Eligibility criteria for clinical trials are specified in natural language and hence they are not amenable to computational processing. In their comprehensive review of formal representations of eligibility criteria, Weng et al.\(^\text{11}\) discuss the variety of intermediate representations used by researchers to overcome this challenge. The authors discuss classification of eligibility criteria along three dimensions: content, use in eligibility determination, and complexities of semantic patterns. The first dimension deals with the information needed to answer eligibility queries. Multiple studies\(^\text{12,13,14}\) have been published characterizing this dimension of eligibility criteria. The TrialBank project\(^\text{14}\) classifies criteria into three large categories: age-gender, ethnicity-language, and clinical. Tu et al.\(^\text{15}\) classified criteria from a clinical perspective: stable, variable, controllable, subjective, and special. Metz et al.\(^\text{16}\) classified criteria for cancer trials as demographics, contact information, personal medical history, cancer diagnosis, and treatment to date. The majority of these classifications are very specific to the downstream task of these studies. Moreover, since most of these are annotated manually, they are also time-consuming and expensive.

Very few studies have explored automatic classification of eligibility criteria. Luo et al.\(^\text{17}\) classified eligibility criteria into 27 semantic categories. They show that machine learning classifiers using semantic types from the Unified Medical Language System (UMLS) as features perform better than those using traditional bag of words features; with J48 decision trees performed better than Bayesian models. Bhattacharya and Cantor\(^\text{18}\) present a study where they automatically map trial protocol documents from the pharmaceutical industry to openly available trial specifications. They compare the eligibility criteria from both sources and propose the creation of template criteria for standardization. Levy-Fix et al.\(^\text{19}\) propose automatic mapping of eligibility criteria to the widely adopted Common Data Model using a clustering method that uses UMLS semantic type based features. Hong et al.\(^\text{20}\) define “diagnostic criteria” as a combination of signs, symptoms, and test results used by clinicians to determine the correct diagnosis, and propose mapping of such criteria to the Quality Data Model.

In this paper, we target a very specific problem of automatically classifying whether an eligibility criterion should be resolved using structured data or by using NLP techniques. This is an application driven problem that is common to a number of approaches undertaken by the biomedical informatics community for the secondary use of EHR data. We present a detailed evaluation of our approach using data from two disparate diagnoses. The paper is organized as follows: in order to evaluate an approach that can automatically classify eligibility criteria, we first describe the creation of a gold standard dataset. This is followed by a description of the features used for the machine-learning based classification task and our results. We then examine errors made by our system, followed by a discussion and conclusion of our work.

Dataset Creation

The National Library of Medicine and the National Institutes of Health maintain the website www.clinicaltrials.gov, a registry and a database of publicly and privately supported clinical studies across the globe. Almost all of the studies described above, which analyze eligibility criteria of clinical trials, use this registry as their data source. We searched the registry with the query “heart failure” and randomly sampled 50 trials from the result. This was repeated for the query “chronic lymphocytic leukemia.” We then extracted all eligibility criteria from these 100 trials and split them into individual criterion sentences using a sentence chunking module from Lingpipe\(^\text{21}\) that was trained on MEDLINE articles, along with custom rules for refinement. The goal was to annotate each criterion with the preferred data source for resolution, either “Structured” or “Unstructured.” We selected trials from two disparate diseases to test the generalization capabilities of our method. The goal was to verify if preferences for resolving these criteria would remain consistent across trials of different diagnoses.

Our annotation team consisted of two senior undergraduate nursing students, a medical student (KR), and a physician (CH). The first author (CS) developed detailed guidelines for the annotators in consultation with the physician on the team. While creating the annotation guidelines, we assumed that the criteria were being resolved by searching for patient information in the EHR software from Epic Systems (Verona, WI) at our institution, The Ohio State University’s Wexner Medical Center. In order to ensure that the annotation guidelines were complete, we
conducted three training rounds with ten trials each. This was followed by a discussion period, and disagreements were resolved by the physician. The annotation guidelines were updated after every training round to reduce differences among annotators. We ensured that trials used in the training rounds were not included in the final set of trials used for the study. The training rounds consisted of 30 trials for annotation; criteria texts and annotations from these trials were then used for feature development.

During the discussions, our annotators argued that although the EHR might have a structured field for a criterion, the field may or may not be consistently used by providers for documentation. We addressed this by assuming that for a particular criterion, if the EHR had an available structured field for documentation, it would be classified as structured. In cases of criteria where evidence from both structured and unstructured sources was required, we treated the annotation as unstructured, since criterion resolution could not proceed unless a clinical note was referred to. The end-goal of the classifier being developed is to separate eligibility criteria that can be resolved exclusively by structured data from others, in order to speed up screening. Thus, if a criterion can be partially resolved using structured data but mandates reading of notes for its full resolution, it cannot be processed exclusively using structured data and hence does not contribute to speedup. We therefore do not consider a separate category for “Structured AND Unstructured.”

Another observation made by our annotation team was the presence of eligibility criteria in trials that could not be resolved by information in the EHR at all. These included criteria that would need to be resolved in person or after the start of the study, such as informed consent, willingness to comply with certain restrictions, and criteria associated with post-recruitment details such as randomization constraints, etc. Therefore, in addition to the two categories of structured and unstructured data, we included a third category “Neither” for our annotations. We also observed that the automatic sentence segmentation was not accurate; these were hand-corrected by our annotators. The final kappa among annotators on the set of 50 heart failure trials was $\kappa = 0.83$, with $\kappa = 0.81$ for the CLL trials; these indicate excellent inter-annotator agreement. The dataset consists of 766 criteria across 50 heart failure trials and 677 criteria across 50 CLL trials. Table 1 summarizes the distribution of annotations across the three categories, which is fairly consistent across the two diagnoses. Figure 1 shows sample criteria across each of the three categories.

### Table 1. Overview of annotations in the dataset

**Figure 1.** Sample eligibility criteria across the three classification categories.

**Unstructured**
- Major heart event or heart procedure within the 6 weeks prior to study entry.
- Stable, chronic, mild to severe heart failure as defined as subjects with symptoms of heart failure who do not require IV diuretics, inotropes, or vasodilators or those that require support with a left ventricular assist device.
- Progressive lymphocytosis with an increase of > 50% over a 2 month period, or an anticipated doubling time of < 6 months.

**Structured**
- porphyria
- Individuals who are morbidly obese
- Has significant, moderate-severe renal dysfunction or disease, confirmed by serum creatinine of greater than 2mg/dl (180 micromol/L)

**Neither**
- Patients must be able to provide informed consent.
- Concomitant administration of oral ACE inhibitor medication from 2 hours before the start of the study drug until 30 minutes after the start of the study drug.
- Patient is physically capable and willing to perform repeated physically demanding tests associated with the study.
Feature Representation

We extracted four sets of features for creating a model to classify the eligibility criteria statements. As discussed earlier, these were designed by examining the criteria from the training rounds. We used MetaMap\textsuperscript{22} for all UMLS related features and the Stanford Parser\textsuperscript{23} for other shallow linguistic features. We explain each feature and the rationale for its design below:

Surface Features
M1. Number of words (excluding stop words): Short criteria can be often inferred from structured data.
M2. Number of numerical quantities: Presence of numerical quantities reduces ambiguity and can thus be inferred from structured data.
M3. Number of arithmetic symbols: Presence of arithmetic symbols such as ‘<’, ‘>’ or ‘=’ typically indicates a criterion that can be easily converted into a structured query.
M4. Number of delimiters: Protocol writers often combine multiple sub-criteria using a semi-colon or comma. Multiple information sources may be required to resolve such a criterion.
M5. Number of measurement units: These are often lab values and can be reliably inferred from structured data.
M6. Number of UMLS concepts: This has the same intuition as M1. Criteria with multiple concepts are likely to be complex and thus would mandate reading of notes.
M7. Number of illustrative terms: A generic eligibility criterion is often explained using examples. Illustrative terms used for such a construction are: \textit{e.g.}, \textit{example}, \textit{such as}, \textit{defined by}.

Syntactic Features
SY1. Number of conjunctions: A single criterion often has multiple sub-criteria in it separated by conjunctions (such as \textit{and, or}). A criterion with multiple sub-criteria is likely to be resolved by reading notes.
SY2. Number of adjectives: Adjectives are used to describe qualitative judgments, possibly making the criterion ambiguous from a computational perspective. It is hard to conclude about such criteria using structured data.

Semantic Features
SM. Semantic types of concepts: Semantic types from UMLS provide a level of abstraction that is intuitive for criteria classification. For example, it is generally accepted that criteria involving laboratory values and medications are resolved using structured data. These correspond to well-defined UMLS semantic types “Laboratory or Test Result” and “Pharmacological Substance” respectively.

Lexical Features
L1. Bag of Words: As discussed earlier, all criteria are from trials of specific diagnoses. Thus, similar words will be commonly used for defining criteria from each of the three categories. These features will capture this pattern.
L2. Bag of UMLS Concepts: This has the same rationale as L1 with one difference: UMLS concepts are often multi-word expressions, and a concept level mapping helps to mitigate this phenomenon.

Results

We evaluated the contributions of different features for the criteria classification task using machine learning classifiers. The evaluation of these tasks was carried out using accuracy as a metric. The distribution of the three categories in our data shows that the simplest classifier, which always predicts the category “Unstructured” for every instance, can achieve an accuracy of 64% on heart failure and 54.4% on CLL. This “Majority” classifier is the simplest baseline.

We chose two different machine learning algorithms for our experiments, namely Naïve Bayes and Support Vector Machines (SVMs). While Naïve Bayes is a simple classifier, it can deliver quick results. SVMs are state of the art machine learning algorithms for classification tasks and work well even with datasets that are not linearly separable. Although it can be time consuming to tune SVM parameters on large datasets, the relatively small dataset in our work meant tuning was not an issue. Following Luo et al.,\textsuperscript{17} we also tried J48 decision trees, but did not observe any significant performance gain in comparison with the Naïve Bayes model.

We set up the classification task in two settings. First, we carried out a leave-one-out validation on a per-trial basis. Of the 50 trials in our dataset, we trained a classifier on eligibility criteria across 49 trials and tested it on the
remaining trial. This was repeated 50 times, such that each trial appeared in the test set once, to calculate the reported accuracy. We refer to this as the trial-dependent setup. Second, we carried out criteria classification independent of their association with a trial. Each criterion statement was considered as a separate instance and evaluation was performed using ten-fold cross validation. While such a setup may induce some knowledge into the model since criteria from the same trial may appear in the training set, it is a more practical setup. When such a system will be deployed for practical use, it would be trained on criteria from different trials. The results of these two evaluations are summarized in Table 2. We found that SVMs outperformed Naïve Bayes significantly; interestingly, the trial-independent setup gave better results with both models than the trial-dependent one.

**Feature Analysis**

The Naïve Bayes classifier assumes that each of the features it uses is conditionally independent of the others, given some class label. SVMs do not make this assumption. They transform a given set of data points into a high dimensional space and construct a hyperplane for classification. We hypothesized that the Naïve Bayes model does not perform well because it does not consider the interaction between different features. In order to verify this, we evaluated the contribution of our various features towards the performance of the two models, using the trial independent setup. We compare feature contributions for both the Naïve Bayes and SVM classifiers. The following sections discuss experiments for these evaluations.

**Naïve Bayes**

We created simple classification models using the Naïve Bayes classifier in combination with the L1, L2, and SM feature sets individually. A fourth model was also created combining all the morphological and syntactic features. All models were created using the Weka toolkit. The results of these individual models are summarized in Table 3.

**Support Vector Machines**

SVMs belong to a class of algorithms known as kernel methods, which have been shown to be very effective for classification. This is achieved through a kernel function, which is a similarity function $K$ that maps two inputs $x$ and $y$ from a given domain into a similarity score that is a real number. Formally, it is a function $K(x, y) = \langle \phi(x), \phi(y) \rangle \rightarrow \mathcal{R}$, where $\phi(x)$ is some feature function over instance $x$. For a function to be a valid kernel, it should be symmetric and positive semi-definite.

To analyze the contribution of different features, we constructed individual linear kernels (regularization parameter $C=0.25$) using each of the four feature sets described earlier: words, concepts, semantic types, and morphology and...
syntax features. This involves creating a kernel matrix (or gram matrix) comprised of similarity values between all pairs of instances in the dataset, obtained using the kernel function \( K \). All models were implemented using the LibSVM library. Joachims et al. also showed that given two kernels \( K_1 \) and \( K_2 \), the composite kernel \( K(x, y) = K_1(x, y) + K_2(x, y) \) is also a valid kernel. This can be achieved by a simple addition of two kernel matrices. Thus, we combined different kernels to test the contribution of individual feature sets towards classification. The results are summarized in Table 4.

Comparing results from Table 3 and Table 4, we observe that SVMs perform better at the classification task by modeling interactions between different features. In the following section we discuss the performance of this classifier across each of the class labels: “Structured”, “Unstructured” and “Neither”. We also discuss common errors made by the classifier in this task.

**Error Analysis**

As discussed in the section on data creation, the corpus is skewed, with the majority of the eligibility criteria labeled as resolved from unstructured data. Table 5 presents the confusion matrix of the SVM classifier (using the “All” kernel combination from Table 4) on the combined data. These errors are representative of the individual datasets as well. Most of the errors stem from the class “Structured,” while the “Unstructured” class has the least.

<table>
<thead>
<tr>
<th>Label</th>
<th>Prediction</th>
<th>Number of instances</th>
<th>Accuracy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unstructured</td>
<td>768</td>
<td>859</td>

</tr>
<tr>
<td>Structured</td>
<td>129</td>
<td>387</td>
<td>64.8</td>
</tr>
<tr>
<td>Neither</td>
<td>46</td>
<td>197</td>
<td>73.1</td>
</tr>
</tbody>
</table>

We examined the criteria for these errors. Many criteria are simply too brief and the classifier has very little context to predict the right label. For example, the criteria “Any etiology” or “Diabetes Mellitus” are labeled as “Structured” but misclassified as “Unstructured.” Similarly, “Previous exposure to KW-3902” or “End stage cancer” are labeled as “Unstructured” but predicted as “Structured.”

Interestingly, some errors also stemmed from information that would be classified as “semi-structured” data by humans. These were discussed by the annotators during our training rounds for consensus. For example, one of the guidelines was to label criteria associated with numerical fields found in ECG and EKG data as “Unstructured,” since they are not present as discrete values in our EHR. The classifier made errors for statements such as “EF < 45 %” or “QRS > 120 msec.” Similar observations can also be made for criteria such as “Folstein MMSE score less than 20” or “Walk < 450 meters during 6 minute hall walk test.”

Although certain criteria statements had a single class label assigned to them, there was a possibility of multiple labels being associated with them. For example, consider the criterion statement: “Adult patients age >= 18 admitted with CHF exacerbation with NYHA Class III-IV symptoms at screening.” The annotators marked this criterion as
“Unstructured,” whereas our model classified it as “Structured.” One can observe that this statement has two sub-criteria: one related to the patient being adult, and the other one about her CHF. While the age related part can be resolved using structured data, the CHF part requires reading clinical notes. A similar claim can be made for “WBC > 1.5; ANC > 500; Plt > 50,000 unless documented as due to disease” which was marked “Unstructured” by our annotators (because of the judgment required to determine if these laboratory abnormalities were related to the disease) and predicted “Structured” by our model.

Some kinds of criteria were quite rare and hence the model was not able to predict the correct label. For example, the criterion “Currently a prisoner” was labeled as “Structured” but predicted as “Unstructured.” This is the sole criterion about prisoners in our dataset. Similarly, “Inability to lie flat for MR study” is labeled as “Neither” and misclassified as “Unstructured.” There were some obvious generalization errors as well. For example, “Current treatment on any Class I or III antiarrhythmic, except amiodarone,” which was labeled as “Structured” but incorrectly predicted as “Unstructured.” In the trials for heart failure, mentions of “Class” are associated with New York Heart Association (NYHA) Class I, II, III or IV and are labeled as “Unstructured” multiple times in the dataset. Similarly, for the criterion “Patients who are unable to refrain from taking acetaminophen” the phrase “unable to refrain” makes it “Unstructured,” however the remaining is a medication that can be looked up in the structured medication list, so our model classified it as “Structured.” A larger labeled dataset or lexical features with longer n-grams could potentially avoid such errors.

Some errors could not be explained. For example, “Patients having undergone revascularization procedures within 6 months” or “Current treatment of calcium channel blockers except for long acting dihydropyridines” were labeled as “Structured” and misclassified as “Unstructured.” Similarly, “End-stage renal disease on dialysis or imminent” was labeled as “Unstructured” (would not be able to determine “imminent” without reading a note) and misclassified as “Structured.”

**Discussion**

Figure 2 outlines the role of our work in an automated clinical trial screening workflow. A number of clinical research studies mandate selecting patients as subjects based on stringent eligibility criteria. Clinical trials are a particular type of such a research study. These eligibility criteria are specified in natural language text (block 1), and trial coordinators examine these criteria to locate information in the EHR (block 2) that can be used to resolve the criteria. This information is present in the form of structured content such as tables and flowsheets (block 2.1), or in the form of clinical notes and reports (block 2.2). Eligibility decisions (block 3) are made based on evidence from these sources.

**Figure 2.** Role of this work in an automated clinical trial screening workflow
There has been a lot of research focused around introducing automation into the process of cohort identification, with various efforts in the research community addressing different stages in the screening process. Recent studies in NLP focus on the development of techniques that can be used to automate cohort identification. These can assist the human effort involved in reading the unstructured content from the EHR for eligibility determination (block 4). A number of studies in the past have proved that structured information such as billing information can be used effectively for cohort identification. These are stored as structured content in the EHR in the form of databases. Simple SQL queries can be used to extract this information (block 5). There has been a large body of work to translate eligibility criteria into such queries. However, to the best of our knowledge, there has been no work in the past to triage an eligibility criterion along one of these two routes. This work is an effort towards introducing automation in this step of the workflow. This work has utility in various applications such as clinical question-answering and decision support where the same problem of choosing a preferred data source for evidence gathering is encountered.

Limitations

This is an initial investigation for a potentially larger problem and is not without limitations. As discussed in the section on dataset creation, we made some assumptions for the task of annotation. Our most crucial assumption was the availability of data in a structured field; in practice, presence of a structured field in the EHR does not imply availability and reliability of the values in that field. Retrospectively, we realized that although the annotation team had high agreement, some decisions were subjective based on the annotators’ knowledge of our EHR, and could differ at other institutions. In some cases, the criterion may be best resolved by looking at both structured and unstructured data which cannot be sped up despite the classification step using our model. Finally, annotations obtained for this study were based only on observing and reading the criteria texts. A retrospective study examining agreement for our annotations with actual screening undertaken by clinical trial coordinators would confirm our findings.

Conclusion

We introduced the problem of identifying the right data source type for resolving an eligibility criterion in clinical trial screening. A gold standard dataset for automating the task using 100 trials (50 for heart failure, and 50 for CLL) was created. We focused on the language used in the criterion text and designed a variety of intuitive features for determining which data source to use to best resolve a particular criterion. These include morphological, lexical, syntactic and semantic features. An empirical comparison of two popular machine learning algorithms shows that a combination of these features results in optimal performance using SVM as a classifier. We note that most of our remaining errors stem from structured criteria being predicted as unstructured. Our system’s current performance shows promise, but has room for improvement. Our work is a step towards efficient automation of clinical trial recruitment by triaging each eligibility criterion to the right data source for its resolution.

Better managing technology-mediated interruptions in the ICU: Examining the role of patient information for improving text message notifications

Preethi Srinivas, PhD1, Madhu C. Reddy, PhD, FACMI2, Anthony Faiola, PhD3
1Indiana University School of Informatics and Computing, Indianapolis, IN; 2Northwestern University, Evanston, IL; 3University of Illinois, Chicago, IL

Abstract
Previous research has identified the need for managing wanted and unwanted interruptions from technology-mediated notifications (TMN) in the intensive care units (ICUs). Current solutions are focused on mobile, asynchronous and context-aware mechanisms that consider a minimal number of factors (location and activity of the receiver). These factors are insufficient for a receiver to effectively decide on whether or not to interrupt their ongoing activities to immediately respond to a TMN. We propose a mobile device solution, known as “patient-enhanced notifications” that presents a preview of TMN with additional patient information. A study comprising of user evaluations and interview sessions helped ascertain that patient vital signs coupled with the actual text message assisted receiving ICU providers in deciding on when to respond to the TMN. We conclude that patient-enhanced notifications has the potential to help ICU clinicians better manage interruptions generated from mobile devices.

Introduction
Hospital intensive care units (ICUs) are intensely complicated environments characterized by a high degree of communication and collaboration between patient-care team members.1,2,3 Team members must often re-align and re-orient their knowledge about the patient, tasks, and goals to ensure high-quality care. Consequently, the need for timely communication of patient information often result in team members interrupting and being interrupted more frequently in the ICU.4 Information and communication technologies (ICT), such as, patient electronic medical records (EMR), pagers, smartphones create new opportunities for communication and dynamic updates for patient care; however, at the same time, they also introduce potential work interruptions through technology-mediated notifications (TMN) such as alarms, alerts, and pop-up messages.4,6,7 Gill and colleagues8 argue that a growth in mobile healthcare-related applications could lead to their increased use while communicating, collaborating, and disseminating tasks between healthcare providers. Although these technologies increase the ability to communicate and collaborate, they also introduce the possibility of someone being unnecessarily interrupted through a phone call or a text message.9 For instance, the introduction of wireless cellphones can lead to increased nurse-physician communication, but at the same time, cellphones can also interrupt the nurse’s or physician’s work. Further, the process involved with deciding whether to respond or to avoid the phone call can increase the already high cognitive load often experienced by ICU providers.10

Sasangohar and colleagues11 define interruptions as “externally or internally generated, unexpected events that may cause a break in the primary task, diverting attention to a related or unrelated secondary task, which can have both negative and positive effects on the interrupter’s or the interruptee’s main task.” (p. 3) Interruptions have also been called distractions, breaks-in-task, and disruptions.5,11,12,13 Several workflow-based studies in healthcare associate interruptions with negative impact on human cognition often leading to medical errors.15-16 For instance, 43% of medication errors are attributed to interruptions,16 and the Institute of Medicine (IOM) identifies interruptions as a potential factor contributing to medical errors.17 Consequently, existing research has focused on interruptions and factors that make them disruptive,5,11,12,13,14 often suggesting a set of design implications on when people can be interrupted.5,25,26,27,28 Although there is a predominantly negative view of interruptions caused by TMN, some studies acknowledge the important information a TMN may carry.9,13 Some examples of positive effects identified include contributing to increased safety, improvements in patient comfort, and increased accuracy.13 Because interruptions can be wanted or unwanted by a receiving ICU provider at any moment, we need to develop approaches for interruption management that increases the usefulness of the interruptions while reducing the negative effects on cognitive load.

Edwards and colleagues9 suggest taking advantage of properly designed asynchronous ICT that can mediate non-urgent interruptions, and divert a phone call to more opportune times. In this paper, we report on a study examining a potential asynchronous solution that involves presenting patient information in addition to the actual text message, to help the individual receiving the text to decide when to respond to a TMN. In the remaining portions of the paper,
we refer to the person performing an action leading to TMN as the “interrupter” or “sender”, and the person receiving the TMN as the “interrupted” or “receiver”. Our research investigation sought to investigate the following research question: “Would patient information such as vital signs in conjunction with a text message be useful in helping ICU providers decide whether or not to immediately interrupt their work to respond to a TMN?”

This paper is organized as follows: First, we review existing research on managing interruptions in the ICU. Second, we briefly describe our work on examining interruptions at an ICU site, including the identification of other additional patient information that is of interest to providers while responding to TMN. Third, we walk you through our study design methodology and results. Lastly, the paper discusses our findings and how our approach has the potential to help receivers better manage interruptions from TMN in the ICU.

Background

Researchers have extensively examined how people manage interruptions. For instance, Harr and Captelinin24 discuss the impact caused by the occurrence of an interruption beyond the interrupted activity through the creation of a “ripple effect”. This research suggests considering the social context in understanding peoples’ strategies for interruption management. On the other hand, some studies suggest considering the cognitive context as well while managing interruptions. Other studies argue that effective interruption management can be achieved through increased awareness among the colleagues.4,27 For instance, the aspect of “awareness related to action” can be used to reduce unwanted interruptions or facilitate wanted interruptions. The strategies people rely on to: (1) make their work visible to their colleagues, and (2) monitor what colleagues are doing, can help promote awareness, subsequently helping decide whether an interruption is wanted or unwanted at the moment.

Grandhi and Jones28 suggest considering “relational context” (such as, the content and urgency of interruption, interrupter-interrupted relationship and so on) while understanding and managing interruptions. The authors of this paper discuss the notion of how the receiver can associate a perceived cost and value to a TMN while deciding how to respond. Two interruption management paradigms are examined: (1) the impact reduction paradigm, which seeks to reduce the cost induced by an interruption by using techniques that either prevent or block TMN, and (2) the interruption value paradigm, which allows the receiver to evaluate an interruption based on its perceived cost and utility from a preview of useful information from the TMN.

Some recent innovations in ICT, such as, reminders and context-aware architecture, have been proposed to reduce interruptions through asynchronous communication. These systems, however, consider a limited number of factors from the receiver’s context. For instance, the communication service proposed by Dahl allows hospital workers to leave digital messages at relevant physical locations (such as patient bedside), so that the intended colleague can retrieve them at a later time. This approach is based on the assumption that hospital workers move between various locations mainly out of work priorities. However, other factors such as social activity at the location, content and urgency of each message, and the relationship of the timeliness of message reception to patient’s condition are not considered.

Previous research has focused primarily on identifying techniques for blocking interruptions in the ICU. For instance, researchers reported reduced interruptions with the introduction of an external signage or intervention that blocks face-face communication at selected locations, while others considered an awareness display that presents information to the interrupter about the workload currently experienced by the interruptee. These techniques, however, focus on the idea that both the sender and receiver are physically co-located and do not provide much assistance when they are geographically separated from each other. Further, these techniques require the receiver to remain within the same space as the interrupter when she does not want to be interrupted.

In this paper, we propose a solution that “adapts” the interruption value paradigm to include patient information for aiding “receiving” ICU providers, while improving their ability to manage interruptions from TMN with reduced cognitive load. This requires providing a preview of patient information (such as vital signs) along with the actual message to provide more context to the receiver while making
sense and deciding to interrupt an ongoing activity (Figure 1). In the next section, we briefly describe the field observations and follow-up focus group sessions, both of which were IRB approved and helped in the development of this approach.

**Examining Interruptions at an ICU Site**

**Observations:** We performed ethnographic field observation including contextual inquiry (of two ICU teams) in a 16-bed medical ICU used to monitor and treat critically ill patients. The observational notes were transcribed and coded using the Locales Framework. We viewed the situated nature of ICU work using the idea of dynamic social worlds. This helped us focus on the interaction at hand. We collaborated with two expert ICU physicians who helped validate our data interpretations and findings. We encourage readers to refer to previous work on understanding and designing for collaborative, sociotechnical environments.

The study site is comprised of electronic information sources such as EMR, patient charting and order notification system, bedside physiological monitors and infusion pumps. The existing technology systems supporting communication between the providers at the study site included electronic resources such as: (1) landline telephones (placed outside patient rooms, at nursing stations and conference rooms), (2) hospital-owned mobile ASCOM cellphones (which does not provide any information regarding the caller when a phone call is received), and (3) pagers (occasionally used for communication between the providers). The pagers are only used to convey callback phone numbers and notifications when a patient needs immediate attention (such as room number of a patient).

Below, we present an example involving a synchronous communication between a nurse and a resident regarding a patient. A nurse (N), who is currently at the nursing station, calls the patient’s resident (R) using cellphone. R, who is currently busy talking with his colleague regarding another critically ill patient, does not know for certain the urgency of the phone call compared to the ongoing face-face conversation. Since R cannot determine who is calling, he interrupts his face-face conversation and answers the call. We report an extract of this conversation.

N: Mr. S from 166 has positive blood culture for staph aureus.

R: What are his current vitals?

N: He has fever with temperature 101, blood pressure is 120 over 90, heart rate 65, respiratory rate is 11, and blood oxygen is 95% on ventilator.

R: All right, I will sign orders to start vancomycin and serial blood cultures.

N: Ok.

R had to interrupt his ongoing activity (face-face conversation with colleague) to respond to a phone call because he did not know who was calling him and the importance of the call. R was able to understand the condition of the patient and the urgency of the information conveyed based on additional patient information (such as current vital signs) provided to him by the nurse.

In an example of asynchronous communication – a resident who is participating in the morning rounds with his team receives a page message “0119865862”. The resident understands that the message is a callback number. Since he does not know the actual patient information that will be conveyed in the phone call, and since he does not know how urgent it is to call back, he steps away from the team to call the number. This results in the resident interrupting his current activity and missing some of the morning rounds discussion.

If the resident in the above example had received a visual cue containing the lab result and vital signs from the nurse before initiating a phone call, this would have been less disruptive. These cues will improve the contextual awareness and also provide implicit information on the priority with which the resident had to respond. For instance, seeing an abnormal temperature, heart rate, blood oxygen saturation in addition to the lab results can indicate to the resident that the patient is having an inflammatory sepsis response. That is, the extra patient-centric information such as vital signs that were discussed during the phone call could have been provided beforehand along with the actual message to expedite the resident’s understanding and decision-making of next steps. Further, the resident would have had more freedom in planning and strategizing when to interrupt an ongoing activity while responding.

**Focus Group:** We conducted a focus group session (FG1) with five ICU providers to understand the type of patient information that receiving providers are interested in while deciding how they responded to TMN. This was
followed by another focus group session (FG2) with two ICU providers and five user experience designers to create a design template that will be presented as preview text message notifications (Figure 2), including fictitious scenarios and information content for the sample text messages used to evaluate our designed solution.

In general, the information shared between providers include: lab/radiology results, patient’s response to medication, procedure completion and corresponding patient’s condition, and follow-up/consult with a specialist. One of the findings from FG1 also pointed to other additional details that can persuade the receiver to pay more attention while deciding to respond to a TMN. For instance, the information perceived by the sender based on the patient’s current condition, i.e., the indirect information perceived from the patient is often used to indicate the “priority/urgency of the message” during communication. FG1 also generated a set of sample text messages that can be shared between ICU providers. Several benefits and challenges to multiple versions of design templates were discussed and clarified in FG2. The design considerations from FG2 included (Figure 2): (1) explicitly depicting the importance of a message with respect to patient’s current condition by coloring the background of the preview notification (red: high; yellow: low; grey: none), (2) explicit color-coding of content to direct the attention of provider to important information that is abnormal or needs attention (red), (3) details on the patient and the sender of the message, and (4) placement of the patient’s current vital signs and the contents of the actual message. The focus group sessions contributed to the generation of fictitious scenarios and sample messages that can be conveyed as a text message notification.

Figure 2. Patient-enhanced notification depicting the actual message (+BC staph aureus) along with additional information such as vital signs and priority of the message (red background color). Content is explicitly color-coded to direct attention to parts of the actual message (+BC) and vital signs (101).

Based on our observations and focus groups, we propose a solution that involves presenting additional information obtained directly (from EMR) and indirectly (such as nurse’s perception) from the patient, along with the actual message as a “preview text message” to improve the receiver’s understanding and awareness of the patient, eventually contributing to making rapid decisions on when to respond to text message notifications. We refer to this “preview text message” notification with additional information as “patient-enhanced notifications.” The remainder of the paper describes the study design and our findings from an initial evaluation of the patient-enhanced notifications.

Study Design

Participants: Twelve ICU providers from the same study site as our fieldwork and focus group sessions participated in this study. The participants of the study are not the same as those who participated in the focus group sessions. The participant included: residents (P1, P2), nurse practitioners (P3, P4), fellows (P5, P6), registered nurses (P7–11), and staff nurse (P12).

Study Procedure: The study consisted of two activities: an evaluation of the patient-enhanced notification and an interview.

Evaluation session: This session was conducted in a quiet conference room where participants were required to use a web-browser (on a workstation) to evaluate the design of patient notifications. The evaluation required each
participant to view a fictitious scenario along with an image of a patient notification (Figure 3). Participants did not receive any instruction manual explaining the design of the patient notifications.

Participants responded to a set of multiple-choice questions. The multiple-choice questions included: (1) How would you react to this notification message? The response choices for this question included immediately, respond later, or do nothing, (2) When do you prefer receiving this notification? The response options for the questions were chosen based on existing research\(^9\)\(^,\)^\(^27\)\(^,\)^\(^41\), where, participants were asked to indicate whether a particular message in a given situation should be delivered immediately or at a future scheduled time. This session included a within-subjects design that required all the participants to respond to all the multiple-choice questions based on all the fictitious scenarios presented along with images of all text message notifications (Figure 3). All participants played the role of receiver of text messages. All the participants also rated their perceived urgency of each message on a scale from 1–10.

![Figure 3. Screenshot of what the participants saw while completing the evaluation session](image)

We utilized two scenarios that required the participants to imagine a receiver’s situation while receiving a text message: (1) high cognitive load and present in patient room and, (2) normal cognitive load and in cafeteria. For instance, a provider playing the role of a receiver was presented a scenario and image as in Figure 3. The participant was then asked to report on when he/she will respond (immediately vs. later vs. do nothing). We presented the image of only one message at a time to examine the initial reaction of providers to the additional information in the patient-enhanced notifications (tested through the study conditions described below).

**Study conditions:** We varied the additional information that can be shared along with the actual text message to assess their value of particular type of additional information. We varied the order that the study conditions were presented between participants to avoid order effects. This study focused on providing the following four levels of additional information in text messages:

1. **None:** In this condition, providers saw only the message with no additional information. The background of the text message was colored grey.

2. **Priority:** This condition provided additional information such as the priority associated with the message. The levels of this condition included: Low and High. Explicit color-coding was used to depict priority information. For instance, the background of text messages was colored red or yellow to depict urgency of the message as high or low respectively.

3. **Vitals:** This condition provided additional information on patient vital signs such as heart rate, blood pressure, temperature, respiratory rate, and blood oxygen content. The levels in this condition included: With and Without. The patient vital signs were again explicitly color-coded with red color to indicate abnormal values.

4. **Combination of priority and vitals:** This condition included a combination of conditions 2 and 3 (Low vs. High and With vs. Without). All the participants were provided with the same study conditions, in a randomized order.
Data collection and analysis: Participants responded to questions administered through the TypeForm website. The TypeForm website has a backend database tool for collecting participant responses. Quantitative data was analyzed using SPSS v.21. Participant responses to the multiple-choice questions were coded for performing descriptive and inferential analysis (1 = respond immediately, 2 = respond later, 3 = do nothing). We explored the receiver’s willingness to respond immediately to a message with different types of additional information. Friedman’s test with the additional information such as: (1) priority (low vs. high), (2) inclusion of vital signs (with vs. without), (3) combination of both (Priority x Vitals), (4) perceived urgency of message (1 – 10), (5) the 2 scenarios, (6) designation of the participant (doctor vs. nurse), and (7) message viewing order (1 – 10) was used to examine the receiver’s preferences for responding to text messages (immediately vs. later vs. do nothing). The rated urgency of these messages tended to be of low variance across the raters and did not cause confusion (Figure 4).

