal issues like daily lives and nutrition; Table 1 lists all topics with their descriptions. Of note, each post can be annotated with several topics (and as such, the topic identification task is cast as a multi-label classification). Overall, the classifier can identify topics of discussions with around 65% F score across all 11 topics. Further methodological details and detailed system evaluation of the CNN classifier can be found in the cited paper.\(^{31}\)

To characterize the impact of discussed topics, for each user (either dropout or non-dropout members), we aggregate numbers of topics of all posts authored by the user, and average the topic numbers by the total number of the user’s posts. As such, an eleven-dimensional distribution of topics can be established for a member in the forum, representing frequencies of topics discussed by the user.

Armed with distributions of topics for all users in the community users, we first did a multivariate t-test to examine the difference of topic distributions between posts of dropout members and posts of other members. For each topic, we then carried out a univariate t-test, adjusted by Bonferroni correction due to multiple comparisons, between the dropout members and other members in the community to test if a significant difference exists. These two static analyses identify the distributional differences between topics of discussions between dropout members and other members.

Finally, we examined how the averaged frequencies of topics change through time for dropout members before they actually quit the community from a longitudinal standpoint, to investigate whether certain patterns of changes could be detected.
**Dropout and interaction.** Member interaction is the primary medium of exchanging social support, which can be complex in online health communities. In this study, we considered two basic aspects of user interactions: number of initial posts versus number of reply posts, and average number of responses received from other members in the community. Initial posts are those posts initializing threads of discussions, which are usually question asking or help seeking which represent needs of support requesting. Previous research has reported that initial posts are vital part of interactions amongst members, and are usually more negative emotionally. Reply posts, usually representing support providing, are those posts responding to the initial posts, which can exert positive influence on the discussion originator (i.e., author of the initial post). As such, the ratio of number of initial posts to the number of reply posts can be seen as how often the user seek support from others rather than actively provide support to others. Average number of responses received when initializing discussions, on the other hand, represent how much social support in average members receive from other ones. Previous studies have suggested that support providing and receiving may have different effects on perceived benefits.

For each member, we counted the number of their initial posts, the number of their reply posts to other member’s threads, and the number of responses received from other people when initiating a thread. We then calculated the two measures described above, and examined how these numbers differ between dropout members and other members. We relied on a Chi-square test (for initial vs. reply) and t test (for number of replies). Like for the topics, we also examined how these numbers change longitudinally before members’ dropping-out.

**Dropout and sentiment.** Sentiment expression reveals how positive the author’s emotion is when posting. We rely on a supervised classifier for sentiment analysis, which is described in. For each of the post, a sentiment score was calculated, representing the degree of positiveness of the overall sentiment expression. Based on the sentiment scores, we first identified if a significant difference exists between the averaged sentiment scores of posts published by dropout members and posts published by other members, by doing a t-test. Second, we illustrated how sentiment of posts changed through time as dropout members approached the time point when they withdrawn from the community, to see if a decline of sentiment actually happened as suggested by our hypothesis.

**Results**

**Identifying dropout members**

6,338 dropout members were identified using our definition, corresponding roughly to 11% of all users that have posting history in the breast cancer forum. When accounting for all users who have posted more than 10 times (i.e., “meaningfully active”) in the community, the dropout members amounted to 42% of these 15,199 users. The identified dropout members posted 570,932 posts in total in the breast cancer forum, with each one posting 90.1 posts in average. The average posting number is roughly the same as the average across all users posted more than 10 times (91.8). 195 out of these 6,338 dropout members have been highly active in the forum, with each of them posted more than 500 times. These “super-users”, although relatively small in number, contributed to roughly 45% of posts identified.

**Longitudinal analysis of dropout members**

**Dropout and topics.** The multivariate t-test between the topic distributions of posts contributed by dropout members and other members respectively yielded a result which supports a difference with p-value less than $10^{-16}$. Average prevalence of each topic for the two types of members is given in table 2 with corresponding p-values based on the univariate t-tests. We did not include MISC in the table because it is a default topic category only given to those posts which are not assigned any topics otherwise. We used 0.001 as the threshold of p-value for significance. Five topics amongst all ten show significant differences in average numbers between dropout members and other members. Specifically, dropout members posted more relevant to diagnosis and treatment, but less about nutrition and daily matters. The hypothesis that dropout members discuss more about treatment and diagnosis than other members is thus supported.

Figure 1 shows how topic frequencies change through time as dropout members approach the time point of withdrawing. The way we illustrate the changes is as follows. For each topic category, we plotted change of its average frequencies in all posts that were published a certain length of time before their authors’ respective dropout time. We used week, days, and post orders as three different measures to show both long term and short term effects. For exami
Table 2. Average prevalence of topics (per post) in posts of dropout members and other members. P-values are calculated by a t tests adjusted by Bonferroni correction. We use 0.001 as the threshold of p-value for significance.

ple, a point $(1, 0.3)$ in Figure 2(a) or 2(d) represents that the average frequency of the corresponding topic of all posts that are published in the final week of their authors’ participation is 0.3. Except for an trend for a higher frequencies of DIAG and HSYS posts in the final weeks, no significant changes of topic frequencies were identified before members’ dropping-out.

Figure 1. How topic frequencies change through time before members’ dropping-out. X axes, which are in reserve order, represent the time point before members’ dropping-out. Y axis is the average topic frequency of all posts that are published in the corresponding time. Units of x axes in (a)(d), (b)(e), and (c)(f) are weeks, days, and post orders, respectively.

Dropout and user interaction. 121,193(3.9%) of all posts in the forum are initial posts of threads. Among them, 31,277 were posted by dropout members, which are 5.5% of all dropout member publications. However, the Chi-squared test indicates no significant difference between dropout members and other members in terms of ratio of initial to reply posts, with a p-value over 0.9. Across the entire forum, an initial post can receive 24.4 replies in average. Dropout members, in particular, can receive an average number of 23.7 replies throughout their community engagement when initializing discussions. A t-test between the numbers of dropout members and other members indicate no significance with p value 0.69. As such, the hypotheses that dropout members receive less reply from other people and that post initial posts more often in the community are both rejected.

In contrast, the ratio of initial posts increases towards dropout time (Figure 3). It is particularly significant from a longer term standpoint, where the ratio of initial posts dramatically increase from around 5% to over 10% in the last 10 weeks of participation before dropping-out. We carried out a supplementary t-test, in which we compare all posts in final 10 weeks and posts before 10 weeks in terms of the initial/reply ratio, and indeed found a significant difference between the two with p value less than 0.001. Short term changes can also be observed, particularly in the final 5 days. Meanwhile, in term of number of replies received, a landslide can be observed in the week view, which roughly
accompanies temporally the ratio increase of initial posts.

Figure 2. How percentage of initial posts and number of replies change through time before members’ dropping-out. X axes, which are in reserve order, represent the time point before members’ dropping-out. Units of x axes in (a)(d), (b)(e), and (c)(f) are weeks, days, and post orders, respectively.

Dropout and sentiment. The average sentiment score (probability of being positive) for all posts in the community is 0.786, while the average sentiment score of dropout member authoring is 0.788, with no significant difference according to a statistical t-test. Longitudinally, an insignificant decline of sentiment can be observed from the week view, but no other patterns can be found. Although we found a tendency of posting more initial posts in the final stage of participation in the previous analysis, no patterns of sentiment change is visible when initial posts and reply posts are considered separately. In contrast to our expectation, dropout members not necessarily express more negative emotion in discussion, and no significant changes of sentiment can be detected before they drop out.

Discussion

Principle findings

Our first hypothesis that dropout members are more likely to discuss certain topics is supported by our experimental results. We find that dropout members tend to discuss more about disease diagnosis and treatment, but less about daily issues and nutrition. Topics of treatment and diagnosis are common in posts that tell stories of one’s cancer journey, or that describe cancer treatment experience. On the contrary, more daily-matter issues like exercises and nutrition are less focused by these users. Not many significant patterns of topic changes are identified longitudinally, except increased frequencies of health system and diagnosis in the final weeks before dropping out. This seems to suggest that although dropout members are more interested in certain topics in general, they do not necessarily shift their focus drastically throughout their participation. The increasing frequency of DIAG is interesting, however. One possible explanation may be that many dropout members were patients who were diagnosed with cancer recurrences or metastasis, which may be followed by the deterioration of the disease.

Our second hypothesis, with respect to user interactions with other members, is partially supported by the results. We originally expected that dropout members receive less replies from other members, which represents a lower level of social support received from other users, and that dropout members post initial posts more often, which represents that they are more likely to be information seekers rather than social support providers. Previous research in online social support groups suggested that emotional support providing is an important motivation of participation and is beneficial to the providers themselves socially, which is a factor that are expected to be negatively correlated with
Figure 3. How average sentiment score changes through time before members’ dropping-out. X axes, which are in reserve order, represent the time point before members’ dropping-out. The first three figures show the average score of posts including both initial and reply, and the last three figures distinguish the two. Units of x axes in (a)(d), (b)(e), and (c)(f) are weeks, days, and post orders, respectively.

attrition.

However, in our static analyses, no significant differences are identified in the static analysis between dropout members and other members with respect to number of replies received, or ratio of initial posts to number of reply posts. The result may have two possible explanations. The first is that neither of the two measures can truly represent the degree of social support exchange in online health communities, and the other is that OHC users, particularly BC forum users, are different from online social support group members studied in previous research in how they perceive and understand benefits.

Although static comparison finds no difference, longitudinally we indeed find a rather significant increased ratio of initial posts at the end of user participation, as well as an insignificant drop of numbers of received replies, which is consistent with findings in the previous research that number of replies is important predictor of dropout. The change is particularly dramatic in the final few weeks from the week view, and in the final 5 days from the day view.

This result, along with results from the static analysis of interactions as well as from previous analyses of topics, possibly shows a more complete picture of dropping-out: dropout members, in terms of support seeking and support providing, are identical to other community members in most of the times throughout their participations; however, certain events, which may be from the real lives of the users such as recurrence of cancer, trigger online behavioral changes and make the users seek much more support than before. At this moment, if these members don’t receive adequate support, dropout may eventually happen.

Our final hypothesis that users express increasingly negative emotions in posts are not supported by our analysis. No significant difference is found between dropout members and other members, and no clear patterns can be identified longitudinally. The results contradict findings in previous research that usages of emotional keywords are associated with dropping out, possibly because keywords of emotions cannot truly represent sentiment. Synthesizing the sentiment and interaction results seems to suggest that changes at the end of participation are mostly peaceful in sentiment, with no evident clue emotionally.

Validity of our dropout member identification method

In this study, we rely on a straightforward method to identify more than 50 thousand dropout users, assuming that these users having an active history but having been inactive for at least 3 years. For a public online health community like breast cancer forum in which the community has no control over its members, identifying dropout members with absolute accuracy is infeasible. Because of the unavailability of gold-standard, evaluation of such identification method is challenging.

In our method, the most tricky part is to choose the \( t \) cut-off, which represents the minimal length of inactiveness for a member to be considered as dropped out. A larger \( t \) would definitely bring a set of dropout members with higher precision, but may excludes eligible dropouts incorrectly. Given the fact that most members joined the community in recent years and the forum was getting increasingly popular, a large \( t \) would lead to a small sample size. As such, the problem becomes a precision-recall trade-off, and our task is to finds the best value that balance the two properly. The oldest posts of our data set date back to Sep 2004, which is roughly 10 years before the data collection. To see how the cut-off impacts the sample size, we show in table 3 number of dropout members identified by setting \( t \) from 1 to 10. It can be seen that sizes of samples shrink rapidly when larger \( t \) is used.

The major false-positives of our method are the users that return to the community after long time inactiveness. To quantify the prevalence of these comebacks, we designed a sanity check experiment in which we calculate the percentage of users who have been inactive for more than 3 years in the community, anytime in the history, but return to the community after the long break, over the total number of users who have been active for more than 3 years. The number we get is 1.2%, which suggests a relatively good precision of our identification method.

What we learned from our topic analysis that dropout members focus more on diagnosis and treatment related themes also reminds us that users may drop out of the community because of death. Their escalated interest in diagnosis and treatment related issues may just be a signal of cancer metastasis, or unsuccessful treatments which may be followed by deterioration of the disease. These members leave the community not because of dissatisfaction towards community usage, and should usually be excluded in the attrition analysis. Similar to the issue of returning of inactive users, in public online communities there is no way to accurately identify dead members. To investigate how much this confounder impacts our results, we extract cancer stage information from user signatures, exclude cancer stage IV users, and replicate all analyses. The rationale is that stage IV users are the ones most likely to leave the community because of death, while stage 0 to stage III breast cancer are believed to have quite high 5-year survival rate. These supplementary analyses show identical findings as we demonstrated previously, and the exclusion of stage IV users does not impact the results. It is noteworthy, however, that the result does not indicate the nonexistence of impact of dead members on our study since not all users have accurate profile information in signatures.

Limitations and Future Work

There are several limitations of this work, which will be important parts of our future work. First, methodologically, our methods identifying dropout members, topic of discussion, and sentiment of posts are all based on automated algorithms that are not 100% accurate. Manual analysis over a small sample set might be a good way to complement the automated analyses. Efforts will also be made in creating better computational tools for topic and sentiment analysis in future work. Second, in this paper we only consider three variables of participation, while many other important ones are not covered such as members’ age, social status, whether there are community debates or conflicts, etc. These variables of interest will be the focus of our future work to study how they impact users’ decision makings. Third, our analyses, especially static ones, present only statistical differences, and such differences do not guarantee real clinical or psychological differences. In this paper, we do not try to identify causations and provide explanations; rather, we focus on detecting interesting correlational patterns that worth exploring by future research with rigorous experimental study designs. Our analysis in this study has captured some signals of what factors may be contributing to
dropout, and we have proposed that it is likely that real life events may trigger the change the way members exchange social support and their foci of discussions. We believe that our study is a showcase of how quantitative methods can be used to analyze OHC content at scale for hypothesis discovery. Further analysis, both qualitative and experimental ones, can be carried out to examine these hypotheses. Forth, a better distinguish between dropout member and lurking members should be made more systematically. Identification of dropout members in public online health communities is a challenging task, and should worth more exploring in the future. For example, one possible solution might be doing expert annotations, followed by supervised learning models. Finally, this study was conducted on a single online health community. It will be interesting to see the impact of these factors in different communities specific to breast cancer as well as to other conditions.

Conclusion

This paper presents a quantitative exploratory study over a popular and active public online breast cancer community to identify the characteristics of members that quit participation. We investigate correlations between community dropping-out and different factors: topic of discussion, sentiment of post, and user interactions in the community. When conducting such a quantitative study, one important methodological question pertains to identifying at scale the users who drop out. We explore strategies to identify such members, as well as static and longitudinal analyses of members’ post history. Dropout members did not show any significantly different patterns in sentiment change when compared to other members in the community. Our findings suggest however that dropout members (1) tend to focus more on diagnosis- and treatment-related topics; and (2) exhibit increased needs of social support at the ending phase of participation, which are less and less fulfilled by other members.

Abstract.

Heart disease is the leading cause of death in the United States. Heart failure disease management can improve health outcomes for elderly community dwelling patients with heart failure. This paper describes DCDS, a real-time data capture and personalized decision support system for a Randomized Controlled Trial Investigating the Effect of a Heart Failure Disease Management Program (HF-DMP) in Skilled Nursing Facilities (SNF). SNF is a study funded by the NIH National Heart, Lung, and Blood Institute (NHLBI). The HF-DMP involves proactive weekly monitoring, evaluation, and management, following National HF Guidelines. DCDS collects a wide variety of data including 7 elements considered standard of care for patients with heart failure: documentation of left ventricular function, tracking of weight and symptoms, medication titration, discharge instructions, 7 day follow up appointment post SNF discharge and patient education. We present the design and implementation of DCDS and describe our preliminary testing results.

Introduction

Heart failure (HF) is an important healthcare issue because of its high prevalence, mortality, morbidity, and cost of care. With the aging of the population, the impact of HF is expected to increase substantially, due to the fact that more older Americans are hospitalized for HF than for any other medical condition. More than 5 million people in the United States have heart failure. One in 9 deaths in 2009 included heart failure as a contributing cause. About half of people who develop heart failure die within 5 years of diagnosis. Overall, HF costs the nation an estimated 32 billion each year [2, 3, 4]. The trial of Heart Failure Disease Management Program in Skilled Nursing Facilities (SNF Study) is a study funded by the National Heart, Lung, and Blood Institute (NHLBI) [5] to evaluate if management of HF in SNFs could improve patient-centered outcomes and reduce hospitalization. A wide variety of data relevant to patient disease management is collected in this study. Thus, it calls for a data management system which accommodates a variety of data types as well as unique data capture needs, such as complicated medication entry. Access to clinical data is another key part in making a personalized healthcare strategy and enhancing the operation and adjustment of HF-DMP. To support real-time healthcare decision, a set of data analysis functionalities such as validation, retrieval, and visualization is required.

An economical, flexible, and scalable data entry system for capturing patient information which supports interoperation plays an important role in large scale, multi-center clinical trials. Unlike paper- or document-based forms, rapidly-deployed web-based electronic interfaces have the advantage of ensuring data quality through built-in data validation mechanisms. In addition, a well-designed electronic system can provide intuitive data visualization and better support health care decision making. While REDCap [1] (Research Electronic Data Capture) is a well-known data capture tool which meets a large percentage of SNF Study needs, there are unique features that REDCap does not provide.

To address this, we present a Real-time Data Capture and Personalized Decision Support System (DCDS) for SNF Study, focusing on real-time data capture and personalized decision support. DCDS supports automated score calculation, visualization of symptoms, and medication history retrieval. Patients benefit from the system because intuitive visualization of symptoms by caregivers may lead to enhanced care, improved outcomes, and reduced risk of death. The caregivers benefit from the system because it is easier for them to make sense of voluminous data and make prompt clinical decisions.

1 Background

Real-time Health Care Decision Support. Access to real-time and meaningful data at the point of care is one of the biggest challenges of the 21st century. In healthcare, a real-time clinical decision support (CDS) system that is shareable across healthcare delivery settings over large geographic regions plays an important role in improving outcomes. CDS technology has been demonstrated to improve the quality and safety of patient care, and is believed to...
be an integral component in improving outcomes [6, 7]. With a CDS system, caregivers can make treatment decisions for a patient based on real-time data. A real-time CDS system brings together data from multiple sources and provides tools for clinicians to access and analyse such data. Properly implemented, it enables patients and caregivers to make timely and informed clinical decisions.

SNF Study is a multi-center clinical trial that focuses on the immediate post-acute patient with HF (i.e. 30 days post hospital discharge) and the immediate post-SNF discharge (i.e. 60 days post SNF admission). The study focus on a vulnerable time period when the patient transitions from one care setting to the next. In addition, patients with HF can have a change in condition fairly rapidly. Therefore, a real-time CDS can be highly beneficial.

**DCDS: Data Capture and Decision Support System.** DCDS is built on the OnWARD [8] framework, a dynamic, secure, rapidly-deployed, and web-based form generator supporting data capture for large-scale multi-center clinical studies. For example, it has been successfully deployed in other clinical trials such as the Heart Biomarker Evaluation in Apnea Treatment trial (HeartBEAT,1RC2HL101417), a multi-institution Phase II clinical trial funded through the American Recovery and Revitalization Act (ARRA). OnWARD is developed using the agile methodology, involving regular communication with researchers/clinicians to collect requirements and update/improve the system progressively. OnWARD automatically translates structured specification of data format into web-based input forms without requiring deeper technical expertise. Thus, OnWARD can be quickly deployed and customized for different types of studies. DCDS inherits the following features from OnWARD:

- Flexible backend database selection. DCDS has an independent backend relational database designated by an investigator to support data entry, retrieval, and validation. This feature allows easy deployment/reuse of existing databases as well as providing complete control by the investigator.

- Dynamic form generation. For every data form, the data types, ranges and data distributions (such as text box, drop-down list) for all data entry points are transcribed into an XML file with specific format, which is in turn translated into an electronic data entry form by DCDS.

- Input validation. To ensure data quality, mechanism for validations on data types and ranges are implemented in DCDS at the time of data entry. Uniqueness of patient identifier are validated to avoid duplicated IDs among different patients.

- Branching logic. This is used to skip certain questions depending on the answers to previous questions. For example, in the medical history form, if the user chooses “no” for the question “Myocardial Infarction,” the next question “If yes, date of most recent MI” will be hidden from the user. The branching logic skip patterns are specified as metadata in the format of (question; condition; value; skip-question; default-value).

**Trial of Heart Failure Disease Management in Skilled Nursing Facilities.** HF challenges our clinical management skills because of unpredictable exacerbations, frequent hospital utilization, and complicated therapeutic regimens [9]. HF patients discharged to SNF have a higher rehospitalization rate and mortality than those discharged home [10], which is surprising since SNF are a major site of transitional care, from hospital to home, for older adults. The SNF Study is a randomized trial in which SNF physicians are randomized to either the HF-DMP managed by HFNA or usual care (UC). Quality initiatives to improve HF care in SNF can be vital to reduce rehospitalization and improve health outcomes for older adults. Although HF-DMP have been shown to reduce rehospitalization in other settings [11, 12], the effectiveness of HF-DMPs has not been studied in SNF. Since the SNF environment is highly regulated and programs are increasingly influenced by financial aspects, HF-DMP must both benefit patient outcomes and be affordable.

Research in SNFs is uniquely challenging. Each facility is its own entity with its own policies and procedures. Although multiple participating SNFs may be owned by the same company, there is considerable variability. A web-based system is exceedingly important to ease data collection burden at multiple sites with flexible software and computer access for study staff.

2 Challenges of DCDS

The HF-DMP is based on best practices for HF care, including documentation of left ventricular ejection fraction (in the form medical history), symptom and activity assessment, weights and dietary surveillance three times a week, medication titration, patient and caregiver education, discharge instructions, and a 7 day follow up visit post-SNF discharge. A specialist trained in Heart Failure Nurse Advocate (HFNA) works closely with physicians and ensures
fidelity of the intervention. Researchers in the SNF Study designed a wide variety of data collection forms to capture patient data in both UC and the HF-DMP group. Those forms fall into three categories (Figure 1): red color for shared forms, green for HF-DMP, and yellow for UC.

- Forms which are used once for baseline descriptive data, such as patient demographics and medical history.
- Forms which are used to collect outcomes data, which clinicians are investigating change over time. Such form include the Kansas City Cardiomyopathy Questionnaire (KCCQ) and Self Care in Heart Failure Index (SCHFI) forms. Clinicians collect the data at baseline and then at the end of the study after 60 days. The changes in scores for health status (KCCQ) and a patient’s ability to manage their heart failure (SCHFI) will help illustrate the usefulness of HF-DMP.
- Forms of HF-DMP, which are used 3 times a week and are interactive for assisting the HFNA in making clinical decisions by using the research protocol. These forms help the HFNA track HF signs, symptoms and weight so as to guide medication management. This kind of data informs the Research Nurse (RN) how to improve a patient’s treatment and intervene if the patient is decompensating from HF. The RN can make treatment recommendations if indicated by the protocol. The UC group has the same data collection forms, but the data is collected by chart review and there is no interactive component in UC. The HFNA is not involved in UC data collection.

Although the general OnWARD framework can fit most of what the SNF Study needs, there still remains a set of challenges. A fundamental challenge in the field of clinical decision support is to determine what characteristics of data make them effective in supporting particular clinical decisions. In HF care, patient’s weight, clinical symptoms, and medication titration are significant in evaluating the status of patients and determine their response to medical therapy. Whether the system facilitates appropriate access to such data affects the effectiveness in supporting clinical decision making.

2.1 Trending Graph Generation

Tracking patient’s weight, signs and symptoms is important for determining the clinical status of patients and gauging their response to medical therapy. The HFNA protocol weights on each patient 3 times a week and recommends
a dietary strategy based on the available SNF menu. The HFNA also assesses patient’s symptoms and activities to assist treatment decisions. However, isolated symptom or weight measure such as “swelling,” “dyspnea,” and “70lbs” is useless when it is evaluated beyond the context of a patient’s condition over time. In this case, trending graph generation is needed for DCDS. Using clinical data collected from patients at bedside, graphs are automatically generated to allow the HFNA to compare changes over time. Trending graphs provide visual clues about trends, gaps and clusters and compare multiple data sets at once that words and equations cannot offer. Based on trending graphs, study nurse can quickly draw conclusions and follow protocols to intervene on a patient’s change in condition in a timely manner.

2.2 Auto-calculation

In SNF Study, several forms require the calculation of scores based on patient surveys such as Demographics, KCCQ, Frailty, and Charlson Commodity Index. These scores form the basis for understanding patient conditions and information about the dynamics of disease when collected over time. The calculation of clinical scores has previously relied on Microsoft Excel, which calculates the scores based on data entered by study staff. Calculations in Excel needs cumbersome operations, which made errors easily, such as referring to the wrong cells or choosing the wrong data area. Automating the calculating process, which is a vital component of DCDS, not only saves time, but also avoids errors.