Interview session: The interview session occurred at the end of every evaluation session. In this session, all the participants responded to demographics-related questions and open-ended debriefing interview questions. The open-ended questions asked about: (1) the overall experience interacting with the designed text message notifications, (2) benefits of additional information while understanding and improving patient-situation awareness, and (3) how the additional information provided along with the actual text message aids in deciding when and how to respond to a text message alert or notification.

Data collection and analysis: Participant responses to the interview questions were audio-recorded and later transcribed for analysis. Qualitative data was coded and analyzed using ATLAS.ti. The post-evaluation interview session provided more information on how the additional information provided along with the actual message aid in deciding when and how to respond to a text message alert or notification. We report themes emerging from the coding of participants responses. Participant responses were also coded to identify suggestions that we used to help us provide some design suggestions for the patient notifications (Table 1).

Results

Quantitative

There was no significant difference among providers in perceptions of how important it is to respond immediately while responding to messages with and without additional priority information ($Z = -1.630, p = .103$). Specific to messages that had additional priority information provided as high or low, providers preferred responding to text messages immediately ($Z = -3.503, p = .04$) if the priority of the message was depicted as high ($M_{High} = 67.19\%$) as compared with those depicted as low ($M_{Low} = 32.81\%$). No significant difference in response preferences was noticed based on the scenarios, or the designation of the participant (doctor vs. nurse). Providers preferred responding to messages immediately ($Z = -3.645, p = .037$) if vital signs were included ($M = 60\%$) as opposed to not including the vital signs ($M = 40\%$) with the actual message. A more detailed exploration of the interaction between priority (high vs. low) and patient vital signs (with vs. without) demonstrates that the presence of patient vital signs coupled with priority of the message affected provider’s preferences in responding immediately to text messages ($\chi^2 (3) = 9.510, p = .023$; Figure 5).

That is, providers preferred interrupting their ongoing activity to respond to text messages based on the priority explicitly conveyed through the background color, and implicitly perceived from the patient vital signs. For instance, receivers interrupted themselves less often for low priority as opposed to high priority messages when they knew the patient vital signs. On the contrary, they had similar preferences for immediate interruption for messages with no vital signs irrespective of the priority of the message. Overall, their preference was also backed by their perception of the urgency with which they had to respond based on the contents of the actual message in relation to vital signs.

Qualitative results

Color-coding: Providers found it easy to rapidly understand and perceive the information conveyed through colors in patient notifications. For instance, P5 noted, “if I see something colored red, I automatically think it is abnormal. I was able to quickly understand that a vital sign is abnormal. Although I don’t really need the coloring, I know what is normal and abnormal. I think the color will help me improve my speed with which I perceive the information presented. This can be very helpful when all I have to do is glance at the phone while I am in the middle of something.”

Using patient vital signs: Providers reported patient vital signs as important information that they can use to rapidly understand a patient’s condition from the message. For instance, P2 noted, “the first thing I want to know when a patient’s lab result is abnormal is his current vitals. Instead of trying to look into EMR or call the nurse, it will greatly save me time and effort if I can just glance at my device and see the message and vitals together. This will help me to quickly determine what has to be done next, do I respond to the message at the moment or continue with whatever I was doing.”

Providers reported glancing at patient vital signs to rapidly determine the time they had to respond to the message. For instance, P1 noted, “if I am in the middle of rounds and if I receive a message with say a lab result and current vital signs, then I will be able to quickly understand the patient’s current condition and how it relates to the lab result, what has to be done and when. If it is something important and needs immediate attention, then I can step away from rounds, otherwise I can respond later to the message. However, I am concerned if I will remember to respond later, you know what I mean?” (this has been addressed as a design suggestion in Table 1)

Explicitly stating information on the urgency of a message shared: Providers reported not paying attention to the background color of patient notifications used to explicitly indicate the priority of the message. For instance, P1 noted, “the patient vital signs are enough for me to know how important the message is. Besides, I might think a message is not really important while a nurse might consider the same message as really important. This is probably why I never noticed the background color of the messages. This might be useful if I see a series of text messages all together. That way I can differentiate which ones are important and which ones are less important.”

Overall, participants reported positive preference for receiving a text message with color-coded patient vital signs during the interview session. In addition, participants provided suggestions, which was used to derive design suggestions for improving the evaluated design of the patient-enhanced notifications (Table 1).

Discussion

There are multiple approaches to addressing interruptions. Some researchers have adopted the impact reduction paradigm to manage interruptions, while others have adopted the interruption value paradigm to aid in the decision-making of response to the TMNs. While using the former can have an impact on the quality of patient care owing to the complex temporal and mobile nature of ICU work, the latter can add to the cognitive load already experienced by the receiving providers while evaluating the cost and utility of every TMN. We chose to adopt the interruption value paradigm because of the freedom it allows for a receiving provider to determine how to respond to a TMN. By using a combination of fieldwork and focus group sessions, we proposed patient-enhanced notifications as a tool to circumvent the added cognitive load while managing interruptions from TMNs. This is a novel contribution that supports offloading the cognitive expense (such as memory, inferential strategies, and knowledge) faced by ICU providers when using technology-mediated communication. Further, our work contributes to the Institute of Medicine’s (IOM) requirements of introducing health IT that does not increase cognitive load or alarm fatigue in the ICU.

</tbody>
</table>

Our evaluation study demonstrated that ICU providers responded immediately to messages that provided more contextual information such as patient vital signs in addition to the actual message. The urgency as portrayed using color was intended to provide an indication for the providers to “glance at” and determine the importance of the notification. However, providers reported that explicitly depicting urgency might not be helpful initially, if only a single message is seen on the mobile device – suggesting that such a feature will be learnt over time. Providers reported finding it easy to direct their attention to abnormal values since they were colored red – similar to their mental model of attributing red color with abnormality. Further, providers reported being able to perceive the urgency of a message implicitly based on the patient vital signs and the actual message. Providers highlighted the inclusion of the patient vital signs with a text message as a significant contributor in aiding their decision on how to respond to the message – patient vital signs were considered as important information that can be “glanced at” during the decision-making of any patient activity. Based on our findings, we also provide some design suggestion for the patient-enhanced notifications (Table 1). Most of these suggestions revolved around the idea of providing more contexts to the receiver as well as simplifying the response process.

**Study Limitations:** This study chose a subset of additional patient information, cognitive, and environmental situations to present. For example, we chose not to vary the time of the day or relationship between the interrupter and patient. We did this to gain more experimental control. Also, the specific options we chose can be implemented in the ICU using existing technologies. For instance, the patient initials, room number, and vital signs can be automatically populated if the device is paired with the EMR; leaving the sender to only type in the actual message and choose the importance of the message with respect to his/her understanding of the patient’s current condition. Another limitation is that this was laboratory-based. Consequently, how providers respond in a real-world setting can be affected by a variety of factors that we may be unaware of.
Conclusion
Managing interruptions is a major challenge in a busy, information-intensive ICU environment. In this paper, we adapt the interruption value paradigm\textsuperscript{27} to suggest an asynchronous technology solution that can help receivers better manage interruptions. We were interested in understanding what features would best support a receiver’s decision-making process in term of deciding whether or not to immediately respond to a TMN. Our proposed solution, also known as patient-enhanced notifications, used additional patient information (current vital signs and priority/urgency of the message perceived by interrupter based on patient’s current condition) provided via text message previews. Our study showed that providers were receptive to the additional information and that it helped them in deciding whether or not to immediately respond to a TMN. We also highlighted some design suggestions, one of which points to combining asynchronous and synchronous communication capabilities of a technology tool. In summary, we believe that introducing an asynchronous mechanism that prompts a response phone call, by sending patient-enhanced notifications, has two positive outcomes. First, it can support a conversation of multiple topics and second, it can support the interrupted in better managing the interruptions generated by the TMN. As to future work, we intend to further examine the differences in better managing interruptions between an asynchronous solution (that facilitates conversation based on only one topic) as opposed to a synchronous solution (that facilitates conversation of multiple topics).

Acknowledgments
We thank the ICU providers for allowing us to observe them. We also thank the ICU providers for evaluating the design of patient notifications and responding to interview questions.

Predicting Negative Events: Using Post-discharge Data to Detect High-Risk Patients

Abstract

Predicting negative outcomes, such as readmission or death, and detecting high-risk patients are important yet challenging problems in medical informatics. Various models have been proposed to detect high-risk patients; however, the state of the art relies on patient information collected before or at the time of discharge to predict future outcomes. In this paper, we investigate the effect of including data generated post discharge to predict negative outcomes. Specifically, we focus on two types of patients admitted to the Vanderbilt University Medical Center between 2010-2013: i) those with an acute event - 704 hip fractures and ii) those with chronic problems – 5250 congestive heart failure (CHF) patients. We show that the post-discharge model improved the AUC of the LACE index, a standard readmission scoring function, by 20 - 30%. Moreover, the new model resulted in higher AUCs by 15 - 27% for hip fracture and 10 - 12% for CHF compared to standard models.

Introduction

Predicting events associated with negative outcomes, such as readmission or death, post discharge is challenging. Traditionally, negative outcome prediction systems are executed at the time of discharge to identify high-risk patients¹. However, such systems are limited in their applicability because patient status often changes after their discharge and risk prediction models are not amended to incorporate such information. This lack of knowledge can result in risk assessment errors and potential readmission penalties, under Meaningful Use regulation, calculated via a payment adjustment factor².

Care providers, as well as the administrators of healthcare organizations, are keen on determining which patients might experience complications that lead to readmission or death, so that they may allocate additional resources to the patients and intervene before a negative outcome transpires³. Unfortunately, resources are limited and decision makers within health organizations (e.g. physicians and care coordinators) specify a subset high-risk patients who can receive special attention while other high-risk patients do not have access to such resources⁴,⁵. Accurately identifying, as well as prioritizing, which patients should be assigned assistance is an important informatics problem.

To investigate the effect of post discharge data in predicting negative outcomes, we focus on several core questions. First, what post-discharge information is available for prediction? Second, how can a post-discharge model be formulated? And, finally, how do different time periods of post-discharge information impact such predictions? In doing so, we examine which post-discharge features are the most important drivers of negative outcome predictions.

We evaluated standard and post-discharge prediction models using three years of data from Vanderbilt University Medical Center’s (VUMC’s) electronic medical record (EMR) system for two phenotypes: 1) an acute condition in the form of a hip fracture and 2) a chronic progressive disorder in the form of congestive heart failure (CHF). The results demonstrate that:

- Running the prediction at successive post-discharge days, and including post-discharge clinical information in the prediction model, outperforms state-of-the-art “at discharge” models, such as LACE⁶,⁷;
- The importance of post-discharge clinical features grows as the prediction horizon for negative events is pushed further into the future; and
- Higher utilization of clinical resources (e.g. appointments and medications) are correlated with a negative outcome.

Background

The number of proposed risk prediction models has increased dramatically over the last decade. Kansagara and colleagues performed a comprehensive systemic review to evaluate the performance of risk prediction models and their suitability for clinical use¹. To evaluate the performance of the risk model, studies usually compare their models to an established model such as LACE. This is a readmission index that provides a risk score to predict the
readmission or death, specifically for CHF patients, using length of stay (L), the acuity of admission (A), comorbidity score (C), and the number of the emergency department visits (E)\textsuperscript{6,7}.

Several studies have shown that post-discharge data can assist in the prediction of negative events in special circumstances. For instance, certain studies focused on surgical quality assessment at the point of discharge observed that over a quarter of the complications are diagnosed post-discharge\textsuperscript{8-10}. In another study, it was found that post-discharge data could improve the prediction of the presence, as well as the severity, of spasticity in upper limbs in the year following a stroke\textsuperscript{11}.

While post-discharge data has rarely been used in readmission prediction, Hersh and colleagues performed a systemic review about the post-discharge environment and its relation to readmission after heart failure\textsuperscript{12}. They reviewed 26 studies published between 1985 and 2011 to evaluate the importance of integrating post-discharge environment in the heart failure readmission model. In the review, only 7 studies included post-discharge data and focused mainly on whether the patient had a primary care provider. They concluded that the socio-economics of the post-discharge environment is a key indicator that affects readmission probability. Another factor that has been found to correlate with readmission is follow-up after discharge. Specifically, patients with a larger number of early follow-ups tend to have a lower likelihood of unplanned readmission, especially for patients with a greater collection of comorbidities\textsuperscript{13-16}.

Methods

In this section, we describe the risk prediction models. First, we describe methods to construct features using data from different post-discharge time windows. Second, we use these features to predict negative events occurring up to a prediction window.

Prediction Model Composition

We represent longitudinal EMR data with an $M^{NT}$ matrix, where $T$ is the length of time for extracted EMR data and $N$ is the number of patients in the cohort. Each row in the matrix represents one patient vector denoted by $t$. For each patient $p$, we divide the longitudinal medical record vector $t$ into three temporal bins: before admission, during admission, and after discharge. For each model, we define an observation window (OW) that specifies the time from which to extract features. Using combination of features, we predict whether the patients would have a negative outcome within a prediction window (PW), where the window starts at the discharge day and ends at the prediction point (PP).

For the purposes of this investigation, we represent outcomes as a dichotomous variable. A patient has a negative outcome if he/she experiences a negative event (-1) in the prediction window and has a non-negative outcome (+1) otherwise. Figure 1 visualizes model settings in which both patients experience negative outcomes, but only the patient in Figure 1b has a negative outcome in the prediction window.

![Figure 1: Prediction model – prediction point before negative outcome](image1)

**Model 1: LACE:** Starting with the most common method in the literature, we build a prediction model using LACE, where $E$ was restricted to the number of the emergency department visits in the past 6 months. LACE assigns points to each variable based on its value, and calculates probabilities by using regression models\textsuperscript{7}. Patients with a score greater than 10 are considered to be high risk. We retrieved the features utilized by LACE from the EMR and calculated the risk score, which was fed as a feature into the prediction model. We consider LACE as the baseline for performance comparison.
Model 2: Before-Admission Model (BAM): To learn whether prior health status can be applied to forecast the future health status of patients, we use only data from before the admission to predict the outcome. Each patient’s entry is assigned to a pre-admission feature vector denoted by \( b \). The BAM matrix is visualized in Figure 2a.

Model 3: During-Admission Model (DAM): We investigated whether the data collected about investigated phenotype is sufficient to predict the outcome. The observation window begins at admission and ends at discharge and is visualized in Figure 2b.

Model 4: At-Discharge Model (ADM): This model incorporates data from before and during admission to predict the outcome, and is visualized in Figure 2c.

Model 5: Before, During admission, and After discharge Model (BDAM): The last model incorporates post-discharge data to predict the patient's outcome, which is visualized in Figure 2d. There are several key parameters to this model: 1) the time window post-discharge to include data, which we refer to as a checkpoint, 2) the length of the prediction window, and 3) ensuring that data prior to negative events does not introduce biased knowledge about an upcoming negative event. Regarding point (3), we remove data from days immediately before the end of the window, which we refer to as the gap. Thus, the model can be specified with a checkpoint \( C \), gap \( G \), a prediction point \( PP \) and prediction window \( PW \).

**Overview of Features**

For the patient records in this study, we extracted the demographics (age, gender) and data ranging from one year before to one year after the first documented incidence of the phenotype under investigation (i.e., hip fracture and CHF). For each patient, we extracted the number of resources that were allocated for treatment, including: 1) medications, 2) laboratory tests, 3) appointments, 4) previous admissions, 5) the average of previous length of stays (LOS), 6) days since the last admission, and 7) the count of the International Classification of Diseases, Ninth Revision (ICD-9)\(^{17} \) in each of the 20 chapters. Table 1 summarizes the features and the temporal period to which they correspond (e.g., before admission, during admission, or after discharge). In addition, we extracted the number of documents, grouped by their type, that were created and stored in the EMR during hospitalization.

Table 2 lists the extracted lab tests, their normal ranges, and the diagnostic purpose of the test. We retrieved the average values of the most common lab tests that were ordered for 80% of the patients during admission and after discharge, including carbon dioxide levels (CO\(_2\)), creatinine, glucose, hematocrit or packed cell volume (PCV), partial thromboplastin time (PTT), potassium (K), sodium (Na). These lab tests are ordered by clinicians to evaluate heart and kidney functionality, electrolyte balances, and blood clotting timing.

Negative Outcome Prediction Over Time

To study the performance of the models over time (specifically the post-discharge data), we predicted the outcome for different prediction points and prediction windows ranging from seven days to one year.

Model Implementation

In this section, we describe the data extraction and provided high-level overview of the prediction algorithms.

Data extraction

We extracted patients who were diagnosed with a hip fracture or CHF, using the 820.* and 428.* range of ICD9 codes, respectively. We excluded patients who had no encounters before admission and after discharge to triage patients who visited the medical center for only that admission. We also excluded repeated admissions for these phenotypes with the aim to only analyze the first admission.

Input matrix: We construct the BAM, DAM, ADM, and BDAM input matrices. For the BDAM matrix, different checkpoint days can influence the prediction’s performance. To remedy this issue, we uniformly sampled checkpoints at random between the discharge and prediction points and averaged the results. This random day
sampling approach provides a viable option for evaluating the model even though the model changes as different amounts of post-discharge data are included.

**Changing the prediction window length:** To understand the change in risk and the effects of the phenotype over time, we varied the prediction window length from 7 to 365 days.

**Model implementation:** We used a random forest classifier from Scikit-learn and conducted a 5-fold cross-validation. For random forest parameters, we used 500 trees with 15 maximum depth and 15 as the minimum split.

To construct the BDAM matrix, we enforced a gap of 5 days for all prediction points except seven days, for which we used a gap of three because it yields four days from which to sample compared to sampling from two days. The values in the post-discharge data depend on the checkpoint location. As shown in Figure 3, different checkpoint locations lead to different BDAM entries for the same dataset (Figures 3a and 3b exhibit the vectors constructed with different checkpoints). To minimize the effect of randomness, we built 100 matrices at each prediction point, randomly sampled checkpoints for each matrix and averaged the area under the receiver operator characteristic curves (AUCs).

**Figure 3: Building BDAM vector using two checkpoints (a) an example of a randomly sampled checkpoint and (b) an alternative sampled checkpoint**

**Important features and their relationship to outcomes**

To characterize the importance of the features in the post-discharge model, we extracted the features that, on average, have the highest importance across all folds. We analyzed the importance of the features that comprise around 50% of the total feature importance. Additionally, we analyzed the non-linearity of features with partial dependence plots. The partial dependence shows the dependence of prediction approximation on a subset of the input variables. It finds the marginal average of the prediction to identify the effect of chosen subsets of features on the prediction probability after accounting for the rest of the input features. For a given predictor, the y values in the partial plot show the average of prediction probability across all trees in the forest.

**Results**

We begin by summarizing the patient populations and their negative outcome rates. Then, we present the performance of the models, with LACE as the baseline. Finally, we report on the importance of the features incorporated in the model and the outcome.

**Patient Population**

This study was based on patients who were admitted to VUMC between 2010 and 2013. We included patients aged 65 years and older and were diagnosed with either a hip fracture or CHF. We excluded patients who did not have an admission on the onset date of the phenotype. This selection criteria yielded 704 hip fracture patients and 5250 CHF patients.

Around 25%, and 21% of hip fracture and CHF patients, respectively, had a negative outcome within 90 days after discharge. As shown in Figure 4, the one-year survival rates exhibited a similar trend. For patients who exhibited a negative outcome within the first 7 days, more than half were admitted to the emergency department or died within the first three days after discharge.
Before Discharge Model Results

Figure 5 reports on the AUC for predicting the negative outcome within one year using LACE, before admission, during admission, and at discharge) models for hip fracture and CHF patients. The x-axis shows the prediction points at which the model was run, while the y-axis corresponds to the average AUC. Across all prediction points, LACE exhibited the lowest AUC values for both cohorts. The before model has similar AUC values as LACE for hip fracture patients, while it has higher AUC than LACE when applied on the CHF cohort. However, the during and at discharge both outperform the LACE and before models. The during model exhibits almost the same AUC as the at-discharge model when predicting the outcome for the CHF patients. By contrast, at discharge model has a higher AUC than the during model for the hip fracture patients.

In both cohorts, the before model had the lowest AUC within the first 20 days. After 20 days, the AUC values increased slightly. The during and at-discharge models exhibited the same trend in performance over time. In CHF, the during model and at-discharge models had the highest AUC during the first two weeks of prediction. Afterwards, the AUC values decline slightly and smoothly until they reach their lowest point at the one-year prediction. By contrast, the AUC values of the during model and at-discharge were the lowest within the first two weeks for the hip fracture patients and increased slightly until they reached their highest AUC values at the one-year prediction.

Post-Discharge Model Results

Next, we analyzed the post-discharge model in two ways: (i) using a single feature representing the days since discharge (post-discharge time), and (ii) all post-discharge data including days since discharge. We analyzed the
results in these two phases given the importance of time in the post-discharge model (i.e., the longer you are out of the hospital, the less likely you are to return).

Figure 6 depicts the AUC values for specific checkpoints for the 7, 14, 22, and 30 days prediction points. The x-axis corresponds to the selected checkpoint. The red dashed-line represents the average AUC for post-discharge model at a given checkpoint, while the diamond and triangles correspond to the AUC of at-discharge model and the traditional LACE model, respectively. The blue solid line represents the AUC for the post-discharge time only model. It can be seen that the BDAM model outperformed all models. Moreover, the AUC values increased as additional post-discharge data are included.

Figure 6: AUC values for BDAM model applied at different successive checkpoints for hip fracture patients at 7, 14, 22 and 30 days negative outcome.

Figure 7 depicts the performance of the LACE, ADM (at discharge) and BDAM (post-discharge) models for different prediction points (where the post-discharge data are averaged across the checkpoints). The upper grey line, lower grey line, and solid black line represent the minimum, maximum, and average AUC, respectively. Both the BDAM and the ADM models performed better than the LACE model by 20 - 30% AUC. In this setting, BDAM had a higher AUC than ADM at all prediction points by 15.8 - 26.5% for hip fracture and 9.7 - 12.1% for CHF patients. Using BDAM, predicting the negative outcome within 7 days had a higher AUC compared to predictions within 30 days.

BDAM results trended differently for the two phenotypes. For hip fracture, the AUC decreased until it reached the lowest values at 21 days, then increased between 21 and 60 days, staying relatively constant afterwards. For CHF, the AUC decreased until 21 days.

Feature Importance

For each prediction point, we retrieved the features that, on average, exhibited the highest importance. At all prediction points in both cohorts, days from discharge and days until prediction point displayed the highest importance. The number of appointments after discharge was the third most important predictor for a negative event within 30 days while clinical communication was the forth or fifth important feature within the same time range.

In hip fracture patients, age is one of the top 10 predictors of a negative outcome within 30 days. Diagnosing hip fracture patients with infectious, blood stream, genitourinary, or circulatory diseases during admission were among the top predictors for readmission within 30 days. In CHF patients, the average number of labs during admission (e.g., creatinine, K, Na, and CO₂) were strong predictors for negative events within 60 days.

Figure 8 depicts the partial dependency plots for the most important features for 7, 21, 30, and 60 days for hip fracture patients. In the partial dependence plot, the x-axis shows the values of the variable. For a given x value, the
y value indicates the probability of the negative outcome after accounting for the values of the other input variables. A small y value indicates a low probability of positive outcome, while a large y indicates a high probability of a positive outcome.

For example, patients who scheduled a small number of appointments after discharge had a higher probability of experiencing a negative outcome. A low and high number of appointments scheduled before discharge were associated with a high probability of negative outcome. In addition, a low and high quantity of post-discharge communications had a high probability of a negative outcome. During admission, patients who were prescribed a larger number of medications and lab tests, in comparison to other patients in the cohort, had a higher probability of having a negative outcome. The partial dependency plots of lab values such as K, PVC, and creatinine depict that abnormal values were associated with a high probability of a negative outcome.

Discussion

Predicting negative outcomes and detecting high-risk patients are challenging problems. Our findings demonstrate that including more information about a patient’s post-discharge status may increase the performance of such predictions. This finding is further supported by the observation that the LACE model, while simple to implement, is likely to neglect many key features that can enhance predictions.

One of the critical discoveries made in this study is that the post-discharge time is a strong predictor on its own for a negative outcome. This result affirms the observation that the longer a patient remains out of the hospital, the less likely they will be readmitted at a future point in time. However, time from discharge in isolation lacks important clinical information, which if included, can further improve prediction quality. Moreover, time until prediction quantifies the amount of information collected post-discharge that is not included in time from discharge.

One of the challenges in building and developing the post-discharge model is determining the time period during which post-discharge data should be collected and used for prediction. In this work, we used a random day model. In practice, a post-discharge model can be executed daily to identify high-risk patients, no matter when they were discharged.

Our analysis demonstrates that risk changes over time, especially during the first three months post discharge. In particular, the first 7 to 10 days are the times when frail patients are at high risk of encountering a negative outcome. A decline of the prediction performance over time suggests a variation in recovery stages for healthy patients and a difference in the risk factors for patients who died or were readmitted within the same time frame. For example, the prediction of hip fracture outcome had the lowest performance between 14 and 21 days. Several factors could cause this such as various pre-existing medical problems, the degree of activity, and the ability to attend follow-ups. Further analysis could be done to identify the change in risk factors (e.g. post-discharge complications), and locate the period of time when those factors are correlated with readmission.
Although accurate prediction is crucial, healthcare providers need to identify the values of features that are associated with a higher probability of negative outcome. Locating such values may assist clinicians in understanding the reasons behind a negative outcome, as well as identify early signs of complications. Direct intervention could be applied to lessen risks through outpatient appointments or home visits. In our risk model, the features can be categorized into clinical factors and clinical resources. Both types of features influence predictions at different levels. Specifically, the amount of clinical resources allocated to treat patients before admission and after discharge could identify the patients who have a high probability of encountering a negative outcome. Similarly, the patients who utilized more treatment resources exhibit a higher probability of experiencing a negative outcome except for post-discharge follow-up utilization. A very low utilization value implies the existence of barriers preventing the patient from going to see their healthcare provider. Even low utilization values for some features, such as the number of labs ordered during admission, are associated with negative outcome occurrence. Measuring the unexpected utilization could be leveraged as an indirect method to identify patients who are at high risk.

Conclusions

This study shows that the inclusion of data in EMRs collected post-discharge can improve the performance of negative outcomes predictions, such as readmission or death. This is notable because it shows that traditional readmission prediction models, such as LACE, which focus on information available only at the point of discharge, would benefit with updates over time (provided the information is available). We illustrated that this finding holds true for both acute (i.e., hip fracture) and chronic (i.e., congestive heart failure) patient populations. It is notable that the primary driving factors of our discovery include: 1) time out of the hospital after discharge and 2) information about the quantity of resources allocated for patients that are both physical (e.g. medication, labs, appointments) and electronic (communication, documents).
While our findings are notable, there are several limitations that we wish to acknowledge, which can serve as guidelines for further investigation. First, this study focused on sampling only one day for post-discharge information. A notable extension is evaluating risk scores on multiple consecutive days to identify changes in risk score and identify patients at-risk to apply early intervention. Second, our models neglected the semantics about clinical status that might be documented in communications between patients and their healthcare providers. For instance, patients who communicate they are in severe pain or experiencing complications from opioid medications may miss their follow-ups. Thus, information intimated to care providers may indicate signs of an impending negative outcome. As such, a notable extension to our approach would be to apply natural language processing to detect and characterize such semantics for enhanced modeling. Third, our model represented various features from disparate EHR resources. However, we did not use all patient data such as vital signs (e.g., heart rate or blood pressure), medication doses, changes in laboratory test values, etc. A future direction is to include additional relevant features while accounting for the ratio between sample size and the number of features.

Adapting Nielsen’s Design Heuristics to Dual Processing for Clinical Decision Support

Teresa Taft1, Catherine Staes, BSN, MPH, PhD1, Stacey Slager, MS1, Charlene Weir, RN, PhD1
University of Utah1, Salt Lake City, Utah

Abstract
The study objective was to improve the applicability of Nielson’s standard design heuristics for evaluating electronic health record (EHR) alerts and linked ordering support by integrating them with Dual Process theory. Through initial heuristic evaluation and a user study of 7 physicians, usability problems were identified. Through independent mapping of specific usability criteria to support for each of the Dual Cognitive processes (S1 and S2) and deliberation, agreement was reached on mapping criteria. Finally, usability errors from the heuristic and user study were mapped to S1 and S2. Adding a dual process perspective to specific heuristic analysis increases the applicability and relevance of computerized health information design evaluations. This mapping enables designers to measure that their systems are tailored to support attention allocation. System 1 will be supported by improving pattern recognition and saliency, and system 2 through efficiency and control of information access.

Introduction
The American Medical Association (AMA) recently issued a statement calling for improved design of health information technology (HIT) systems that reduces cognitive workload, stating that, “health IT is misaligned with the cognitive and workflow requirements of medicine”. Problems with healthcare information display have been shown to reduce a user’s ability to detect changes, cause delays in finding information, increase working memory demands, lead to confusion, and lead to confidence in wrong judgments. Few electronic health records (EHRs), currently in use, improve comprehension. In drawing the conclusion that many HIT systems lack needed usability, the Institute of Medicine (IOM) called on the governing boards to require HIT, used in the diagnostic process, to demonstrate usability, incorporate human factors knowledge, and provide clinical decision support. In response to concerns and recommendations, the Office of the National Coordinator issued new meaningful use regulations, which took effect in 2016, requiring usability testing and reporting of HIT systems seeking certification.

Jakob Nielsen, a leader in IT usability design and evaluation, created a taxonomy of design heuristics that could be used by usability experts to inspect systems, which he advises should be adapted for any specific interface. In addition to this heuristic evaluation, Nielsen recommended follow-up user testing, which may include observations, ‘think aloud studies’, and interviews. Nielsen demonstrated that testing three to five users at two sites per iteration is sufficient for identification of most usability issues. Think aloud methodology, based on protocol and analysis techniques of Ericsson and Simon (1980), is also informative and is widely used in usability and interface design. Although more recent iterations of usability heuristics have been created, they all build upon Nielsen’s work.

Psychologists have been discussing two different styles of thinking for at least the last 50 years, however the terms System 1 and System 2 were first used by Stanovich and West and were more recently popularized and illustrated by Kahneman in his 2011 book, Thinking Fast and Slow. In this paper, we will use the terms S1 and S2 to discuss the two ways of thinking. S1 refers to the cognitive process operating when patterns are quickly recognized and assumptions are effortlessly made regarding the situation. Automatic, response is determined without conscious awareness. S1 consists of layers of associative memory organized into patterns or schemas that when activated produce the experience of instant pattern recognition and supports rapid automatic responses. Difficult tasks, made up of many small decisions, that are well learned to the point of expertise, such as reading, talking, and driving are easily activated in complete units by S1 processes. Recognition, “thinking” and decision-making feels effortless and requires very little cognitive attentional resources. Because S1 cognitive processing involves spreading activation through tightly associative networks, common biases occur. On the other hand, S2 cognitive processing occurs when attention is required for a task, either because it is novel, complicated, or involves a significant risk. Focused attention, as is required by S2 cognitive processes, is quite effortful and limited, rather like a flashlight beam in a very dark room. As a result, S2’s slower, more deliberative reasoning processes can easily be interrupted, overwhelmed, or exhausted. Anything that draws attention away from S2 focus can displace the information in working memory. The default cognitive processing mode is S1, but the common cognitive activities of S2, such as planning and simulating possible outcomes, as occurs during intentional decision-making, are also usually in play.
Many studies show that the two systems operate in tandem. Context affects the differential reliance on the two systems with S1 functions dominating when situations are overwhelming, emotional, or urgent and S2 dominating during highly analytical ‘hyper-focused’ thinking.

In addition to recommending usability testing, the Institute of Medicine has reported that electronic medical systems provide the opportunity to reduce diagnostic error by supporting clinician’s dual cognitive processes, System 1 and System 2, by providing information in ways that enhance pattern recognition and provide rapid access to specific data and tools that assist in cognitive processing needed for medical decision making. Designing effective decision support for clinicians in the complex working environments of healthcare requires understanding of these two modes, their relatively different information needs and the differential mechanisms required for providing support. Consideration should be given to supporting S1 pattern recognition, in signaling S2 that attention is needed, and providing S2 with timely, accurate, understandable information to support an efficient, accurate analysis. Methods of measuring the alignment of S1 and S2 with HIT systems design are lacking.

Description of a Health IT Problem
At University of Utah Healthcare (UUHC), major efforts are underway to improve the delivery of healthcare, through standardizing care processes, implementing and evaluating clinical decision support, and measuring the value of care. To improve the efficiency with diagnostic testing and management of acute knee pain in the outpatient setting, care process models were implemented, along with alerts to be delivered at the point of care and order sets to guide diagnostic and referral practices. The primary goal of the new acute knee pain care process model was to reduce the use of advanced imaging (i.e., MRIs) without first obtaining a radiograph (i.e. x-ray). Clinical decision support resources were implemented with Epic to support this goal. Specifically, two alerts could fire as a physician began ordering in the EMR. One alert informed the physician that a new knee pain order set was available as “order entry” was clicked; a second alert, which only fired if the physician attempted to order an MRI and the system could not detect a knee x-ray for the patient in the preceding 6 months, advised the clinician that x-ray should be obtained before MRI. The alerts included links to a flowchart and an order set that could be opened from the alerts. The order set consisted of a short list of ordering options with radio buttons for selection.

Usage data indicated that the alerts were canceled 95% of the time (n=1170/1236) over a 12 month span (unpublished data). Analysis of ordering practices showed that the clinical pathway resources did not achieve their objective to reduce the proportion of MRIs ordered without a prior x-ray. Before expanding or abandoning alerts, it is important to evaluate the reasons for the ineffective clinical alerts and associated smart order set, and identify areas of improvement in design that could be applied to future evaluation and design of HIT systems for encouraging compliance with best practices. We hypothesized that the lack of usage of the alerts concerned usability problems with the alerts, and dual processing considerations. To explore the S1 and S2 principles described above, we performed a usability evaluation of the active alerts and associated order set which were implemented in a limited set of outpatient clinics at UUHC.