2.3 Medication History

Medications play a pivotal role in heart failure management. National guidelines for HF-disease management clearly delineate medications and target doses that will result in the best patient outcome [13]. Titration of medication can indicate improved quality of care for patients. Titration of diuretics in response to volume overload can help avoid HF decompensation and hospital admission. Medication titration according to pre-determined protocols is an important part of the intervention. Therefore, it makes sense to record medication changes occurring in response to the HF-DMP and to UC, and subsequently determine the effect medication titration has on outcomes. A medication history database for tracking, analyzing, and monitoring is another key component of DCDS.

The weekly medication form in SNF keeps daily records of medication name, dosage and frequency of every medication for each patient. The unique features required of this form are as follows:

- Auto completion for medication names. Due to the fact that medication names are often complex terms, clinicians can make errors when inputting medication information. The addition of real-time auto completion on medication names is a necessary functionality to improve efficiency and reduce error in the weekly medication form.

- Auto retrieval of medication history. Medication regimens can be lengthy and capturing medication information for each visit can be cumbersome. Since many medications prescribed to a patient infrequently change substantially, it is efficient for clinicians to directly modify the current medication information using the medication information of the previous day.

- Easy modification of medication. Based on medication information from the previous day, clinicians may add or delete medications to the current medication list. They may also need to modify the dosage or frequency of an existing medication. A user-friendly data entry interface which facilitates history-based medication information capture is required.

- Tabular form. In contrast to list form, a tabular medication form which allows structured collection and representation of information about medication, dosage, and frequency through a dynamic interface is desirable. Moreover, since the total number of medications is not predetermined, DCDS needs to be able to dynamically add or delete rows from the table.

3 System Design and Implementation

In this section, we present the design and implementation of DCDS. Initial development of the DCDS workflow was accomplished with close collaboration between the SNF investigator team and the DCDS development team. Figure 2 illustrates the workflow, including data collecting, decision support, and care delivery. In the SNF Study, patient’s clinical information is collected at bedside by the HFNA, and processed through DCDS to generate data reports to support HFNA management strategy.
Figure 2: Overview of our Real-time Data Capture and Personalized Decision Support System. Nurses collect patient information and conduct a clinic assessment. Data is ingested into DCDS. The system then generates timely clinical reports of the patient, such as weights, symptoms, and medications history. HFNA uses these reports to support clinical decision making. The clinician then delivers care by making changes to patient’s HF management if necessary. The HFNA captures changes to clinical care in DCDS. This work cycle is repeated during a patient’s entire SNF stay.

DCDS is developed using the Ruby on Rails web application development framework. It involves three seamlessly integrated modules: Data Specification, Data Capture, and Decision Support. Data Specification is the key step before Data Capture. All the metadata forms are specified to facilitate dynamic form generation. The metadata specification is captured in Excel sheets, which are converted to XML specification files by DCDS. The XML files then are directly loaded to the relational database of DCDS. After loading of the data specification, DCDS dynamic form generation engine automatically displays the form content for Data Capture. In the review and reporting phase, DCDS’ Decision Support component generates customizable reports using real-time data in the database.

3.1 Data Specification

Data Specification involves three types of metadata: variables, value domains, and permissible values. A form consists of a collection of variables, whose specification includes datatype, distribution, descriptive label, and value domain. The value domain of a variable has associated permissible values that determine which values are allowable for the specified domain. For a categorical value domain, each of its permissible values serves as an option of the drop-down menu list; for a numerical value domain, its permissible value specifies the valid range.

3.2 Data Capture

DCDS has built-in data capture features, such as data validation, multiple data type supporting, and branching logic. For the unique needs of SNF Study, we provide the following functions to improve the efficiency of data capture.

**Auto Calculation for Clinical Scores.** Calculation formulas are stored in the backend database. Each formula involves a number of questions in the same data entry form, divided into two groups: conditional questions and result questions. As a user enters data in the conditional questions from the web interface, a javascript function is triggered and automatically fills in the result entry with the correct value based on the formula. For example, in the KCCQ form (Figure 3), 10 scores are filled automatically based on the answers to the previous questions. This avoids the additional needs for using separate Microsoft Excel or any other calculation tools.

**Auto Completion of Medication Names.** A backend medication dictionary is imported beforehand. We extract the generic medication names from RxNorm [14], a normalized naming system for generic and branded medications provided by the National Library of Medicine (NLM). We built the “auto completion” function this way: When a user enters the first letters of a medication name, the system automatically pops up a list of all partially matched medication names.
names containing the input string as a substring for the user to choose.

![KCCQ Auto-calculation](image1)

**Figure 3: KCCQ Auto-calculation.**

![Medication Form](image2)

**Figure 4: Medication Form.**

**Auto Retrieval of Past Medications.** In the SNF Study, medication information is recorded daily. The automatic retrieval process is divided developed in these steps: When a user creates a new medication record, DCDS finds the previous record by date, and then automatically retrieves the medication history from that record and displays it in a table, as shown in Figure 4. Pre-processing is needed to make this process efficient: if a medication was labeled “discontinued,” it would not be displayed.

**Easing the Burden on Medication Modification.** After retrieving the medical information from the previous record, DCDS provides users with the ability to make changes to each medication to generate a new medication order for the current day. They can increase or decrease the dosage or frequency by choosing the appropriate option in the drop-down menu. There is also an option named “Discontinue” in the drop-down, which is used to remove the corresponding medication from the order. The process of adding a new medication goes as follows. First enter in the medication name with the help of auto-completion; then click the “Add” button; then a new row with the medication name is added to the table. Other fields capturing dosage or frequency information need to be filled by the user. DCDS preserves each medication list from each day, which means that even if a medication is discontinued one day, the medication history is still preserved for the previous day. In this scenario, it does not overwrite the medication list and HFNA truly follows medication management trends.
3.3 Decision Support

To support clinical decision making, we designed several reporting tools to help data tracking and analyzing. Tabular form of medication history along with the changes in weight and symptoms provides an intuitive grasp of patient’s condition and helps HFNA deliver appropriate care.

**Tabular View for Medications.** The form generation engine in DCDS provides two basic layouts: List View and Tabular View. The Tabular View displays a multi-row and multi-column layout. The medication form in SNF has eight columns: date of visit, medication, change, indication, dosage, unit, frequency, and change based on HFNA recommendation. Among the eight fields, “Date of Change” and “Medication” are two key fields. The “Change” field contains five options: no change, change in dosage, change in frequency, add new medication and discontinue. “Indication”, “Dosage”, and “Unit” fields are text fields. The “Frequency” field records medication frequency, which includes four options: once a day, twice a day, three times a day, or as needed. The last field “Other Frequency” is a text field as a supplement to the standard “Frequency” field.

![Medication History](image)

Figure 5: Medication History.

**Weight-Trending Graph.** Tracking of weight over time is a key aspect of SNF Study. Doctors track weight closely for patients with HF because weight gain due to fluid retention is an early sign of decompensated HF. The information is used to prescribe medication to patient and also to review response to medications. For the purpose of usability and analysis, the graph needs to be as interactive as possible. We use Google Charts along with Javascript to fulfill this purpose. Google Charts fit our requirements and have proved useful. Javascript is used to dynamically show and hide the graph.

![Weekly Weight](image)

Figure 6: Weekly Weight.

Weight-Trending graph has the following elements:

- Intelligent Y-axis. The Y-axis of the graph, which represents the weight over different time intervals, adjusts
itself according to the present value range of weight so that small changes in weight are easily visible.

- **Time Interval Adjustment.** Graphing range can be switched from 1 day to 1 year according to the length of the period during which a patient is under observation. This way the HFNA can zoom in and out at different time intervals.

- **Mouse Pointer Value.** At any point, the graph shows the value of the weight with the date corresponding to the current position of mouse pointer.

**Symptom Analysis.** Various symptoms can be present for different patients in different ways. To know how these symptoms are changing over time for a particular patient proves to be of great importance in SNF Study. It makes sense to implement a chart or table that gives all the required information about various symptoms of a patient in a concise manner. This not only saves HFNA’s time but also creates simplicity and improves recognition of changes in a patient condition.

![Patient Symptom Report](image)

**Figure 7: Symptoms.**

- **Tabular Form.** About 12 different symptoms are analyzed. Displaying such information in a chart may create confusion. Therefore it makes sense to follow a tabular form approach. It simplified the design and served the purpose beautifully.

- **Symptom Progress.** ‘+’ indicates that the symptom has increased, ‘-’ indicates that the symptom has deceased, ‘=’ indicates that the symptom is the same as the previous, ‘N/A’ indicates that symptom progress is not available, ‘X’ indicates that symptom was not previously recorded so there is a lack of information to be shown.

- **Colors.** To make the table even more interactive, in addition to different symbols, we added appropriate background colors. Green indicates an improvement, red a worsening, yellow the same, gray no records, and white not available.
4 Results and Evaluation

In total, we created 22 clinical forms containing 584 questions and 175 branching logic in DCDS. The basic demographic form assigns a study identifier for easy tracking, which is used as the universal key for other 21 forms. We stored 4103 medication names in our backend database to enable auto completion of medication entry and 5 calculation formulas: Demographics, KCCQ, Frailty, SCHFI and Charlson Commodity Index. DCDS is presently used in 43 facilities in the Denver area. The SNF Study is still enrolling and currently (March 2016) it has enrolled 365 patients including 44 in Cleveland.

4.1 Evaluation

Compared to traditional paper-based method of data capture, structured electronic data capture has several advantages. It reduces the data collecting burden, supports quality reporting, improves the capability of informing researchers, and ultimately, enhances patient care. An important benefit of DCDS is that through the VPN, users can access the system anywhere. SNF staff usually goes to many facilities, including patients’ homes. With easy access to the system, they can get on DCDS anywhere and do not need to return to the office to enter data.

In this section, we compare DCDS with Paper-Based method to evaluate the unique design of DCDS for HF-DMP study. We designed a survey to evaluate the two methods (paper froms vs DCDS), including aspects of entering, tracking, usability, customizability, consistency, and representation. We invited 3 professional research assistants and 2 nurses in the SNF Study to take the survey and collected their comments and notes about the two methods. Each participant did data entry using paper-based HF-DMP workflow (data was entered into DCDS later), then performed the same HF-DMP workflow on a different patient and directly captured data into DCDS.

In the figures: a) Entering denotes how long and easy to complete the forms; b1) Tracking(in medicatin and weekly visit) denotes how difficult to track the changes of symptom and weight; b2) Scoring(in KCCQ) denotes how difficult to track the changes of symptom and weight; c) Usability denotes overall usability; d) Customizability denotes the overall customizability; e) Consistency denotes how difficult to make sure information you write is correct; f) Representation denotes how well the information represented.

Figures 8, 9, 10 show the average ratings of three selected forms: 1) Medication, 2) Weekly Visit and 3) KCCQ. Each form was rated on 6 aspects and each aspect was measured on a scale from 1-10 with 1 being the hardest and 10 the easiest. Figure 8 shows that the ratings of DCDS are way ahead of the paper-based method in all aspects. With respect to the testers’ comments, “Didn’t have to retype out names for DCDS” and “Takes a long time with the amount of meds” for paper-based method confirmed that DCDS is well-designed, as a result of auto completion of medication names and tabular view of the medication history. However, in Figures 9 and 10, the results are different. Our DCDS is only leading in tracking and scoring, which shows a gap from our expectation. From the comments and notes for these two forms, we found several reasons. These include: “Papers are easy to carry and write down any notes,” “Booting up computers, login and access to web-based tools is cumbersome,” “Patients are less willing to expand on answers when sitting in front of computers, which seems to be a more formal interview.”

A detailed analysis revealed that participants preferred using DCDS in situations of cumbersome repeating input, long-
term tracking, or scoring. The results demonstrated that our design is practical and user-friendly. Another interesting finding is that patients are more willing to answer questions using a paper-based method. They prefer casually talking with a nurse rather than a formal interview in front of a computer.

5 Discussion

As we can see in the evaluation section, evaluators preferred using paper to record clinical information than using DCDS. It took more time to boot up the computer, connect to the VPN and sign into DCDS than to fill out a form. However, the results showed increased satisfaction with the ease of data entry, graphing for symptom tracking and auto calculation for clinical scores. The data processing done by DCDS made clinical decision making easier as data was presented in charts and graphic forms, making day to day comparisons of clinical data straightforward. In addition, the advantages of DCDS are not obvious from one or two patient visits. As researchers become more familiar with DCDS, their efficiency likely increases. In the short-term, especially for a study such as SNF, users may spend more time in using DCDS. However, the long-term benefit in ease of exploring and managing clinical information of patients is important. Since all data are captured in DCDS on each patient, it provides a rich dataset for real-time data analysis.

Health care data standards are another important aspect which we need to consider and integrate into our DCDS in future work. Using the guideline of data standards, such as HL7, we can use standard terminologies, data formats, methods and protocols for data exchange, integration, representation, and decision support.

6 Conclusion

In this paper, we present DCDS, a real-time data capturing and personalized decision support system, for SNF Study to investigate the effectiveness of HF-DMP in improving outcomes for older frail heart failure patients undergoing post-acute rehabilitation. The results show that DCDS is clearly superior to existing manual approaches in data retrieval, data visualization, and easing the burden for cumbersome data entry.

Improving Veterans Access to Care through Telehealth and Local Fire Departments

Hamed Abbaszadegan, MD, MBA1,2, Umar Iqbal, MD2, J Edward Maddela, MD2, Khaleel Hussaini, PhD2, Manolo Moneda, RN, BSN, MBA1, Shakaib Rehman, MD1,2

1Phoenix VA Healthcare System, Phoenix, Arizona; 2University of Arizona College of Medicine, Phoenix, Arizona

Abstract
The VA Healthcare System has long been on the front lines of cutting edge telehealth care delivery. Fire departments have also been changing their approaches to emergency care by including new health and medical services. Pairing these two existing services will provide Veterans instant access to healthcare providers. The Clinical Informatics Department at the Phoenix VA recognizes this and has collaborated with local fire departments to reach out to Veterans in need. A pilot study with the City of Chandler Fire Health & Medical (CFHM) was initiated to improve healthcare access for Veterans residing in Chandler, Arizona. CFHM already has infrastructure to assist the VA through its Community Paramedic (CP) Program. Two algorithms of care were developed for the CP program to provide instant access for their patients identified as Veterans through an on-site, real-time telehealth visit with a VA Nurse Practitioner (NP). Additionally, these NPs will deploy community paramedics to Veterans with a high Care Assessment Need score within the service locale of CFHM in an effort to prevent ER visits and readmissions. These algorithms, the telehealth technology, and 6 months of data will be presented for this system's demonstration.

Problem
Access to care is a national problem in all healthcare systems due to provider shortages. Improper use of emergency room resources for non-emergent needs has become a national health care crisis. Often, lack of care coordination has been a major limitation. The Phoenix VA Healthcare System has been working diligently at addressing this problem over the last few years. Telehealth and clinical informatics are a major solution to leverage alternative means of enhancing care delivery.

Purpose
The purpose of this pilot is to identify Veterans in the City of Chandler who may need nonemergency services, and reach out to them in a predictive fashion prior to emergency scenarios. We aim to demonstrate that combining the resources of two service industries, a local VA health system and a city fire department through telehealth can potentially positively impact access to care, care coordination, and prevent care crisis scenarios.

Description
In our innovative program, there are two models of which CHFM and the Phoenix VA Health System provides telehealth remote care to Veterans. In the first model, when a Veteran activates the 911 system, CHFM responds in the usual fashion for an emergency call. If the call is deemed non-emergent, the Veteran will be cared for by CFHM through use of telehealth interface to connect Veterans to the VA instantly. Veterans can be seen remotely by a VA employed NP who has full access to the EHR with abilities to order medications, request consults, and even request an earlier in-person appointments. If the call is emergent, the Veteran is transported to an ER per prior protocol. The other model focuses on non-emergent follow up care via telehealth. Using the Care Assessment Need (CAN) score, a predictive analytic tool predicting high risk/high utilizers, patients are enrolled into this pilot project program. The CAN score is based on factors reported including but not limited to: prior ED utilization rates, hospital admission and readmissions in the last 90 days, age, and a number of chronic disease medical problems. This patient data is generated daily based on the zip codes where CHFM provides service. Once the data is generated, demographic information is shared with CHFM to coordinate care with the VA’s NPs scheduling Veterans for a telehealth visit.

Degree of Service Deployment
The prototype has been running for 3 months at the time of proposal submission. We are successfully seeing approximately 5-7 Veterans per week in conjunction with Chandler Fire Department and collecting data. We plan to present the 6 months’ intervention data at the meeting. Preliminary data is showing promising results, and all parties involved including Veterans, Chandler Fire, and the VA are providing positive feedback to this leading edge system that promotes an innovative method of healthcare delivery.
Carelign©: Upgrading from Outdated Paper Handoffs to Real-Time, Interdisciplinary Handoffs
Subha AiranJavia, MD1,2, Jacqueline Soegaard, SB1,2, Jillian Olsen, BA2, Geoffrey Bass, MD, MBA1, Damien Leri1, Glenn Fala1, Rich Urbani1, William C Hanson, III MD1,2
1University of Pennsylvania Health System, Philadelphia, PA; 2Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Abstract The acute care of patients involves a multitude of moving parts – from teams of physicians, nurses, and interdisciplinary providers, to an array of tests, medications, and clinical information systems. Physician teams often use paper “handoffs” not only for transitions in care, but also to organize these parts to work together. These documents, however, are outdated soon after being printed. Moreover, valuable information written on these printouts seldom gets communicated promptly to other providers, if at all. To improve the quality of transitions, interdisciplinary care, and clinician efficiency, Penn Medicine created Carelign ©: a responsive web application with real-time clinical data and an interactive, editable, electronic handoff with full mobile functionality. Designed via close collaboration between physicians and developers, Carelign © gathers information from over 10 different systems into one clinically intuitive display. Our real-time, shared, and easily accessible handoff interface provides a timely view of the patient’s problems and the team’s plan for each. Viewable by all providers, including not just clinicians, but also nurses, technicians, phlebotomists, social workers, clinical nutritionists, and others, Carelign© is transforming clinicians’ daily workflow and interdisciplinary team interaction.

Description Carelign © is a homegrown, responsive web application designed by frontline clinicians, residents, medical students, interdisciplinary providers, and developers. Device and operating system agnostic, Carelign © is accessible from anywhere hospital computers, workstations on wheels, smartphones, tablets, or personal laptops as long as the device is connected to the hospital’s secure network via WiFi or VPN. Carelign © was developed and launched in 2 phases: Version 1 (V1) in August 2014, provided real-time access to objective data, and Version 2 (V2), implemented January through July 2016, adds an iterative, collaborative plan of care used in handoffs and to create progress note assessment and plans. Utilizing HL7 messages, direct database queries, and web services/APIs, Carelign © pulls information from our many different information systems: ADT (demographics and visit information), Cerner (lab data), Radiant (imaging), Navicare (patient location), Epic (provider and encounter data), Sunrise Clinical Manager (care team, vital signs, allergies, and medications with administration record), and others. Accessing all this critically important data previously required going to multiple different programs. Now it is available at any time, through an intuitive display optimized for smartphones. Initial time motion observations revealed that accessing Carelign © on mobile devices was 22 times faster than logging into the inpatient EHR on a workstation on wheels. Although originally designed for inpatient use, Carelign © has become widely used by our home care clinicians and interest in other “off-label” uses continues to rise: from food services using it to verify diet orders at meal delivery to workgroups aiming to provide a better foundation for interdisciplinary discharge planning.

Beyond data review, V2 adds handoff functionality that is arguably more transformative, moving away from free text boxes to discrete, collapsible data elements organized in a way that facilitate rounding, critical thinking, and list management. Key features include the ability to archive information, tag items as anticipatory guidance, and view qualitative content arranged by problem or by task. Carelign © also provides extensive functionality for list-based management of patient and team tasks. We have implemented Carelign © V2 across almost all inpatient clinical services at the Hospital of the University of Pennsylvania, Penn Presbyterian Medical Center, Pennsylvania Hospital, and Penn Medicine at Rittenhouse, with the goal of transitioning the last few services by the end of July 2016. Almost two years after the launch of V1 and 6 months into V2, over 3,000 unique patient records are viewed weekly between >23,400 sessions amongst >3100 unique users: 40% physicians & advanced practitioners (including 7% attendings), 45% nurses and 13% other clinical users (pharmacists, therapists etc). Provider surveys comparing analogous medicine teams using Carelign © compared to our previous handoff system, demonstrate that residents report significantly higher satisfaction and safer written handoff content with Carelign ©, as well as a near-significant improvement in workflow efficiency.

By upgrading our handoffs and care coordination from a paper-based system to Carelign ©, a shared and interactive application with a fully functional mobile interface, we are improving user satisfaction and efficiency, subjectively improving written handoff safety, and hope to demonstrate an improvement in interdisciplinary care.
Assessment Center API: A Software Component Model for the Integration of Patient Reported Outcomes (PRO) into Clinical Care

Michael Bass, MS¹; Paul Harris, PhD²; Rob Taylor²; Justin Starren, MD, PhD³; Joshua Spuhl, MS⁴; Jimmy Johnson⁵; Jason Guattery, MS⁵

¹Department of Medical Social Science, Northwestern University, Chicago, IL ²Department of Biomedical Informatics, Vanderbilt University, Nashville, TN ³Northwestern University Clinical and Translational Science Institute, Chicago, IL ⁴University of Utah Health Care, Salt Lake City, UT ⁵Washington University School of Medicine, Saint Louis, MO

Abstract. The Assessment Center API https://www.assessmentcenter.net/ac_api¹ is an easy to implement system that enables system integrators to offer Patient Reported Outcomes Measurement Information System (PROMIS) ² instruments within their patient-facing portals and applications. In this system demonstration, we will first provide an introduction to Item Response Theory (IRT) and computer adaptive testing (CAT), the underlying principal in the administration and scoring of PROMIS instruments. Next we will highlight the key features and workflow of this API system focusing on the integration with the API endpoints. Results from four case studies that have implemented the API will be presented. This will demonstrate the diverse range of approaches used in collecting PRO data in both clinical and research-based. The four test cases will come from the following systems: REDCap³ developed at Vanderbilt University, mNPOR developed at Northwestern University, mEVAL developed University of Utah and WUPRO developed at Washington University School of Medicine.

Background and System Description. Item response theory (IRT) and computer adaptive testing (CAT)⁴⁵ have been used successfully for decades in education, licensure, achievement testing, personality assessment, and selection of military personnel. By only administering questions targeted to the subject’s ability or trait level, testing times can be cut in half while at the same time improving overall test reliability⁵. Most recently IRT and CAT have been applied to the domain of health-related quality of life in the form of patient reported outcomes (PRO)⁷ which provide information about a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a physician. The reduction of patient burden is the primary motivation for implementing an IRT-based administration and scoring algorithm in the PROMIS instrument framework. These algorithms were initially developed and deployed in Assessment Center⁸, which provides a turnkey solution for researchers to conduct PRO research. This platform is not suitable for clinical research and workflow because Assessment Center is based on a “software as service” (SAS) delivery model and would not satisfy security or workflow requirements of most clinical settings since patient data would be stored outside of an organization’s infrastructure. For these reasons a portable component model was developed for the use case of administering PROMIS instruments which can be integrated into an existing clinical system. The API is based on a RESTful architecture that follows a lab or order-based clinical workflow/paradigm. First order(s) for a PRO assessment are placed to the API. Next, the PRO assessment is administered to the patient, representing the processing of the order(s), followed by the retrieval and integration of results from the API. The API was initially released in 2012 and has been successfully integrated into both research and clinical based systems that have patient-facing interfaces. We will present results and key integration points from a selection of production clinical and research systems that have implemented the API. We will also present the usage of the API endpoints, by demonstrating the calling syntax and returning formats. Finally, an example Javascript application will be presented that demonstrates how a clinical patient facing workflow, intended to capture PRO data, can be built using this API system. The most recent work on this project has been the porting of the API system to architecture suitable for embedding in mobile platforms. Demo applications in both Android and iOS will also be presented, this will highlight the versatility of the API.