Objectives
The purpose of this paper is to explore the relationship between common usability metrics and a dual process perspective. Mapping usability evaluations to the dual cognitive processes may be an important step in improving the application of usability testing in the design and implementation of EHRs in order to better support cognition in medical decision-making. Therefore, our specific objectives were to: a) conduct a usability evaluation of active alerts and the associated order set, and b) map the usability violations to the dual cognitive processes.

Methods
Qualitative and descriptive methods were used to perform this study. The usability evaluation included heuristic analysis, simulation with think aloud, and semi-structured interviews. The user study was conducted at two primary care outpatient clinics that are part of the University of Utah Healthcare enterprise, located in Salt Lake City Utah. The two clinics both use the Epic EHR. Family practice physicians were asked by their supervisor to participate in this quality improvement study. Both resident and experienced physicians were recruited in order to reflect actual practice (N=7).

Phase 1: Heuristic evaluation of alert-related artifacts
Three authors (TT, CS, and SS) independently performed a heuristic evaluation, interacting with the system, two knee pain alerts (BPAs), and an associated order set (SmartSet). Problems encountered were logged and categorized.
using Nielsen’s ten usability heuristics. The two ‘Error’ heuristics were combined for efficiency.

**Phase 2: User study using simulation and observation and semi-structured interview**

A think aloud simulation user study was conducted at two family practice clinics where the HIT had been deployed in a pilot implementation for the preceding year. We developed a knee pain vignette, which was evaluated and refined based on feedback from three primary care providers. Physicians who agreed to participate were presented with the patient vignette and were given instructions on how to ‘think aloud’ while they entered orders into the EHR. For example, we instructed: “I want you to speak out loud any thoughts that you have as you are using the EHR system to enter orders for the patient. For example, you might say, “I want to enter a visit diagnosis, so I click here.” Describe what you would do.” Or you might say, “What just happened there? I didn’t expect that,” or “I don’t know what this is for,” or “I really like this...” We are looking for things you like, things you don’t like, what you would change.

The study duration was 30-40 minutes per participant. Physicians accessed a test version of the EHR system on a laptop computer in a conference room at their clinic site. Each physician responded to two alerts. Response to the alerts and the reasons physicians gave for canceling them were recorded.

The patient vignette was the following: A 24 y/o male with no past medical history comes to your office after sustaining a knee injury while playing soccer 2 days ago. He reports that he collided on the field with another player. His right knee came into contact with the player’s knee. He remembers his knee being 'pushed back'. It may also have been twisted. He doesn't recall any discrete pop. He fell down and was unable to bear weight at the time. He was helped from the field and didn't return to play. Shortly after, his knee had some bruising of the kneecap, swelling, and was stiff. He borrowed a friend’s crutches, wrapped the knee with an ace wrap, and iced it for the next 24 hours. He also took Aleve, 1 tablet every 12 hours. The pain has not improved, and he is still needing the crutches. The ‘stiffening' has worsened, and he feels like it is too painful to walk on. He hasn't moved it much, but doesn't think it locks up. He didn't go to work today or yesterday. He works as a computer programmer.

The findings on the physical exam were:

- Pt walks without bearing weight on affected knee, which is flexed to 30 degrees wrapped.
- Pt has bruising of his kneecap, with diffuse tenderness, most notably over mid patella.
- There is a joint effusion.
- Passive range of motion is limited to 70 degrees of knee flexion. Knee extension and flexion strength is normal.
- Joint line is non-tender. No tenderness of tibia/fibula.
- LCL/MCL are within normal limits.
- ACL/PCL testing is not possible secondary to his pain.

The physician was given the clinical vignette with the following instructions: “Imagine a patient has come to your office after injuring his knee. I have entered a chief complaint of ‘Acute Traumatic Knee Pain’ in advance of the visit. Imagine that you have examined him and found the information in this vignette and you are now ready to write orders. Please “Think Aloud” as you enter orders for the patient in EPIC as you would if you were seeing him in clinic.”

The investigators recorded usability issues that were observed or voiced in the think aloud simulation, recording the EHR location and the description of the Problem. Immediately following the ‘think aloud’ observation, the investigators asked participants the following 12 guided questions and manually recorded the responses. (Table 1)

**Table 1. Guided questions.**

</tbody>
</table>
Following the user study, usability problems were classified by heuristic sub-categories developed by the authors, based on a review of the literature and the prior heuristic evaluation. An additional category of transparency was added to address physician concerns regarding accuracy of the information. The subcategory list was expanded as needed for coding of problems that didn’t fit well in the initial subcategories. (See appendix A)

**Phase 3: Dual process coding**
Problems found in the usability assessment were translated into specific heuristic subcategories. An initial coding protocol was created by the authors (TT and CW) based on their knowledge of the literature about dual processing and was subsequently developed iteratively through several rounds of independent coding by the authors. Definitions for S1 and S2 were identified by a search of the literature and refined through discussion. Once the coding protocol was established and a final level of acceptable inter-rater reliability was reached (92.9%), TT independently mapped the identified usability problems to the Dual Cognitive processes (S1 and S2). The protocol guideline for coding usability errors and subcategories is listed in Table 2.

**Results**

The evaluations identified 36 usability errors in the alerts and associated order set. Half of the errors (n=19, 52.7%) were discovered through heuristic analysis. Other errors were suspected, but confirmation with users was needed. The remaining errors (n=17, 47.2%) were confirmed or discovered during the user study. Two-thirds of the identified usability errors (n=23, 64%) were mapped to interference with S2 cognitive processes and one-third of the errors (n=13, 36%) were mapped to interference with system 1 processes.

Table 3 includes the list of errors classified by heuristic, and mapped to the relevant cognitive process. During the user study, five types of response to the alerts were observed (Table 4). Physicians attempting to accept the alerts consistently had difficulty managing the alert functions. We documented ten reasons that physicians gave for canceling alerts (Table 5). Physicians gave more than one reason. Seven reasons that alerts were canceled were associated with efficiency and three reasons were associated with trust in the accuracy or function of the alert.

Discussion

This study integrated two approaches to assessing usability and design of HIT. The first approach was a traditional usability study. The second was a mapping of the usability issues in the context of its support or interference with dual cognitive processes. Investigators identified five ways that physicians responded to ineffective alerts, reflecting various levels of attention, effort, and deliberation. Ten reasons for cancelling of alerts were also tracked with seven related to efficiency, and the remaining three reasons related to trust in the information or function of the alert. Alerts are intended to focus S2 cognition on something important, however, the reasons given for cancelling the alerts provided evidence that the alerts were not supporting the needs of S2 cognitive processes. These needs included the ability to focus without distraction, to evaluate the validity of information, and to efficiently accomplish goals. In mapping the usability errors of a clinical pathway within an EHR to a S1/S2 model, we found that nearly 2/3 were problems with supporting S2 logical decision processes. Adaptations of appendix A may prove to be useful for usability evaluation and specific HIT design recommendations to support S1 and S2 processes.

Distrust in the accuracy of recommendations provided by the system and the skill with which physicians avert the interruptions to their cognitive processes through cancellation of alerts stand out in this study. Although the alert firing algorithm appeared on the surface to be timely and targeted, physicians spoke with the clicker that these alerts were not useful, as they almost always cancelled them. Physicians adapted to a complex environment by focusing on proven ‘targets’ and away from less productive ‘noise’. To avoid training physicians to view alerts as ‘noise’, consideration should be given to implementing accuracy and usability testing prior to any alert deployment and post deployment monitoring. Physicians stated that previous experience with alerts that provided erroneous information reduced their trust and reliance on alerts. Consideration should be given to disabling of alerts that do not meet an accuracy threshold with requirements determined by likelihood & severity. Methods that increase transparency, including metadata and links to source information, may reduce uncertainty and increase trust in alerts. In developing & evaluating CDSS, including an additional heuristic of ‘transparency’ with Nielsen’s design heuristics may promote design that increases physician trust in information.

Physicians reported difficulty in managing the functionality of EHR subsystems that they rarely used. Evaluation of the alerts showed that they were more complex than was necessary and poorly matched with the users mental models and workflow. This poor match contributed to difficulty physicians experienced in predicting the results of interaction with the system. Simplification of alerts and improved labeling may help to reduce high cancelation rates. A workflow analysis prior to design could have revealed that ordering decisions are made prior to clicking the order tab. Support for cognitive processes at the point of decision-making may be far superior to corrective alerting, which comes sometime after a decision has been made.

The focus of information technology design has been primarily on functionality (the ability of the system to meet functional requirements, once the user is trained to use the system), however the failure of many functional systems demonstrates the need for usability to be addressed in the earliest stages of clinical decision support system (CDSS) design, rather than as an afterthought. Prototype driven CDSS design shows great promise in allowing usability evaluation to take its place at the forefront of the CDSS train, rather than its usual position as the often forgotten caboose. Careful evaluation before deployment of alerts is paramount if we are to avoid training physicians to cancel all alerts. Design methods should include iterative usability testing conducted by usability experts who can see the project with fresh eyes because they did not build it, whenever possible.
Limitations
This study investigated methods for mapping the dual cognitive processes to usability assessment. Problems were identified in an alert that was almost always canceled, creating an opportunity to discover many usability errors. Specific errors identified in other systems will necessarily be different and the percentage of problems that affect S1 and S2 can be expected to vary. Although usability errors were mapped to not supporting one system or another, resolution of a problem created by the usability error was not addressed and at times, the alternate cognitive process may manage the task, or both cognitive systems may be involved in this process. The evaluation was only applied to one setting. Validation and generalizability of the methods will be determined by future work. In addition, these methods should be adapted for specific use.

Conclusion
Support for the intuitive and analytical dual cognitive processes is needed in CDSS design. ‘Alert Blindness’ attributable to cognitive focusing on reliable ‘targets’ rather than ‘noise’ must be addressed if alerts are to be effective in supporting deliberative S2 clinical decision-making. Standard alert monitoring, usability testing, and reporting are needed for alerts embedded in the electronic ordering systems. Turning off alerts identified as ineffective or inappropriate could restore their usefulness as a ‘fire-alarm’ redirect of S2 attention to vital concerns. Improved accuracy standards, and transparency of system delivered information along with greater simplicity and consistency in technology functions are needed to enable S1 to automatically manage these activities, freeing the working memory of S2 for needed analytical processes.

Improved design of systems to present integrative views that support S1 automatic processing and to support clinician control of their own S2 attention allocation is needed. Standard measures to assess and report CDSS effect on cognition should be adopted to support design, evaluation and comparison of clinical pathways within a healthcare system. The mapping of usability issues to support for the dual cognitive systems, as was done in this study, is one approach that may prove useful for designing HIT systems that more effectively support the diagnostic process.

Automating Guidelines for Clinical Decision Support: Knowledge Engineering and Implementation

Geoffrey J. Tso, MD1,2, Samson W. Tu MS2, Connie Oshiro PhD1, Susana Martins MD MSc1, Michael Ashcraft MD1, Kaeli W. Yuen1, Dan Wang PhD1, Amy Robinson PharmD1, Paul A. Heidenreich MD MS1,2, Mary K. Goldstein MD MS1, 2

1VA Palo Alto Health Care System, Palo Alto, CA; 2Stanford University, Stanford, CA

Abstract

As utilization of clinical decision support (CDS) increases, it is important to continue the development and refinement of methods to accurately translate the intention of clinical practice guidelines (CPG) into a computable form. In this study, we validate and extend the 13 steps that Shiffman et al.5 identified for translating CPG knowledge for use in CDS. During an implementation project of ATHENA-CDS, we encoded complex CPG recommendations for five common chronic conditions for integration into an existing clinical dashboard. Major decisions made during the implementation process were recorded and categorized according to the 13 steps. During the implementation period, we categorized 119 decisions and identified 8 new categories required to complete the project. We provide details on an updated model that outlines all of the steps used to translate CPG knowledge into a CDS integrated with existing health information technology.

Introduction

Clinical decision support (CDS) has been shown to improve the quality of healthcare delivered.1,2 With rising utilization of an electronic healthcare record (EHR) in clinical practice, there are increasingly more opportunities to incorporate CDS into additional aspects of the healthcare workflow. In order to improve the effectiveness, adoption, and sustainability of CDS implementations, there has been an increased interest in implementing systems that encapsulate more medical knowledge.3,4

Clinical practice guidelines (CPG) continue to hold promise as a source of evidence-based medical knowledge, and there has been significant work aiding the translation of this knowledge into software systems.5-7 However, guidelines often contain gaps and ambiguities, making it difficult to implement or operationalize the knowledge into a computable format.5 These shortcomings result in varied interpretations of the same recommendation and decreased adoption.8,9 With the aid of clinical experts, it is possible to interpret and complete the knowledge required to implement intentions of the guidelines completely; however, this process is not yet standardized and there are many aspects to consider for a successful end product.5

Shiffman et al. formalized steps for translating the knowledge contained in guideline text into a computable format that could be operationalized into a CDS specification.5 Since the publication of the seminal paper, most CDS implementations must consider integration directly with another system, and knowledge modeling techniques have continued to develop. In this study, we validate and update the steps in the Shiffman model, and we extend them to apply to the full process of implementing a CDS system based on CPG knowledge. We show that, in addition to deriving CDS knowledge completely from guideline documents, implementing a CDS system often requires changes to the design specification.

Methods

Clinical Decision Support System

We conducted this study during a modified implementation of ATHENA-CDS, an automated CPG-based CDS system that was developed at the Veterans Health Administration (VHA) of the Department of Veteran’s Affairs (VA) Palo Alto Health Care System. ATHENA-CDS uses CPG knowledge encoded in Protégé, a knowledge acquisition program developed at the Stanford Center for Biomedical Informatics Research (BMIR).10 The CPG Knowledge Base (KB) and patient EHR data are processed by the BMIR EON Guideline Interpreter system, which generates patient-specific conclusions, including recommendations for management, evidence base for the recommendations, and a summary of patient data that is relevant to decision-making.11 Clinical modules were developed, modified, or updated to provide CPG recommendations, in the context of a clinical dashboard, for the
management of five chronic diseases domains: hypertension (HTN), chronic kidney disease (CKD), heart failure (HF), hyperlipidemia (HLD), and glycemic control in type 2 diabetic patients (DM).

Implementation Context

Within Veterans Integrated Service Network (VISN) 21 of the VHA, the Pharmacy Benefits Management (PBM) group has developed a primary care clinical dashboard built on top of the VA clinical data warehouse. The dashboard provides tools for clinic team members to monitor VA clinical performance measures. ATHENA-CDS was modified to generate and display guideline-based management recommendations within the clinical dashboard.

Implementation Decision Categorization

During the development of the KBs from CPGs and the integration of ATHENA-CDS into the clinical dashboard, we recorded major implementation decisions that required interdisciplinary discussion or impacted parallel or downstream project activities. Three project members (CO, SM, KWY) extracted the decisions from meeting notes and created a spreadsheet that detailed the clinical domain, date, topic, references, issue/questions, and disposition of each decision. One project member (SWT), an experienced knowledge engineer, evaluated each decision to categorize the decisions into one of the 13 steps defined in the Shiffman model (Table 1). A senior clinician (MKG) evaluated the initial categorization, and working with the knowledge engineer, developed a consensus categorization of the decisions and proposed new categories for the list of decisions that could not be categorized. The project team, which included clinicians, knowledge engineers, and system implementers, agreed upon the final list of new categories.

Results

We identified 119 decisions made at project meetings over a 29-month period (Examples in Table 2). During the study period, CPGs for HTN\textsuperscript{12}, DM\textsuperscript{13}, CKD\textsuperscript{14}, HLD\textsuperscript{15}, and HF\textsuperscript{16} were selected to be encoded for the KBs. Eighty of the decisions were categorized within the Shiffman model. Table 3 shows the incidence of ATHENA-CDS developmental decisions that had been categorized for each step in the model. The remaining 39 decisions were analyzed and, through consensus, placed in new categories (Table 4).

1191
Most of the new steps are generalizable to all CDS implementation projects. One of the categories, Reconciliation of Multiple Guidelines, is especially derived for CDS that utilizes multiple knowledge sources. Using these observations from our study, we extend and update the Shiffman model, incorporating the eight additional steps (Table 4) that were required to implement ATHENA-CDS. Figure 1 contains the activity flow for the proposed model with 21 steps. The diagram shows that not all of the steps need to be performed in a specific order.

Figure 1. Activity diagram of updated CDS implementation model.

Here we will describe all of the 21 steps in more detail. Starred steps are new additions to the model.

1. Knowledge Preparation

1.1. Guideline Selection

Many guidelines from different organizations/writers can exist on the same topic. Choosing which guideline to implement is an important step in the development process that can affect many of the subsequent steps. In choosing which guidelines to implement, we considered several factors: validity, level of evidence, applicability in the clinical context, institutional recommendations, local practice variation, and ease of operationalization. Furthermore, within each guideline, individual recommendations also need to be selected for implementation. For some of the clinical domains, we had the choice of using recommendations or sections of recommendations from either VA/Department of Defense CPGs or those from professional societies. Whether a recommendation could be operationalized and applied to the clinical context was an important factor in the selection process.

1.2 Guideline Reconciliation *

Reconciling multiple guidelines is a new proposed step in CDS implementation. If multiple CPGs or other knowledge sources are used within the knowledge base of the CDS, differences in recommendations from each guideline must be reconciled to prevent interactions or conflicts in the CDS logic. An important feature of ATHENA-CDS is taking account of comorbid conditions when making recommendations for the index condition. For the five clinical domains in ATHENA-CDS, many of the CPGs discussed overlapping topics (eg. blood pressure
managers. Reconciliation was necessary to prevent conflicting recommendations from the CDS. We found that reconciliation between the guidelines was most important when there was a possibility of drug-drug interactions or different usages of the same medication class. For ATHENA-CDS, domain experts worked with knowledge engineers to ensure that the resulting knowledge corpus was complete and accurate.

1.3 Markup

In this Shiffman step, a guideline is converted from text into a semi-structured representation in order to identify and tag components relevant to operationalization of a CPG. In his paper, Shiffman describes an XML-modeling approach that decomposes a CPG into Guidelines Elements Model (GEM) component elements. For our purposes, an XML approach that marks up documents individually did not facilitate translation of the guideline knowledge into a Protégé knowledge base, so we took a different approach. We used a collaborative team approach for organizing the information in terms of the guideline model used in ATHENA-CDS KBs. The resulting representation facilitates the operationalization process as an intermediate view that focuses on elements important to the final knowledge encoding, such as: eligibility criteria, clinical algorithms, goals, definitions, concept hierarchies, clinical scenarios and decisions, interventions/drugs, and schemas for rating evidence quality and recommendation strength.

2. CDS Knowledge Specification and Encoding

2.1 Atomization

In order to execute the recommendations in a CPG, the recommendations in the narrative text need to be extracted and reduced to computable forms. Atomization achieves this by removing unnecessary text and identifying and normalizing the key concepts. Extraction of the guideline concepts can be performed manually or through natural language processing and text-mining tools. These concepts can then be normalized to terminologies in a custom or local library or to standardized terminologies such as Logical Observation Identifiers Names and Codes (LOINC). As an example, in the HF CPG, the selection criteria for the recommendation of an aldosterone receptor antagonist states that a patient should have:

Serum creatinine <2.5 mg/dL (or an estimated glomerular filtration rate >30 mL/min/1.73 m²) without recent worsening and serum potassium <5.0 mEq/L without a history of severe hyperkalemia

The atomization process extracted the following concepts from the statement: serum creatinine, estimated glomerular filtration rate, recent worsening, serum potassium, history of, and severe hyperkalemia. The criteria of <2.5 mg/dL, >30mLmin/m², and <5.0mEq/L were also extracted.

2.2 Deabstraction

Deabstraction is the process of converting generalized or high level concepts into specific concepts that can be operationalized. In the aldosterone receptor antagonist example, “severe hyperkalemia” needs to be converted to a more specific concept such as “serum potassium level above 1.5meq/L above normal.” While this example is relatively straightforward, other concepts can be more complex. For example, the atomized concept “metoprolol” can be further specified to individual formulations such as metoprolol tartrate or metoprolol succinate. The latter is reported to be more effective than the former in clinical trials and would be preferred. Therefore, careful attention is necessary to ensure adherence to evidence-based practice in the deabstraction process.

2.3 Disambiguation

In some CPGs, decision variables in recommendations can be vague and not mutually exclusive. For Disambiguation, Shiffman gives an example of this involving asthma exacerbation severity in which the descriptions for different severity levels contain ambiguous terms that could overlap. Ambiguity in a CPG can be the result of limited supporting evidence or lack of consensus. While the guidelines recommendations encoded into ATHENA-CDS did not require this type of disambiguation, there were recommendations that contained decision variables that have multiple incompatible interpretations (e.g., different cutoff values for abnormal laboratory test results). However, the translation of these variables into operational concepts was categorized as a deabstraction since they did not require delineating two mutually inclusive recommendations.

2.4 Verification of Completeness

This step ensures that recommendations provide guidance for all clinical scenarios. The goal of verification is to identify gaps in the decision criteria or in the recommended actions. The deabstraction and disambiguation process
often elucidates these gaps. In the example above, the criteria for starting an aldosterone antagonist do not account for the scenario where the serum creatinine and estimated glomerular filtration rate (eGFR) have not been measured. In addition, while the criteria for starting the medication allow for values of either serum creatinine or eGFR, the subsequent dosing recommendations provide dosing recommendations based on eGFR but not serum creatinine.

2.5 Build Executable Statements

After the guideline knowledge has been atomized, deabstracted, disambiguated, and verified for completeness, it is ready for translation into full executable statements that can be encoded into the CDS logic. The example we have been building in the previous steps could result in refined logical criteria such as:

\(((\text{serum creatinine} < 2.5\text{mg/dL or eGFR rate} > 30\text{ mL}) \text{ and (absence of 20\% rise in serum creatinine from the lowest recorded value in the last 90 days) and no history of serum potassium level} > 1.5\text{mEq/L above normal}}\)

This refined statement continues to have abstract or ambiguous concepts such as “normal” potassium. As can be seen, preparing guideline knowledge is often an iterative process that continues until the logic can be fully encoded.

2.6 Explanation

In addition to building executable statements, an important aspect of preparing the guideline knowledge involves providing the user with the reasoning behind each recommendation. Healthcare providers often want to know the evidence behind a recommendation when it goes against their normal practice. Explanation can also fill gaps in provider knowledge. In addition, user interface screen real estate is often limited, preventing the display of every detail of a recommendation or the evidence.

2.7 Knowledge Representation and Encoding*

This is a new step that encompasses the process of encoding the knowledge prepared in the previous steps. Shiffman presumed that the knowledge would be encoded in rules with decision variables. We implemented ATHENA-CDS using a rich guideline model that required decisions on specifying how the knowledge will be represented (e.g., how a domain ontology that includes taxonomies of medical conditions and drug interventions should be organized and how incomplete information should qualify suggested drug recommendations). In addition to deciding how the logic will be encoded, details on standards and conventions, version control, and the organization of data are important considerations that will facilitate the implementation process as well as future maintenance and extension. This step also includes making adjustments to the CDS logic based on the CDS design specifications described below in the steps involving EHR and Local System Integration. Once the knowledge representation has been determined and the knowledge has been aligned to specifications, the knowledge encoding can be performed.

3. EHR and Local System Integration

3.1 Workflow Integration

3.1.1 Data Origin Identification

In order to understand how the CDS integrates into the workflow, it is necessary to identify the clinical data sources. Data can come from historical records stored in the data warehouse. Other data can originate from certain steps in the clinical workflow and get recorded at point of care through data entry into the CDS or EHR.

3.1.2 Recommendation Insertion Identification

Determining how users will want to use the system and where recommendations should be inserted in the workflow informs design development to enhance the adoption and effectiveness of the CDS. For example, ATHENA-CDS generates recommendations on guideline-concordant changes to a patient’s active medication regimen. As a result, the CDS was designed so that the recommendations are presented to the clinician while he/she is reviewing data at the point of care and before completing the order entry process.

3.2 CDS Alignment, Adaptation, and Enhancement

3.2.1 CDS Alignment*

In many healthcare organizations, there are multiple types of CDS integrated into the provider workflow. A successful CDS implementation ensures appropriate integration in the existing architecture. For this project,
ATHENA-CDS was being integrated within a clinical dashboard showing metrics on specific performance targets. Since decision criteria and therapeutic targets drive the recommendations provided by ATHENA-CDS, they were modified to align with the numerator and denominator criteria of the performance metrics implemented by the dashboard. This alignment enables a user to have a consistent experience across the system. CDS Alignment can also involve the process of specifying the responsibilities of a CDS when there is an overlap in functionality with other systems. Unlike the “CDS Enhancements” step (discussed below), CDS alignment does not create new CDS capabilities, but utilizes existing capabilities. In contrast to the “Associated Beneficial Services” step (also discussed below), this step involves modifications to CDS capabilities so that they are consistent with existing CDS services.

3.2.2 CDS Adaptation*

Similarly, adaptation with the local EHR must be considered in the implementation of guideline recommendations. Specific components of the recommendation might need to be aligned with data available to the CDS. For example, if clinical information is not readily retrievable from the EHR, then alternative data sources must be established or limitations of the system must be acknowledged. Early consideration of the local system in the knowledge preparation process can reduce the chance of late modifications or removal of a recommendation. For example, many veterans receive obstetrics care outside of the healthcare system and pregnancy is not always documented in the EHR. As a result, a decision was made to consider pregnancy out of scope of ATHENA-CDS, and providers were advised to use their clinical judgment in women of reproductive age. CDS adaption involves changes to the implementation, not because of existing CDS capabilities that need to be aligned, but because of the characteristics of the local population and the data available in the EHR.

3.2.3 CDS Enhancements*

During the implementation and subsequent maintenance of a CDS project, new healthcare information technology (HIT) can emerge and interoperability between systems can improve. The availability of new data and enhancements to the EHR may allow for the implementation of new CDS capabilities. During the ATHENA-CDS implementation, the ability to check a patient’s adherence to prescriptions based on medication possession ratios became available through pharmacy data analytics. This new capability allowed for the implementation of CPG recommendations that could not be implemented before. In contrast to the use of associated beneficial services to complement CDS recommendations described by Shiffman, CDS enhancements entail changes in the CDS recommendations generated by the system.

3.3 CDS Delivery

3.3.1 Action Type Definition

The culminating step in CDS is an output that is ultimately used clinically. The majority of outputs can be classified in three action categories: gathering information, interpreting information, performing a task, and organizing care. Gathering information can come in the form of monitoring a clinical variable according to a specific criteria or schedule. Interpreting information usually results an output such as a diagnosis, prognosis, or clinical status. Recommended tasks can include prescribing medications, performing a procedure, documenting in the medical record, advocating a policy or practice, or preparing for a guideline-directed activity. Organizing care involves directing the flow of care for a patient in the form of deposition, follow-up, and referral.

3.3.2 Associated Beneficial Services

Shiffman describes this step as linking action types to services that offer design patterns for facilitating clinical care. Common use cases involve linking a prescription with a pharmacy system, sending an study order to a lab, or sending a referral to the designated department. These use cases facilitate the implementations of specific CDS recommendations using new or existing services, but do not alter the CDS recommendations themselves. For this project, ATHENA-CDS was being integrated with an existing clinical dashboard with an established set of associations. No additional decision regarding beneficial services arose during the development of the system.

3.3.3 Terminology Mapping*

An increasingly common task in HIT is data mapping to facility interoperability between systems that use different naming conventions. As a result, terminologies and concepts encoded into the knowledge representation such as laboratory studies and medications have to be mapped to those in other systems. For our project, a mapping table was needed for the data retrieval interface between ATHENA-CDS and the EHR. Similarly, the output of ATHENA-CDS had to be mapped to the clinical dashboard’s data repository and terminology usage.
3.2.4 User Interface Design

Best principles of user interface design must be used to make an effective and usable CDS. In addition to the standard design issues such as formatting of the look and feel to ensure readability and usability, consideration must be made in terms of user workflow, balancing space-efficiency, and the number of clicks required to perform a task. These design decisions can be constrained since most CDS are integrated into an existing system and must conform to or stay within the capabilities of the existing design.

4. Testing

Verification and validation of the encoded system is vital before a CDS system is deployed and should be performed throughout the development process. Verification is the process of ensuring the system operates according to requirements specifications. During this process, encoded logic and knowledge are tested to make sure they work as intended. CDS verification can be achieved though appropriate selection of real or engineered patient data with comparison to a reference standard. Validation of a CDS system ensures that the system performs what the end user requires. Validation can be achieved by quantitative and qualitative studies that measure the completeness and clinical appropriateness of system-generated recommendations.

5. Project Management

Management of the project throughout the implementation process is important in ensuring a cohesive and complete software product. There are many decisions that are related to the project as a whole. These decisions can affect the previous steps by influencing the scope of the project as well as the organization and timing of tasks. Project management also facilitates appropriate communication and resource allocation and tracks progress. For this study, these administrative decisions often related to resources such as scope, human resources, and financing. Other project management decisions that were important in a CDS implementation process included decisions on organizational policies, information technology challenges, analytics support, deployment details, and quality/feature control.

Discussion

With the immense amount of medical knowledge available, CPGs provide clinicians with access to concise expert or evidence-based knowledge sources. However, there are numerous barriers that reduce the use of CPGs in clinical practice. The Shiffman model describes a process for translating CPGs into a general requirement specification for a CDS that can be developed in isolation and implemented later in any setting. The resulting specification accounts for input variables from the CPG. In contrast, our model describes the extended process of taking a CPG, converting the knowledge into a computable format, and integrating that operationalized knowledge into a context-specific live user-facing system. As a result, the design specification and implementation process required consideration of variables specific to the VISN 21 environment as well as the national VA system.

In the analysis of our implementation, the incidence of decisions demonstrates that some steps of the original Shiffman model required more discussion and thought than others. It is possible that this variation reflects the importance and complexity of some of the steps in regards to their effect on the project as a whole. Three of the steps required a great deal of team discussion. Selection of an appropriate, usable, and valid medical knowledge is a fundamental step in clinical practice, and it is not surprising that the guideline and guideline recommendation selection process was a major point of discussion for ATHENA-CDS. Similarly, the importance of usability in the adoption and effectiveness of CDS continues to be underscored, and user interface design decisions were heavily discussed for our CDS implementation. Lastly, verifying the completeness of recommendations is a complex process that necessitates the input of both clinical and knowledge engineering experts.

Conversely, some steps, such as Markup, Atomize, De-abstract, Disambiguate, Build Executable Statements, and Define Associated Beneficial Services are either not reflected or under-represented in our formally recorded decisions. This finding can be explained by three factors. First, some of Shiffman’s and our additional implementation steps are optional. For example, the need for Shiffman’s Associated Beneficial Services and our CDS Alignment and Enhancements are contingent on the implementation context. Define Associated Beneficial Services step was performed prior to our project during the implementation of the clinical dashboard. Second, while the concepts behind the Markup and Build Executable Statement steps are still essential in implementing a narrative guideline, their definitions needed to be broadened, as there is no consensus technology used for this task. Lastly, the organization of our project team, and the limitation of using recorded implementation decisions as the basis for
categorization can explain the under-representation of steps such as Atomize, De-abstract, Disambiguate. For many of the knowledge representation tasks, our experienced knowledge engineers perform these tasks without requiring significant input and are not reflected in the recorded decisions of the project.

As more CDS systems are integrated into EHRs, more attention needs to be placed on how they interact. It is not uncommon that the logic of each system is encoded by multiple different groups or vendors. As a result, the design specifications for these CDS do not take into account other systems. Alignment of CDS and reconciliation of multiple CDS in the same system are developing areas in informatics that will need continued investigation as CDS implementations increase.

Similarly, interactions between CPGs have been a known issue in both clinical practice and CDS. CPGs, in general, are brief in their discussion of comorbid conditions. In ATHENA-CDS, each chronic disease KB is derived from CPGs, and the CDS provides recommendations independent of the other KBs. The KBs were specifically encoded to reduce possible interactions produced by the system. However, additional investigation is needed to make multimorbidity support feasible in working implementations.

While we have attempted to generalize our findings, other implementation projects will likely face different challenges. As HIT continues to evolve rapidly, the methodology and complexity of each step will likely change. Continuing to define the methods and steps in translating evidence-based knowledge into CDS will help ensure successful implementations. In addition, efforts should continue to standardize formats for guidelines that facilitate their implementation both clinically and computationally.

Conclusion

We validated and extended steps in Shiffman’s approach to making guideline recommendations computable. We identified additional knowledge engineering and implementation categories needed because of multiple comorbidities and guidelines, actual system implementation, and integration with existing HIT tools.

Automating Performance Measures and Clinical Practice Guidelines: Differences and Complementarities

1Samson W. Tu MS, 2Susana Martins MD MSc, 2Connie Oshio PhD, 2Kaeli Yuen, 2Dan Wang PhD, 2Amy Robinson PharmD, 2Michael Ashcraft MD, 1, 2Paul A. Heidenreich MD MS, 1, 2Mary K. Goldstein MD MS

Abstract

Through close analysis of two pairs of systems that implement the automated evaluation of performance measures (PMs) and guideline-based clinical decision support (CDS), we contrast differences in their knowledge encoding and necessary changes to a CDS system that provides management recommendations for patients failing performance measures. We trace the sources of differences to the implementation environments and goals of PMs and CDS.

Introduction

Performance measures and clinical decision support (CDS) are methods to improve quality of care. Both performance measures and CDS systems rely on clinical evidence, often summarized in clinical practice guidelines (CPGs), to define the standards of care. They are inter-related but distinct. Performance measures seek to improve care by retrospectively measuring the quality of the care provided to populations of patients, while CDS focuses on prospectively providing evidence-based therapeutic recommendations and alerts that are custom-tailored for the circumstances of particular patients. CDS may include performance measurement information as feedback to health professionals; however, in this paper we will use the term CDS in the sense of providing timely information and advisories to health professionals to assist decision-making. Once performance measures have been established, health care systems can provide CDS in order to improve performance on the items that are being measured. To improve the quality of care beyond providing aggregated data, the first step is feedback about performance for each patient with respect to the targets being measured. The next step is to add CDS to give additional recommendations about how to manage the condition to achieve the target.

In this paper we seek to concretely characterize the ways performance measures and guideline-based CDS differ yet can be complementary to each other by closely analyzing two pairs of performance-measure and CDS implementations. In the first pair (Analysis 1), we examine the implementations of similar clinical recommendations as performance measures and as CDS, and highlight how the implementations differ in their workflow integration, cohort definitions, definition of compliance, use of data, and output formats. We categorize the rationales for the divergence in inclusion and exclusion criteria of performance measure and CDS. In the second pair (Analysis 2), where a CDS system is used to provide guidance on the management of patients who have failed particular performance measure, we describe the necessary changes to the implementation of CPGs in a CDS system and how the recommendations of the CDS system can complement performance measure status in a provider’s dashboard.

Background

The Veteran Health Administration (VHA) of the Department of Veterans Affairs (VA) has been a leader in health care quality assessment and improvement [1]. Not only did it implement quality-improvement efforts that were guided by performance measurements [2], it also pioneered the application of evidence-based CPGs at points of care [3]. For more than ten years, our group at VHA Palo Alto Healthcare System has used the ATHENA CDS system, a knowledge-based system to provide CDS for guideline-based care, to investigate issues related to the operationalization, testing, and deployment of CPGs [4-7]. The basic system architecture includes Protégé [8] knowledge bases (KBs) that contain computer-interpretable CPG recommendations encoded using a domain-independent guideline model, a guideline interpreter execution engine that applies the encoded recommendations to patient data to generate patient-specific recommendations, and client programs that display the recommendations to and interact with CDS users. Initially focused on hypertension, the ATHENA CDS system now includes knowledge bases in several other clinical domains, such as hyperlipidemia, chronic kidney disease (CKD), diabetes mellitus (DM), heart failure (HF), and opioid therapy for non-cancer chronic pain [9-11].

For each knowledge base, the ATHENA CDS system evaluates decision criteria to determine guideline-concordant management goals and recommended actions for a patient. This computational infrastructure of the CDS system
would seem well suited to evaluate performance measures as well, since implementing performance measures involves using similar data and criteria. Performance measures focus on numerator and denominator criteria to determine whether a patient is included in the target population of the performance measure (the denominator criteria), and, if included, whether their care satisfies the definition of quality care (the numerator criteria). In 2011, our group was afforded the opportunity to study the processes and results of automating performance measures and guideline-based recommendation for patients diagnosed with heart failure in ATHENA CDS.

In a subsequent effort, we adapted the ATHENA CDS system to provide guideline-based recommendations to improve the care of patients who fail performance measures. Within the VA, the Veterans Integrated Service Network (VISN) 21 Pharmacy Benefits Management (PBM) group has developed a clinical data warehouse, based on an SQL Server database. The PBM group has built a clinical dashboard for use by both managers and individual providers, including nurses, pharmacists, physicians, and other members of the health care teams. The dashboard provides tools to monitor the clinical performance measures used by VA, focusing on the diabetes, heart disease, and hypertension measures as the priority areas identified by the leadership. The clinical dashboard is available to clinical managers for information about the primary care providers they manage and to primary care providers for managing their own panels of patients. The dashboard provides a stoplight-type report (red/yellow/green on each performance measure) which can be viewed both as a “panel” view (a provider’s panel of patients) or as a visit view (patients coming into clinic today, for visit planning). Our group undertook a project to complement the dashboard’s implementation of performance measures with detailed CDS for patients who fail to satisfy these performance measures. This opportunity allows us to examine what is different about a CDS system used in the electronic health record vs a CDS system used within a performance measure dashboard.

Method

To investigate concretely how automated performance measure systems and guideline-based CDS systems differ from and complement each other, we performed two analyses.

Analysis 1: Comparing Implementations of Heart Failure Performance Measure and CDS Systems

The analysis consists of comparing a heart-failure performance-measure (HF-PM) system that implements National Qualify Forum (NQF) Measure 0081 on the use of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy for left ventricular systolic dysfunction [12] and the ATHENA HF-CDS system that implements similar recommendations from the 2013 ACC/AHA guideline for the management of heart failure [13] (See Figure 1).

ATHENA CDS systems structure recommendations in terms of the EON guideline model [14, 15]. This guideline model formalizes a CPG as a knowledge structure containing eligibility criteria, goals or targets of therapeutic interventions, and a clinical algorithm that provides distinct decisions and action choices for patients in various clinical scenarios. The guideline model includes expression languages for performing queries and for encoding decision criteria [14]. At run-time an expression-evaluation module of the execution engine uses patient data to evaluate expressions and conclude whether a decision criterion evaluates to true or false for a patient. The evaluation of decision criteria helps to generate therapeutic recommendations appropriate for a particular patient.

To implement performance measures, we extended the EON modeling and execution infrastructure. Because we wish to compute a collection of performance measures using the same data set, we organize performance measures into groups, such as measures applicable to inpatient cases and measures that are applicable to outpatient cases. To improve system efficiency, we identified, for each group, common criteria that are applicable to all measures in the group. (For example, for the outpatient performance measures, one required criterion is that a patient has an outpatient encounter during the measurement period.) These common criteria (implemented as EON eligibility

---

1 We actually implemented NQF performance measures 0081 and 0083, where the NQF 0083 is a measure that evaluates the use of beta blockers for patients with heart failure. For the sake of simplicity, we report the results derived from the use of ACE inhibitor and ARB. The conclusions that can be drawn from the use of beta blocker are similar.

2 Specifically, we implemented recommendations related to ACE inhibitors and ARBs in [13]: ‘ACE inhibitors are recommended in patients with HFrEF and current or prior symptoms, unless contraindicated, to reduce morbidity and mortality. (Level of Evidence: A)’ – Yancy 7.3.2.2.’ and ‘ARBs are recommended in patients with HFrEF with current or prior symptoms who are ACE inhibitor intolerant, unless contraindicated, to reduce morbidity and mortality (Level of Evidence:A) – Yancy 7.3.2.3
criteria) are part of a performance measure’s denominator criteria. Each performance measure within a group has a set of inclusion criteria (all of which must evaluate true for a patient to be in the denominator population), a set of exclusion criteria (any of which, if evaluated to true, excludes a patient from the denominator population), and a set of criteria to achieve (any of which, if evaluated to true, puts the patient in the numerator population). Because modeling a performance measure’s numerator and denominator criteria uses the well-tested EON expression language for encoding the criteria and executing them against patient data, these extensions were easily implemented.

While NQF 0081 provides an initial level of specifications regarding the numerator, denominator inclusions, and denominator exclusions for these measures, in order to operationalize the computation of the measures we had to interpret the measures in much more detail. For instance, the denominator exclusions in NQF #0081 are defined quite broadly as follows: “Documentation of medical reason(s) for not prescribing ACE inhibitor or ARB therapy”, “Documentation of patient reason(s) for not prescribing ACE inhibitor or ARB therapy”, “Documentation of system reason(s) for not prescribing ACE inhibitor or ARB therapy.” In order to better specify such broad exclusion criteria, we consulted other heart failure performance measures that had more specific definitions for denominator exclusions. For instance, the VA External Peer Review Program (EPRP) has a FY2012 technical manual that specifically defines an inpatient performance measure of “HF patients with left ventricular systolic dysfunction (LVSD) who are prescribed an ACE INHIBITOR or ARB at hospital discharge.” The measure’s denominator exclusions include: “Patients who had a left ventricular assistive device (LVAD) or heart transplant procedure during hospital stay” and “Patients who have a Length of Stay greater than 120 days”. Similarly, other NQF- endorsed heart failure performance measures related to ACE inhibitors and ARBs, such as NQF #0610, specify additional denominator exclusions, such as “Evidence of metastatic disease or active treatment of malignancy (chemotherapy or radiation therapy) in the last 6 months.” We have pooled the exclusion criteria from these various sources and used them as operationalized denominator exclusions of NQF #0081.

We evaluated the performance of HF-PM using a convenience sample of 340 VA patients. Out of the 340 patients, 73 outpatient cases and 33 hospitalizations satisfy initial eligibility criteria. A preliminary validation of the accuracy of the system on 12 inpatient hospitalizations and 20 outpatient cases demonstrates that the system successfully generates conclusions for the ACE-inhibitors/ARB and beta-blockers performance measures in the majority of cases.

To operationalize the ACE inhibitor and ARB recommendations in the 2013 ACC/AHA guideline, we followed the methodology outlined by Shiffman [16] for making explicit the translation of document-based knowledge: markup of the text; atomization; de-abstraction; disambiguation of concepts; verification of completeness; and addition of explanations. We have identified additional steps not in Shiffman’s categorization and have reported them in a separate paper [17]. In the rest of the paper, we refer to the ATHENA CDS system that implements the heart-failure CPG recommendations as HF-CDS.

Implementing similar recommendations, first as performance measures and then as part of a CDS system, afforded us the opportunity to systematically analyze how different usages of the same recommendations have implications for workflow integration, cohort definition, definition of compliance, use of data, and output formats. We describe the findings in the Results section.

Analysis 2: Use Guideline-Based CDS to Complement Performance Measure Evaluation

The second analysis involves a production implementation of performance measures in the VA VISN 21 dashboard and a modified ATHENA CDS system (called ATHENA PMtoCDS) designed to provide decision support on the management of patients who have failed the performance measures. To provide recommendations that are consistent with performance measure evaluations, we made the necessary changes to the existing CDS implementations of guidelines for the management of type II diabetes mellitus, hyperlipidemia, heart failure, chronic kidney failure, and hypertension. We also developed a prototype user interface that integrates the outputs of the performance-measure dashboard and ATHENA PMtoCDS. The user interface allows a user to drill down from the top-level display of performance measure evaluations to see recommendations from ATHENA PMtoCDS on how to improve compliance with the performance measures (Figure 2). In this pairing of performance-measure and CDS systems, we demonstrate the complementarity of the two systems in achieving the institution’s clinical objectives.
Figure 1. In the first pair of systems, the Heart Failure Performance Measure system (1a) is designed to generate reports on whether a cohort of patients satisfies the NQF 0081 performance measure. ATHENA HF CDS System (1b) is designed to generate detailed management recommendations for guideline-based care at the time of a patient encounter.

To make the CDS advisories consistent with performance measures, we modified the original encodings of the guideline recommendations. The advisories generated by ATHENA PMtoCDS for patients who fail specific performance measures are passed to the dashboard for display to users in the context of the performance measure evaluations. Parallel to Analysis 1, we report as results our analysis of the workflow integration, cohort definition, compliance definition, use of data, and design features of user interface of the CDS. In this analysis our focus is on changes that are necessary to integrate CDS recommendations in the context of a performance-measure-oriented dashboard.

Results

Table 1 at the end of section highlights the main results of the analyses.

Analysis 1: Comparing Implementations of Heart Failure Performance Measure and CDS Systems

We will contrast performance measures and guideline-based CDS implementations in terms of workflow integration, cohort definitions, compliance definition, use of data, and output structure.

1. Workflow Integration

Both the HF-PM and the HF-CDS systems are research prototypes that were not deployed in actual clinics. The design of the HF-PM system involves the system processing, in batch mode, the data of a cohort of patients to see whether their treatments satisfy performance measures. The HF-PM system evaluates performance measures for both inpatient and outpatient cases. Both aggregated results and results for individual patients are stored in a database accessible to providers or administrators when desired. The HF-CDS system, on the other hand, evaluates patient-specific current clinical care and prospectively recommends best practices based on the encoded guideline recommendations. The CDS system also brings relevant patient data into one display with layered information to reduce the cognitive burden of searching the EHR for the information required for decision-making. Past ATHENA CDS deployments focused on providing decision support to primary care providers in outpatient clinics. For example, ATHENA HTN, the hypertension management version of ATHENA CDS, would pop up a CDS window when a provider selected a patient who was eligible for guideline-based care. The window would contain recommendations based on the JNC/VA guideline for the management of hypertension and the available patient data.

2. Cohort Definitions

Next we report the results of the comparison between HF-PM and HF-CDS systems in terms of identifying patients who should be included in performance measure evaluations and CDS support. As described in the Methods section,
we use as a case study the ACE inhibitor recommendation based on NQF 0081 [12] and the 2013 HF guidelines [13]. To make the criteria comparable, we examine the cohort definition of the outpatient component of NQF 0081 only.

HF-CDS makes use of 13 criteria that determine whether or not a recommendation should be made on ACE inhibitor or angiotensin II receptor blocker (ARB) for a patient with heart failure. HF-PM uses 33 criteria to select the cohort of patients eligible to have a prescription for an ACE inhibitor or an ARB.

We identified 8 criteria that are identical, 16 HF-PM criteria that are handled differently in HF-CDS, 10 criteria that are in HF-PM only and 3 criteria that are in HF-CDS only.

• Similar criteria differed in definition and modeling choices
  We organize the 16 instances in which similar criteria were handled differently in HF-PM and HF-CDS systems into 3 categories:
  a. Role of clinical judgment: HF-CDS alerts providers to conditions that require clinical judgment when recommending ACE inhibitor while HF-PM excludes these patients from the cohort/denominator in order to improve specificity. Performance measures exclude specific reported adverse events such as hypotension, hyperkalemia, worsening renal function due to ACE inhibitor or ARB. HF-CDS displays both the recommended drugs and the adverse events and allergies to providers and leaves the choice of whether to prescribe the recommended drugs to their judgment. Other clinical conditions were also excluded by performance measure, such as presence of aortic stenosis, hypertrophic cardiomyopathy, renal artery stenosis, stage 3 chronic kidney disease, eGFR between 30 and 59, and active prescription for aliskiren, are handled in the HF-CDS by explicitly alerting the provider to these conditions.
  b. Differences in sources: First, the heart-failure guideline used as the basis for HF-CDS does not contain an enumeration of ICD 9 codes used to define heart failure. Subject matter experts weighed in to define the list of ICD 9 codes and included cardiomyopathy codes that were excluded in the sources that we used to define heart failure for NQF 0081. Second, the definition of the thresholds for ejection fraction in the performance measure was more stringent (less than 40) than the threshold used for HF-CDS (less than or equal to 40).
  c. Differences in the timing and retrospective/prospective nature of performance measure and CDS: Pregnancy was modeled differently in the two systems. In HF-PM we look at the data retrospectively for pregnancy codes in order to exclude pregnant women from the denominator population. HF-CDS was designed to give close to real time advice. Given that many VA patients receive pregnancy care outside of VA and thus the relevant pregnancy codes may not be up-to-date in VA data, we decided to issue an alert to all women of childbearing age about the use of ACE inhibitor.

• Criteria unique to HF-PM
  HF-PM had 10 unique criteria that are not applied in HF-CDS. They can be grouped into two categories:
  a. Active in health care system: HF-PM excludes patients who are not active in the health care system using criteria such as visit in past 12 months and absence of death. In HF-CDS there is no need for this filter since CDS applies to patients with a scheduled visit, and are already known to be active in the health care system.
  b. Differences in sources: Our modeling of performance measure was based on documentation from national sources that mentioned exclusion criteria that were not cited in HF guidelines. These include use of hydralazine prior to ACE inhibitor/ARB (NQF 0610), multiple myeloma (NQF 0610), active prescription for pulmonary hypertension medications (NQF 0610), heart valve surgery (NQF 0610) and previous admission for hyperkalemia (NQF610).
  c. Differences in goals: HF-PM excludes patients with potential limited life expectancy while the HF-CDS offers the recommendations since the life-prolonging measures are often also measures that reduce symptoms and contribute to quality of life.

3 The categorized HF-PM criteria sum to 34 because one HF-PM criterion, eGFR<60, is broken up into eGFR<30 and 30<=eGFR<60, as HF-CDS uses them differently. The categorized HF-CDS criteria do not sum to 13 because multiple HF-PM criteria (e.g., adverse reactions) are handled uniformly in HF-CDS (e.g., adverse reactions not treated as absolute contraindications are displayed with recommended drugs).
• Criteria unique to HF-CDS

The three criteria that are unique to HF-CDS-only can be classified into three types:

a. Differences in sources: HF-CDS used creatinine values in addition to eGFR and ICD 9 codes for chronic kidney disease to exclude patients.

b. Difference in the scope of CDS: Because of the complexity of managing end-stage heart failure, stage D patients are excluded from the scope of HF-CDS.

c. Differences in output: Because HF-CDS generates recommendations on the choice of medications to prescribe, the presence of ACE inhibitor or ARB on the current medication list suppresses such recommendations.

3. Definition of Compliance

The NQF 081 performance measure defines a patient satisfying the denominator criteria as compliant with the performance measure if the patient was prescribed either ACE inhibitor or ARB. HF-CDS, on the other hand, preferentially recommends ACE inhibitor as the drug of choice, because of its well-founded evidence base and lower cost, and recommends ARB only if a patient is intolerant of ACE inhibitor.

4. Use of Data

Although both systems have access to all data in the EHR we note a distinction in temporal requirements when defining eligible patients. ATHENA CDS uses all data available in the electronic medical record with limited temporal restrictions on specific criteria while performance measure applies stricter temporal limits in many inclusion and exclusion criteria. For example, the NQF 081 performance measure requires the presence of a heart failure ICD9 code in the 2 years prior to the measurement period while for HF-CDS it is sufficient to have an ICD9 code for heart failure at any time. This difference supports the goals of the distinct systems: in performance measure to improve the specificity of the cohort leading to better credibility of results and in CDS to provide full presentation for review by providers in the context of care.

5. Output Formats

The performance measure primary output is geared to administrators wishing to evaluate the quality of care provided to patients at a given site or over a specific region or to health care professionals to identify missed opportunities to improve care. For HF performance measure, the raw output for each patient consists of a listing of each inclusion, exclusion, and numerator criteria and the evaluated results as determined from patient data. This listing is then transformed into summary statistics showing the number of patients who qualified for the measure and what proportion of these met the performance measure (i.e. met the numerator criterion). Secondary analyses showing various percentages of patients meeting certain exclusion criteria or failing to meet certain inclusion criteria are also computed to facilitate understanding of various contributing factors.

In contrast, the CDS output is a patient-specific advisory geared towards providers with the assumption that they will review the information and apply their clinical judgment. It is in a layered graphical user interface. The top level contains patient data, whether a patient reached the guideline goal, alerts, and detailed therapeutic recommendations. Therapeutic recommendations contain multiple guideline-compliant choices, each with patient specific indications, contraindications and adverse events highlighted. In a second layer we provide additional drug-related information such as the need for monitoring, drug dosing and other relevant alerts. The objective of the design is to bring the most important information for the decision making process upfront and to display additional relevant information upon user demand.

Analysis 2: Use Guideline-Based CDS to Complement Performance Measure Evaluation

To assist clinicians providing best practices in the performance measure environment we modified ATHENA CDS, originally developed as a standalone CDS system, into ATHENA PMtoCDS, a CDS system that provides advisories for patients failing performance measures. In the following we describe the changes made so that ATHENA PMtoCDS can play this role.

1. Workflow Integration

Instead of triggering CDS at the point of care, ATHENA PMtoCDS is designed to display pre-computed CDS recommendations when a provider reviews a panel of patients on the VISN dashboard. The software that computes dashboard performance measure is configured to generate a set of cases that fail the performance measures and to
pass the set to ATHENA PMtoCDS, which then generate the CDS. The dashboard displays patients’ performance with respect to VA performance measures as a population-based summary and as individual patient records. For a patient who fails to meet selected performance measures, a user can bring up ATHENA PMtoCDS recommendations that suggest how to manage the treatment of that patient.

2. Cohort Definitions

Because the performance measure system filters out patients who satisfy performance measure targets, CDS recommendations will not be generated for those patients. As originally implemented, ATHENA CDS provides recommendations regarding all patients independent of their treatment goal. For example, in the ATHENA-Hypertension CDS system, if a patient’s blood pressure is within the target range the system may recommend substitution from less desired to more preferred antihypertensive agents. These recommendations would never be generated in the performance measure environment since only patients with blood pressures above target would be eligible for the CDS. Another example is the way CDS manages glycemic control in patients with type II diabetes. The VA performance measure for the target HbA1c is less than 9% while in a point-of-care CDS system the target would be set by the provider in conjunction with the patient and can change over time. The cohort of patients receiving ATHENA PMtoCDS recommendations is restricted to those whose HbA1c is greater than 9%.

3. Definition of Compliance

As described above, having ATHENA PMtoCDS work in conjunction with the performance measure dashboard means changing the HbA1c goal from an individualized, patient-provider agreed-upon target HbA1c to a single HbA1c goal (of less than 9%). Because recommendations and messages are given only to those who fail this performance measure, and are above this threshold, there are recommendations that would either not be given, or given only regarding a subset of patients rather than all patients. For example, if a patient has a HbA1c<6%, and meets certain other criteria the CDS would issue a message that he/she is potentially at increased risk for cardiovascular events; this message would not be issued when considering only those patients with a high HbA1c. Similarly, if a patient’s bicarbonate level is less than or equal to 21 mEq/L, an alert would normally be given regardless of their HbA1c level. Thus because of the pre-filtering of cohort receiving CDS, some guideline recommendations or alerts become inapplicable or are applied to a subset of patients.

4. Use of Data

The differences described in the results of Analysis 1 in how performance measures and CDS use patient data also apply to Analysis 2. Integration with the dashboard, however, enables the CDS to access data that are computed by the dashboard. This allowed for the implementation of CPG recommendations that could not be implemented before. For example, the dashboard computes the medication possession ratio (MPR) that indicates the level of adherence to the prescribed medications. If the MPR is less than 0.9, then ATHENA PMtoCDS issues a message, alerting the provider that the patient may not to be adhering to his/her therapy and re-evaluation of clinical strategy may be warranted. A recommendation to increase dose or to add additional medications may not be appropriate if a patient is not adhering to the prescribed regimen of existing medications.

5. Output Formats

Unlike the previous versions of ATHENA CDS, which were directly integrated with the VA’s CPRS, the display is generated using the same Microsoft Report Server tool that generates the dashboard performance results. The advantage of using the same Report Server tool for display is that consistency of text font, size, colors, and navigation icons, i.e. the look and feel, between the CDS display and other dashboard pages can more easily be attained. Even then, to minimize possible confusion it is necessary to ensure that displayed terms from the ATHENA PMtoCDS output are made consistent with their counterparts in the dashboard.

The findings of the two analyses are summarized in Table 1. The ‘Analysis 1’ columns contrast the HF-PM and HF-CDS applications along the dimensions of workflow, cohort definition, definition of compliance, use of data, and output format. The ‘Analysis 2’ column indicates the changes to the CDS system so that it supplements a dashboard application that computes and displays performance measure information. For those patients who fail to satisfy specific performance measures, ATHENA PMtoCDS recommends changes to the management of the patients according to clinical practice guidelines relevant to the performance measures.
Table 1. Major findings: (1) Comparison of HF-PM and HF-CDS systems (Analysis 1) and (2) Necessary changes to ATHENA PMtoCDS for it to supplement a dashboard application that computes and displays performance measure information (Analysis 2).

Discussion

We use the implementations of two pairs of performance measure and CDS systems to demonstrate concretely how evaluating performance measures and CDS differ and yet can complement each other. In the first analysis, we compare the implementations of similar performance measures and guideline recommendations in the same computing environment, and systematically analyze how the resulting systems differ in workflow, definition of cohort, definition of compliance, use of data, and output formats. We attribute the differences in cohort definitions to discrepancies in the sources of the performance measures, the retrospective/prospective differences of performance measures and CDS, and, above all, in the role of clinical judgment in providing CDS. While performance measures need to be applied more narrowly to a denominator population for which the numerator criteria unambiguously apply, CDS recommendations can be provided to target patients whose management is entrusted to providers who can exercise their judgment based on data and knowledge that may not be available to the CDS system.

Analysis 2 explores the necessary changes to a CDS system for it to complement the performance measure services provided by the dashboard. We see how the pre-filtering of patient eligibility limits the recommendations that a CDS system can provide and how the consistency requirement between the performance measure system and CDS system forced the CDS system to re-define the therapeutic targets to achieve and to modify its output format.

In Analysis 1 we repurposed the ATHENA CDS infrastructure to compute performance measures. Even though CDS and performance measure program appear, on the surface, to be quite different because they produce different outputs, both programs are based on the recommendations from the same clinical evidence. Seen in this way, the underlying building blocks for both are either the same or very similar. Both make use the same medical conditions, medication lists, ICD9 codes, laboratory measurements and numeric cutoff criteria. Because we had previously encoded the heart-failure recommendations in a Protégé knowledge base, these building blocks, in the forms of Protégé classes, formalized criteria, and mappings from VA data sources, were already available for reuse when we encode performance measures for the heart-failure performance measure project. Having control of the execution engine also allows us to annotate the computed results with explanations (e.g., specific patient data causing a patient to fail an inclusion criterion) that help a user understand the computed performance measures. The disadvantage of repurposing the CDS infrastructure is that ATHENA CDS is designed to provide decision support for individual patients. It suffers from performance issues when computation is required for a very large patient cohort. Using SQL to implement performance measures, as the VISN 21 dashboard does, means that queries are applied to sets of patient data at a time, making the computation much more efficient.

Placing CDS in the service of improving the achievement of performance measures is not the only way to relate CDS and performance measures. In the literature we see additional possibilities. Fonarow et al.[18] used performance measures to measure the effectiveness of guideline-based CDS. They showed improvements in 5 out of...
7 process performance measures among HF patients after 24 months of intervention that included clinical decision support tools, structured improvement strategies, and chart audits with feedback. LeBresh et al. [19] developed a “Get With The Guidelines” program that integrated a patient management tool with performance measures and guideline summaries. They found significant improvements from baseline to the fourth quarter in 11 of 13 measures[19]. Neither the Fonarow et al. nor LeBresh et al. studies used CDS that provides patient-specific management recommendations generated from automated CPG. Walter at al [20] used the best practices defined in CPGs to create performance measure. Using colorectal cancer screening as a case study, they identified a number of pitfalls in using CPGs to define performance measures that are similar to our findings about the differences between CDS and performance measures, such as not accounting for provider judgment when scoring performance measures. Finally, van Gendt et al. [21] used performance measures developed independently of CPGs to evaluate completeness of CPGs and to offer the possibility of improving CPGs. The authors formalized performance measures as goals that CPG recommendations should satisfy. For example, a performance measure may measure the percentage of diabetes patients with albumin value measured in a 12-month period. They analyzed a Type-2 DM CPG to see whether the paths in the CPG would achieve the goal of having an albumin measurement within that period. They found that, out of 35 performance measures studied, 25 (71%) suggested that there are problems with CPGs they used in the study.

Conclusion

Our analyses demonstrate that (1) the same evidence-based treatment recommendations are implemented differently as performance measures and as management advice in a CDS system and (2) a CDS system can help patients achieving compliance with performance measures but would require significant modifications so that it complements a performance dashboard in a consistent manner.

Abstract

The electronic health record (EHR) provides an opportunity for improved use of clinical documentation including leveraging tobacco use information by clinicians and researchers. In this study, we investigated the content, consistency, and completeness of tobacco use data from structured and unstructured sources in the EHR. A natural language process (NLP) pipeline was utilized to extract details about tobacco use from clinical notes and free-text tobacco use comments within the social history module of an EHR system. We analyzed the consistency of tobacco use information within clinical notes, comments, and available structured fields for tobacco use. Our results indicate that structured fields for tobacco use alone may not be able to provide complete tobacco use information. While there was better consistency for some elements (e.g., status and type), inconsistencies were found particularly for temporal information. Further work is needed to improve tobacco use information integration from different parts of the EHR.

Introduction

Social and behavioral factors such as tobacco, alcohol, and drug use are increasingly recognized as key factors for many causes of disease, disability, and mortality in the United States. A number of studies have been published describing the linkage between behavioral risk factors and their associated morbidity or mortality\(^1\)\(^4\). For example, worldwide, direct tobacco use is responsible for more than 5 million deaths each year\(^5\). The National Academy of Medicine (NAM; formerly Institute of Medicine) have emphasized the need for improving existing datasets, developing new data sources, and establishing strategies and models for incorporating social and behavioral factors and their interactions in its 2006 report on “Genes, Behavior, and the Social Environment: Moving Beyond the Nature/Nurture Debate”\(^6\). In a recent NAM report on “Capturing Social and Behavioral Domains and Measures in Electronic Health Records: Phase 2”, tobacco use and exposure was featured among the domains recommended for inclusion in the electronic health record (EHR)\(^7\).

The widespread adoption of EHR systems, in turn, provides an opportunity for clinicians and researchers to access a large amount of information about an individual’s social history including substance use. Within EHR systems, documentation of social history, including tobacco use, can range from structured and coded data to free-text narrative. A number of studies have focused on the examination and representation of social history information\(^8\)\(^-\)\(^12\). Other studies have involved developing natural language processing (NLP) techniques for the automated identification and extraction of substance use information, with a particular emphasis on tobacco use\(^8\)\(^,\)\(^13\)-\(^18\).

In this study, we sought to investigate tobacco use information collected in multiple structured and unstructured sources within an EHR system. NLP techniques, as previously described, were used to extract tobacco use statements from free-text for comparison with structured sources in order to characterize content, consistency, and completeness of this type of information for patients within a single system.

Background

In early work, a multi-institutional study was conducted to characterize social history information in clinical notes from different sources (MTSamples\(^19\), University of Vermont Medical Center [UVMCC; formerly Fletcher Allen Health Care], and University of Minnesota-affiliated Fairview Health Services [FHS])\(^10\). We evaluated adequacy of several existing models including HL7 CDA-based models\(^20\) and openEHR\(^21\) archetypes for representing social history information. From this, initial models for tobacco, alcohol, and drug use were developed in this study. Table 1 illustrates part of the model used to represent information within a social history statement for tobacco use.

In a 2014 follow-up study, 525 tobacco use entries from the social history module of the Epic EHR at UVMCC, including structured fields (e.g., for smoking status, type, and frequency) and a free-text comment field, were
manually reviewed to characterize the contents and quality issues of the free-text comments. Results from the study showed a range of potential data quality issues between the structured fields and free-text comments.

To exploit the information from clinical text, we developed a NLP pipeline for detecting substance use (alcohol use, drug use and tobacco use) statements and extracting relevant elements of substance use. Unlike many of the previous NLP studies included in the 2006 i2b2 challenge which focused on the extraction of smoking status, our goal was to extract additional semantics related to tobacco use including tobacco use beyond smoking (e.g., smokeless tobacco) and smoking status (e.g., pack-use and temporal information). In this work, we leveraged existing linguistic resources and domain knowledge from the earlier studies, as well as the Propbank resource and the MiPACQ corpus to boost extraction performance for tobacco use elements. The resulting NLP tool achieved good performance for extracting a wide breadth of substance use free text information.

Method

Setting and Study Design

This study involved a retrospective analysis of tobacco use information collected from clinical notes and the social history module of an enterprise implementation of the Epic EHR (Epic Systems Corporation, Verona, WI) at University of Minnesota-affiliated Fairview Health Services (FHS). Fairview Health Services had been using EpicCare in one of its physician practice groups (Fairview Physicians) for over eight years. Other practices were supported by Allscripts, Eclipsys SCM, McKesson Paragon, and paper processes. Starting October 2010, two paper-based Fairview regional hospitals successfully went live with Epic clinical and revenue cycle applications. Then in March 2011, Fairview’s two largest hospitals which are academically-based went live simultaneously.

In the social history module of Epic EHR, each entry includes structured fields for tobacco use information such as smoking status, start date, quit date, as well as a free-text entry for comments as shown in Figure 1. While some clinicians use templates that pull in information from the social history module, many clinicians continue to document tobacco use information within clinical notes in free text format outside of the tobacco use module most often as part of a social history section in the note (e.g., “The patient continued to smoke about half pack a day.”). Most of the structured social history data is entered by nurses and medical assistants during ambulatory patient visits based on direct answers from patients or on questionnaires completed by patients. Tobacco use information within a note is usually entered during patient visits and is considered a required element for face-to-face ambulatory encounters in our healthcare system (as well as most others).

Figure 1. Tobacco use data entry in the social history module including comments. ©2016 Epic Systems Corporation. Used with permission.
From 337,506 adult patients (age>=18) who had a most recent social history entry in 2015 and social history entries associated with at least two prior encounters, a set of 384 patients was randomly selected as the cohort for this study to provide for a confidence level of 95%, and margin of error of 5%. For each patient, all tobacco use entries (including structured fields and free-text comments) from the social history module and provider-authored clinical notes (e.g., progress notes, history and physical examinations, discharge summaries, and admission note) were obtained. Figure 2 shows the overall high-level process of the study.

All clinical notes used in this study were collected from the University of Minnesota research clinical data repository. The repository contains documents between 1993 and 2016 from the Epic EHR, as well as documents from affiliate clinics for variable time periods. Extracted notes were pre-processed to add newlines into appropriate places based on text features such as letter capitalization, punctuation, and special letters. Sections (e.g., “Assessment & plan” section in progress note) along with the section header (e.g., “Present illness”, “Social history” and “Assessment & plan”) within each note were extracted by an NLP section extraction component. Afterwards, text within each section was split into sentences by a sentence splitter component. The approach used in our earlier study22 was used for processing sentence content as follows. First, a classifier was used to detect tobacco use statements from sentences. Tobacco use statements were then parsed by Stanford parser26 to obtain constituent and dependency parses of each sentence. The constituent parse of a sentence provides syntactic cues for later tobacco use elements extraction while the dependency parse of a sentence provided the dependency structure of the sentence. A dependency structure represents a directed graph between the tokens of a sentence (e.g., subject, modifier and preposition). With constituent and dependency parses, tobacco use elements (“Amount”, “Type”, “Status”, “Temporal”, “Method” and “Frequency”) were extracted by a substance use element extraction tool leveraging a large vocabulary of smoking-related items.

To extract the same tobacco use elements (e.g., “Amount” and “Status”) from free-text tobacco comments in the tobacco use module (Figure 1), our approach was modified slightly. Values were first collected from structured fields in social history module of Epic EHR system and were mapped to appropriate elements (e.g., “Amount” and “Status). The resulting tobacco use information from structured tobacco use fields, free-text tobacco use comments, and clinical notes with tobacco use statements were the analyzed for content and quality issues within the cohort.

![Figure 2](image_url)

**Figure 2.** Overall high-level study process resulting in information from free-text comments, structured tobacco use fields, and clinical notes.

**Analysis of Tobacco Use Information**
The content of tobacco use elements collected from the structured tobacco use fields, free-text tobacco use comments and extracted from clinical notes with tobacco use were characterized as distributions of patients, tobacco use elements and new tobacco use elements patterns of all three tobacco use information sources. A similar coding schema developed and applied in a previous study was used to examine the consistency between structured data and information extracted from unstructured data as shown in Table 2.

As observed in the previous study, a wide range of data consistency issues exists with the tobacco use fields from the social history module and free-text comments. For example, patients may have conflicting information even within a short time span. One patient with respect to smoking status was recorded as “Passive Smoker” in the structured smoking status field while the clinical note from the same day states “trying to quit smoking” and a comment states “quit date 10/30/2009”.