Integrating a Dialogue System into a Virtual Patient Consultation

Leonardo Campillos-Llanos, PhD, Dhouha Bouamor, PhD, Éric Bilinski, Anne-Laure Ligozat, PhD, Sophie Rosset, PhD, Pierre Zweigenbaum, PhD
LIMSI, CNRS, Université Paris-Saclay, Orsay, France

Abstract

We present a prototype of a dialogue system simulating a virtual patient in a medical consultation. The system is integrated in a tool aiming at providing continuing education to medical doctors, and the current version supports the French language. The conversational agent developed by LIMSI allows medical students and practitioners to train and improve their social and attentional abilities during the history-taking stage of a consultation. We will explain the difficulties found in medical dialogue processing. A first challenge is to process specialized terms and match them with the patient’s clinical record defined by the clinical case designer: natural language understanding of doctor’s utterances. A second challenge is to generate utterances which simulate patient speech: taking a layman’s perspective. Additionally, the system needs to cope with case-specific questions and to handle dialogues for new clinical cases in a robust way. We will outline the strategies and resources for managing linguistic and terminological variation to carry out these tasks. We will show the methods we use to achieve a natural user interaction, by addressing the structural variation of users’ interventions and taking into account dialogue phenomena such as anaphora and ellipsis.

Description and purpose

Virtual patients (VPs hereafter) allow trainees and practising doctors to develop expertise in diagnosis or clinical reasonings. Patient-Genesys, an interdisciplinary project managed by Interaction Healthcare, aims at developing a computer tool for creating digital clinical cases to provide beginning and continuing education to health professionals in French language. The system works as follows. On one side, a medical trainer creates the clinical case to be simulated by selecting a scenario and an avatar, and by providing a description of the VP’s health state expressed in plain text as a clinical record. On the other side, a trainee is placed in a situation where s/he has to perform a consultation with the VP. This is represented by an avatar with 3D animation in real time (Interaction Healthcare). The trainee can ask questions through text input to obtain information from the VP. LIMSI’s natural language dialogue system analyses the user’s input and replies according to the clinical record. The reply is output by a text-to-speech system (Voxygen) with lip synchronization. Lastly, the trainee may formulate a diagnosis or verify drug interactions (VIDAL), and receive feedback. The Angers University Hospital (CHU d’Angers) provides medical expertise to the project.

Conclusion

The system has been tested by project partners and at public demonstrations. The text dialogue interface which is the focus of this demonstration is available online for the 3 cases developed to date: anesthesia, hypertension and pneumopathy.

Acknowledgments

This work was partly funded by BPI through the FUI project grant PatientGenesys (F1310002-P).

ExplodeLayout: Comprehending Patient Subgroups in Large Networks
Bryant Dang BS\textsuperscript{1}, Joseph Mathew MS\textsuperscript{1}, Tianlong Chen BS\textsuperscript{2}, Suresh K. Bhavnani PhD\textsuperscript{1}
\textsuperscript{1}Institute for Translational Sciences, University of Texas Medical Branch, Galveston, TX;
\textsuperscript{2}Department of Physics, University of Houston, Houston, TX

Abstract
Networks have been used to successfully identify and comprehend patient subgroups based on their characteristics (e.g., comorbidities or genes) with the goal of designing targeted interventions, a cornerstone of precision medicine. However, current network layout algorithms often fail to reveal patterns in large and dense networks despite having significant clustering. We therefore developed an algorithm called ExplodeLayout, which exploits the existence of clusters to automatically “explode” a traditional network layout with the goal of separating overlapping clusters to enhance their comprehensibility. We demonstrate the use of this algorithm to visualize a large dataset extracted from Medicare consisting of readmitted hip-fracture patients and their comorbidities, which enabled clinicians to comprehend patient subgroups and their comorbidities, and to infer mechanisms related to hospital readmission.

Introduction
Although network visualizations have enabled researchers to identify and comprehend patient subgroups based on their characteristics (e.g., genes or comorbidities),\textsuperscript{1} current layout algorithms such as Fruchterman–Reingold (FR) often fail to reveal such subgroups despite the networks having significant clustering. For example, Fig. 1A shows a bipartite network consisting of all 30-day readmitted hip fracture patients (n=6150) extracted from the 2010 Medicare database that had at least one of the 8 significant comorbidities shown. Unfortunately, the network layout generated by FR is difficult to comprehend due the overlapping clusters despite (1) the network having strong clusteredness (co-clustering modularity\textsuperscript{2}=0.440) that was significant (p<.001) compared to 1000 random permutations of the network, and (2) the use of distinct colors to denote each co-cluster of patients and comorbidities. Here we demonstrate ExplodeLayout an approach that exploits information about such clusters to enhance their comprehensibility.

Method and Results
ExplodeLayout is implemented in R, and requires as input (1) coordinates of network nodes generated by a traditional force-directed algorithm such as FR, (2) the number and members of co-clusters generated by a modularity algorithm\textsuperscript{1} (standard in most network applications), and (3) a user-selected circle radius using a scroll bar to determine the distance by which the node clusters are moved. The algorithm uses these inputs to (1) generate an imaginary circle for the given radius with n equidistant points, where n=number of the clusters, (2) move the nodes within each cluster by the same distance and angle such that the centroid of that cluster coincides with one of the points on the circle. As shown in Figure 1B, this transformation effectively “explodes” the cluster locations by preserving the distances among nodes within the clusters, and by not preserving the distances among nodes across the clusters. This trade-off between not preserving inter-cluster node distances and having greater separation between the clusters enables a researcher to comprehend the relative size and topology of each cluster. An optimal layout is generated iteratively by the researcher to achieve a desired balance between cluster separation and layout compactness.

Layouts generated from ExplodeLayout have enabled important insights\textsuperscript{1} into the risk factors for subgroups of readmitted hip-fracture patients, and therefore could be an important complement to force-directed algorithms such as FR. However, for networks with a large number of clusters, the user would need to select a large circle radius to enable cluster separation, resulting in unused space in the center of the layout. We therefore implemented the ability to specify the number of nested circles enabling the central region of the layout to be filled and therefore still maintaining separation with compactness. In future research we plan to automatically suggest to the user the appropriate number of nested circles, which can be modified and therefore enable the rapid generation of compact and comprehensible layouts consisting of hundreds of thousands of nodes, and with many patient subgroups.

Automated Evaluation and Training for Interprofessional Education using Virtual Patients and Providers

Debajyoti Datta, MS1, John Owen, EdD2, Valentina Brashers, MD2, Casey White, PhD3, Laura E. Barnes, PhD1

1Systems and Information Engineering, University of Virginia, Charlottesville, VA; 2School of Nursing, University of Virginia, Charlottesville, VA; 3School of Medicine, University of Virginia, Charlottesville, VA

Abstract
Adverse events resulting from medical errors cause significant morbidity and mortality and cost billions of dollars annually. Communication failure within healthcare teams is a leading cause of medical errors. Interprofessional Education (IPE) has been demonstrated to improve healthcare team communication and prepare students and clinicians to deliver safe high-quality team-based collaborative patient care. Health professions schools and care delivery organizations (especially Accountable Care Organizations) are integrating IPE into their training activities across the learning continuum to meet new accreditation and licensing standards; therefore, educators need reliable outcome measures to assess whether learners are gaining essential team care competencies. Few validated objective observational instruments that measure these competencies behaviors are available, and their effectiveness in achieving rigorous learner assessment is limited. Furthermore, most current IPE training is performed with standardized patients making it very expensive and cost-prohibitive to many organizations. To address the deficiency in training tools for IPE, we designed a system specifically for IPE training, a platform for Virtual Patient and Provider Interprofessional Teamwork Objective Structured Clinical Examinations (VPP-ITOSCE). Virtual human patients have been used in training medical students in interpersonal communication skills and demonstrate a significant correlation between medical students interviewing a standardized patient and a virtual patient.

Specific Problems/Purpose
To develop an integrated platform that utilizes virtual patients and providers as well as state-of-the-art natural language processing to assess teamwork competencies. Currently this is being used for a Rapid Response Scenario for a patient with Chronic Obstructive Pulmonary Disorder (COPD). The patient is refusing treatment and it is upon the nurse to convince the patient to have the medicine. A virtual doctor is also present in the scene and the nurse is evaluated on the complete teamwork competency during the clinical examination scenario. The system will be evaluated based on the accuracy of question classification by the NLP engine and the response by the virtual agent, the grading comparison between a human evaluator and the automated system and the overall ease of interaction between the nurse and the system.

Key Features and Innovation
The demonstration involves nursing students interacting with a realistic virtual avatar on screen and using text input ask scenario questions. Behind the scenes, the system uses state of the art natural language processing using convolutional neural networks along with realistic animations and sounds to create realistic responses. The student is graded automatically based on pre-specified criteria. The system is built using a modular framework to ease extension to other scenarios.

Deployment
Currently we have conducted preliminary testing with a group of nursing students and will pilot test the system in the near future.
**Tiresias: Knowledge Engineering and Large-Scale Machine Learning for Interpretable Drug-Drug Interaction Prediction**

Achille Fokoue, MS, Oktie Hassanzadeh, PhD, Mohammad Sadoghi, PhD, Ping Zhang, PhD
IBM T.J. Watson Research Center, Yorktown Heights, NY

**Abstract**
Accurate prediction of potential Drug-Drug Interactions (DDIs) is a major requirement both in drug development and in patient care. In this demonstration, we present Tiresias, a system that takes in heterogeneous sources of knowledge as input and provides as output an accurate and interpretable prediction of potential drug-drug interactions. We will show various components of the system that perform knowledge curation from public sources of drug data, large-scale similarity analysis across all drugs using several similarity measures, and feature selection and efficient learning using a logistic regression model to not only predict potential DDIs, but also explain the reason behind each prediction. We will show an evaluation of the system using knowledge derived from an old drug database from 2011, verifying the predictions and explanations with recently discovered interactions and their evidence. The system includes APIs and interfaces that expose the outcome of each of the components to users and developers and enable integration within existing electronic health record and patient data management systems.

**System Description and Areas of Innovation**
In this demonstration, we will take the audience through various steps of building a scalable predictive model that can accurately predict drug-drug interactions for newly developed or existing drugs. Figure 1 shows the architecture of our system. Apart from the end result of DDI predictions, each component comes with an API that will be used to show the system’s features during our demonstration. First, we will show visualizations of several subsets of the knowledge graph constructed from various public sources of drug data [1]. We will then go over the similarity analysis component, which computes several similarity measures including but not limited to a measure based on chemical-protein interactome (CPI) profiles, measures based on mechanisms of action and pathways, and a measure based on Anatomical Therapeutic Chemical (ATC) classification system. The output of this component is used as input to a large-scale machine learning process that utilizes similarity matrices to generate features and adopts a logistic regression model to perform the prediction. A highlight of the system is the ability to interpret the predictions using a ranking of the most important features and how each similarity measure and source of knowledge contributes to the calculated confidence in a predicted DDI. A Web interface is designed using the APIs that allows the users to search for DDIs for a given drug and get explanations for each DDI that include details of similarity measures and contributing factors for the DDI.

![Figure 1. Tiresias architecture: knowledge curation, large-scale similarity analysis and learning, and powerful APIs.](image)

**Current Deployment:** Our system is fully implemented and the APIs are currently made available on an internal version of IBM Watson Developer Cloud [2] at Alpha maturity level. Our large-scale similarity analysis and learning is implemented on top of Apache Spark. We have performed thorough experiments that clearly show the effectiveness of our method in both predicting new interactions among existing drugs and among newly developed and existing drugs [3]. More details of our methodology, how it compares with state-of-the-art in DDI prediction, and detailed experimental results are presented in: [http://ibm.biz/adrrtechreport](http://ibm.biz/adrrtechreport).

DOT, an Interactive Reporting Dashboard for Visualization of Order Set Development and Utilization Patterns across an Enterprise

Nathan C. Hulse, PhD\textsuperscript{1,2}, Jaehoon Lee, PhD\textsuperscript{1,2}, Tim Borgeson, MBA\textsuperscript{3}

\textsuperscript{1}Intermountain Healthcare, Salt Lake City, UT; \textsuperscript{2}Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; \textsuperscript{3}Cerner Corporation, Kansas City, MO;

Abstract
Successful computerized physician order entry (CPOE) implementations rely on building and maintaining a useful catalog of standardized order sets for use in a centralized knowledge repository. Collectively, these order sets represent a significant investment of effort and expertise in capturing and distributing best clinical practice throughout an enterprise. In order to address an important gap of understanding how order sets are both created and used in practice in our EHR installation, we have developed DOT (Data on Order set Transactions), an interactive dashboard aimed at informing content owners about how their order sets are being used in practice. The various views in the dashboard provide insight about many facets of knowledge utilization in the CPOE system, including evolution of the baseline templates, usage patterns by user group, location, and time, personalized order set library descriptors (including modification summaries), and line-item detail usage. The dashboard uses algorithms and pattern recognition to inform content authors about more relevant trends, including recommended optimizations to the order sets themselves (additions, removals, changes in selection status, etc). We anticipate that this type of utility will provide useful insight and feedback for those tasked with content governance and maintenance in CPOE systems.