Table 2. Examples of observed inconsistencies and discrepancies in tobacco use data at the individual patient level.

| Smoking status    | Tobacco use statement and tobacco use comment inconsistent with smoking status field | Smoking status: Passive Smoker  
Comment: quit date M1/D1/Y1  
Statement: The patient is trying to quit smoking |
| Packs/day         | Tobacco use statement and tobacco use comment inconsistent with Packs/day field | Packs/day:  
Comment: half a pack a day  
Statement: He currently smokes around 1/4 pack of cigarettes per day |
| Years             | Tobacco use statement and tobacco use comment inconsistent with Years of smoking field | Years:  
Comment: chewed x 12 years, 2 tins per day  
Statement: She smokes about a pack a day for about 12 years |
| Type              | Tobacco use statement and tobacco use comment inconsistent with Type field   | Type: Cigarettes  
Comment: Occasional cigar  
Statement: Significant for tobacco use |
| Start or quit date| Tobacco use statement and tobacco use comment inconsistent with Start or Quit date field | Quit date: M2-D2-Y2 00:00:00  
Comment: quit 6 1/2 yrs ago  
Statement: The patient is a former smoker who quit on M3/D3/Y3 |

To compare tobacco use data from different sources, tobacco use elements extracted from clinical notes and comments were mapped to structured fields. The “Amount” element extracted from tobacco use statements includes broader information than “pack/year” field. For example, the value for amount in the tobacco use statement “Significant for tobacco use” is “Significant”. Also, “Temporal” element can hold more information than “start/quit date” and “years”, such as the statement “The patient is a life long nonsmoker” does not provide start or quit date.

In addition, tobacco use elements extracted in free-text comments or statements can be expressed in numerous ways (e.g., “10/02/79”, “18 Aug 2008”, “x 10 yrs”, “1 ppd” and “half a pack”). In this study, we developed mapping strategies to normalize numbers and map different expressions of “Amount”, “Packs/year”, “Start/Quit date”, “Years” and “Type” in free-text tobacco use comments and statements into the structured tobacco use fields.
Results

For the 384 patients, 377 (98.2%) had tobacco use entries with the smoking status specified as a value other than “Not Assessed” (e.g., “Former smoker” and “Never smoker”); 201 (52.3%) had clinical notes with tobacco use statements, and 68 (17.7%) of patients have tobacco use comments. Figure 4 shows the overlap of the presence of notes, comments and tobacco use entries at the patient level. As shown in Table 3, only 17.7% of the patients had tobacco use comments data; fewer patients had both clinical notes with tobacco use information and tobacco use comments; and a large portion of patients had clinical notes with tobacco use information. Figure 5 shows the distribution of elements within each of the three sources.

The numbers of elements extracted from each source are listed in Table 3. We observed that a large amount of duplicate tobacco use information exists within the structured tobacco use entries. Of 5,754 entries, only 944 (16.4%) of them were unique data with different dates since information in the social history module for patients appears often to remain unchanged across encounters and therefore the same information is propagated between encounters. For clinical notes, 590 (65.8%) out of 896 tobacco use statements were unique, and only 153 (7.9%) of tobacco use comments were unique (i.e., again due to propagation of the entry between encounters).

Figure 5. Distribution of tobacco use elements from each source.

Figure 6 shows the number of tobacco use elements and the date entered or documented for all patients over a 14-year period (2002 to 2016). Green data points signify free-text tobacco use comments and show a similar pattern as data points from structured tobacco use fields. This is likely related to free-text tobacco use comments being entered within the same user interface as the structured data fields. Compared with the other two sources, tobacco use data points from clinical notes did not show as much of an increase with time.

Figure 6. Tobacco use elements input patterns of all patients.

Figure 7a shows longitudinal distinct tobacco use information each year in an example patient start 2004 -14 with and without tobacco use elements extracted from free-text tobacco use comments and clinical notes. Each data point represents the number of distinct tobacco use elements documented within the year. The number of unique tobacco use elements for this patient increases with inclusion of information from the unstructured data sources. New tobacco use information can be plotted for the same patient with time (Figure 7b) resulting in a similar pattern. Figure 7c summarizes new tobacco use information aggregated for the patient cohort. As shown in the three figures, tobacco use information extracted from the structured tobacco use fields combined with information extracted from tobacco use comments and clinical notes provide more complete information than data from a single data source.
Figure 7a. Distinct tobacco use elements of an example patient.

Figure 7b. Tobacco use new information patterns of the same example patient.

Figure 7c. New tobacco use elements patterns of all patients.

With respect to the quality and consistency of tobacco use information from the three sources, Figure 8 shows the consistency rate of five fields between tobacco use elements collected from the structured fields, comments, and clinical notes. Compared with other data fields, there was a large amount of inconsistency with “start/quit date”
between EHR module entries, comments, and notes. Other data fields demonstrated much better consistency, which implicates the overall reliability of tobacco use information.

**Figure 8.** Data consistency between structured data and unstructured data.

Some inconsistencies were also found within structured tobacco use fields. Below examples show part of the pipe-delimited entries of the structured tobacco use fields limited to status information, in a format of “date |tobacco_use|quit_date|pack/year|years|smokeless_tobacco”. These examples also show the large amount of duplicated tobacco use within the structured tobacco use fields.

**Discussion**

The results in this study provide good insight into the characteristics of tobacco use content and quality issues from structured tobacco use fields in social history module, tobacco use comments in the same module and tobacco use statement in clinical notes. This work is an initial step to extract and integrate large amount of substance use information stored within EHR systems using automatic tools based NLP techniques. The approach used in this study can be easily generalized for other substance use types such as alcohol use and drug use and potentially more broadly to data represented in both text and structure fields over time. The results illustrate some of the fundamental issues of integrating substance use information from different sources. The data used in this study is limited to a single health care system of one institution with a medium sized cohort. The results will, therefore need to be
validated in other settings. Also, the automated methods will likely need modifications before being applied to other EHR systems.

We observed data consistency issues between tobacco use information from different sources, which particularly presents challenges in integrating tobacco use information from different sources and using the combined date for decision support, research, public health, and other primary and secondary uses. While we expect for data to potentially change with time as smoking status changes (e.g., a smoker who subsequently quit), we encountered discrepancies on the same date and changes in status over time that were nonsensical. For example, the smoke status of a patient as follows changed between structured tobacco use records within structured tobacco use fields and free-text tobacco use statements. The structured tobacco use fields also failed to capture this status change. The change was documented into a clinical notes at some point in between. More efforts are needed to determine adequate strategies for addressing and integrating inconsistent data from different sources, which may also need to be based off of use cases for how the data will subsequently be used.

Besides inconsistency between tobacco use information from different sources, we also noticed inconsistencies within the structure tobacco used fields such as unchanged “Years” of tobacco use or slightly different amount for “Packs/day” (e.g., 0.5 vs. 0.3). These issues indicate that the tobacco use information extracted from structured need to be further processed and normalized before integrating with tobacco use information from clinical notes and comments. Also, these issues may indicate the need for better EHR user training or improved user interface to help user entering valid data values.

Issues were also observed with comparing certain data such as “0.5 pack” vs. “10 cigarettes” or slightly different amounts “0.75 pack” vs. “0.5 pack”, “6 years ago” vs. “6.5 years ago”. Moreover, in tobacco use statement from notes and comments, tobacco use elements can be documented using various expressions with different levels of detail (e.g. “10/02/90” vs. “Feb 90” and “half pack per day” vs. “0.5 pack/day”). These issues highlight the requirement for good mapping (e.g., “former smoker” to “quit”) and normalization (e.g., “half” to “0.5”) strategies (e.g., “0.5 pack” is same as “0.75 pack”) for NLP components.

As shown in the Figure 6, more tobacco use data were entered into the social history module in recent years. We speculate that the increased entry of data in the social history module is due to a combination of factors, likely including increased attention to entry of social history information and the requirement of asking this by certain regulations (i.e., Meaningful Use requirements).

This study is limited in one substance use type, and a next step will therefore include more substance use types such as alcohol use, drug use, or caffeine. We also noticed large amount of free-text comments and statements with smoke exposure information and use of e-cigarettes, for which we did not address in this study and which represents an area of further development. Also, except for the structured tobacco use fields in the social history module, other potential EHR fields that may also include tobacco use information were not included in our analysis.

Conclusion

Overall, we applied an NLP pipeline with components to detect tobacco use information from tobacco use statements in clinical notes and tobacco use comments from social history module of Epic EHR, as well as retrieved structured information from the tobacco use EHR module. The extracted tobacco use information was analyzed over a cohort of patients, characterizing tobacco use EHR content and quality issues. Our results provide insights into the challenges with reconciling and integrating this data for secondary uses. The results indicate the structured tobacco use data alone like do not provide complete tobacco use information. Further work is needed to improve approaches for integration of tobacco use information from different parts of the EHR.

Abstract

Delirium is a fluctuating disturbance of cognition and/or consciousness associated with poor outcomes. Caring for patients with delirium requires integration of disparate information across clinicians, settings and time. The goal of this project was to characterize the information processes involved in nurses’ assessment, documentation, decision-making and communication regarding patients’ mental status in the inpatient setting.

VA nurse managers of medical wards (n=18) were systematically selected across the US. A semi-structured telephone interview focused on current assessment, documentation, and communication processes, as well as clinical and administrative decision-making was conducted, audio-recorded and transcribed. A thematic analytic approach was used.

Five themes emerged: 1) Fuzzy Concepts, 2) Grey Data, 3) Process Variability 4) Context is Critical and 5) Goal Conflict. This project describes the vague and variable information processes related to delirium and mental status that undermine effective risk, prevention, identification, communication and mitigation of harm.

Introduction

Delirium is defined as a fluctuating disturbance of cognition (memory, language, orientation) and/or consciousness with reduced ability to focus, sustain, or shift attention. Delirium may impact 14–56% of all hospitalized elderly patients, 2,3 and is associated with poor outcomes, including: increased length of stay, increased likelihood of falls and accidents and discharge to a nursing home . Delirium causes diagnostic dilemmas for physicians and due to the need for increased monitoring, is often a significant burden on nursing staff.4

Several factors make delirium a difficult clinical problem. The first is that delirium often goes undetected: the prevalence of undiagnosed delirium was found to be as high as 32-67% on general medical units, 65% in emergency departments 3 and 86% in nursing homes.5,7 Across 22 studies, Steis and Fick found that nurses’ recognition of delirium symptoms ranged from only 26% to 83%.8 Complicating matters is that delirium may be the result of a variety of causes including: urinary tract infections, post anesthesia effects, pain, and iatrogenic effects from medications.9 A confounding issue in dealing with the problem of delirium is the distributed responsibility for care in inpatient settings. For example, a nurse may note that the patient is confused; this information is likely recorded either in a narrative note or in verbal handoffs or both. Physicians will likely not read the note and unless the nurse informs them verbally, then physicians will likely not be aware of the problem. Since fluctuation in alertness is the hallmark of delirium, multiple observations must be recorded to quantify the problem. Some of the communication norms may be implicit, as individuals may assume that when nothing is mentioned, there is not a problem.

Clinical decision support interventions were shown to increase delirium detection rates. However, despite increased recognition, these interventions were relatively ineffective in improving outcomes in patients with delirium.10-14 In some settings, increased detection of delirium did not result in changes in patient care.11,12,15 In studies showing improved outcomes, improvements appear to be associated with a multidisciplinary approach, including enhanced communication and shared awareness of goals across the healthcare team.6,16-18 Current practices regarding nurses’ data collection and communication processes related to mental status are not well understood. This study helps to fill that gap.

In this paper we describe a qualitative analysis using semi-structure interviews with inpatient nurse managers of acute medicine floors across the Veterans Health Administration (VHA). The purpose of this study was to understand how information about patients' mental status (with a focus on delirium) is recorded, transferred,
communicated and tracked. This formative work was intended to inform the future development of a shared information space for the healthcare team to support communication, decision making, action planning and tools such as decision support technology.

**Conceptual Framework**

Successful detection and treatment of delirium depends on the healthcare team sharing information effectively. Effective communication requires not just sharing information, but sharing one’s beliefs regarding the meaning and implications of the information, expectations regarding the distribution of responsibilities and beliefs about the cause. Based on our belief that shared situational awareness drives effective clinical care of individuals’ with delirium, we based this work on Herbert Clark’s theories of communication. Clark proposes that communication and language are for the general purpose of creating “joint action” or activities with “rational organization around a common goal“19-21 (p. 69) Joint activities involve mechanisms for coordination (e.g. establishing definite reference, negotiating responsibility), for establishing common ground (understanding the intentions, roles, responsibilities and knowledge of each other), for accumulating coordination rules over time (through learning, minutes, and policy) and for the ubiquitous need for constant repair of miscommunication.

**Methods**

**Settings and Study Participants**

The Central Institutional Review Board of the VA, as well as the University of Utah and the Salt Lake City VA local IRBs approved the study. A convenience sample of nurse managers from 18 VA medical-surgical patient care units was selected from across the U.S. Four worked in the VA western area, four in the eastern, three in the southern, and one in a central area. Participants ranged in age from 38-57 years with a mean of 43.5 years. Their years of experience in the VA ranged from 6 months to 29 years with the modal experience at 10-13 years. The majority of nurses had bachelor's degrees (n=6) or master's degrees (n=5). Unit selection maximized variability: medicine, dialysis, rehabilitation, telemetry, transplant, and combined medical/surgical. The average census on units ranged from 6-29 (mean = 18.5) patients.

**Setting**

The VA is supported by VISTA, a mature electronic health record or EHR, (Stage 7 HIMSS Analytics) which includes clinical documentation, closed loop medication administration, orders management, decision support, and data warehousing. The clinician-facing component of VISTA, called CPRS, has standard templates for electronic documentation with the capability to create site-specific and unit-specific electronic forms for clinical documentation.

**Interview Guide Development**

The semi-structured interview guide was developed by the authors (CW, NS and BG) to address 1) current practices in managing and communicating patients' mental status changes, 2) decision-making processes for staffing and resource use, and 3) practices for communication between and within the various clinical roles. The semi-structured interview was piloted and refined during interviews with two nurse managers before the study began.

**Procedures**

The team recruited potential participants through phone contact with the site’s nurse executive and email invitations sent directly to participants. After the consenting process was completed, two researchers (BG, NS) completed telephone interviews using the semi-structured interview guide. The specific interview questions are in the Appendix. The interviews lasted 15-20 minutes at the minimum and sometimes up to an hour for a few and a median of 25”. They were recorded, transcribed, verified for accuracy and de-identified by a professional transcriptionist. Transcripts were loaded into Atlas.tiTM for analysis.

**Data Analysis**

The team used an iterative process of qualitative content analysis.22 After group calibrations, each member of the team independently created “pre-codes” or short text that paraphrased the text. The associated quotations were
discussed and aggregated by assigning more abstract codes in an iterative consensual process of group discussion and re-coding. Final thematic categories were identified by grouping quotations, comparing and contrasting content through discussion and network display analysis and final re-reading of the original text for validation. The authors (CW, BG, and TT) jointly reviewed all 18 of the interviews using Atlas.ti™.

Results

We organized the concepts identified in our analysis into five thematic categories referring to mental status information content and processes: Fuzzy Concepts, Grey Data, Process Variability, Context is Critical, and Goal Conflict. Each is described below with representative quotations.

Theme 1. Fuzzy Concepts: References to mental status are generally “fuzzy” and imprecise

References to acute mental status changes range from informal to moderately structured. A variety of terms are used including: confusion, acute confusion, agitation, altered mental status, delirium, dementia, and, at times, more colloquial terms like “wacky” and “sundowners.” We noted significant reluctance by nurse interviewees to use the word “delirium” unless patients were formally diagnosed as having the condition: One nurse said, “Nurses don’t diagnose.” The most common term nurses mentioned was “confusion.”

Use of structured mental status data is limited to designated fields in EHR templates (e.g. nurse admission note for orientation) and is usually non-specific for delirium (e.g., patient is alert and oriented 4). Delirium is not typically formally assessed in general medical surgical units unless orders such as the Richmond Agitation and Sedation Scale (RASS) and the CAM (Confusion Assessment Method) were rarely used. The methods for assessing mental status and the timing at which the assessments occurred were viewed as being a matter of nurses’ individual clinical judgment.

Some institutions used a structured format for handoffs, such as SBAR (Situation, Background, Assessment Recommendation), as a framework for their handoff forms. However, this framework is not specific enough to ensure consistent documentation and communication of mental status: “The oncoming nurse has their blank SBAR form and they fill it out during their verbal handoff.”

</thead>
<tbody>
<tr>
<td>The term delirium is rarely used.</td>
<td>“Regarding like behavior, you know, as far as being agitated, calm, cooperative, all of those different kinds of things as well…” “Unfortunately a lot of people use dementia…when it’s not always the case.”</td>
</tr>
<tr>
<td>Assessments are non-specific for delirium</td>
<td>Is delirium formally assessed? &quot;Yes, sort of.&quot; “It’s not a specific dementia or confusion assessment tool.” “We just do the mental status exam. So we look at orientation, whether they’re oriented to person, place, time; and then whether they’re awake, lethargic, unresponsive to, sedated…” “We rarely assess somnolence. Honestly, we rarely have patients that fit that criteria so they are more tuned into…alert and oriented and then relate to what the patient is not oriented to.”</td>
</tr>
<tr>
<td>And then on your unit do you have a particular way that you’re defining either delirium or acute mental status changes?</td>
<td>“Acute mental status change would be one. A lot of times what I hear just between nursing staff is a lot of times they’ll talk about sundowner’s.” “I don’t really see the actual word delirium being said, but we just would use the words, he just got confused all of a sudden.”</td>
</tr>
</tbody>
</table>

Theme 2. Grey Data: Information regarding mental status is invisible or difficult to find
Grey data refers to information that is not available in the EHR, either at the individual, ward level, or system level. As a result, this information can’t be easily accessed for decision-making. Information can be difficult to find, either because it is not integrated with other data that makes it meaningful, because it is in a non-useful format, or because it is buried deep within clinical notes. Nurses’ use of templates for documentation makes it difficult for physicians to locate relevant information because they are lengthy, not created to display information “at a glance” and do not allow indicators for critical information. In addition, key information such as the patient’s risk for developing delirium or trends in mental status signs and symptoms tend to be verbal and informal. Often mental status information is not recorded.

<td>“No, it’s just an Excel spreadsheet that people developed.”</td>
</tr>
<tr>
<td></td>
<td>“Well, we have a…we have a process for, but it’s not a formal…every delirium assessment which is one on every patient I co-sign the note, so anybody that scores a two or above I put in the folder, but I make sure my nurses are following up so I have a list going back over the last year on anybody that scored two or higher.”</td>
</tr>
<tr>
<td>Hand-offs vary and are often</td>
<td>“They have like a spreadsheet that they have information on all of our patients. Let me look at the headings and see if we’ve got that [mental status] as one of our headings.”</td>
</tr>
<tr>
<td>unstructured</td>
<td>“. . .my floor that just designed our own hand-off sheet, charge nurse to charge nurse, and it will say who the high acuity patients are; it will say who the heavy patients are.”</td>
</tr>
<tr>
<td>Persistence of paper</td>
<td>“That’s a paper form, but we…”</td>
</tr>
<tr>
<td></td>
<td>“Oh, yes. Well, if there’s an ‘order’ for neuro check, then . . .we have a paper form to fill out. . .”</td>
</tr>
<tr>
<td>Lack of trended data</td>
<td><em>Q. If you wanted to know how many patients had delirium last month on your unit, how would you find that out?</em>  &quot;That’s a very good question. I don’t know if I could tell you that.”</td>
</tr>
<tr>
<td></td>
<td>“If I were just to go into the CPRS, I would have to go back and look at every patient.”</td>
</tr>
</tbody>
</table>

Theme 3 “Process Variability” in measurement, information exchange and documentation processes.

The methods for assessing mental status and the timing at which the assessments occurred were viewed as being a matter of nurses' individual clinical judgment. Mental status information is also communicated in at least 4 ways: (1) in written form as part of the her formal clinical note templates or narrative, (2) verbally (handoffs, phone calls, rounds, hallway conversations) and (3) in electronic forms outside of the EHR (e.g. spreadsheets), and (4) on paper (e.g. Nurse’s paper “brains” which are thrown away after the shift is over). Guidelines for when, where and how to communicate are not standardized and are largely left up to nursing judgment. Nurses sometimes call physicians and then document the phone call in a note with the title "physician notification" or in an “addendum” to another note.

Timing of nursing documentation is often disjunctive with changes in the delirious patient’s condition. Nursing documentation may occur once in 4 hours, once per shift, or mental status may not be documented regularly at all. The assumption is that if a patient’s mental status changed the information would be communicated verbally. Thus, verbal communication often serves as the mode for sharing mental status information.

</tbody>
</table>
doctor and the doctor comes in and the patient is fine.”
“They are free to call at any time they have a concern.” “We can go to the doctor any time and tell him that he’s really agitated or anxious or confused…”
“I’ve got a physician group that are currently not receptive as much as I would like for them to be to have a collaborative relationship with the nursing group”

Documentation processes vary, are non-systematic and often unstructured.
“there’s not one unified place for multiple disciplines to document on the plan of care... they can be in multiple places, but they’re all within CPRS”
“There’s no way through CPRS as far as I know at this point in terms...to extract that data.”
“If they have specific things that they have to do regarding that patient, they document it in their individual disciplinary notes”

Assumption that delirium will be discussed
“We’ll talk about discharge, which would talk about their delirium if they were confused, that placement.”
We wouldn’t necessarily bring up a diagnosis of delirium, but we would say maybe the patient is confused or whatever and they require a sitter. That’s about as much as would be discussed

Assessment and documentation depend on nursing judgment: no systematic way to collect data.
We don’t have any nurse-driven, you know, protocols or anything like that to identify someone that’s at risk for delirium, but it’s certainly something that the nursing staff looks out for.”
“It’s up to the nurse to write about it.”

Mental status information is not monitored
“But as far as acute mental status changes, it’s not something that’s routinely reported at the facility level.”
“as far as tracking that, I couldn’t even promise that. I wouldn’t know how to say in the last month how many people had it.”

**Theme 4. Context is Critical:** The meaning of mental status information is derived from context, clinical expectations and baseline comparisons.
The interpretation of mental status information requires fully knowing the patient’s condition. Patients at risk are rarely formally identified. Few participants reported protocols for instituting systematic monitoring or nursing interventions for patients at risk (with the exception of ETOH withdrawal protocols). The concept of identifying patients at risk was even difficult to explain to interviewees. Red flags reported by nurses that required enhanced action included a sudden change in mental status (from a normal baseline), a fall, or a behavioral difficulty. Resistance to “diagnosing” delirium was frequent.

<th>Theme 5: Goal Conflict - Tension exists between patient safety requirements, diagnostic dilemmas, nurse’s staffing levels, accountability and cost. These tensions impact information use.</th>
</tr>
</thead>
<tbody>
<tr>
<td>The response to a finding of delirium is largely increased monitoring (with the resultant increased demand for nursing resources) with the goal of maintaining patient safety. Identifying the cause is often secondary and “confusion” may often be viewed as a permanent state like dementia. When physicians are called, it is often regarding a perceived safety threat or behavioral problem, so patients who are confused but less active are not brought to the physician’s attention. Staffing decisions are often based on verbal descriptions of behavior rather than perceptions of risk. The question addressed is often restricted to whether a higher acuity floor is needed or more nurses. The prevalence of the problem and the importance of keeping patients safe creates a significant burden and most units use sitters and other high-cost options.</td>

Discussion

In this study we conducted interviews of Nurse Managers of inpatient medical units to explore how information about patients’ mental status is recorded, transferred, communicated and shared. Our focus was on policy and normative processes, as we did not observe practice patterns. We found that information processes for mental status data lack consistency, specificity, and meaning. Our most important findings suggest significant variation across settings. In addition, data collection and recording is often disjunctive with the timeframe to act (e.g. notes are written every shift but patients status may change much more rapidly than this), thus leaving critical information to be communicated verbally. This results in increased cognitive load for nurses because notifying physicians requires deliberation. Finally, much of the text about delirium is embedded in narrative note descriptions and did not support systematic processes for tracking patients with delirium at a unit or institutional level for the purposes of stewardship. These results will be discussed below in terms of communication theory, implications for development of cognitive support for nurses and nursing workload.

Problem with Vague Reference and its effects on Communication and Coordination

Managing acute mental status changes require coordination among the clinicians involved in the patient’s care. Achieving that coordination depends on effective communication. Theorists have noted that effective
communication requires a clear reference to the subject or *Definite Reference*. Failure to have definite reference results in a loss of shared focus among a team and a demand for increased effort to interpret and understand data. Because humans are “cognitive misers,” vague references to mental status may rarely get the attention required to disambiguate. In other words, if nurses and physicians refer to mental status using vague terminology (e.g., wacky) and indefinite specification (e.g., timing of onset, specific descriptors), then people fill in the information gaps with their own automatic and potentially inaccurate expectations.

The clinical context of delirium makes more precise communication particularly important. Physicians and others need to be able to correctly interpret the meaning of a nurses’ notation of abnormal mental status in the patient record. Similarly, nurses need to know about the patient’s risk for delirium, possible attributions of cause, and the degree to which managing delirium should be considered in relation to the goals of care in order to organization their assessments. Other research supports our findings that communication about mental status appears to be imprecise, relying on orientation ratings taken once per shift and using verbal and other informal modes and implicit protocols. Finally, the evidence that physicians rarely read nurses’ notes limits the impact of physicians’ therapeutic decision making due to the inadequate mental status information that nurses currently document.

The illusion of effective communication has been well studied. Individuals overestimate the effectiveness of their communication and have difficulty inferring the goals or the meaning of other’s discourse or writing. This phenomenon was found in medical handoffs as well as typical human interaction. Individuals may be especially prone to misunderstandings when they are exchanging information that is not clearly specified. Errors in communication also occur when people are under a high cognitive load, which is commonplace in clinical care settings. Although only suggestive, our findings regarding the variability and imprecision in documentation and communication processes may be contributing factors to the lack of quality of care for patients with delirium.

**Cognitive Support from EHRs**

Our results support a conclusion that current EHRs fail to provide the level of support for shared situation awareness of the patient’s mental status needed for healthcare teams to appropriately identify and treat delirium. Herbert Clark’s communication theory is very relevant in several areas. Establishing *definite reference* or precision regarding how mental status is referenced is probably the most obvious application. It is simply not easy in the distributed clinical setting to fully understand and grasp vague mental status references measured differently by many individuals and inconsistent rules for communication. Mental status terms often are without reference to context and the diversity in goals are assumed. An example is the prevalence of nurses only measuring orientation, when other metrics or descriptors might be more informative. In addition, nurses may need decision support in order to provide explicit communication to physicians, that would include baseline, additional measures and some information to support a shared understanding. about possible causes if they know them when they communicate without feeling like they are unduly responsible. Technology could really assist this process by pulling text references to mental status as in a “heat map” and include mental notation beyond delirium to better exclude dementia as a default and to express other important attributes, such as depression and anxiety, in the shared display. Time course is very important to diagnosis and so the display should have a time course.

One design feature that may improve communication is shared information displays, which offer an “at a glance” view of data from multiple sources, allowing viewers to develop shared situational awareness. Currently in healthcare the most prevalent form of shared information display is the unit’s whiteboard. Xiao et al. found that whiteboard uses include: team attention management (e.g. drawing attention to salient patient factors), communication, problem-solving/negotiation and staff assignment. Research on electronic whiteboards in operating suites and emergency departments has shown that they can facilitate improvements in both administrative and workflow efficiencies as well as team performance.

**Nursing Workload**

The lack of specificity in language and documentation for mental status data has direct implications for the daily planning and organization of nursing staffing. Confusion, wandering, and behavioral outbreaks present significant risk for the patient and increased workload for nurses. Interviewees in this study often expressed concern over how the patient’s mental status impacted staffing and assignment decisions. Nurses need precise and measurable information about mental status in order to inform decisions at the shift and institution level. The tension between costs and staffing requirements may lead to heavier workloads on nurses raising the issue of safety of patient care.
Limitations

This study has several limitations. First, although data was collected from 18 care facilities across the U.S., they were all within only one health care delivery system (the VA). The distribution of respondents mitigates some concerns, but all respondents were working in one information system and under similar nurse staffing organizational systems. In addition, our conclusions are tentative because we did not observe the flow of information directly. Our conclusions are based on results from Nurse Manager interviews; as a result, there is some degree of social desirability bias as well as simple inaccuracies.

Conclusions

Documentation and communication processes for mental status information appear to be variable, informal and imprecise. Interpretation of mental status data for nurses’ clinical decision-making requires information on context standardization and precision in references to altered mental status, and integration of information with goals of care. The ability to provide stewardship decisions may require better data capture, decision support tools, and also better communication processes.

Abstract
Clinical quality measures (CQMs) are important tools for the assessment and improvement of health care quality. Federal requirements initially set forth in the American Recovery and Reinvestment Act, and advanced in subsequent stages of the requirements, codified electronic health record (EHR)-based CQM reporting, and have made automated CQM implementation a priority amongst the clinical and informatics communities. Nevertheless, the processes surrounding CQM implementation and validation remain complex, time-consuming, and largely undefined. We collected issue-tracking data during the course of an agile and rigorous collaborative project to build an analytics platform for the Knight Cardiovascular Institute at OHSU, with nine heart failure CQMs defined by the American College of Cardiology (ACC) as an exemplar. Using a mixed methods approach we provide an overview of our CQM implementation and validation process, identify major roadblocks and bottlenecks, and make recommendations for other professionals working in the area of health care quality assessment and improvement.

Introduction
Health care quality is commonly understood to derive from a combination of structures, processes, and outcomes in the clinical setting.1 Measurement of these factors is enabled through the use of clinical quality measures (CQMs), which are used to calculate the proportion of relevant cases (usually patients or visits) that meet the target criteria. CQMs are an essential component of the quality improvement process. The passage of the American Recovery and Reinvestment Act in 2009 introduced the Health Information Technology for Economic and Clinical Health Act, which incentivized the adoption of electronic health record (EHR) systems meeting meaningful use requirements, including the ability to submit CQMs.2

CQM implementation exists on a continuum of automation. Some CQMs are only available in human-readable format, while others, called electronic CQMs (eCQMs), which are intended to be implemented electronically, are available in computer-readable format and are explicitly designed to interface with EHR data and systems. Human readable CQMs, including the measures discussed in this paper, require manual interpretation and mapping to the appropriate clinical concepts. They are not designed specifically for electronic data sources or information systems. It is possible, however, to manually translate human-readable CQM logic into computerized queries and map the clinical concepts to electronic data fields. This electronic implementation of human readable CQMs offers a number of advantages over manual calculation. After initial implementation, for example, calculation of EHR-based automated CQMs is less time- and resource-intensive. Also, automated CQMs can be calculated on an ongoing basis, allowing for ongoing monitoring of care provision and the detection of temporal trends.

Unfortunately, the electronic implementation of human-readable CQMs is non-trivial. The process of interpreting a CQM specification, mapping it to a data source, and demonstrating validity of the measure can be difficult and time-consuming. Few resources exist to guide this process. Moreover, it has been shown that the quality of clinical data underlying CQMs and eCQMs is often poor,3 making it difficult to differentiate between implementation problems and data quality problems at the validation stage. Studies of the implementation of computer-readable eCQMs, which should be more straightforward than electronic implementation of human-readable CQMs, have revealed significant difficulties and roadblocks. A study commissioned by the American Hospital Association (AHA), identified a number of challenges in eCQM implementation and calculation, included difficulty in using eCQM specifications, problems with existing eCQM tools, and issues surrounding the documentation of relevant clinical information in a format accessible by the eCQMs.4 Another study, which looked at five eCQMs from the National Quality Forum (NQF), found problems with the completeness, accuracy, and overall computability of the measures. The authors determined that implementing eCQMs required substantial expertise and manual development.5 It can be inferred that the implementation of human-readable CQMs is even more fraught with challenges.
Over the past year and a half we have used an agile, collaborative approach to implement a set of nine human-readable cardiovascular CQMs as electronic, EHR-based CQMs. By analyzing data from a customized issue tracking database, our intent is to uncover actionable information regarding the processes and workflows involved in this project. What categories of work took more or less time than expected? What were the bottlenecks? What recommendations would we make for planning a similar project going forward?

Methods

Setting

Since July 2014, the Informatics Discovery Laboratory (IDL), an agile, results-driven program within the Department of Medical Informatics and Clinical Epidemiology at Oregon Health & Science University (OHSU) has partnered with the Knight Cardiovascular Institute (KCVI) at OHSU in order to develop, evaluate, and maintain an analytics platform capturing information related to quality of care and health care delivery. The multidisciplinary IDL team included informaticians, a data architect, a developer, a project manager, a data analyst, and research assistants, dedicating to the project a combined total of 2.35 full-time equivalents in the first fiscal year, and 2.81 full-time equivalents in the second fiscal year. The pilot project of this collaboration, which was completed in February 2016, focused on the implementation of nine heart failure CQMs, according to the specifications of the American College of Cardiology (ACC). The nine measures are summarized in Table 1.

Table 1. Summary of ACC heart failure CQMs. *LVEF: Left Ventricular Ejection Fraction; **ACE: Angiotensin-converting-enzyme inhibitor; ARB: Angiotensin Receptor Blocker; +ICD: Implantable Cardioverter Defibrillator

The analytics platform was built upon an existing health information technology platform, the Integrated Care Coordination Information System (ICCIS), which includes a robust CQM calculation and reporting engine. ICCIS was developed to support Care Management Plus, a care coordination, quality improvement, and information technology model developed for use by primary care clinics.

Design and Data Collection and Management

Early in the process of implementing and evaluating the ACC measures, the IDL recognized the need for an issue tracking and change management system, leading to the development of a specialized Microsoft SharePoint site. This site allowed collaborators on the project to open, modify, assign, update, and close tasks, decisions, requests, and issues. Each task could be categorized as belonging to a specific measure, or belonging to all the heart failure measures. Following the completion of the heart failure CQM project, we extracted the following fields from the SharePoint site: task name, subproject (measure), date opened, last date modified, and status (open, closed, or noted). Once a task was opened it was not closed until it was completed, even if the work was temporarily put on hold. It must therefore be emphasized that task durations were more representative of how long it took to complete a task than how much time was actually spent working on a task. It should also be noted that many of the tasks overlapped significantly, and had complex interdependencies.

The dataset underwent a number of cleaning steps. First, we eliminated decisions and future issues, keeping only those item types that required time during the study period to complete. Second, we limited the dataset to
completed items. Third, we combined ACC measures 6 and 7 (beta-blocker and ACE/ARB therapy, respectively), since the two measures are intended to be paired and much of the work on them was performed in parallel. Fourth, due to missing tasks and completion dates related to project management, we removed all project management issues from the dataset. Finally, some work had to be done to identify the completion dates of several items that had unintentionally been left open on the SharePoint site. Missing completion dates were located by searching project emails and metadata from files and ICCIS.

Analysis

We used a general inductive approach to derive and apply category labels based on the issue tracking data. Three of the investigators used an iterative, open coding approach to create a set of exhaustive and mutually exclusive categories to capture the different types of work involved in the development and evaluation of the measures. The final category for each task was determined through consensus. For each task we calculated the number of days from date opened to final date modified to estimate the amount of time required for completion. We referred to this metric as task-days, in order to emphasize the possibility of concurrent rather than purely sequential work. Overall task-days were summed across measures and across task categories. The duration of the work for each measure was also calculated. Basic summary statistics were calculated for each category both within and across each of the measures. Gantt charts were used to visualize the temporal relationships between tasks.

Table 2. We derived eight categories of work necessary for implementing, validating, and utilizing EHR-based CQMs. The categories are listed from top to bottom in roughly expected order of occurrence.

Results

We derived seven categories of tasks from the issue tracking database, which included a total of 116 tasks in the final dataset, as summarized in Table 2. The total number of tasks per category ranged from six (informing and updating stakeholders) to 45 (system development and debugging). The time required per task varied greatly; the mean was 54.5 days, with a standard deviation of 112.9 days. The shortest tasks, on average, were related to informing and updating stakeholders, and the longest were related to synthesis and analysis. The issue tracking database also included 15 tasks related to project management, which were not recorded at the measure-level.

The complete, end-to-end implementation, validation, and reporting of each of the ACC measures required, on average, 459.9 task-days, lasted an average of 265.8 calendar days, and had an average of 8.4 tasks. The overall distribution of tasks and durations by category and measure are shown in Figure 1. The number of recorded tasks for each measure ranged from three (the symptom assessment, symptom management, and patient education measures) to 21 (the paired medication measures). The work on the paired medication also took the greatest number of task-days total to complete (955). The patient education measure (measure 5) took the fewest task-days (54). Complete measure-level summary statistics are presented in Table 3.

Table 3. A summary of the work conducted for each measure. “All measures” in this case denotes tasks that were assigned to all measures, not a combination of tasks related to individual measures.

Figure 2 shows the overall workflow of the project, broken down by task category and measure. This highlights the nonlinear nature of the approach, with several measures requiring the development team to step back to a previous area. For instance, measure 1, outpatient LVEF assessment, required several repeated efforts in system development and debugging in order to identify the correct patients and the correct visits within the ICCIS system. Measure 9, post-discharge appointment scheduling, required extensive data exploration to locate and extract follow-up appointment information, which caused delays in measure development and debugging.

Discussion

We completed the implementation of nine clinical quality measures related to cardiovascular care from standard EHR data; this task took, on average, 459.9 task-days of effort and 8.4 separate tasks per measure. We highlight the work categories, the iterative nature of the process, and challenges below.

Derived work categories and process

Our work focused on the electronic implementation of traditional (human readable) CQMs, rather than computable eCQMs, but it is still informative to compare our process to published work on eCQM implementation. The AHA, for example, proposes an iterative eCQM implementation process involving five major steps. That process includes: “gap analysis,” which can be mapped to Data exploration; “data extraction and eCQM calculation,” which is related to System and Measure development and debugging; “validation;” and “downstream uses of eCQM results,” which is largely undefined but could be said to include synthesis and analysis and informing and updating stakeholders. The AHA framework also includes “data capture and workflow redesign” within the implementation and validation iteration, which we see as a future step in our process. Therefore, despite the fact that eCQMs are meant to be more straightforward to implement than non-computable CQMs like the ACC measures, the only category of work we captured in the issue-tracking data that is not included in the AHA framework is the actual...
interpretation of each measure. Similar frameworks, such as that from the Office of the National Coordinator (ONC) for HIT, also have the organizational structure required highlighted, which was particularly important in our process.

**Figure 1.** Number of tasks and time spent on tasks in each category, by measure. Tasks assigned to all measures are not included here.

The most significant difference between our derived process and those described by the AHA and ONC is the inclusion of a step focused on workflow and documentation changes and improvements, which was outside the scope of the work we have completed to date. Our work, however, has informed an ongoing project focused on improving documentation in order to improve adherence to clinical guidelines and the accuracy of the ACC heart failure CQMs. As informaticians, we found we could accomplish a great deal prior to this necessary set of steps; now, other collaborators can move forward with workflow and documentation changes after current data quality and extraction have been optimized.

**Nonlinearity of implementation process**

Initially, we had anticipated that the CQM implementation and validation process would be largely sequential, with certain areas of iteration around system development and debugging and measure development and debugging. Because we were building on the existing, robust ICCIS system, we expected that there would be minimal system development and debugging, and that what we did find would be concentrated near the beginning of the project. We expected that each measure would follow a reasonably predictable progression, starting with interpretation of the measure specifications, and ending with efforts to inform and update stakeholders. The inpatient LVEF measure (measure 2), as visualized in Figure 2, roughly follows this linear process. Some of the other measures, however, including outpatient LVEF assessment, ICD implantation counseling, and follow-up appointment scheduling (measures 1, 8, and 9, respectively) followed a less structured, more iterative path, requiring extended work related to system development and debugging and data exploration. Tasks that applied to all measures were similarly nonlinear. The difference between the expected process and the observed process is visualized conceptually in Figure 3. At any stage of the process it was possible to discover an issue that required returning to any of the preceding stages. Measure debugging, validation, or synthesis and analysis, for example, might uncover system errors, like problems with data flow or population selection. System development and debugging, in turn, might reveal that a data element was being used differently than originally anticipated, which would require further data exploration to find a better element, or even interpretation, to select a similar concept that might be documented more consistently. In general there were frequent returns to system development and debugging, in order to customize the ICCIS system to the requirements of the KCVI project.

**Example roadblocks and challenges**

EHR data are often fragmented and unstructured, which makes it difficult to map concepts from CQMs to elements within the EHR, as well as incomplete or otherwise unreliable, which necessitates more complex

Figure 3. Expected process, which is mostly linear with specific instances of iteration at the development and debugging stages, and observed process, which may include substantial iteration.

measure logic. The ACC heart failure measure specifications refer to CPT Category II codes that capture specific clinical problems and actions necessary for the computation of these measures. Our institution, however, does not utilize these codes, which means that we instead had to identify, extract, and map other sources of this information. As shown in Figure 2, the paired medication measures (measures 6 and 7), which quantify clinician performance on the prescription of evidence-based beta-blockers and ACE/ARB for patients with a history of decreased systolic function, required substantial iterative work related to measure development and debugging and validation, largely because of EHR documentation limitations. After beginning to implement the measures based on medication data, we learned that clinicians documented medication adherence and medication exceptions in two other structured fields, depending upon setting. These fields, however, were not always used consistently, were unreliable, and were sometimes out of date; some patients who were labeled as having exceptions were in fact on the appropriate medications. To account for this data quality problem we needed to develop and evaluate significantly more complex logic.

Another unexpectedly complex problem involved the identification of relevant patients and the attribution of those patients to the appropriate providers for group- and provider-level performance calculation and reporting. Many of the system development and debugging tasks captured in the outpatient and inpatient LVEF measures (measures 1 and 2) and under all measures related to this work. In implementing the LVEF measures we initially had to develop system rules and processes for the identification and extraction of relevant patients and their data, which were different for the outpatient and inpatient populations. In a series of tasks related to all measures we also addressed how these patients were, in turn, “assigned” to providers for performance calculation. There are numerous models of attribution in CQM systems.15, 16 Two common approaches are to attribute patients to primary care providers or the most recent care provider. These approaches, however, may not be appropriate in settings where care is delivered by teams or in settings where providers frequently see referral patients. Instead, we used a multiple attribution rule, where all providers who saw a patient during the measurement period received “credit.” Implementing this rule, even within a robust CQM system like ICCIS, involved substantial technical effort.

A substantial amount of synthesis and analysis was performed through the course of iterative efforts to develop visualizations and reports that provided the KCVI stakeholders with the type and granularity of information they needed, as captured in the Figure 2 workflow for all measures. Many different versions of the reports were
developed, tested, and reworked before arriving at a final product that was information-dense, comprehensible, and actionable.

Overall, in the course of implementing and validating the nine ACC heart failure measures we identified a number of significant roadblocks, often involving complexities of EHR documentation and patient identification and performance attribution. We also discovered that CQM implementation is an unavoidably iterative process, with seven distinct stages of work.

Limitations

The issues-tracking data described in this paper were a byproduct of an operational, real-world, agile process, and were therefore not collected with the same care as traditional research data. Therefore, there was a certain degree of inconsistency in how and when the issues were opened and closed. Moreover, many tasks were left open for an extended period while no actual work was being done, usually because of task interdependencies or because other tasks were taking priority. Both of these factors could impact the calculated task durations. Other tasks, especially those that were straightforward or could be completed rapidly, were not tracked at all. Many of the simpler measures, therefore, had incomplete tracking data. We expect, therefore, that our final dataset suffered from some degree of inaccuracy and incompleteness.

One specific problem resulting from incomplete tracking data was limited tracking of tasks related to project management. The CQM implementation efforts required significant administrative and organizational efforts that were not reflected in our data. Examples of such tasks include training, recruitment, infrastructure and tool development, communication, and project planning. The work done in this area was significant and vital for the execution of the overall project, and future research should be done to fully understand the role of project management in successful analytics development and implementation.

It is also important to note limitations in generalizability of our findings due to setting and clinical focus. Data elements relating to heart failure, including relevant assessments and patient care steps, are unique and may therefore present challenges that would not be seen in all clinical areas or subspecialties. We also faced unique challenges in implementing these measures for a cardiovascular institute providing both inpatient and outpatient services within an academic tertiary care medical center. Nevertheless, we believe that our findings and be extendable and informative for other CQM implementers in diverse settings.

Conclusion

Through a mixed methods analysis of issue-tracking data, we derived a set of seven categories of work relating to the end-to-end implementation and evaluation of valid and reliable automated EHR-based CQMs. These align well and expand on prior work in this area. We encountered a number of expected and unexpected challenges during this work, which were captured by these data. These challenges derived largely from EHR documentation limitations, and from back-end and calculation-related challenges, and new features needed to support data analytics. We also encountered substantial iteration, which was, in some cases, not only unavoidable, but also a vital feature of a complex development and knowledge discovery process. In other cases, this iteration could have been avoided through an exhaustive exploration of user needs and documentation practices at the start of the CQM implementation project.

Abstract

Words which have different representations but are semantically related, such as dementia and delirium, can pose difficult issues in understanding text. We explore the use of interaction frequency data between semantic elements as a means to differentiate concept pairs, using semantic predications extracted from the biomedical literature. We applied datasets of features drawn from semantic predications for semantically related pairs to two Expectation Maximization clustering processes (without, and with concept labels), then used all data to train and evaluate several concept classifying algorithms. For the unlabeled datasets, 80% displayed expected cluster count and similar or matching proportions; all labeled data exhibited similar or matching proportions when restricting cluster count to unique labels. The highest performing classifier achieved 89% accuracy, with F1 scores for individual concept classification ranging from 0.69 to 1. We conclude with a discussion on how these findings may be applied to natural language processing of clinical text.

Introduction

Word Sense Disambiguation (WSD), a common task in Natural Language Processing (NLP), is the process of determining the precise meaning of an ambiguous word for a given instance in text. For example, the word “cold” in biomedical text can refer either to rhinovirus (e.g., “the common cold affects many people”) or cold temperature (e.g., “the patient felt cold in the room”). In this task, we have a single representation “cold” that can possess one of multiple, distinct definitions, depending on the use of the word. WSD is usually achieved through analyzing the context in which the word appears1. Recent popular biomedical WSD applications include disambiguation of terms2, 3 plus abbreviations and acronyms4.

Another difficult but similar task to WSD is to differentiate two terms that have different representations, but similar meanings. For example, dementia and delirium are similar in manifestation, but they are separate, independent conditions. Delirium or Acute Changes in Mental Status is defined as a fluctuating disturbance of cognition (memory, language, orientation) and/or consciousness with reduced ability to focus, sustain, or shift attention5. Delirium may impact 14–56% of all hospitalized elderly patients6, 7, and is associated with poor outcomes, including: increased length of stay, increased likelihood of falls and accidents and discharge to a nursing home. Delirium causes diagnostic dilemmas for physicians often trying to discriminate delirium from dementia in elderly patients, and due to the need for increased monitoring, is often a significant burden on nursing staff8. They are different clinical events and this poses important implications in treatment and other aspects of case management. However, there are inconsistencies in even provider representations. Researchers found that clinicians inconsistently document delirium in veteran electronic health records, even when there is a confirmed diagnosis9. Additionally, they use alternative terms such as “disoriented”, “muttering”, and “showing confusion” in documenting delirium10. Inconsistent documentation in general causes clinical care team members to expend extra effort to validate data11. Prolonged delirium in care settings poses significant risks of cognitive impairment and death12. Therefore, it is vital to identify and treat it quickly. However it is often not recognized, or misdiagnosed as dementia or another psychiatric condition13. Dementia recognition is likewise important, yet early-onset dementia is often misdiagnosed, which can have devastating consequences on patients and their families14.

Data that capture how semantic elements interact in text may help explicate the differences between two separate terms that have similar meanings. This may be especially useful in distinguishing incidents of dementia or delirium in text. This study explores the application of such data to clustering and classifying exercises, as an initial effort to explore the use of it to differentiate two related terms and other NLP tasks.
Background

Semantic predications provide a representation of biomedical text that has been distilled to simple assertions, consisting of the semantic elements expressed in the original text. SemRep\textsuperscript{15}, an NLP application, extracts semantic predications from PubMed title and abstract text. For example, SemRep takes the following text:

“…calcium channel blockers…reduce the risk of dementia…”\textsuperscript{16}

and extracts this semantic predication:

Calcium Channel Blockers (Pharmaceutical Substance) PREVENTS Dementia (Disease or Syndrome)

SemRep identifies the two prominent arguments in the text and their preferred terms from the UMLS Metathesaurus (C0006684 Calcium Channel Blockers and C0497327 Dementia), and the predicate, or relationship that binds them (PREVENTS) as indicated in the UMLS Semantic Network. SemRep also identifies the semantic types, or subject classes of the two arguments, indicated in parentheses. To better define this semantic predication topologically, one could refer to Calcium Channel Blockers as the opposite argument to Dementia, and visa-versa.

There is a resource that provides semantic predications for research and other purposes. The Semantic MEDLINE database\textsuperscript{17} contains over 84 million semantic predications extracted by SemRep from the biomedical literature from 1900 to 2015.

These data structures may shed light for differentiating delirium and dementia; however, a basic analysis demonstrates substantial contextual similarities between the two terms. Semantic predications containing either term share many co-occurring elements. Delirium, the smaller in terms of total unique semantic elements with which it occurs, shares all of its predicates, 54% of its opposite arguments, and 98% of its opposite argument’s semantic types with Dementia, in semantic predications containing both terms extracted from literature published from 2005 - 2014.

An analytical method such as clustering may provide differentiation between delirium and dementia as they appear in semantic predications. Expectation Maximum (EM) clustering\textsuperscript{18} was designed to identify latent, or implicit variables from mixture models of shared probability density functions. Concept data drawn from the Semantic MEDLINE database can be characterized as representing a mixture model, where each concept belongs to subpopulations in which it interacts with other semantic elements. To activate instances of the EM algorithm, one must prescribe an amount of clusters presumed to be representative of the data. Algorithms such as Bayesian Information Criterion (BIC) determine an optimal cluster count which then enables the EM clustering process.

Frequency data and its membership in mixture models has previously been exploited in classification\textsuperscript{19}. EM Clustering has previously been applied in a semantic clustering context\textsuperscript{20}, including efforts for building sense inventories for abbreviations in clinical notes\textsuperscript{21}. This work applies EM Clustering and other machine learning techniques to data extracted from the Semantic Medline database.

Objectives

The purpose of this work is to determine if (a) interactive rate data follow a clustering behavior expectant of data drawn from a mixture model, and (b) this data could successfully be used to classify concept sense. Applying interaction values, i.e., representations of how each concept interacts with other semantic elements, to a clustering method, might potentially identify clusters of expected proportions. These values might also be used to train an effective classifier to identify instances of several concepts. Specifically, we wanted to answer the questions:

- Do unlabeled datasets of semantically related concept pairs exhibit two distinct clusters of equal or similar proportions when subjected to BIC modeling and EM clustering?
- When labels are included, how do data instances cluster?
- Could a dataset for several concepts, where there is matching data for another semantically related concept for each concept in the dataset, be applied to training several different types of classifiers? If so, what classifier would perform best?

To explore these questions, we analyzed data from several semantically related concept pairs including delirium and dementia. We first subjected datasets of concept pairs to two clustering processes, the first without the concept labels, then the second with the labels restored. We then applied the data for all concepts to training and testing several classifier algorithms.
Methods

Data Procurrence and Preparation

We gathered the following features for each term for a ten-year period (2005-2014) from the Semantic MEDLINE database: frequency of the term appearing as an argument in the database, count of unique terms appearing in the opposite argument position, count of unique semantic types of the terms in the opposite argument position, count of unique predicates, count of unique semantic type-predicate combinations, and count of unique opposite argument-predicate combinations. We retrieved this data according to date of entry (EDAT) into the PubMed database. We aggregated it in one-month intervals to form vectors for these six features in order to provide many instances for the clustering and classifier training tasks. The following example is an instance of this data for Dementia. The features are concept label, concept occurrence frequency, unique opposite argument frequency, unique predicate frequency, unique semantic type frequency of the opposite argument, unique semantic type-predicate combinations, and unique opposite argument-predicate combinations:

Dementia, 160, 39, 12, 19, 29, 45

In other words, for this given month, there were 160 instances of the concept “Dementia”, 39 unique concepts appearing with it in the opposite argument position, 12 unique predicates, 19 unique semantic types represented among the opposite argument concepts, 29 unique semantic type-predicate combinations, and 45 unique opposite argument-predicate combinations. We gathered this data for the following concept pairs (Table 1):

Table 1. Concept Pairs

The additional pairs were rated as significantly semantically related by three clinicians in a former study. All but one concept yielded 120 instances. Abortion (C0156543) yielded 116 instances, or, in other words, there were insufficient data for four months of the 10-year collection period to produce data for this study. We did not use any imputation methods to create data for the four missing instances in this dataset.

After retrieving the data, we normalized the values of each quantitative feature for each concept by scaling on a mean of 0 and a standard deviation of 1. For each concept dataset, each quantitative feature was represented in a single vector, forming a total of six vectors with 120 values each, for each dataset, except for the Abortion dataset, where there were six vectors with 116 values each. The corresponding concept label formed an additional feature vector in each dataset; these labels were excluded for the first clustering exercise (described in the following section). For classifier training, we also randomized the instances and split the dataset into a training subset (80%) and a testing subset (20%).

Clustering Analysis

We applied a model-based clustering approach suggested by Fraley using the MCLUST software package in R. This technique implemented BIC in combination with EM Clustering and hierarchal agglomeration to find and execute the best model (including cluster count and characteristics) for a given dataset. This is done under the premise that the data in question is drawn from a mixture of multiple probability distributions. In addition to cluster count, output also includes cluster characteristics such as volume, shape, and orientation, according to the best model. We also documented the covariance matrix model implemented in determining the best BIC model (and cluster count). We analyzed each dataset for each concept pair, removing the concept labels from the instances before processing.

The software also included functionality to cluster labeled data for cluster classification by applying Eigenvalue Decomposition Discriminant Analysis. We applied this process to the concept pair data while including concept class labels. This exercise allowed us to view how the concept pair data instances divided into categories when matched against possible classifications.
Classifier Training

Using the data for all 12 concepts, we trained several types of classifiers, specifically a Support Vector Machine, a Random Forest (i.e., tree structure), a Neural Network, and a Naïve Bayes classifier, because these are identified as commonly used in the related task of WSD\textsuperscript{26}. We employed the following R packages for the four classifier types, to create basic versions of their resulting products:

- Support Vector Machine: libSVM (in the e1071 package)\textsuperscript{27}
- Random Forest: randomForest\textsuperscript{28}
- Neural Network: nnet\textsuperscript{29}
- Naïve Bayes: e1071\textsuperscript{27}

This was a simple, exploratory exercise, to analyze the results from a variety of classifiers. In addition to the training data, we added the following parameters to each classifier instance:

- SVM: A cost value of 100; Gamma value of 1.
- Random Forest: Importance of predictors assessed; 2000 trees produced.
- Neural Network: Five neurons in a single hidden layer; initial weight value of 0.1; weight decay of 0.00005; 200 maximum iterations.
- Naïve Bayes: (all application default settings implemented)

Otherwise, the basic default parameters provided by each application were used.

Results

Clustering Analysis

Of the six concept pairs, all but one exhibited two clusters of similar or equal proportions, in terms of data elements (Table 2) when clustering data without their concept labels. There were three covariance models, and individual cluster characteristics identified for all datasets. All clusters were ellipsoidal, but some otherwise exhibited variation.

Abortion-Miscarriage  CHF-Pulmonary Edema  Delusion-Schizophrenia

Dementia-Delirium  Heart-Myocardium  Stroke-Infarct

Figure 1. Cluster plots of concept instances and predicates

For the five pairs exhibiting 2 clusters, the cluster ratios match or closely follow the 50 / 50 ratio of data instances (i.e., 120 instances for each concept) with little overlap where the ratio deviates from an evenly divided split. The best model for the dataset for Abortion and Miscarriage contained five clusters of varying proportions.

When we restored the labels to the data, and subjected it to an additional predictive process implementing Eigenvalue Decomposition Discriminant Analysis\(^3\^\) where each known class is modeled with the same covariance for each class, the results changed. The same covariance models resulting from the unlabeled clustering exercise were applied. The purpose of this was to observe which labels were associated with which cluster in each pair, when matched against possible classifications, although other outcomes from this modified process are also of interest. Abortion and Miscarriage are now represented by two clusters (because there are two classes represented in the data), and there is slightly reduced overlap for two of the concept pairs (see Figure 2).
While providing a basic, popular package for neural networks, nnet does not support multiple hidden layers. Experimentation revealed that five neurons in the single hidden layer produced the best results. Other limited experimentations enabled us to do some basic tuning to the other types of classifiers using the parameters already noted.

Each classifier yielded different composite accuracy scores, measured by the percentage of classifications in the testing data correctly predicted (Table 3). All but the Naïve Bayes classifier’s accuracy exceeded 80%.

Table 4. Precision (P), recall (R), and F1 scores from classifier performance for individual concepts.

Discussion

This exercise demonstrates that people communicate differently about similar topics, even if (as in the case of Dementia and Delirium) that communication may share a substantial portion of contextual semantic elements. That difference can be found in analyzing data that captures how semantic elements interact.

In the first clustering exercise, 80% of the clustered concept pair datasets gave an affirmative answer to the study’s first question “Do unlabeled datasets of semantically related concept pairs exhibit two distinct clusters of equal or similar proportions when subjected to BIC modeling and EM clustering?”. Five of the six pairs identified two distinct clusters of proportions matching or similar to the count of instances for each concept. The cluster not exhibiting this behavior contained data for the Abortion-Miscarriage data. As mentioned earlier, the abortion data contained 116 instances, (as compared to 120 instances for all other concepts). The effect of this on the results is unknown, although the difference in the instance counts is quite small. When restricted to two clusters (there being two classes), modeling with the same covariance matrix, the Abortion-Miscarriage data behaved similarly to the other pairs.

Overall, the classifier training and testing exercise provided an affirmative answer to the question “Could a dataset for several concepts, where there is matching data for another semantically related concept for each concept in the dataset, be applied to training several different types of classifiers?”. Training multiple types of classifiers provides potential expectation of results for similar exercises using this type of data. The Support Vector Machine yielded the best overall accuracy. With the exception of Pulmonary Edema, F1 scores produced by the SVM for concept classification match or exceed those of the other types of classifiers, including delirium (0.82) and dementia (0.95). The Naïve Bayes classifier provided the overall lowest accuracy and F1 scores.

We compared these results to those of a similar task, WSD, where the researchers applied a new Expectation Maximization-based algorithm to determine the exact sense of the term “cold”\(^3\). Their top-performing model achieved 0.89 accuracy, which was comparable to the SVM we trained and most of the other state-of-the-art systems described in their work (the highest achieved being 0.93 by a Naïve Bayes application). In our similar task, we differentiated the sense of several terms, with the SVM, achieving F1 scores ranging from 0.69 to 1, with an average score of 0.89.
Implications in Future Work

Understanding differences in how individuals communicate about dementia and delirium may shed further light on distinguishing the two terms in text. To understand the results further, we reviewed instances of feature data for the 10 years, and found there is more variety in the predicate-opposite argument combinations in delirium as compared to dementia. Combinations that individually occur less than ten times comprise 37.7% of the delirium data, as compared to 18% for dementia. This means that, in the biomedical literature, authors communicate about delirium in more ways than dementia in terms of predicates and individual argument combinations. For predicate-semantic type combinations, there was much less variation, whereas combinations occurring less than ten times accounted for 1.4% and 4.5% of dementia’s and delirium’s data, respectively, suggesting that authors are more likely to communicate in more established predicate-semantic type patterns. These type of communication differences likely affected data behavior in the clustering and classifying exercises.

The data were drawn from the biomedical literature. Would similar data from clinical text yield the same results? There have been efforts to extract relational data from clinical text\textsuperscript{31, 32}. A proficient software application that extracts semantic predications from text may assist in answering this question. We are currently developing an application that extracts semantic predications from clinical text. Data with definitive instances of events such as delirium and dementia could be used to extract the initial semantic predications, to build a database of these data structures drawn from clinical text. This could be accomplished by using clinical text with a high certainty of such events.

A variation of sense differentiation in clinical text could address content where the author is uncertain of the event that is taking place, or if the resulting clinical text suggests this. For example, if a clinical note implied uncertainty regarding whether a patient had dementia or delirium, perhaps it could be determined by the way the author recorded it. Semantic predications extracted from clinical text where there is a high certainty of the events as recorded (as noted before) could be used to train an SVM classifier that in turn could be used to analyze data drawn from clinical text exhibiting less certainty. For the semantic predications extracted from the latter text, labels addressing the concepts of interest would have a generic indication, such as “Condition X”. For example, instances of dementia and delirium, where certainty of either is small, could be relabeled in this manner. Such work could reinforce an extended viewpoint on how word sense is identified, by taking into consideration the certainty with which a diagnosis or other assertion is recorded. It could complement and possibly incorporate research addressing the subjective properties of assertions in text\textsuperscript{33}.

A specific application could assess an author’s certainty in documenting diagnoses and other narratives addressing biomedical phenomena. For example, an application could alert a clinician discussing a diagnosis of Disease X that he or she is communicating about it in a manner consistent with Disease Y. This could be especially useful for diagnostically problematic conditions such as delirium. Application performance could be determined by processing relevant text, and interviewing the author to assess certainty in the recorded phenomenon.

In this study, we used semantic interaction rate data drawn from semantic predications to explicate the different senses of several semantically related pairs. There may be other NLP clinical text applications for which this type of data may be useful. It could drive temporal information retrieval\textsuperscript{34} by identifying documents with a high concentration of a given concept and frequent interactions with other semantic elements within a timeframe of interest. It could also be implemented in semi-supervised learning tasks, requiring temporal concept data, such as certain approaches to coreference resolution\textsuperscript{35}.

Limitations

The classifier exercise utilized a dataset limited to 12 concepts. However, it was intended to be an exploratory exercise implementing data of semantically related concepts, which was accomplished with this dataset.

This is an elementary exploration of analyzing interactions among semantic elements in text. We used a simple form of frequency data to capture semantic element interaction characteristics. It included temporal counts, but not other artifacts, such as, the most common predicate (e.g., PREVENTS) or opposite argument (e.g., calcium channel blocker), or other element for the given time period. Different expressions of semantic element interaction data may provide deeper insight to this phenomenon in text.

Factoring in SemRep’s performance in accurately identifying semantic relationships in the original text is outside of the scope of this paper, but would be an interesting subject for a future study addressing that topic.
Acknowledgements

We wish to thank Guy Divita for his contributions to this paper. This work was funded by the U.S. Department of Veterans Affairs, Health Services Research & Development (HSR&D), Project ID: CRE 12-321. This work was also supported in part by the intramural research program at the U.S. National Library of Medicine, National Institutes of Health.

Conclusion

We applied interaction rate data extracted from semantic predications to clustering and classification exercises to determine if this data displayed expected clustering behavior, and could be used to classify concept instances where there were instances of several semantically related concept pairs in the dataset. Clustering of unlabeled data demonstrated two clusters of equal or similar proportions for five of the six concept pairs. When labels were included, all concept pairs demonstrated two clusters of equal or similar proportions. Four different classifiers were trained and tested. Accuracy for all classifiers ranged from 0.72 to 0.89, with a Support Vector Machine achieving the highest results. The outcomes for all these exercises pose interesting questions and potential applications in sense differentiation and other NLP tasks.

Learning Clinical Workflows to Identify Subgroups of Heart Failure Patients

Chao Yan, MS1, You Chen, PhD1, Bo Li, PhD1, David Liebovitz, MD2, Bradley Malin, PhD1
1Vanderbilt University, Nashville, TN; 2University of Chicago, Chicago, IL

Abstract
Heart Failure (HF) is one of the most common indications for readmission to the hospital among elderly patients. This is due to the progressive nature of the disease, as well as its association with complex comorbidities (e.g., anemia, chronic kidney disease, chronic obstructive pulmonary disease, hyper- and hypothyroidism), which contribute to increased morbidity and mortality, as well as a reduced quality of life. Healthcare organizations (HCOs) have established diverse treatment plans for HF patients, but such routines are not always formalized and may, in fact, arise organically as a patient’s management evolves over time. This investigation was motivated by the hypothesis that patients associated with a certain subgroup of HF should follow a similar workflow that, once made explicit, could be leveraged by an HCO to more effectively allocate resources and manage HF patients. Thus, in this paper, we introduce a method to identify subgroups of HF through a similarity analysis of event sequences documented in the clinical setting. Specifically, we 1) structure event sequences for HF patients based on the patterns of electronic medical record (EMR) system utilization, 2) identify subgroups of HF patients by applying a k-means clustering algorithm on utilization patterns, 3) learn clinical workflows for each subgroup, and 4) label each subgroup with diagnosis and procedure codes that are distinguishing in the set of all subgroups. To demonstrate its potential, we applied our method to EMR event logs for 785 HF inpatient stays over a 4 month period at a large academic medical center. Our method identified 8 subgroups of HF, each of which was found to associate with a canonical workflow inferred through an inductive mining algorithm. Each subgroup was further confirmed to be affiliated with specific comorbidities, such as hyperthyroidism and hypothyroidism.

Introduction
Heart failure (HF) is one of the most common indications for admission to the hospital among older adults. HF manifests in a clinically detectable manner when the heart is unable to supply an adequate flow of blood to meet the body’s needs. HF is an important contributor to both the burden and cost of national healthcare expenditures. Over five million people in the United States are estimated to exhibit HF to some degree and management of the disease costs the nation an estimated $32 billion annually. In 2001, the American Heart Association and American College of Cardiology refined the HF phenotype into four gross stages, which has led to the development and deployment of a wide array of management options for HF treatments. Yet, management of the disease is complicated by the fact that it often associates with a diverse collection of comorbidities (e.g., anemia, type 2 diabetes, various infections, and thyroid problems), which can manifest in different manners and combinations across the evolving stages of the disease. As a consequence, HF is also one of the conditions leading to high readmission rates in hospitals. Healthcare organizations (HCOs) have established treatment protocols and workflows for HF patients with different comorbidities and stages of progression. Additionally, to improve the definition and management of HF, various investigations have been conducted to computationally specify the phenotype and workflows affiliated with its management.

Traditionally, research has aimed to refine HF into several clinical subphenotypes based on heart-related issues, such as systolic or diastolic heart failure. These are natural subtypes that HCOs can rely upon to design specialized treatment plans or clinical workflows. While such research, and subsequent clinical designations, can assist HCOs to more effectively manage HF patients, they often rely on an expert informed perspective and experience. As a consequence, they involve a substantial amount of human effort and focus on clinical phenomena that are expected to categorize the HF population. To reduce human effort and learn clinical concepts (or management pathways) that are not necessarily anticipated, several studies have shown that data-informed methodologies can be invoked to infer complex comorbidities, clinical workflows, and care teams. Many of these studies rely on the co-accesses to patients’ electronic medical records (EMRs) to infer collaborative care teams or workflows for specific diseases, however, such studies have focused on all possible diseases and the workings of an HCO in general. In doing so, they have neglected how such views are influenced by conditioning the investigation on a specific complex disease, such as HF.

The investigation communicated in this paper is motivated by the expectation that complex diseases, like HF, are associated with a range of workflows in an HCO. These workflows are unlikely to be explicitly documented because
they are associated with subtypes of the disease and/or comorbidities that lead to *ad hoc* coordination. If such workflows can be detected through a data-informed method, they may be refined and resourced by an HCO to more effectively manage patients of a certain HF subtype.

Thus, in this paper we study four-months of EMR data, collected in 2010, from Northwestern Memorial Hospital for over 750 HF inpatient episodes. We introduce a data-informed framework to infer the underlying workflows that transpire in the clinical enterprise. We then map the learned workflows into a similarity measure to characterize patients into different subgroups. Finally, we show that these subgroups have a strong correlation with a range of diagnoses (e.g., hyper- and hypothyroidism) and procedures. Specially, our investigation suggests there are a minimum of 8 subgroups of HF patients, each of which is associated with a canonical workflow. It should be recognized from the outset that a subgroup does not indicate that they are a distinct population in their phenotype per se, but that they are a subgroup in the manner by which they are managed.

**Background**

This paper introduces a framework to identify subgroups of HF via inferred clinical workflows. Since this work involves workflow subgroup identification via inference methods, we take a moment to review related work in 1) workflow modeling and 2) subgroup discovery. When possible, we show how these methods have specifically been applied to HF populations.

**Workflow Modeling**

Workflow modeling and analysis has shown promise in a wide array of settings, ranging from general business management to specific clinical domain domains. For instance, van der Aalst and colleagues demonstrated how high-level Petri nets can model the workflows in an office environment, with a particular focus on how information systems support the control of office work\(^\text{17}\). They developed a workflow management system (WMS) prototype based on such formalizations. They subsequently extended the notion of a WMS to support dynamic changes\(^\text{18}\). Workflow modeling from a clinical perspective is more complex than many office settings because HCOs are composed of a large number of interacting departments and individuals who coordinate as availability and need dictates.

Still, there has been some success in this domain. In particular, Chen and colleagues introduced a method to infer clinical workflows and measure their efficiency via the utilization of EMR event logs. It was shown that these workflows naturally partition into four general types according to their average and variance in their efficiency\(^\text{11}\). They posited that certain inefficiencies were likely due to the complexity of the patients. While the methods introduced in their investigation enabled the evaluation of workflow efficiency, it did not condition the workflows on specific patient phenotypes or determine if subgroups for the management of a specific disorder led to the manifestation of disparate workflows. EMR access logs were also used by Li and colleagues to infer workflows through a method based on hidden Markov models (HMMs)\(^\text{19}\). These HMMs were utilized to characterize the behavior of EMR users, as well as detect anomalous activities. However, this investigation did not study the clinical meaning of the workflow or how they could be specialized to certain patient subgroups.