Introduction
One of the important challenges of the information age in medicine is that knowledge evolves and expands quickly and keeping it current, useful and vibrant inside clinical knowledge bases requires significant investment. It is common for knowledge content to become outdated, and for content owners to become disconnected with knowledge consumers. Knowledge management lifecycle patterns characterized in information systems literature speak to the importance of taking the usage data that surround knowledge artifacts, compiling it into coherent units, and making that feedback available to knowledge workers through an active channel that facilitates learning. Given the significant investment in building out a new order set catalog in an ongoing EHR installation, we decided to build a visualization framework that gives content owners insight into how their order sets are being used.

System Description
In late 2013, Intermountain Healthcare and Cerner Corporation announced a strategic partnership, including an enterprise rollout of the Cerner EHR platform, and a joint development effort aimed at delivering novel informatics solutions for healthcare organizations. One of the strategic priorities of Intermountain’s Cerner installation focuses on implementing and measuring usage of best practice care throughout the system, with a particular emphasis on knowledge delivered in the form of order sets. In order to better inform content authors about how their content is used, we built DOT, an interactive dashboard that presents order sets’ uptake within the Cerner system. In this system, order set usage data is routinely extracted from the Cerner Millenium database and exported to Intermountain’s enterprise data warehouse. With this data, we implemented an interactive dashboard using Tableau software to allow content domain experts the ability to review how and where their content is being used. The dashboard provides several innovative views of this data including:
1. Visualization of order sets catalog ordering patterns against main order set templates, as well as aggregated ‘favorites’ data (personalized order sets derived from the original templates)
2. Summary views of individual and collective favorite order sets against the baseline template, highlighting common changes in content patterns (and potential opportunities for content refinement or user training)
3. Temporal view of content uptake over time, with dynamic filters for locations, providers, and user roles
4. Line item usage data, including detailed usage patterns of orders, implications of selection status, and modifications to order sentence detail
5. Actionable recommendations for content optimization, including additions/removals of orders, changes in selection status, order sentence detail

System Implementation
The system has been co-developed by members of Cerner and Intermountain’s informatics and analytics groups, with an early focus on content owned by the critical care, cardiovascular, and pediatric divisions. It is currently available for use in a beta release for specific clinical department analysts, with full enterprise release scheduled for fall 2016.

Demonstration of GuideVue® mobile clinical guideline technology

Presenters:

- M Sriram Iyengar, PhD, Associate Professor of Biomedical Informatics, Texas A &M Health Science Center, Houston, TX
- Jose F Florez-Arango, MD, PhD, Research Assistant Professor of Biomedical Informatics, Texas A &M Health Science Center, College Station, TX
- Jack W Smith, MD, PhD, Professor of Biomedical Informatics, Texas A &M Health Science Center, Houston, TX

Abstract

Originally developed at NASA, award-winning GuideVue® is a complete technology for authoring, publishing, data reporting, and managing media-rich structured clinical guideline apps for healthcare providers and patients. The system is based on theoretical foundations of Felder-Silverman learning theory and Persuasive Technology.

There are five major components. The Author enables non-programmers to rapidly create media-rich mobile apps using an intuitive drag and drop, point and click interface where guidelines are presented as a series of steps in which each step can contain images, audio, text, video, data forms, communications, medical calculators and other capabilities. The Player apps are native IOS and Android apps into which guideVue apps are downloaded and executed. The Publisher provides one-click dissemination of guideVue apps for android and IOS platforms, the Reporter provides detailed usage reports, including compliance tracking, of guideVue apps with time/location stamping, and the Administrator enables system, app, and user management. Once downloaded into the mobile device, guideVue apps can function even without connectivity, making the technology very suitable for global health and developing country application, as well as supporting disadvantaged populations in the USA.

In this systems demonstration the presenters will provide a live demonstration of the entire system showing the creation of guideVue apps, publishing, executing the apps, compliance reports, and user/app administration. Existing apps for disaster response, global health, chronic disease, patent self-management will also be demonstrated. A summary of published research on Community Health workers and patients will be presented.

Specific Health Care Problem Addressed

Poor comprehension and adherence to clinical guidelines and procedures by health workers and patients has serious adverse effects on patient safety, risk of medical complications, length of hospital stay, healthcare costs, readmissions, and health outcomes. The problem is magnified among disadvantaged populations and in global health contexts where educational attainment and health literacy are low.

Deployments

Several pilot projects have been completed or in progress in Colombia, South India, Special Operations command, VA clinic (Pittsburgh), US Army Institute for Surgical Research, Shell Health, MD Anderson Cancer Center, The Ministry Health & Social Protection of Colombia, and others.
SMART on FHIR Platform for Interoperable Healthcare Applications

Joshua Mandel, MD1,2, Daniel Gottlieb, MPA2, Dan Fritsch, PhD3, Kenneth D. Mandl, MD, MPH2,1

1Harvard Medical School Department of Biomedical Informatics, Boston MA; 2Boston Children’s Hospital Computational Health Informatics Program, Boston MA; 3Polyglot System, Inc., Morrisville, NC

Abstract

We will demonstrate the core components of the SMART on FHIR Platform for Interoperable Healthcare Applications, providing an end-to-end view of the process of building and testing a clinical application using our developer tools and sandbox environment, and publishing the application in our publicly accessible SMART App Gallery where it becomes available for discovery. We will show how applications can be written against a standardized set of Meaningful Use data elements expressed using HL7 FHIR profiles that align with clinical terminologies including SNOMED CT, RxNorm, and LOINC, and then run with interactive patient selection and an OAuth-based access control mechanism. This approach enables secure integration of third-party, externally-hosted applications into diverse EHR and patient portal environments. We will discuss the platform’s adoption and deployment metrics as well as the challenges involved in app development. Finally, we will show how Meducation, a commercially available SMART app built against the platform, relies on these components to run unmodified within our own test environment as well as in commercial EHR systems.

Purpose

SMART Health IT is a standards-based technology platform designed to enable an ecosystem where third-party applications can integrate, unmodified, into diverse Health IT systems including EHRs, patient portals, and data warehouses. The platform is intended to address the needs of patient, provider and researcher end-users by stimulating a competitive landscape of apps that serve clinical care, wellness, and public health use cases. It is also intended to reduce the need for software developers to create custom data field mapping and security infrastructure each time an app is deployed in a new system. The system provides standards-based functionality for app development, testing, publication, and discovery, including a one-click “try it” button where potential users can run an app against a simulated EHR.

Deployment

The SMART platform has been deployed in multiple EHR vendor system including Cerner and Epic, and is in active clinical use at healthcare organizations including Boston Children’s Hospital, Duke Medicine and Intermountain Healthcare. We are also working with over a dozen EHR vendors through the Argonaut Implementation Program and the Sync for Science initiative to support wide-scale adoption.

1Tennessee Valley Healthcare System VA, Nashville, TN; 2Vanderbilt University Medical Center, Nashville, TN; 3University of Southern California, Los Angeles, CA; 4UC San Diego, La Jolla, CA 5Lincoln Peak Partners, Westborough, MA.

Abstract: The PCORNet program is a 4.5 year two-phase initiative that is supporting 33 health data networks using the PopMedNet™ data network software. PCORNet’s original version of PopMedNet™ was not designed to support peer-to-peer collaborations between networks, collective model estimation and specification, automated query execution approvals, or heterogeneous local software environments. We modified the PopMedNet™ portal and created a PopMedNet™ Adapter to enable these functionalities, which integrate with our evolving pScanner analysis software. This system demonstration highlights a collaboration between the PCORNet infrastructure development team (Lincoln Peak) and the pSCANNER CDRN analytics and software development teams to integrate a distributed analytics software suite with end-to-end functionality for use within the PCORNet infrastructure. Many of the system components are portable to other common data models, and the tools and modules will be discussed in this demonstration.

System Overview: We developed software modules that interface between the PCORNet data mart client adapter and the expanded pSCANNER analysis engine to address the need for (1) network-to-network collaborations, (2) menu-driven analysis specifications, (3) heterogeneous computing environments, (4) estimation of a network-wide model without case-level data transfer, and (5) visualization of analysis results. The resulting system includes the following features: regulatory approval and management user interface, horizontally partitioned model estimation with results identical to pooled data, data transformation and analytic execution plan programming representations based on widely used standards (Health Quality Measures Format [HQMF], Predictive Model Markup Language [PMML]) with translation modules to site-specific analysis engine, such as R or SAS, and results data visualization and graphing. The analytics core includes site-specific load-balancing (DAN), open source analytics and R-interface (OCEANS) analytics modules, and data visualization, table generation, and graphing components for study results.

Network to Network Collaborations and Protocol Approvals: We added a workflow to PopMedNet™ that enables any member of the network to propose a protocol to a subnetwork of collaborators through the portal. The data elements in a proposed protocol include specifications for the source data (e.g. PCORnet CDM, OMOP, custom data definition), specifications for analysis types (e.g. cohort discovery, privacy-preserving multivariate model estimation), requirements for local data and software environments, the type of local review process (manual vs. automated execution), and IRB and regulatory approval information. If a protocol is approved, multiple analytic queries can be submitted across the network under a single collaboration agreement.

Analytic Plan Representation & Translation: The software tools include a user interface that assists in developing data transformation rules from PCORNet CDM to flat analytic flat file by representing the query in HQMF, and including a translation modules at the site that translate the HQMF to SQL code, uses Hibernaner or SQLRender or other tool to translate between dialects of SQL, and passes the SQL into the site specific data processing engine. In the same way, predictive modeling analysis is developed within a UI, stored as PMML, and translated into site-specific analysis code through a translation engine, one for each flavor of common analysis platform (e.g. R or SAS). This allows data sites with different software environments to seamlessly collaborate on analysis protocols.

Privacy-Preserving Analyses: The DAN (Distributed Analytics Network) coupled with OCEANS (Observational Cohort Event Analysis and Notification System) provides an open source fault tolerant mechanism for processing analysis requests across available institutional resources. This includes a scalable mechanism for distributing requests across analysis engine resources, permitting asynchronous, parallel requests. OCEANS operates as both an analysis engine and workflow adapter, providing a strongly typed interface for analysis requests into other common engines, such as R. We also developed R and Java modules for distributed risk models (e.g., linear regression, logistic regression, Cox proportional hazards models, and support vector machine) that decompose optimization (using the Newton-Raphson Algorithm) to local private data to get faithful results as if models are trained on pooled data.

Data Visualization and Graphing: The software also includes Javascript based graphing functions developed within D3, a well-known graphing engine, for representation of prediction and association models, descriptive statistics, propensity score balancing and common ground assessment, and sequential surveillance methods (such as sequential probability ratio testing).

Deployment: The system is in use within the pSCANNER CDRN and each of the components is all open source and has been released with regular incremental updates. A portal link page to the open source releases and screenshots of the system is available at http://pscanner.ucsd.edu/Analytics/. PopMedNet™ was developed by the Department of Population Medicine at Harvard Pilgrim Health Care. Lincoln Peak Partners is the Software Development and Technical Partner for PopMedNet™.
Beyond SMART: Remote Decision Support with CDS Hooks

David P. McCallie Jr, MD, FACMI1, Joshua Mandel, MD2, Howard R. Strasberg, MD, MS, FACMI3, Scott P. Narus, PhD, MS4, Kevin Shekleton1, Peregrin Marshall5
1Cerner Corp., Kansas City, MO; 2Harvard Medical School, Boston, MA; 3Wolters Kluwer Health, San Diego, CA; 4Intermountain Healthcare, Salt Lake City, UT; 5RxREVU, Denver, CO

Abstract: FHIR®, HL7’s emerging data access standard, has rapidly gained attention as an appropriate model to standardize application programming interfaces (APIs) for access to HealthIT data. Concomitantly, the SMART® Health IT specification has become accepted as a way to embed “apps” into Health IT workflows. The combination of these two technologies, colloquially known as “SMART on FHIR”¹, has attracted interest as a way to create vendor-independent “substitutable apps” that can be plugged into a variety of EHR and other systems. SMART on FHIR currently provides only for synchronously-launched apps, where the user chooses to initiate the app via a link or a menu choice. The SMART group has recently proposed CDS Hooks, a set of specifications building on SMART and FHIR to provide a more deeply integrated user experience. The paradigm instruments a native EHR with an event model, triggering calls to remote CDS services when specific user activities occur (e.g., “prescribe a drug”, or “open a patient record”). These CDS services can respond with advice, alternative suggestions, and in-context app launch links that can be presented to the user in accordance with explicit user experience guidelines.