**Subgroup Identification**

There is evidence to suggest that identifying subgroups of patients based on their clinical conditions can be applied to design personalized treatment plans. For instance, Mugge and colleagues identified a subgroup of patients with nonrheumatic atrial fibrillation (Afib) with an increased risk for cardiogenic embolism by assessing left atrial appendage function\(^\text{20}\). They identified two distinct patient groups according to appendage flow patterns: 1) well-defined peak filling with visible fibrillatory contractions of the appendage wall and 2) irregular, very low, peak filling with almost no visible appendage contractions. While such subgroup identification is notable from a descriptive perspective, it focuses on clinical diagnosis and, thus, neglects how to design management routines for Afib patients in a healthcare environment that is subject to communication challenges and resource limitations. Soulakis and colleagues\(^\text{16}\) utilized the EMR access logs of over 500 HF patients to identify seven networks of around 5000 care providers. However, this work is limited in that it neglects the association between the network of care providers and the clinical conditions of the patients.

**Methods**

We designed a data-informed framework to identify HF subgroups to consist of three steps: 1) infer patient subgroups through event sequences, 2) learn a workflow for each subgroup and 3) assign diagnosis and procedure codes as phenotype labels for each subgroup. To gain intuition into how this framework works, we begin with an introduction of the dataset used in this investigation.
**Dataset**

The dataset for this study is summarized in Table 1. The records are drawn from comprehensive access logs and billing information derived from the EMR system at Northwestern Memorial Hospital (NMH) over a four month period during 2010. This dataset, which we refer to as NMH-D, consists of 1,138,555 access events distributed over 16,567 unique inpatient stays. We extracted all patients diagnosed with heart failure by selecting any patient with an ICD-9 code in the range 428.0 through 428.9 and we refer to this specific HF extract as the NMH-HF dataset. Each access event is affiliated with the following attributes: 1) pseudonym of the inpatient, 2) ID of the EMR user, 3) reason for the access event (as designated by the user according to a pull-down list), 4) date and timestamp for the access, 5) general physical location in NMH where the patient is located, and 6) the clinical service on which the patient is managed (e.g., general medicine vs. obstetrics). Each inpatient episode is affiliated with its ICD-9 billing codes, which were assigned after discharge.

Table 1. A summary of the datasets in this study.

We use the *Reason for Access* in the dataset, as opposed to the EMR user, as the smallest level of granularity associated with a workflow to mitigate noise in the analysis. Specifically, for each inpatient *i*, the corresponding event sequence *R* defined in Table 2 is a series of ordered reasons for access. To orient the reader, the following is an example of a sequence of reasons one might encounter for a certain inpatient:

... → Attending Physician/Provider → Primary Staff Nurse → Resident-Inpatient Primary Service → Pharmacist → ...

In this work, we define an *n*-block as a sequence of *n* consecutive access events (with *n* ≥ 2). Thus, a 2-block is defined as two consecutive access events. For instance, if an access event *Attending Physician/Provider* has a consecutive access event *Primary Staff Nurse*, then *Attending Physician/Provider* → *Primary Staff Nurse* is the corresponding 2-block. In fact, 2-blocks reflect the order relations between two neighbor events. If 2-blocks appear infrequently in event sequences, then the order relation between its containing two events are weak, which could be utilized by our framework to filter weak order relations, most of which are noise in EMR system functionality.

**Subgroups Identification Framework**

The framework is composed of three main components: 1) generate patient subgroups via refined event sequences, 2) learn workflows for the subgroup population, and 3) extract diagnosis and procedure labels for subgroups. Here,
refined event sequences are the transformation of original event sequences through applying filtering based on frequency. To help the reader understand our framework, we provide a legend of the common notation invoked throughout this paper. The specific algorithmic process associated with the framework is communicated in Figure 2.

1) Generate Patient Subgroups by Refined Access Sequences

The subgroup identification process is partitioned into five steps: 1) filter high frequency reasons contained in each event sequence in $D$ into $D_i$, 2) generate 2-blocks in $D_i$ and create a set $D_{(2\_block)}$, 3) filter low frequency 2-blocks in $D_{(2\_block)}$ into $D'_{(2\_block)}$, 4) use 2-blocks in $D'_{(2\_block)}$ to refine sequences in $D_i$ to form a new sequence set $D'$ and 5) clustering subgroup patients by using similarity of block elements in refined sequences in $D'$. Each of these steps is detailed in the following descriptions:

Filter high frequency reasons. Each raw event sequence in $D$ can contain high frequency event reasons. We remove high frequency reasons because they correspond to the most general aspects of the workflow. These are unlikely to communicate clinical context that is critical to modeling a specific workflow. For example, both Primary Staff Nurse and Primary Assistive Staff appear the greatest number of times in event sequences. While it is anticipated that nurses provide support to patient care, they are critical to almost all aspects of the inpatient setting. In many respects, general nursing staff is akin to the stop words (e.g., prepositions or articles) in natural language text. And, as many investigations in natural language processing have illustrated, such information, can be triaged to improve pattern discovery. The new event sequence set $D_i$ is generated by filtering the high frequent reasons.

Generate 2-blocks and filter low frequency (or noise). These two steps are incorporated because the event sequences are extracted from the access logs of EMR system, which contain noise in the order of relations. We assume that noisy relations exist in low frequency blocks and, thus, filter weak relations from the event sequences $D_i$.

To do so, each event sequence in $D_i$ is segmented into blocks by invoking the 2-blocks in $D'_{(2\_block)}$. Thus, each event sequence is represented by varying sized blocks. With this transformation and linkage, $D_i$ is transformed into $D'$. Thus, $D'$ is the set of sequences where high frequent reasons and low frequent 2-blocks are both removed. The
processing details are described from lines 6 through 17 in the algorithm in Figure 2. For example, after the process above, a patient in our dataset has a new sequence formed by two blocks $b_1 \rightarrow b_2$, where $b_1$ is a reason sequence:

```
Resident - Outpatient/ED/Proc Primary \rightarrow Patient Care \rightarrow Radiology Technologist \rightarrow Registration
```

and $b_2$ is

\[
\text{Rehab Assigned Therapist} \rightarrow \text{Consultant} \rightarrow \text{Rehab Assigned Therapist} \rightarrow \text{Charging/Orders} \rightarrow \text{Med Rec Coding}
\]

$D'$ is represented by linkage of new blocks and we extract all of the blocks in $D'$ into $D'(n\_block)$. At this point, we filter out low frequent blocks in $D'(n\_block)$ to generate a new set $D'(n\_block)$.

Next, we cluster patients into subgroups using their associated blocks in $D'(n\_block)$. To do so, we generate a patient-by-block matrix $M_{PB}$ to represent relations between patients and blocks. We then apply a polynomial kernel on $M_{PB}$ to transform it to a new matrix $M_{PB}'$ and perform $k$-means clustering.\(^1\)

---

**Input:** $D$, a set of event sequences; $m_r$, the number of filtered lowest frequency 2-blocks; $m_b$, the number of filtered lowest frequency blocks; $m_b$, the number of filtered lowest frequency blocks; $m_g$, the number of filtered highest frequency blocks; $m_r$, the number of filtered highest frequency blocks;