Purposes of the system: A growing number of organizations are now offering remote CDS services for deployment into EHR workflows. In the past, these remote services required custom code by EHR vendors, limiting the number of services that could be integrated, and indirectly suppressing CDS innovation. CDS Hooks provides a standards-based way to address these problems. We will demonstrate our pilot experience of the integration of multiple remote CDS services into a commercial EHR. The demo will include CDS integration triggered by multiple common workflow events, as well as a variety of modes of integration, including modal, non-modal, and ambient alerts. We will also discuss suggestions for enhancements that have emerged from the pilot testing process.

Deployment status: Pilot demonstrations of CDS Hooks have been shown in several public settings, and include support for multiple CDS service providers. Production deployment is expected in 2016.

CEDAR: Better Data Sharing Through the Authoring of Better Metadata

Mark A. Musen, M.D., Ph.D., Martin J. O’Connor, M.S., Marcos Martínez-Romero, Ph.D.,
Attila L. Egyedi, Debra Willrett, M.S., John Graybeal, and the CEDAR Team
Center for Biomedical Informatics Research, Stanford University, Stanford, CA, USA

Abstract

The ability to find and access biomedical datasets that are stored in online repositories depends on the quality of the associated metadata. There is a growing set of community-developed standards for defining such metadata—often in the form of metadata templates. The practical difficulties of working with these templates are tremendous, however. The Center for Expanded Data Annotation and Retrieval (CEDAR) is developing technologies to assist in the management of biomedical metadata. By discovering patterns in existing metadata and by linking templates to biomedical ontologies, CEDAR is assisting the authoring of new, high-quality metadata. The availability of comprehensive and expressive metadata will facilitate data discovery, interoperability, and reuse.

System Description

CEDAR is building a suite of tools, known as the CEDAR workbench, that form a pipeline for authoring metadata. ¹

**Metadata Template Repository:** We have developed a standardized representation of metadata templates together with Web-based services to store, search, and share these templates. Templates created using CEDAR technology are stored in our openly accessible community repository. Researchers access the repository to search for appropriate templates to annotate their studies. Web-based interfaces and REST APIs enable access to all metadata templates, as well as to all the metadata collected using those templates.

**Metadata Template Creator and Template Editor:** Two highly interactive Web-based tools simplify the process of authoring metadata templates. The Template Creator allows users to create, search, and author metadata templates. Using interactive look-up services linked to the NCBO BioPortal (http://bioportal.bioontology.org), template authors can find terms in ontologies to annotate their templates and to restrict the values of template fields. The Template Creator automatically produces a user interface specification as it builds a template. The Metadata Editor uses this specification to generate a forms-based acquisition interface for acquiring individual metadata components.

**Intelligent Authoring:** To ease the burden of authoring high quality data sets, a recommender framework learns associations between data elements and suggests context-sensitive metadata values. The system can recommend possible values for metadata elements during the submission process. These value suggestions are based on an analysis of previous submissions in our metadata repository. To evaluate this approach, we analyzed all the publicly available metadata in the GEO data repository (http://www.ncbi.nlm.nih.gov/geo). We then developed an interactive Web-based value-recommender system that uses the results of this analysis to help drive GEO-oriented submissions.

Evaluation

Our team includes several community-based groups who are helping to develop and evaluate our current prototype system. These collaborators include (1) the BioSharing initiative (http://biosharing.org), which catalogs metadata standards for describing biomedical experiments, (2) ImmPort, a data warehouse of immunology-related datasets, and (3) the Human Immunology Project Consortium Standards Working Group, which designs new metadata templates and channels experimental datasets to the ImmPort repository. We successfully have represented metadata from several hundred studies provided by these groups within the CEDAR workbench. We also are working with the LINCS project (http://www.lincsproject.org) to develop a more robust metadata management pipeline that supports the authoring of metadata for a wide range of studies. Collaborations with other scientific consortia are in the planning stage, with the long-term goal of making all biomedical data easier to find, access, integrate, and reuse. ²

Acknowledgments

CEDAR is supported by NIAID grant U54 AI117925 through funds provided by the trans-NIH BD2K initiative.

VA’s New Electronic Health Management Platform (eHMP): Novel Features for Activity Management and Notifications

Jonathan R. Nebeker MS MD,1,2 Shane McNamee MD,1 David Douglas MD,1 James Hellewell MD,1,2 Kristian Johnson RN,1 Jessica Murphy MD,1 Ron Moody MD,3 Charlene Weir RN PhD1,2
1-Deptment of Veterans Affairs, Washington DC; 2-University of Utah, Salt Lake City UT; 3-Accenture Federal Services, Chantilly VA.

Abstract

VA has just completed the first read-write release of the Enterprise Health Management Platform (eHMP), its next generation EHR system. eHMP builds upon VA’s VistA EHR system with a data aggregation layer using JavaScript Object Notation (JSON)/Fast Healthcare Information Resources (FHIR), a service layer using modern open-source components, and a user interface layer that allows addition of compliant applications from outside VA. eHMP aggregates and standardizes data from 130 VistA instances, the Department of Defense, and community partners. The software development kit for the user-experience framework and the resource development kit for the data aggregation layer allow incorporation of applets made by others. This demonstration highlights two novel features: Activity Management and Notification services.

Description

Activity Management service allows support for clinical-process standardization. We combine business-process-management, decision-support, publish-subscribe, complex-event-processing, and team-management services to manage long running clinical processes. The initial use cases are simple tasks and consult requests. Simple tasks follow the process (but not web services) aspects of the OASIS standard for human tasks. Providing much more robust handling than consumer task-management software, this standard allows closed-loop management of task states and handling of failures through escalation or notifications back to requestor. The second use case is consult requests, which uses business process management notation and OpenCDS rules to describe and execute a process from initiation, pre-requisite validation, scheduling (including external referrals), and completion of the initial evaluation. This capability intentionally does not have backwards compatibility with CPRS/VistA and, thus, can address severe limitations of that system with communication, tracking, and escalation.

Notification service is based on the HL7 working standard for Unified Communication Service with significant extensions. The most notable extension is the handling of 10-levels of priority as generalized methods of salience varying from blocking or distraction from current workflow to subtle emphasis of information within a workflow. Levels of salience also incorporate a dimension of whether a task requires completion to resolve the notification. This notification capability is also not backwards compatible with CPRS/VistA to allow for superior alert and notification processing in eHMP. VA will gradually turn off alerts in CPRS/VistA and selectively re-implement them in eHMP to allow for appropriate presentation and automatic resolution, suppression, and escalation.

By the time of the presentation, read-write version will be deployed in a limited number of sites. At the time of submission features are in final stages of development.
iCONCUR: informed CONsent for Clinical data and biosample Use for Research

Lucila Ohno-Machado, MD, MBA, PhD, Hyoneui Kim RN, MPH, PhD, Elizabeth Bell, MPH, Xiaqian Jiang, PhD, Dexter Friedman, Claudiu Farcas, PhD
Health System Department of Biomedical Informatics, UC San Diego, La Jolla, CA

Abstract
The current practice of obtaining informed consent from patients for use of their health data for research largely depends on “blanket” consent, which involves reading a long text that is difficult to understand. As an alternative approach we developed a prototype system called iCONCUR, a tiered e-informed consent system that elicits patient preferences for clinical data sharing for research. We piloted it in two outpatient clinics of UC San Diego Medical Center. We will demonstrate our iCONCUR tool and to share our initial experience. Based on lessons learned from this pilot, we are currently developing a production version of the iCONCUR system.

System Description
iCONCUR was designed to support a granular level of control on data sharing by patients. It provides a way of granting data sharing to specific data items as well as to specific types of data users (Figure 1). iCONCUR was developed as a web-based system for easy access and use, and is hosted securely within the firewalls of our medical center. After signing into the system patients can indicate their data sharing preferences by unclicking the items they do not wish to share with particular types of data users. The data items listed in the taxonomy were determined based on the user survey and the analysis of data requests at UCSD. Patients can revise their sharing choices as frequently as they want to. The data sharing preference information is delivered to UCSD’s data concierge service, a clinical data retrieval service offered jointly through the Health System Department of Biomedical Informatics and the CTSA at UCSD. The data concierge provides clinical datasets to data requestors honoring the most up to date sharing preference at the time of data set generation. The detailed information on the data concierge transaction (e.g., data user, data use purpose, data items shared, and date/time of the data provision) is fed back to iCONCUR so that patients can check how their data are used for research by visiting the MyDataUse page in iCONCUR.

In the current phase of the project, we are focusing on augmenting iCONCUR (1) by improving the user interfaces for data sharing preference selection and data usage inspection and (2) by providing a means to incorporate proxy decisions on by authorized users.

We plan to implement the iCONCUR system for the entire UC San Diego Health System. We will conduct a larger scale survey of 1200 patients to elicit their data sharing preferences and to evaluate the effectiveness of web-based tiered informed consent system on helping patients make truly informed decisions on data sharing.
The MobiGuide Distributed & Personalized Patient Guidance System

Mor Peleg, PhD¹, Yuval Shahar, MD, PhD², Silvana Quaglini, PhD³

¹University of Haifa, Haifa, Israel; ²Ben Gurion University, Beer-Sheva, Israel; ³University of Pavia, Pavia, Italy

Abstract

MobiGuide is a ubiquitous, distributed and personalized decision-support system (DSS) for patients and their care providers. Its central DSS applies computer-interpretable guidelines (CIGs) to provide patient-specific recommendations by matching CIG knowledge with patient data that are stored in a personal health record (PHR) in interactive user-driven or proactive data driven manner. The PHR integrates data from hospital medical records, mobile biosensors, and recommendations and abstractions output by the DSS. CIGs are customized to consider the patients’ psycho-social context, quality of data, and patients’ preferences; shared decision making is supported via decision trees instantiated with patient utilities. The central DSS projects personalized CIG knowledge to a mobile DSS operating on the patients’ Smartphones that applies that knowledge locally. The system was evaluated with 10 atrial fibrillation (AF) and 19 gestational diabetes (GD) patients and their care providers in hospitals in Italy and Spain, respectively. The compliance of both patient groups to self monitoring was very high. For example, the GD patients’ self-measurement rate of Blood Glucose Levels [99%], was significantly [P<0.01] higher than that of a similar group of 247 patients managed by the hospital’s GD clinic [87%]. The system changed the clinicians’ diagnosis of 2 AF patients and resulted in starting insulin early for 2 GD patients. Patients indicated increased safety as the most important benefit. We will present a typical operation of MobiGuide (patient and doctor).

System purpose and innovation

Since the 1990’s, researchers have been developing decision-support systems (DSSs) based on computerized implementations of clinical practice guidelines. Such computer-interpretable guidelines (CIGs) can provide patient-specific recommendations during patient encounters, hence they have the potential to increase the impact on clinicians’ behavior. Traditionally, the users of CIG-based DSSs have been clinicians. The European project MobiGuide provides ubiquitous, distributed decision-support to patients in their normal environments as well as to their care providers.

The MobiGuide DSS goes beyond traditional DSSs in several ways. (1) Engaging patients: Patients are empowered by getting personalized alerts from the MobiGuide system, during their daily life, anytime, anywhere; (2) a novel mechanism of (a) considering non-clinical contexts in the customization of the CIG, including the system’s quality of data. The CIG is customized by secondary contexts, such as the patient living alone, and by technical contexts, such as a low battery or lack of an Internet link; (b) personalizing the customized CIG, by matching common events in the patient’s life with the customizable contexts. For example, a personal vacation event might be associated with the generic, though customized “irregular schedule” context that it induces. Personalization also involves specifying local preferences, (e.g., patient’s meal times on weekends), so that reminders could be delivered according to the patient’s schedule. Shared decision-making is also supported via decision-trees containing Markov models (e.g., to select an anti-coagulation drug), instantiated with patient’s utilities for various health states; (3) novel architecture for efficient distribution of decision support between a central DSS and a mobile DSS operating on the Smartphone. The central DSS has access to the full CIG and to all patient data, while the mobile DSS has access only to XML segments of the CIG knowledge that are relevant to the current patient state and are projected by the central DSS according to CIG monitored data patterns, to data measured by the sensors within the past several weeks and to partial PHR data; (5) Semantic data integration into a personal health record (PHR), which uses HL7’s virtual medical record (vMR) model to integrate data from hospital medical records, biosensors, abstractions found in patient data by the mobile or central DSS, and patient-specific recommendations delivered by the DSS. Storing vMR instances in the PHR supports data notification that is key for communication between system components; (6) The modular architecture allows plugging in different components (e.g., different decision-support engines like the decision-tree engine) and sensors, and uses generic UIs: one for patients and one for providers suitable for any chronic clinical domain.

The system was successfully evaluated with the help of patients and care providers in collaboration with hospitals in Spain and Italy in the domains of GD and AF. We will present the evaluation results. See web site for screen shots and publications: http://www.mobiguide-project.eu/
The Consent, Contact and Community Framework for Patient Reported Outcomes: Connecting ResearchKit to the Health System with FHIR

P.B. Pfiffner1,2,3, I. Pinyol1, M.D. Natter1,2 and K.D. Mandl1,3,4

1 Boston Children’s Hospital, Computational Health Informatics Program, Boston, MA; 2 University Hospital Zurich, Research Centre for Medical Informatics, Zürich, Switzerland; 3 Harvard Medical School, Department of Pediatrics, Boston, MA; 4 Harvard Medical School, Department of Biomedical Informatics, Boston, MA

Abstract

ResearchKit, Apple’s open source iOS framework, enables researchers to readily collect personal health data and patient reported outcomes (PRO) from patients “in the wild”, using their smartphone. ResearchKit is research backend agnostic, however, hence researchers must implement secure data serialization and transmission facilities themselves or choose a third party provider.

We present “The Consent, Contact and Community Framework for PRO” (C3-PRO), an open source toolchain that connects any ResearchKit app to the widely-used clinical research infrastructure Informatics for Integrating Biology and the Bedside (i2b2). This toolchain leverages the emerging health data standard Fast Healthcare Interoperability Resources (FHIR) for on-device concept representation, data serialization, and transmission. FHIR resources move creation of on-device surveys from code to file format and its use throughout the toolchain means individual components are readily substitutable.

Purpose

The development of mobile research apps – apps that collect PRO data from participants and from device sensors – has been greatly simplified by Apple’s ResearchKit, released in spring 2015. As demonstrated by the advent of ResearchStack, the Android counterpart to ResearchKit, tools for mobile development are constantly improving. Server side, many ResearchKit apps make use of SAGE services to manage participant accounts and to deliver data back to the researchers.

While this setup has already commoditized several parts of end-to-end research app development, there are still areas that researchers need to tackle. For researchers wanting to use a backend under their control, this involves:

- creating surveys and collecting responses, tasks performed programmatically
- encrypting PRO data before sending it over the wire
- providing robust, scalable server-side endpoints for the apps to connect to
- verifying the source of incoming PRO data server-side
- decrypting incoming PRO data
- storing incoming PRO data securely and in queryable form into a research database or health record system

With C3-PRO we have built an end-to-end, open source toolchain addressing these issues, consisting of four pieces. The toolchain leverages the FHIR standard for data representation and transmission and i2b2 for data storage and analytics.

The iOS framework translates between FHIR “Questionnaire” resources and ResearchKit’s in-memory representation of a survey. This means developers can use validated surveys in form of a FHIR resource instead of having to hand-code a survey task; a task that one has to repeat on Android with ResearchStack. The iOS framework also includes facilities for symmetric and asymmetric (public-key) encryption, reverse geocoding, HIPAA-compliant data de-identification and more.

Our server components use FHIR interfaces (or encrypted versions thereof) making any component substitutable. The front line component, our “C3-PRO Receiver”, can be run on Amazon for easy scalability. It performs OAuth2 dynamic client registration with each app instance and subsequently only accepts authenticated data. Since incoming data is encrypted, the receiver cannot inspect research data. It will then enqueue all authenticated resources for downstream consumption.

Our second server-side component, the “C3-PRO Consumer”, lives behind the institution firewall and consumes resources that have been enqueued by the receiver. This means it’s protected from the internet and only sees authenticated data. It also has access to the private key and is therefore able to decrypt incoming research data, ending up with a FHIR resource.

The third server-side component, the “i2b2 FHIR cell”, is an i2b2 plugin (cell) that accepts FHIR resources for mapping and storage into i2b2. This cell is being developed into a generic FHIR i2b2 cell, demonstrating the substitutable approach we are taking. It also performs the necessary data mapping to store PRO data meaningfully into i2b2.

Deployment

The C3-PRO toolchain is available open source, fully documented and with a permissive Apache 2 license, on GitHub (http://c3-pro.org/architecture.html). At the time of writing it was in production use by our own C Tracker hepatitis C ResearchKit study and partly by the Feverprints study, also from Boston Children’s Hospital. Here we will demonstrate a) how C3-PRO uses ResearchKit and ResearchStack to display FHIR Questionnaires on the smartphone, and b) how completion of a survey on the smartphone results in new data appearing in i2b2.
Bridging the Gap Between Public Health and Clinical Provider: The PHRASE Interoperable Platform for Improving Decision Support

Marc Tobias, MD¹, Naveen Muthu, MD¹, Robert Grundmeier, MD¹²

¹The Children’s Hospital of Philadelphia, Philadelphia, PA, USA; ²Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

Problem: Currently, the public health community has a wealth of information regarding infection surveillance, chronic disease best practices, and other insight that is frequently difficult for providers to access. A common method for dissemination is via e-mail, which is not patient specific and may result in delayed diagnosis and intervention. Systematic delivery of decision support at the point of care can potentially improve clinician knowledge and reduce care variation, leading to better outcomes for patients while reducing cost.

Solution: The Public Health Risk Assessment Support Engine (PHRASE) was created to address this need for further integration between the public health community and frontline healthcare providers. It allows for the identification of a target population using patient characteristics like demographics, location, symptoms, vital signs, or any other data stored in the electronic health record (EHR) system. In addition, recommendations can be entered for each alert by public health officials to help drive decision support. To deliver these alerts to healthcare providers, we utilize software that accesses the data in the EHR. This data is cross-referenced with the public health rules in PHRASE. Patients who match the criteria have an alert displayed in real-time within the EHR with recommendations from the public health official (Figure 1). Similar solutions have been attempted in the past, but questions remain concerning architecture, interoperability, governance and usability. PHRASE differs from prior solutions in being compatible with current and future standards for interoperability. The interaction with the EHR was accomplished via two different platforms: 1) SMART on FHIR and 2) Care Assistant, which is The Children’s Hospital of Philadelphia’s homegrown integration software. The use of these platforms allows for scalability to institutions across a broad range of EHR vendors (Figure 2).

Status: PHRASE has established feasibility at one institution and is now expanding to a multi-institution pilot.

LHC-Forms and Related Widgets for Capturing and Tuning Health Data

Ye Wang, MS¹, Paul Lynch, MS,¹ Ajay Kanduru, MS,¹ John Hook,² Lee Mericle, MS,¹ Christophe Ludet, MS,¹ Daniel J. Vreeman, PT, DPT, MSc², Clement J. McDonald, MD¹

¹National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA
²Regenstrief Institute, Indianapolis, Indiana, USA

Abstract: NLM’s Lister Hill National Center for Biomedical Communications (LHC) has developed four inter-related open source, web-based, JavaScript tools for gathering and processing clinical data: 1) **LHC-Forms** is a data capture widget designed in partnership with Regenstrief Institute to produce a browser executable form from a stored form description. LHC-Forms supports HL7 data types, repeating groups of questions, survey scoring, validation checks, answer lists, and default values that can be derived from answers given to preceding questions. LHC-Forms can execute any LOINC panel as a form, and generate an HL7 v2 message of the entered data. Try it: [https://lhc-forms.lhc.nlm.nih.gov](https://lhc-forms.lhc.nlm.nih.gov). 2) **Clinical Table Search Service** is an auto-completion tool that provides an autocomplete menu to fields that take answers from large tables. It is accessed via URLs whose parameters control what table to search, which fields to return to the choice menu grid, and which fields of the selected item to store as hidden content in the input fields. Our implementation provides preconfigured access to many clinical tables: LOINC, RxTerms, ICD-10-CM, many NCBI genomics tables, COSMIC and others. Try it: [https://clin-table-search.lhc.nlm.nih.gov](https://clin-table-search.lhc.nlm.nih.gov). 3) An **LHC-Form building tool**. Try it: [https://lhc-formbuilder.lhc.nlm.nih.gov](https://lhc-formbuilder.lhc.nlm.nih.gov). 4) A JavaScript **validator and converter for UCUM units of measure**. Try it: [https://ucum-validator.lhc.nlm.nih.gov](https://ucum-validator.lhc.nlm.nih.gov).

The four modules can be used together or separately in web applications.

System Description: Purpose: To provide a set of sophisticated but easy to use open source web modules that can be used within existing web applications and provide pre-configured support for standard clinical vocabularies (LOINC, RxNorm, UCUM, SNOMED CT) and genomic identifiers. Developers can also configure arbitrary external tables, such as local patient and doctor registries, to work with these widgets. LHC-Forms and its sister modules are designed to work together in LHC-Forms--or separately with other applications that follow its interface specifications. LHC-Forms can produce HL7 v2 messages, and will produce FHIR clinical reports in the future. The Clinical Table Search Service supports the HL7 coded-value types: coded with exceptions (CWE) and coded with no exceptions (CNE). Both the Clinical Table Search Service’s auto-completer and LHC-Forms can be downloaded as pre-built packages for integration in a web-application, so that forms and auto-completers can be rendered with just a few lines of code. Current usage: 1) We are using LHC-Forms and the Clinical Table Search Service to model a v2 HL7 clinical genomics implementation guide which is up for HL7 ballot Sept 2016 (view full version at [https://lhc-forms.lhc.nlm.nih.gov](https://lhc-forms.lhc.nlm.nih.gov) by selecting the second example in the left column). 2128

\(^1\)University of Texas Health Science Center at Houston, TX; \(^2\)University of California, San Diego, CA; \(^3\)University of Oxford, UK; \(^4\)National Institutes of Health, Bethesda, MD; \(^5\)University of Michigan, Ann Arbor, MI

Abstract

bioCADDIE (biomedical and healthCAre Data Discovery Index Ecosystem) is a joint effort of biomedical researchers, informaticians, administrators, publishers and a funding agency, to facilitate the discovery of available data through the development of a Data Discovery Index (DDI). The initiative is funded as part of the Big Data to Knowledge (BD2K) program by the National Institute of Health. This demonstration session introduces the functional prototype of the DDI, DataMed, developed by the Core Technology Development Team (CDT), in conjunction with members of the community (Pilot Projects, Working Groups, and supplements to existing NIH-funded projects). DataMed currently covers an indexing pipeline and metadata unification for 23 data repositories selected from various biomedical subdomains. An advanced search engine presents these resources to end users. The web interface integrates several tools for specific research purposes that were developed by bioCADDIE-funded pilot projects. The demonstration aims at introducing DataMed to the informatics community and obtaining feedback from the audience.

Overview of the System

The increasing number of scientific data sets, many of which are often difficult to find online but if utilized properly could accelerate research creates the need for a data discovery index (DDI). The primary objective of the bioCADDIE CDT is to design and implement a DDI web application with a user-friendly interface that enables users to browse, search and get recommendations of datasets that best satisfy their specific interests, preferences, and needs. Our goal is to do for data what PubMed did for the literature. DataMed consists of 3 main components (Figure 1):

- A repository ingestion and indexing pipeline that maps disparate metadata from diverse data sources, into a unified specification provided by various working groups organized by bioCADDIE and related communities. This pipeline has an automated component that provides controlled translation and curation of metadata using special tools such as a transformation language and JSON-Path.
- A terminology server for terminological consistency that includes several specific ontologies such as MeSH, the Gene Ontology and the NCBI Taxonomy, which are mapped via UMLS integration.
- A web application based on the search engine that uses the discovery index for locating appropriate datasets from the processed set of repositories. This engine also uses the terminology server to expand queries using synonymous terms. In order to provide a better user experience, two modes have been designed offering basic and detailed (advanced search) options.

The DataMed demonstration will cover an overview of the web interface to the search engine and will be based on a few common search scenarios. The aim is to introduce the system to the audience and to interact with and directly collect feedback from end users of the system.

Current Status: DataMed is currently available for exploration at [http://datamed.org](http://datamed.org), encompassing 649,055 datasets from 23 different repositories ([https://datamed.org/repository_list.php](https://datamed.org/repository_list.php)) that include 10 different data types ([https://datamed.org/datatypes.php](https://datamed.org/datatypes.php)). The CDT is working to incorporate new repositories to expand the content of the DDI as well as on validating, testing and improving ranking algorithms to retrieve relevant personalized search results. We are also conducting user and usability testing.

**Acknowledgements.** bioCADDIE is funded by NIH U24AI117966 and has many more team members and collaborators than would fit the author list for this abstract. They are listed in our web site at [http://biocaddie.org](http://biocaddie.org).