**Output:** $C = \{C_1, C_2, \ldots, C_s\}$, subgroups of patients

```
1: Let $\phi = \{(\varphi_i, f_i)\}$ ← (reason ID, frequency) tuple set from $D$
2: $D_r \leftarrow D \setminus (\text{top } m_r \text{ reasons with high frequency in } \phi)$
3: $D'(2\_block) = \{(\varphi_i, f_i)\}$ ← 2-block set from $D_r$
4: Let $B(2\_block) = \{(\varphi_i, f_i)\}$ ← (2-block, frequency) tuple set from $D_r$
5: $D'(2\_block) \leftarrow D'(2\_block) \setminus (\text{top } m_b \text{ 2-blocks with low frequency in } B(2\_block))$

\[
\text{Output: } \phi = \{(\varphi_i, f_i)\} \leftarrow \text{reason ID, frequency) tuple set from } D
\]

\[
\text{Return: } C = \{C_1, C_2, \ldots, C_s\}, \text{ subgroups of patients}
\]

---

**Figure 2.** Pseudocode of the cluster generation algorithm.

2) **Learn workflows for each subgroup**

Each subgroup is clustered using blocks in $D'(n\_block)$. Each event sequence (a patient episode) is characterized by these blocks. We group all blocks characterizing a subgroup into a workflow to represent the clinical process for this type of HF patient. We then invoke an inductive mining algorithm (as implemented in ProM\(^{22}\)) to infer and visualize workflows.

3) **Extract Diagnosis and Procedure Labels**

---

\(^1\) Applying the kernel makes it easier to separate groups by projecting the data into a higher set of dimensions.
Care must be taken when learning workflows through a data-informed strategy, as they may not have labels that readily translate into administrative applications. This is important because the clinical workflows that are based on expert knowledge are associated with known semantics. Thus, we aim to relate inferred workflows to clinical context. To do so, we assign labels to each subgroup’s workflow by discovering the billing codes that are the most discriminative for the workflow.

The labels for each workflow are derived from a series of processes. First, we extract the most frequent diagnosis and procedure codes from all inpatients in each subgroup. Next, we apply a Z-test (hypothesis testing method based on proportionality) to compute the p-value for each diagnosis and procedure codes in each subgroup\(^23\). For each subgroup \(C_a\), the most distinguishable billing codes between pairs of subgroups \((C_a, C_x)\), \(x\neq a\), are extracted. Finally, we union these the distinguishable codes to characterize each subgroup and their affiliated workflows.

**Table 3. A summary of the number of patients and representative conditions for the HF subgroups.**

Results
This section reports on results from 1) a general view of the 10 identified distinct subgroups and 2) a case study of two representative subgroups - in terms of their affiliated workflows and the diagnosis and procedure codes that distinguish the subgroup from others.

HF Subgroups Identified
By applying the framework to the 785 CHF inpatient episodes, we discovered 10 distinct subgroups as summarized in Table 3. For reference purposes, we use $C_i$ to represent subgroup $i$. In this table, each subgroup is labeled using descriptions of the representative diagnosis and procedure billing codes. For instance, $C_1$ is a subgroup affiliated with general heart failure, $C_7$ is affiliated with allergies associated with HF, and $C_8$ is affiliated with hypothyroidism. We note that we neglect subgroups $C_7$ and $C_8$ because of their small size (only 5 and 6 patients, respectively). The representative billing codes come from two sources: 1) distinct codes between this subgroup and any other subgroup, and 2) high frequency codes associated with this subgroup.

Table 3 also reports the size and clinical label of each subgroup. It can be seen that each subgroup has a distinct specialized phenotype. For instance, $C_1$, the largest subgroup, is affiliated with the diagnosis of HF, which indicates that most of the patients went through a process associated with management of general comorbidities (e.g., hypertension, primary cardiomyopathies, and coronary atherosclerosis). $C_{10}$, the second largest subgroup, is affiliated with chronic kidney disease (CKD).

Case Study of Hyperthyroidism and Hypothyroidism in HF
To understand the intuitive nature of the identified subgroups, we report on a case study that compares two subgroups. Specifically, we focus on subgroups $C_6$ and $C_9$, which are similar in the number of patients they cover (58 and 34, respectively) and correspond to two typical HF subtypes. We illustrate the differences in these subgroups in terms of their clinical concepts and inferred workflows.

Clinical Differences. Figure 3 shows the concordance of the frequency distribution for the most significant codes (based on their p-values) affiliated with the $C_6$ and $C_9$ subgroups. Specifically, each ($x,y$) point corresponds to a specific code, where $x$ and $y$ is the proportion of patients in $C_6$ and $C_9$ who received the code, respectively. As such, codes that are close to the dashed diagonal line indicates they have a similar frequency in the two investigated subgroups. Clearly, these codes do not distinguish between the subgroups. By contrast, codes that are distant from the line can distinguish one subgroup from the other. In this figure, we marked diagnosis codes with a star and procedure codes as a circle.

We found that the patients in cluster $C_6$, were primarily diagnosed with i) hyperpotassemia, ii) disorders of phosphorus metabolism, iii) acute kidney failure, unspecified, and iv) thrombocytopenia. This combination of diagnoses makes sense intuitively. This is because excess potassium and phosphorus caused by hyperthyroidism are both associated with kidney failure\textsuperscript{21}. Based on knowledge of these symptoms, it can be inferred that this subgroup suffers from Hyperthyroidism HF.

By contrast, the 34 patients in cluster $C_9$ have the following diagnosis labels: i) unspecified acquired hypothyroidism, ii) osteoporosis, and iii) unspecified essential hypertension. Osteoporosis is obviously associated with hypothyroidism because of a decreasing amount of calcium. And thus, we label $C_9$ with Hypothyroidism HF.

These HF subgroups demonstrate that differences in the inferred learned workflows may be associated with the clinical status, as well as procedures performed on the patients.

Workflows Differences. Though subgroup $C_6$ covers a larger number of patients than $C_9$, we find that it exhibits a simpler workflow structure (as shown in Figure 4). To illustrate, we first compare the main reasons of these two workflows. Subgroup $C_6$ contains: i) Other Physician, ii) Covering Therapist, iii) Coordinator, and iv) Advanced Practice Nurse as the main reasons (and corresponding roles), which appear to be affiliated with a generic healthcare process. By contrast, the workflow for $C_9$ has a more complicated structure, in which there is a greater diversity in the reasons. Specifically, this structure includes i) Student Nurse, ii) Consultant, iii) Patient Care, iv) Assigned Staff, v) Advanced Practice Nurse, vi) Coordinator, vii) Anesthesiologist, viii) Dietary Clerk, ix) Radiologist, and x) Rehab Assigned Therapist.

Moreover, this workflow contains some special reasons, such as xi) Radiology Nurse/Resident/Technologist and xii) Radiology management, which are likely linked with the diagnosis of osteoporosis induced by hypothyroidism. This case study suggests that our initial hypothesis – that HF subtypes associate with different workflows and management
processes – has standing. Moreover, we believe this case study is a clear illustration of how data-informed workflow mining can be leveraged to learn different subgroups of patients that can be subsequently labeled in a clinically meaningful manner.

Figure 3. Concordance in the frequency of the diagnosis and procedural billing codes between HF subgroups C_6 and C_9.

Figure 4. A simplified view on the workflow structure of subgroups (a) C_6 and (b) C_9.
Discussion

We introduced a method to identify subgroups of HF through refined event sequences and subsequently infer workflow and phenotype for every subgroup. This approach is substantially different from the traditional definition of phenotypes rooted solely on metabolic and clinical observations. The subgroups identified in our framework share similar workflow patterns, suggesting they are managed in a similar way in clinical practice. To the best of our knowledge, this is the first investigation to show that subgroups of a complex disorder, such as HF, can be learned through workflows (in the form of event sequences) in the clinical enterprise. Our findings are further notable because they suggest that workflows stretching across departments and wards of an HCO can be learned from EMR utilization. We believe this methodology provides opportunities to make management strategies explicit and tune resource allocations accordingly. At the same time, we believe the learned workflows have standing because they were shown to correlate with diagnoses and procedures codes exhibited in the corresponding patient groups (information that was not used in the clustering process). As such, it may be possible to develop predictive models that assign a patient to a predefined and semi-personalized management regimen.

Despite our discoveries, we acknowledge that this is a pilot study on an HF population. There are several limitations of this project, which we wish to highlight for further refinement and future investigation. First, we relied on ICD-9 codes in the 428.* range, rather than rigorously validated computational phenotypes of HF to define our cohort. Though the HF phenotype is considered a relatively well-defined diagnosis, it is a disease with multiple stages and confounding factors (as our hyperthyroidism and hypothyroidism subgroups illustrated). It is further conceivable that some of the patients who presented to Northwestern Memorial Hospital for a certain primary diagnosis (e.g., stroke) might have been treated for HF without its documentation in an ICD-9 billing code. As such, we believe that our selection criteria enable a highly precise investigation, but does not cover the gamut of HF patients.

Second, the workflows associated with the HF subgroups were only reviewed by one clinician. Rather, we mainly relied on identifying subgroups of HF in an information theoretic sense (e.g., similarity analysis of sequences of access reasons). Our method identified 10 subgroups and it appeared as though 8 had a clear clinical context differentiating from other subgroups (while 2 were too underpowered due to a small number of patients to make any judgement about). Still, before inferred workflows can be relied upon, they will require review by additional administrative and clinical experts to determine if they can be translated into decision support tools for an HCO.

Finally, we recognize that the size of the HF cohort is relatively small. During the four months of documented inpatient stays, we encountered less than a thousand patients treated for HF. Although our work yielded meaningful findings, we may not have captured all of the notable workflows or diagnostic labels for such workflows. For such an investigation to be useful for the HCO, we will need to investigate a large sample size over a longer period of time. It would also be ideal to compare the workflows, and the associated labels, with EMR data from other healthcare systems.

Conclusions

HF is a complex condition accompanied by diverse complications that progress across, a minimum of, four stages. HCOs have adopted various strategies (e.g., optional treatment plans for different developmental stages and complications) to improve quality of life for HF patients and reduce burden, as well as cost, for healthcare systems. Identifying subgroups of HF can assist in the management of patients with this disease. We introduced a data-informed framework to identify subgroups of HF patients through utilization of the EMR. For each subgroup, we provided external validation via the diagnosis and procedure codes of the corresponding patients. Our framework was evaluated on the event sequences of 785 HF inpatients from a large academic medical center. In doing so, we identified 8 HF subgroups, each of which was confirmed to be associated with a specific condition of HF (e.g., hyperthyroidism and hypothyroidism). Furthermore, each subgroup was characterized by different patterns of workflow. For instance, hyperthyroidism associated HF involved more complex workflows than hyperthyroidism HF. We acknowledge that this investigation is a pilot study and further investigation is required with administrative review and validation across disparate healthcare enterprises.

Breach Risk Magnitude: A Quantitative Measure of Database Security

William A. Yasnoff, MD, PhD1,2
1NHII Advisors, Arlington, VA; 2Johns Hopkins University, Baltimore, MD

Abstract
A quantitative methodology is described that provides objective evaluation of the potential for health record system breaches. It assumes that breach risk increases with the number of potential records that could be exposed, while it decreases when more authentication steps are required for access. The breach risk magnitude (BRM) is the maximum value for any system user of the common logarithm of the number of accessible database records divided by the number of authentication steps needed to achieve such access. For a one million record relational database, the BRM varies from 5.52 to 6 depending on authentication protocols. For an alternative data architecture designed specifically to increase security by separately storing and encrypting each patient record, the BRM ranges from 1.3 to 2.6. While the BRM only provides a limited quantitative assessment of breach risk, it may be useful to objectively evaluate the security implications of alternative database organization approaches.

Introduction
Breaches involving unauthorized disclosure of substantial numbers of identified electronic medical records are occurring with increasing frequency. These events damage the trust of the public in health information systems, may seriously harm patients whose data is exposed, and are very costly to the organizations responsible for holding the data. As a result, preventing data breaches has become a very high priority in the design and implementation of clinical information systems.

This paper describes a quantitative assessment methodology to evaluate the impact of database architecture on the risk of security breaches. By applying this quantitative methodology, it is shown that alternative architectures can reduce these risks. This suggests that use of quantitative breach risk measures may be useful in guiding the design of more secure clinical information systems.

Need for Quantitative Breach Risk Assessment
Databases have traditionally organized information to facilitate rapid search and retrieval operations, while the security of the stored information has in general been a secondary consideration. Although it is relatively easy to measure and/or calculate the response time for database search operations, there are no existing quantitative measures that can assist information architects in evaluating the potential for security breaches when considering alternative possibilities for organizing and storing data.

There have been a number of prior efforts to develop security metrics. Zhang et al described a semi-quantitative approach for assessing enterprise security that attempts to model the behavior of potential attackers using the variables of intent, objective, and consequence as input to a Markov decision process. However, the specific parameters of the model are unknown and must be estimated in each case. Harel et al described a “misuseability weight” that evaluates the sensitivity level of exposed data. This sensitivity is used to calculate an “M-score” that incorporates both the quantity and quality of the information at risk, but does not include any assessment of the difficulty of obtaining access. Aissa et al defined a value-based cybersecurity measure that attempts to quantify the potential dollar losses of intrusions for specific stakeholders. Bhattacharjee et al proposed a more complex scheme for assessment of overall enterprise level information security risk that assigns a specific risk level to each enterprise information asset based on its “threat-vulnerability” pair, and suggests specific actions of decreasing stringency to ameliorate risks for high, medium, and low risk assets respectively. Finally, Aime et al described the risks of security metrics in general, noting that the use of such metrics does not replicate the performance of experts and therefore they must not be used in isolation. However, none of this prior work describes a metric that can provide specific, easily calculated results incorporating both the quantity and degree of difficulty of accessing information.

Consistent with prior recommendations to identify and establish measures that provide insight into potential risks, the breach risk magnitude measure was developed. Its fundamental assumption is that breach risk is related to the number of potential records that could be exposed by a specific sequence of authentication processes (typically passwords), while it is decreased when more such authentication steps are required for access. In other words, additional authentication steps make it less likely that an unauthorized access will occur. This is consistent with an
intuitive understanding of the incentives of a potential attacker: a target is more attractive when either fewer obstacles need to be overcome to gain access or more records can be obtained by circumventing those obstacles.

**Desiderata of Breach Risk Measure**

Before attempting to define any quantitative measure of a previously subjective characteristic, its desired properties should be considered and described. These properties, which represent the requirements that must be met, allow the characteristics of the resultant measure to be assessed to determine if the goals have been achieved. An alternative set of requirements might lead to a substantially different measurement approach.

To be useful, a breach risk measure should be:

1. Roughly proportional to our intuitive sense of the level of risk;
2. Higher when the level of risk increases and lower when it decreases;
3. Able to express a very wide range of risk levels;
4. Straightforward to calculate across a variety of systems; and
5. Easily understood and interpreted.

The first three properties represent accuracy, proportionality, and scalability respectively, while the last two relate to ease of use.

**Methods**

The development of the measure was guided by the intuitive notion that a system allowing access to a larger number of records with a smaller number of authentication steps is inherently more vulnerable to compromise. This is consistent with concepts of event likelihood and impact/severity described in the risk assessment guidelines from NIST\(^8\). In this case, the likelihood of an event is assumed to be inversely proportional to the number of authentication steps, while the impact/severity of an event relates to the number of records exposed.

Based on these ideas, the breach risk assessment is defined as the ratio of the number of records that are accessible divided by the number of authentication steps required to enable that access. The larger the value, the higher the risk. To accommodate a wide range of values, the breach risk magnitude (BRM) is expressed as the common logarithm of the breach risk assessment.

As an example, assume a system with one million records, all of which can be accessed by the system administrator with a single authentication step. In this case,

\[
\text{Number of accessible records} = 1,000,000 \\
\text{Number of authentication steps} = 1 \\
\text{Ratio of accessible records to authentication steps} = \frac{1,000,000}{1} = 1,000,000 \\
\text{Breach Risk Magnitude (BRM)} = \log_{10} (1,000,000) = 6
\]

By expressing the measure as a log value, much like the Richter scale for earthquake magnitude\(^9\), an extremely wide range of values can be communicated quickly and easily. For example, the above system with only 100,000 records would have a BRM of 5, while the same system with 10,000,000 records would have a BRM of 7. Thus, each increase of one in the BRM value represents 10 times the potential security vulnerability.

In a given system, there are typically several different classes of users that access records using different procedures. There may be individuals who only are permitted to access their own record, researchers who may access a large subset (or all) of the records, and a system administrator who typically has access to all the records. Recognizing that the security vulnerability of a system relates to its weakest link, the BRM value for a given system is calculated as the maximum value for any class of users with access to the stored records. In many such systems, the user class with the maximum BRM will be the system administrator.

Calculation of the BRM measure does not require access to operational database systems. The input parameters of number of records and number of authentication steps for each user are evident from the organization of a database implementation. For example, any user given the capability to search the entire database by definition has access to all the records.
Results of Breach Risk Magnitude (BRM) Application

The BRM measure was evaluated for several sample database system configurations, each with one million records. Table 1 shows the calculation for a standard relational database management system. Three types of users are allowed in this example: 1) individuals with access to only their own record; 2) searchers who may access all the records for search purposes; and 3) system administrators who may access all data for any purpose. The BRM value for this system is 6.

Table 2 shows the effect of requiring a second authentication step for searching or for the system administrator to access the records. While the risk ratio drops by 50%, the BRM measure only decreases to 5.7.

Table 3 shows the impact of separating the demographic data from the remainder of the data for each person’s record, a commonly proposed technique for increasing security. A separate password is required to access the demographic and non-demographic data. While the searcher users no longer have access to complete records, the system administrator can still access all the data, albeit with three passwords. Therefore, the BRM for this approach only decreases to 5.52.

Table 4 shows the results for a different data storage architecture known as the personal grid10. The personal grid is specifically designed to improve the security of personal information by storing each person’s data in a separate file with its own separate encryption. The encryption/decryption key for each file consists of two distinct and independent parts, one supplied by the user and the other by the system.

Since each record is separately encrypted and there is no inverted index of the records (like in a relational database), searching with the personal grid must be done sequentially one record at a time. To accelerate this prohibitively slow process, search operations are parallelized using cloud computing. When a search is needed, a large number of servers (e.g., between 500 and 10,000) are allocated temporarily (in a cloud computing environment) and each server simultaneously processes its share of the records. For example, with a database of 1,000,000 records, each search server would evaluate between 100 and 2,000 records (for 10,000 or 500 search processors respectively).

Finally, in the personal grid, no system administrator has access to any of the records in the database. System administrators only can access the system portion of the key for each record; the user portion is supplied by each user and is unavailable except when the user is logged in. Two separate system administrators are required to initiate a search operation, and no users (even system administrators) have access to any of the search servers when they are operating.

Since this architecture is designed to improve security, it is not surprising that its BRM value is between 1.3 and 2.6 depending on how many search servers are available for allocation. Note that this is several orders of magnitude lower than the 5.52 to 6.0 range for the prior examples of standard relational systems.

Discussion

A major security issue for health information systems is the potential for large-scale loss of data from a single unauthorized intrusion. These concerns have been reinforced by multiple, large-scale, widely reported examples of huge health data breaches, such as Anthem\(^\text{11}\) and Premera\(^\text{12}\). Such incidents have contributed to the widespread belief that central repositories of health records will not be trusted by consumers\(^\text{13}\). However, methods to objectively quantify this perceived risk have not been available.

In assessing the breach potential of database systems, it is generally understood that the risk is greater when the number of records available increases or the number of authentication steps needed to access records decreases. This observation is the basis for the BRM measure, which is designed to quantify this notion in an easily computable and understandable form. The BRM measure can also be viewed as an assessment of the “hacking reward/risk ratio” that provides a numerical representation of the number of records that will be accessible (the “reward”) for each authentication step (the “risk”). This is consistent with the observation that larger databases are more attractive targets for unauthorized access, and are more likely to be breached if there are fewer obstacles (i.e., authentication steps) needed for entry.

The results for the examples above show the usefulness of the BRM. For a standard relational database system, where a single authentication of a system administrator can provide access to the entire one million record database, the BRM value is 6. Adding an additional authentication step for data access only reduces the value to 5.7, while separating the demographic from non-demographic data results in a value of 5.52. This is consistent with the modest improvement in security provided by these alternative access arrangements.

However, when a substantially different architecture designed to improve security (the personal grid) is evaluated, the BRM measure drops dramatically to between 1.3 and 2.6 (depending on the number of search servers used). This shows clearly the security advantages of the personal grid, which separately stores and encrypts each patient’s record, thereby eliminating any path to access of the entire dataset in unencrypted form. This quantification of the security improvements for such an architecture could be very helpful to any organization considering its use.

Note that the security improvements of the personal grid result in longer search times and higher costs than an equivalent relational database. While retrieval of individual records (e.g., for clinical care) remains immediate, searching across 1 million records in a personal grid with 500 parallel processors is estimated to require about 80 seconds and cost $0.44\(^\text{10}\). For a fixed number of processors, both search times and costs will vary in direct proportion to the total number of records. However, the cost does not change with the number of processors since the overall CPU time required (which is the basis of the cost) is independent of how many search servers are allocated. Thus, personal grid search times may be reduced at no additional cost by utilizing the maximum number of parallel servers available.

In terms of the desiderata for such a measure described above, the BRM appears to meet all the criteria. It is consistent with the intuitive notion that risk is higher when more records can be exposed with fewer steps. Its quantitative nature inherently results in higher values when the risk is higher and vice versa. Since it is expressed as a logarithmic value, it can describe a very wide range of risks over many orders of magnitude. It is easy to calculate and does not depend on the specific characteristics of various system configurations. Finally, as has been shown by the examples described above, it is straightforward to interpret.

Limitations

The BRM measure for security assessment provides a specific, limited assessment of breach risk. It is not designed or intended to provide a comprehensive assessment of security risk, as it ignores several important factors that may contribute to security vulnerabilities including, but not limited to:
1. Strength of passwords/encryption. The BRM measure assumes that each authentication step functions as an effective barrier to system access and does not account for stronger or weaker passwords or encryption methods. It also does not consider the use of automatic account locking after multiple failed login attempts, or multi-factor authentication techniques. A possible variation on the BRM calculation would be to count each authentication factor separately, so two-factor authentication would be equivalent to two separate authentication steps.

2. Time factors. When data is distributed or stored inefficiently, it may take longer to retrieve. As a result, an attacker attempting to copy all the data may require an extended time period, making detection of the attack more likely. The BRM measure does not account for this possibility.

3. Other search risks. When data is distributed and must be fetched from other (outside) systems, the fetch process exposes the data to additional risks of interception or alteration. Such potential risks are not included in the BRM measure.

4. Personnel risk. Most data breaches involve some level of cooperation from insiders. The BRM measure does not assess the reliability of personnel, security training that may be provided, or the screening processes used for hiring.

5. Direct attack on unencrypted data. The BRM measure assumes that data are encrypted and cannot be accessed via an “out of channel” process that evades the normally required authentication procedures.

6. Number of users with maximum record access. In calculating the BRM, only categories of users are evaluated. The number of users having “maximum access” to records in a system is not considered. The BRM is based on the user category that provides the maximum access with the minimum number of authentication steps. Clearly, the larger the number of users in this “maximum access” category, the more likely it is that one such user’s credentials could be compromised.

7. Organizational, physical, and policy issues. The BRM measure does not include these potentially important factors.

In essence, the BRM measure only provides an estimate of the security risk of a specific data architecture and its associated access protocols. It will yield useful comparative results only if all other factors, including those described above, are held constant. Other methods should be used to assess security risk issues beyond the scope of the BRM measure.

Finally, in situations where the underlying database architecture of an application cannot be changed (e.g., when the database is a tightly integrated feature of a commercial EHR system), the BRM would only indicate the current level of risk, but would not be able to guide actions that can reduce that risk. In such cases, the BRM may be of limited value.

Conclusion

The breach risk magnitude (BRM) quantitatively measures the potential security vulnerability of databases. For a given system, it is calculated as the maximum value of the common logarithm of the number of accessible database records divided by the number of authentication steps needed to achieve such access. Estimating security risk for data organization and access arrangements and evaluation of the impact of alternatives can be facilitated using the BRM measure.

Abstract
A fundamental understanding of multitasking within nursing workflow is important in today’s dynamic and complex healthcare environment. We conducted a time motion study to understand nursing workflow, specifically multitasking and task switching activities. We used TimeCaT, a comprehensive electronic time capture tool, to capture observational data. We established inter-observer reliability prior to data collection. We completed 56 hours of observation of 10 registered nurses. We found, on average, nurses had 124 communications and 208 hands-on tasks per 4-hour block of time. They multitasked (having communication and hands-on tasks simultaneously) 131 times, representing 39.48% of all times; the total multitasking duration ranges from 14.6 minutes to 109 minutes, 44.98 minutes (18.63%) on average. We also reviewed workflow visualization to uncover the multitasking events. Our study design and methods provide a practical and reliable approach to conducting and analyzing time motion studies from both quantitative and qualitative perspectives.

Introduction
Nursing or clinical workflow describes a wide range of steps or activities that health personnel execute to accomplish an activity in patient care. A fundamental understanding of multitasking within the workflow of nurses is important in today’s dynamic and complex healthcare environment. Demands for healthcare and nursing care to become a more patient-centered, efficient, effective and cost effective process, while also producing high quality patient outcomes can result in work that is fragmented due to interruptions or multitasking. Kalish and Abersold (2010), identified nurse’s work as complex and error prone. Although nurses may manage interruptions or multitasking well, it is important to gain further understanding of nursing workflow in order to develop strategies to minimize errors and maximize processes that enhance patient safety. As techniques to measure nurses’ workflow are limited, we reviewed the definition of multitasking and time motion studies being conducted commonly to model clinical workflow.

Multitasking and task switching
Multitasking requires a conscious shift in attention over a short time span between different tasks. The definition of multitasking depends on context. Lay understanding of multitasking is the performance of two or more tasks simultaneously. Healthcare researchers often define multitasking in similar ways. The related concepts of concurrent multitasking, dual task performance, parallel task performance, interleaved multitasking, and sequential multitasking describe various aspects of the cognitive processes believed to be associated with multitasking. Because these concepts overlap and intertwine, below we reviewed the definition and established the scope for our observational study.

Walter (2015) investigated on the concept of multitasking and found that multitasking has been defined in various ways; it could be concurrent multitasking (or dual task), interleaved multitasking (also called task switching), or sequential multitasking. Functional MRIs showed evidence for multitasking and task switching and the use of computer models of stimulus response activity helped our understanding of cognitive processes in the laboratory setting. Cognitive process theorists proposed that multitasking may actually be rapid task switching. Recent work in neuroimaging, eye tracking and computer simulation demonstrated that multitasking could be considered as the rapid cognitive process of task switching. However, cognitive processes examination, using fMRI, eye tracking, or computer simulations are unobservable in the real world setting.

Task switching has also been described as a rudimentary function of cognitive control requiring the flexible ability to configure and reconfigure tasks to meet shifting internal and external demands and cues. Draheim (2016) define task switching as “the ability to allocate attentive resources to several tasks sequentially and fluently reallocate
attentive resources from one task to another.” Task switching involves the performance of two or more different tasks in a rapidly integrated process and depends on several factors including complexity of task as well as familiarity of task. The daily workflow of nurses requires the performance of various skills or activities, such as communication, education, medication administration, electronic and paper documentation, as well as frequent and rapid shifts between these activities. Doing more than one thing at a time is colloquially referred to as multitasking and has been defined as “simultaneous performance of two discrete tasks.” In our study, we were unable to observe the rapid cognitive processes associated with task switching in a naturalistic setting. Therefore, we operationalized our definition of multitasking as the observable performance of two or more tasks simultaneously, for example, talking to a patient and preparing medication. Conversely, we defined task switching as alternating or changing between two separate tasks, sometimes rapidly but observably. We limit our definitions to observable behavior, as opposed to cognitive processing.

Studies measuring multitasking and task switching

Time-Motion Studies, or Time and Motion Studies, have been successfully adopted as a working method to describe and assess clinical workflow in healthcare environments. The National Library of Medicine’s controlled vocabulary thesaurus defines a Time-Motion Study (TMS) as “the observation and analysis of movements in a task with an emphasis on the amount of time required to perform the task.” TMS consists of two major components: time and motion analysis. Motion analysis represents workflow, which is a sequence of “steps” or “tasks” for a process or an event; time analysis focuses on time duration of the tasks or the entire process. Time-motion studies have been commonly used to discover nursing staff work patterns, workflow efficiency and multitasking.

Measuring multitasking or task switching enables healthcare organizations to improve efficiencies, quality and safety, workflow, and clinician job satisfaction. Various methods have been used in the study of multitasking and task switching, including qualitative studies and observational studies using paper, pencil and stopwatches, post observational interviewing, observational studies using electronic data collection devices as well as mixed-methods studies using an excel spreadsheet for data collection during the observation phase.

Although several studies have been published that have similar aims of measuring multitasking and task switching in the clinical setting, each has a slightly different design with respective strengths and limitations. Using electronic methods, Westbrook (2007) developed a Personal Data Assistance (PDA) program, called Work Observation Method By Activity Timing (WOMBAT), that allowed observers to select and record behavior from a list of categories. These categories included: direct care, indirect care, medication tasks, documentation, professional communication, ward related activities, in transit, supervision, social or non-work communications, and other tasks outside of these categories. The PDA software allowed the observer to document both multitasking (adding tasks occurring at the same time) and interruption (pausing tasks that had been interrupted) occurrences. This method provided detailed results with a high level of accuracy secondary to time stamping and duration recording functions of the software. However, it lacked the ability to record a detailed picture of each task switching or multitasking event; rather, it simply allowed the observer to denote that an event falling into one of these two categories occurred (task switching or multitasking). Lack of a universal definition of “interruption” and the inability to reliably capture these interruptions, limited the trustworthiness of the data.

Bastian (2016) conducted a time motion study focused on determining workflow (task switching) patterns in the healthcare setting, which utilized Excel spreadsheets to record observed data. This method required observers to enter an activity ID into the Excel template. All other cells populate automatically with time stamp, duration, and full task ID name. Graphical visualizations include pie and bar charts generated from Excel for the percentages in terms of time spent on tasks in each task category. Although user friendly, this data collection method failed to identify the complex details associated with task switching. Also, because of the automatic timestamp (associated in a one-to-one manner with one task), task switching and multitasking failed to be captured, thus limiting the interpretability of nursing activities from the data.

Non-electronic methods of measuring multitasking and task switching have also been used, although considerably less reliable due to manual recording processes necessitating time away from the observation. For instance, traditional stopwatch and paper methods have been used to record multitasking and task switching of clinicians. In a time motion study conducted by Edwards (2009), observers shadowed clinicians for two to four hour periods using real time stopwatches and a paper/pencil observational tool system. Another study focused on the changes in communication tasks rather than patient care functions, in which written documentation and audio recordings were used to record
communication events. The audio recordings were used to accurately monitor interruptions and were later analyzed and transcribed. Although effective in recording communication, multitasking, and task switching activities, observers were responsible for both timing the duration of events and providing detailed written accounts. Observation accuracy was limited because of time necessary for paper-pencil documentation. Additionally, non-verbal communications failed to be captured. Lastly, Berg (2013) utilized interviews along with handwritten documentation of observations to obtain clinicians’ perspectives on their experiences with workflow interruptions. In this study, the observers - experienced nurses - documented six categories (type of activity, duration of the activity, location, persons, interruptions, whether the clinician was the recipient cause of the interruption, and continuation of activity after interruption), which were recorded in written form on a semi-structured template. While audio recordings and post-observation interviews may be useful adjunct methods to an electronic time-motion methods, handwritten documentation methods lack reliable because of the time required of the observer to record data rather than fully observing clinicians behavior.

In summary, studies using a time motion method to study clinical workflow were inconsistency in their approaches. Zheng (2011) proposed Suggested Time And Motion Procedures (STAMP) to standardize research for time motion studies. Following STAMP, we designed a time motion study to understand and visualize nursing workflow on multitasking and task switching activities. We used TimeCaT, a comprehensive electronic time capture tool to capture data for our time-motion study. TimeCaT is a web-based application, optimized for tablets and iPads developed by the Department of Biomedical Informatics at The Ohio State University. It is a fully customizable, web-based, time capture tool designed for time motion studies. TimeCaT can be used to evaluate multitasking, task switching, and inter-observer reliability, and can be used on any internet capable device. TimeCaT has also been optimized to support data capture using touch enabled devices. We loaded selected nursing activities on TimeCaT (Figure 1), trained student observers, and validated the data capture process using the inter-observer reliability module included in TimeCaT.

Our study was a pilot project for a larger study aiming to understand top of license nursing practice. The purpose of this pilot project was to establish the rigor of the time motion method. With the preliminary data, we were able to describe nursing workflow in three activity dimensions: communication, task, and location. Communication includes with whom nurses are interacting; hands-on tasks include tasks requiring nurses to physically touch to perform a task (i.e. start an IV); and location includes where nursing activities take place. We explored these three activity dimensions, across the continuum of time to understand the phenomena of multitasking and task switching in nursing practice.

Methods
Setting and Sample
After obtaining IRB approval, the study was conducted on a medical-surgical unit at The Ohio State University Wexner Medical Center (OSUWMC). The observations occurred in the general patient care areas including the nursing station, hallway, medication room, patient room, and supply areas. This was a pilot study in which we used a convenience sample of registered nurses. The nurses met the following inclusion criteria: (1) full-time staff Registered Nurses (RNs) working at OSUWMC with more than two years of acute care nursing work experience and (2) greater than or equal six months of work experience on the study unit. Informed consent was obtained for this observational study at the time of recruitment.

Observed nursing activities
We observed all nursing activities including anticipated nursing activities and activities which may be classified as non-value added. Anticipated activities include but are not limited to; hand-off (shift reporting), direct patient care
Inter-observer reliability assessment (IORA) participates as well as other unit personnel. This also helped introduce the study and study personnel to the nurse observations. All trial observations occurred in the study site which allowed student observers to be familiar with the inter-observer reliability assessment to ensure study fidelity and data validity prior to beginning actual research. Based on the Needleman-Wunsch sequence alignment algorithm from bioinformatics, the proposed method returns a normalized score that represents an overall sequence agreement. Table 2 presents three IORA training results from two observers. Their performance was improved over time. The IORA provided useful information for observers’

Student observers

In order to obtain quality observational data, we recruited three nursing student as our observers, including one nursing PhD student and two undergraduate senior nursing students. With their background and clinical experience, they were familiar with nursing workflow and were able to recognize and distinguish various nursing activities. All observers understood the study purpose, and were required to participate in research meetings in which of the nursing activities definitions were established. Observers were trained with trial observations for at least 12 hours, and three rounds of inter-observer reliability assessment to ensure study fidelity and data validity prior to beginning actual research observations. All trial observations occurred in the study site which allowed student observers to be familiar with the environment as well as the on-site observation. This also helped introduce the study and study personnel to the nurse participates as well as other unit personnel.

Inter-observer reliability assessment (IORA)

The establishment of IORA protocols and guidelines is the priority in validating a time motion study. We used the IORA provided in TimeCaT,35 a robust, comprehensive method for inter-observer reliability assessment.37 It considers four types of agreements on the workflow observation: 1) proportion-kappa (P-K): evaluates the naming agreement on virtually created one-second activity, based on the Kappa statistic. P-K provides a global assessment of the agreement over time; 2) naming-kappa (N-K): a systematic pairing approach based on time-overlap, and provides a Kappa statistic representing the agreement on activity naming; 3) duration-concordance correlation coefficient (DCCC): agreement on the duration of an activity. It is the concordance correlation coefficient and intends to provide a means to evaluate the correlation concerning activity duration; and 4) sequence-Needleman-Wunsch (S-NW): agreement of the sequence of activities. It is an assessment focusing specifically on the order of activities recorded. Based on the Needleman-Wunsch sequence alignment algorithm from bioinformatics, the proposed method returns a normalized score that represents an overall sequence agreement. Table 2 presents three IORA training results from two observers. Their performance was improved over time. The IORA provided useful information for observers’
training and a meaningful quantitative IORA report. In addition, we visualized clinical workflow by their sequence and duration, as presented in Figure 2. Each colored band represents an activity; the width of the band represents the duration of the activity. For example, EHR charting and EHR review are two activities which occurred more frequently and longer in duration than other activities. We were also able to compare the activities observed by Observer A against to the activities observed by Observer B. The side-by-side workflow visualization (Figure 2) in TimeCaT allowed us to offer immediate feedback to our observers after the training sessions.

Procedure

Student observers obtained informed consent from the observed nurse as well as permission from patients for observing their care. Each observation lasted for four hours over preset time periods: 7am to 11am, 11am to 3pm, or 3pm to 7pm, depending on availability arrangement. No identifiable information or health records were collected. The study was approved by the Institutional Review Board (IRB) at The Ohio State University.

Results

We completed a total of 56 hours (fourteen valid 4-hour observations) with 10 registered nurses, including eight observations from 11am to 3pm, five observations from 3pm to 7pm, and one observation from 7am to 11am. Among the 14 observations, three were on Monday, one on Tuesday, one on Wednesday, five on Thursday, and three on Friday.

Multi-tasking

In a 4-hour observation time block, nurses had 124 communications and 208 hands-on tasks on average. We considered that nurses were multitasking when they were engaged in communication and hands-on tasks simultaneously. We found that nurses were multitasking 131 times on average, which is 39.48% of all times; the total multitask duration ranges from 14.6 minutes to 109 minutes, 44.98 minutes (18.63%) on average. Multitasking duration seemed higher from 7am to 11am, but because we had only one observation during that time frame, we were not able to be conclusive.

Table 3 shows more details for each observation and the proportion of multitasking in frequency and duration (second). For example, Observation 1 occurred from 11am to 3pm, a 4-hour observation. During the observation, the nurse communicated 132 times with others and performed 171 hands-on tasks. The nurse multitasked (having communication and hands-on task simultaneously) 105 times, which is about 34.65% of all times. The duration of multitasks is 37.97 minutes, 15.76% of the total duration.
We also examined workflow visualization (Figure 3) to explore the location of nursing activities occurred. We presented the workflow in three activity dimensions: communication, hands-on task, and location. We visualized these three activity dimensions across the continuum of time with colored bands representing different activities; the width of the band represents the duration of an activity. The activities on the three activity dimensions, and at the same horizontal position, represent multitasking. The workflow visualization can be interpreted as who the nurse was talking to, while doing what, and at what location. We found that nurses usually charted at the nursing station or on the hallway. They sometimes charted while they were traveling/walking to another destination. When they were reviewing or charting on the electronic health record, they were often talking to their patients or to other professions. Nurses usually called out when reviewing or charting, but could receive phone calls at anytime and anywhere. Task switching often occurred between related activities, such as reviewing and charting electronic health records, switching between direct patient care activities (e.g. procedure, vital sign, medication administration). Another example of related activities was calling out and electronic health record review. Calling out required looking up pager or phone numbers using the electronic health record, so these two activities were often closely linked.

**Discussion**

**Self-created multitasking vs. unexpected interruption**

During this pilot study, we observed that multitasking and task switching could be self-directed, such as consulting with other professions while reviewing patient records, talking to patients for assessment and documenting results simultaneously, charting while walking, and assessing patients while administering medications. Self-directed multitasking and task switching were considered being more efficient at work and are likely contributing to their job satisfaction. Conversely, we also observed unexpected multitasking or interruptions, such as receiving phone calls anytime and anywhere, or mini-conversations with others while preparing medications. Some interruptions are important as they could be reminders, alerts, or another higher priority task. However, interruptions also increase cognitive load, decrease the speed of information processing in human prefrontal cortex, and result in errors. While multitasking is necessary and an important skill in healthcare systems, it is important to assess and recognize its impact on patient care. For example, allowing patients direct contact with nurses, through the use of pagers, could increase patient satisfaction, but it may also increase unexpected interruptions. Such interruptions could potentially contribute to safety issues, particularly if nurses are performing critical procedures or preparing complex medication regimens.
Currently, no model exists to evaluate multitasking. Multitasking could be self-directed or not, and could increase or decrease efficiency. To help explicate these workflow nuances, we used a workflow visualization method to understand the phenomena. We defined multitasking and task switching and designed the time motion study to capture observable nursing activities from three activity dimensions: communication, hands-on tasks, and location over the continuum of time. Using TimeCaT, we were able to analyze nursing workflow from the timing and frequency of the three activity dimensions and investigate the context and rationale via workflow visualization. Our study design and method provides a practical and reliable approach to conducting and analyzing time motion studies from both quantitative and qualitative perspectives.

Figure 3. A Snapshot of nursing workflow visualization

Visualizing nursing workflow: communications, hands-on tasks, and locations of nursing activities
Study limitations

Observing nurses in one unit in one hospital within one academic health system limits generalizability of our study. Data collection occurred over a two-month period which may introduce bias due to seasonal variations in hospital admissions. Participation bias was also a limitation, as nurses volunteered to participate in the study. Also, observations could be limited due to that humans may not be able to accurately record every action that is occurring, especially in a high stress clinical situation. We may have missed collection of data, particularly in rapidly changing hands-on tasks, communications or locations/movements of nurses. To minimize observational bias, all our observers were required to establish IORA before their observation data could be considered as valid thus also insuring study fidelity. We could not guarantee 100% accuracy, but we minimized the inconsistency between observers through rigorous training and clearly defining definitions of communications, hands-on tasks, and locations.

Future direction

In our study, we only recorded nursing activities that were observable. However, nurses often multitask and task switch in their thinking – critical thinking – which is unobservable. For example, nurses may juggle various needs of patients, family, and co-workers. Future research should investigate the impact of multitasking by assessing perceived workload at the end of observation to strengthen study findings. In addition, working within the complex healthcare environment of today, nurses must provide care that is efficient and effective. There is a growing body of literature that describes the workflow of nurses in an acute care environment. It has been found that nurses spend a considerable amount of non-value added time on activities that could potentially be delegated to other team members who could accomplish the care safely and with greater cost effectiveness. Inefficiencies in organizational systems also contribute to non-value added time. To date, there has been no empirical work that has aligned nursing practices and workflow or examined these practices relative to the notion of “top of licensure”. Top of license nursing practice addresses how nurses spend their time across the care continuum and examines “non-valued-added” work which could be executed safely by other healthcare personnel. As this is a pilot project under a larger nursing practice study, our ongoing and future research will explore top of license nursing activities and provide a strategic solution for providing higher quality and more efficient care.

Conclusion

We conducted a time motion study to capture communications, hands-on tasks, and locations of nursing activities. We also described our methodology in detail, and demonstrated a practical and reliable approach for other researchers. With the observational data, we were able to identify the amount of multitasking being carried out by nurses in their daily work, and provide a vivid pictures of nurses’ activities via a workflow visualization. Even though multitasking sometimes cannot be avoided, it has been noted that “Multitasking, a media-driven bias toward dramatic scenarios, and an emphasis on meeting institutional goals in the form of documentation have led to a culture of action-based practice, which interferes with nurses’ ability to simply be with patients. In order for nurses to be fully present with their patients, the cultural norm of multitasking and the emphasis on doing must be reexamined within the context of patient care.” We plan to continue the time motion study with a larger sample of nurses to observe their workflows and activities, with the hope of providing a quantitative observational study with statistically rigorous evidences to describe the work of nurses. Future research also includes applying the approach and methodology to investigate the workflow change before and after the implementation of a new practice model or a new technology.

Moderating the Influence of Current Intention to Improve Suicide Risk Prediction

Nawal A. Zaher, MSc¹, Christopher D. Buckingham, PhD²
¹AASTMT, Cairo, Egypt; ²Aston University, Birmingham, United Kingdom

Abstract

When assessors evaluate a person's risk of completing suicide, the person's expressed current intention is one of the most influential factors. However, if people say they have no intention, this may not be true for a number of reasons. This paper explores the reliability of negative intention in data provided by mental-health services using the GRiST decision support system in England. It identifies features within a risk assessment record that can classify a negative statement regarding current intention of suicide as being reliable or unreliable. The algorithm is tested on previously conducted assessments, where outcomes found in later assessments do or do not match the initially stated intention. Test results show significant separation between the two classes. It means suicide predictions could be made more accurate by modifying the assessment process and associated risk judgement in accordance with a better understanding of the person's true intention.

Keywords: Suicide Risk, Suicide Intention, Clinical Risk Judgment, GRiST, Decision Support System

Introduction

Intention is a mental state that represents a commitment to carrying out an action or actions in the future. It is one of the most important components for assessing the risk of a suicide attempt by mental health practitioners but it is also difficult to measure. It relies on people being assessed giving accurate self reports and there are many reasons why this may not happen. The problem is not so much with those who indicate a degree of positive intention because this alerts the assessor to the need for exploring intention further. Intentions can be evaluated as representations of possible actions or plans set to achieve a goal; realistic and established plans with steps taken towards the goal indicate increased underlying intention.

While it is reasonable to claim that the presence of current intention of suicide is an indication of risk, the absence of intention does not necessarily dictate the opposite. Patients may, knowingly or unknowingly, hide their intentions, which raises reasonable doubt regarding their statement of intention.

The difficulty with people who say they have no intention is that validating their statement depends on an absence of evidence and this is difficult for assessors to validate. In effect, it stops further investigation into the current intention, diverts attention elsewhere, and can mean important information is lost. The overall risk judgement is compromised as well as a comprehensive understanding of the underlying symptoms and causes. The assessor’s evaluation plan and course of action are affected, which results in a mismatch between interventions and outcomes. It happens with a “no” answer because of its categorical nature, as opposed to a “yes” answer, which can be further investigated to attenuate its influence on risk judgements.

This study uses data from a web-based decision support system (DSS) called the Galatean Risk and Safety Tool, GRiST to determine the reliability of people’s expressed absence of suicide intention. The goal is to identify cues that would enable assessors to change how the absence of current intention is conceived. If it is possible to detect unreliable absence of intention, the assessment process can be changed to explore it further or, at the very least, the influence of the stated absence of intention on the assessor’s judgement of suicide risk can be reduced.

The next section provides an overview of the nature of mental health risk data and how it is collected by GRiST. The paper then introduces an algorithm to classify people’s negative intentions of suicide as being reliable or unreliable. The results are presented and followed by a discussion about how the algorithm could be incorporated in risk evaluation tools to improve their accuracy.

Background

Questions about patients’ intentions direct assessors and DSSs towards the cues that are most relevant to the risk being assessed; some or all of these could be masked if people have stated an absence of intention. It leads to two major problems. The first is missing data, where relevant data is not collected because the assessor thinks it is not needed. The second concerns outcomes because people wrongly assessed as low risk may not receive required

1274
interventions and can go on to make a suicide attempt. Assessments are made more difficult by the volatile nature of
stated intentions, which is compounded by factors such as impulsiveness and deception or denial. In short, we lack
insight into the intention of others\textsuperscript{15}. The GRiST DSS attempts to penetrate the gloom by collecting a large amount
of contextual and historical data, in addition to the immediate risk history and behaviour, so that a holistic picture of
a person can be drawn. This is the data set used for modeling and evaluating current intention.

1- GRiST Mental Health Data

GRiST is a tool for helping practitioners assess and manage multiple risks associated with mental-health problems,
including suicide, self-harm, harm to others, self-neglect and vulnerability. The tool represents expert consensus,
elicted by preliminary interviews conducted with mental health practitioners\textsuperscript{16} and refined through feedback from
using the tool in practice\textsuperscript{13,17}. The level of suicide risk is measured in GRiST using membership grades (MGs). They
are generated from the person’s assessment data into a common value between zero and one that represents each cue’s
risk input\textsuperscript{12}. The relationship between input MGs and associated risk judgements given by assessors is learned across
all assessments in the GRiST database to provide a model for predicting the risk judgement for a new assessment\textsuperscript{12,13}.

2- Current Intention of Suicide

The clinical risk judgment distributions for GRiST assessments that have “yes” and “no” answers (Figure 1) show
that the mean risk for the “yes” group is 0.5201 and for the “no” group is 0.1764. This is a significant clinical
separation, with people being treated differently when having more than a three-point greater risk level, where 0 is
minimum risk and 1 is maximum risk.

It could be argued that intention is more accurately predicted by attitude and behaviour\textsuperscript{3,18}, rather than by a simple
YES/NO question but their ability to interpret the reliability of someone’s lack of current intention has not been
modeled. For GRiST, current intention is not binary for a “yes” answer because it opens up a number of additional
questions to assess the degree of intention. In contrast, a “no” answer blocks off any further direct exploration of
current intention and may also cause other factors to be masked because of a perceived reduction in risk. An indirect
approach to evaluating the “no” answer is required and this paper pursues it by investigating whether any of the
multiple GRiST cues can differentiate between the reliability of assessments’ claimed lack of intention.

Proposed Algorithm

Although GRiST does not directly collect intervention and outcome information following an assessment, it does
contain relevant data for those patients who have more than one assessment. An important piece of information
recorded for all patients who have a history of suicide attempts is the date of the most recent attempt. If this has

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{Distribution of clinical risk judgment for patients with current intention of “yes” (the top figure) and “no”
(the bottom figure).}
\end{figure}
changed between assessments then it means the person has carried out a new suicide attempt and is therefore an outcome we can use in our analysis.

This paper analyses all those assessments that had no current intention and are followed by a subsequent (repeat) assessment. The idea is that people with a new risk episode will have a less reliable absence of current intention than those who did not carry out an attempt between assessments. If the two groups of patients can be distinguished, it should be possible to determine a reliability measure for the negative answer and a principled way of adjusting the assessment process accordingly.

1- Defining the Classes

The parent population for the study sample is 71,024 assessments, consisting of 27,947 patients, of which 12,595 have repeated assessments. Of these, only 6,502 assessments have a current intention answer of “no” in an assessment which also has a subsequent one (i.e. it must not be the most recent assessment). The reliability of the answer is crudely evaluated by inspecting the subsequent assessment to find out whether this patient has had a repeat episode since the assessment, indicated by a new date for the most recent attempt. If so, the answer to current intention is marked as unreliable. This produces two classes: those people with a reliable negative intention, Class Rno, and those with an unreliable answer of “no”, Class Uno. The size of Class Rno is 4,458 assessments, and the size of Class Uno is 2,044 assessments.

2- Feature Selection

Having established the two classes, the task is to learn the defining features that distinguish them. The Maximum Likelihood Estimate (MLE)\textsuperscript{19} of the mean and variance of each feature in each class is calculated assuming a Gaussian distribution. MLE provides an interpretable parametric form and has a significantly low computational cost compared to other parametric techniques like Bayesian estimation\textsuperscript{20}. Then the normalized Euclidean distance\textsuperscript{21} between the two classes is calculated for each feature to produce the distance vector shown by Equation 1

\[
d = \sqrt{\frac{\left(\bar{\mu}_{\text{Rno}} - \bar{\mu}_{\text{Uno}}\right)^2}{\bar{\sigma}_{\text{Rno}}^2 + \bar{\sigma}_{\text{Uno}}^2}}
\]

where \(\bar{\mu}_{\text{Rno}}\) and \(\bar{\mu}_{\text{Uno}}\) are the average assessments of class Rno and class Uno respectively and \(\bar{\sigma}_{\text{Rno}}^2\) and \(\bar{\sigma}_{\text{Uno}}^2\) are the variances of Rno and Uno. Each element of the distance vector represents the distance between Rno and Uno for a particular cue.

The top 20 cues arranged in descending order of the distance measure, d (Table 1), are appealing candidates for the feature vector. Although these produce the largest class separation, some will be missing from assessments if the assessors do not ask about them due to absence of intention. The table gives the number of occurrences of each of the cues in the dataset and the percentage of assessments where they are missing. The cues with the least amount of missing data and the most influence are the first seven cues. If only these are used, the classifier will have a larger sample and be more reliable because only assessments with data for all the cues in the vector are used for the estimation of model parameters and for testing. These cues all happen to be related to previous history of suicide, which now becomes a selection criterion for the unreliability measure. It means a different measure will need to be calculated for other subsets of the population that do not have a history of suicide.

It is encouraging, but not surprising, that the most influential cues are also the most commonly collected. GRiST was built on the pooled expertise of mental-health practitioners\textsuperscript{16} and one would expect them to ensure they identify and collect the most important data for assessments. The literature also confirms the importance of cues related to past history for predicting suicide risk\textsuperscript{4,13,22,23}.

### 3- Classifier Model

There are many approaches to binary classification, the most prominent of which is logistic regression. Although it is powerful and appropriate, we decided against it for our approach because the heuristic method for choosing features was not designed to produce regression vectors. It could have been achieved using exhaustive search but it would have been limited to samples with all features present in the vector and over fitting may have occurred due to selecting features based solely on classification results.

Instead, features are independently chosen using a fully parametric probabilistic model to generate the conditional density functions on the assumption that each feature has a Gaussian distribution. Features do not all need to be in the same patient vector, which means selection can include any assessments where they individually occur, making the sample size for selecting each one larger than would be the case for regression.

The classes are represented by two Gaussian distributions, with means and variances calculated using MLE for the top seven cues shown above (Table 1). The classification decisions are based on a minimum error rate threshold in each dimension. An example for the classifier model for one dimension: the most recent suicide attempt date, which is the top cue, is shown below (Figure 2). In each dimension the classifier needs a threshold to separate the two classes. The optimum threshold \( \rho \) that minimizes the probability of error is the MG value at the point of intersection of the two Gaussian distributions representing the two classes (Figure 1). Equating the two sides and substituting for \( \rho \):

\[
\frac{1}{\sqrt{2\pi\sigma_{Dno}^2}} e^{-\frac{(\rho-\mu_{Dno})^2}{2\sigma_{Dno}^2}} = \frac{1}{\sqrt{2\pi\sigma_{Kno}^2}} e^{-\frac{(\rho-\mu_{Kno})^2}{2\sigma_{Kno}^2}}
\]

Simplifying the expression yields Equation 3 with the coefficients \( a_2, a_4, a_6 \) given by Equations 4, 5, and 6 respectively. The threshold \( \rho \) that minimizes the probability of error in each dimension is calculated for each dimension individually by solving Equation 3.

\[
a_2 \rho^2 + a_4 \rho + a_6 = 0 \tag{3}
\]
Figure 2. Classifier model for Cue 1, “date of most recent suicide attempt”, showing the Gaussian distribution for each class, Uno and Rno (unreliable and reliable no intention respectively), and the decision threshold for this dimension, based on the cue’s membership grade, MG.

Figure 3. Distribution of MG values for cue 1, “most recent suicide attempt”, RHS: MG values of cue 1 for class Uno, LHS: MG values of cue 1 for class Rno.
The idea is to find the input MG for each of the seven cues that split the classes most accurately. Each cue will independently indicate the most likely class by whether the assessment MG for the cue is above or below the threshold value.

The natural distribution of data shown (Figure 3) supports the Gaussian assumption adopted. Nevertheless, considering more skewed models may be of interest, but will add some complexity to parameters and threshold computations.

4- Decision Fusion

The last stage of the classification process is combining the decisions from all 7 cues (dimensions) into one decision as to whether an assessment belongs to Class Rno or Uno. This can be done by voting over the decisions of each cue or summing their probabilities that the assessment is in one class or the other. This paper combines the two methods because a majority vote among the hard decisions taken by each dimension does not take into account the accuracy of each dimension.

First a hard decision is made for each cue by comparing the value of the cue’s MG to the threshold. The cue’s vote is then weighted based on how well it separates the classes. This is determined by calculating its positive predictive value (PPV) using Equation 7

\[ ppv = \frac{tpr}{tpr + fpr} \quad (7) \]

where TPR is the true positive rate and FPR is the false positive rate. The PPV shows how powerful each dimension (cue) is individually, with a higher PPV signifying more separation of the two classes in that dimension.

The PPV value for each cue is used to weight the overall decision obtained from its corresponding dimension as in Equation 8

\[ v = \sum_{i=1}^{7} ppv_i d_i \quad (8) \]

where \( ppv_i \) is the positive predictive power of dimension \( i \) and \( d_i \) is a Boolean variable that represents the decision from each cue, which is given a value of ‘1’ for class Uno and a value of ‘0’ for class Rno.

The output of the fusion process, \( v \), is compared to a threshold \( v_{th} \) such that if \( v > v_{th} \), then the decision is Rno, otherwise the decision is Uno. To choose \( v_{th} \), the Receiver Operating Characteristics (ROC) curve is plotted using different values for \( v_{th} \) so that the point with the maximum accuracy is chosen. The figure below (Figure 4) shows the ROC curve of the best performing model and its distance from the line of no discrimination.

![ROC curve](image)

**Figure 4.** ROC curve showing TPR against FPR for different decision thresholds.
Results
After filtering out assessments with incomplete vectors (i.e. where one or more of the top seven cues in Table 1 are missing), the size of Class Rno is 1,154 and Class Uno is 1,903. The model was tested by combining the two classes into one group and then applying 10-fold cross validation, where the group is split into 10 equal-sized sets of randomly selected assessments. Each set is used once for testing with the remaining 9 sets used for training to give 10 sets of test results that were pooled.

1- Accuracy
The average accuracy of the 10 splits is 0.847 while the percentage values of TPR, FPR, false negative rate (FNR) and true negative rate (TNR) at different setups are shown below (Table 2). The point with the highest accuracy is not necessarily the best operating point. It depends on which of the cells needs to be maximized or minimized. For the sake of risk assessment, the TPR is probably the most important but the FPR is also significant because false alarms would erroneously impact on the assessment process as well as exaggerating the risk and potentially triggering unnecessary interventions.

Table 2. Classifier statistics showing average performance, best performing split and worst performing split for Class Rno. TPR is the true positive rate, or hits, FPR is the false positive rate or false alarms, TNR is the true negative rate, or hits for Class Uno, and FNR is the false negative rate or misses.

<td>39.99%</td>
</tr>
</tbody>
</table>

2- Chi-square test
To verify the significance of the results a Chi-square test was performed to check if the classification decision (Rno or Uno) is dependent on whether the person subsequently repeated a suicide attempt or not. The sample sizes on which the test was performed and the results of the classification at the minimum FPR are shown below (Table 3). The test gives $\chi^2 = 886.5033$ which equates to a probability very close to 0: the classifier deviates from chance at the $p < 0.01$ significance level which means the decision classes are dependent on repeated episodes.

Table 3. Classifier results at maximum accuracy. Rno predicts no repeat episodes and Uno predicts repeat episodes.

</tbody>
</table>

The most encouraging feature is that the unreliable intention decision has very few errors: only seven out of 407, which means it is not generating false alarms that would dilute the effect of warning practitioners. Although the assessments classified as reliable have many more errors, where people go on to repeat, the status quo is to consider all assessments as reliable. Ideally, we would like to move as many as possible of these into the unreliable class but, for now, the real impact of the research is in demonstrating that unreliability can be meaningfully predicted so that practitioners take the warning seriously.

Conclusion
The results show that assessments where the answer to current intention of suicide is “no” can be divided into two classes, unreliable and reliable negative intention. A non-standard method was used due to the amount of missing data in the samples but future work would explore more conventional methods such as regression, support vector machines, and decision trees, for example. Either way, the classification is based on other cues collected during an assessment, which can be used to develop a reliability measure for current intention that smooths the influence of intention on the clinical risk judgement. Instead of having a categorical “no intention”, a graded value for intention
could be generated where some negative intention statements could even be regarded as the opposite. Alternatively, the classification based on reliability may be incorporated as a risk factor on its own, or incorporated in some of the cues that are already included in the risk assessment.

Alerting assessors to unreliability of intention would, in itself, help improve the data collection process, by ensuring assessors pay attention to issues that would not normally be considered for low-risk people. The top seven cues (Table 1) used for our reliability measure have a significant percentage of missing data and our results strongly support the need for them to be collected as a matter of course. However, they are all related to previous history of suicide and the next step is to determine whether a suitable reliability measure can be found for people without a history. The non-history cues from Cue 9 (Table 1) suggest this will be possible because they are able to separate the classes; a reliability indicator is needed because the table shows the cues are missing from a high percentage of assessments and should certainly be collected for those patients without a history of suicide. The upshot will be a measure applicable for all populations that will increase assessors’ understanding of suicide risk and help prevent future attempts.

ABSTRACT

Semantic role labeling (SRL), which extracts shallow semantic relation representation from different surface textual forms of free text sentences, is important for understanding clinical narratives. Since semantic roles are formed by syntactic constituents in the sentence, an effective parser, as well as an effective syntactic feature set are essential to build a practical SRL system. Our study initiates a formal evaluation and comparison of SRL performance on a clinical text corpus MiPACQ, using three state-of-the-art parsers, the Stanford parser, the Berkeley parser, and the Charniak parser. First, the original parsers trained on the open domain syntactic corpus Penn Treebank were employed. Next, those parsers were retrained on the clinical Treebank of MiPACQ for further comparison. Additionally, state-of-the-art syntactic features from open domain SRL were also examined for clinical text. Experimental results showed that retraining the parsers on clinical Treebank improved the performance significantly, with an optimal F1 measure of 71.41% achieved by the Berkeley parser.

INTRODUCTION

Natural language processing (NLP) technologies are important for unlocking information embedded in narrative reports in electronic health record (EHR) systems. Although various NLP systems have been developed to support a wide range of computerized medical applications, such as bio-surveillance and clinical decision support, extracting semantically meaningful information from clinical text is still a challenge.

In the biomedical domain, semantic relation extraction systems, such as LSP, MedLEE, MedEx for clinical text and SemRep for biomedical literature, have shown good performance and been widely used in different applications. These early-stage systems were often based on manually extracted patterns, following the sub-language theory. According to the sub-language theory, the language of a closed domain (e.g., medicine and biomedicine) has special syntactic patterns as well as a limited number of main semantic types. Therefore, possible semantic relations could be identified by restricted constraints of syntactic and/or semantic patterns. However, a careful examination of syntactic alterations that express the same semantic relations in biomedical text reveals that even in a semantically restricted domain, syntactic variations are common and diverse. Thus, the coverage and scalability of manually extracted patterns may not be sufficient for those syntactic variations. In recent years, promoted by increasing challenges held by different portals (e.g., BioCreative, BioNLP, i2b2 and SemEval), more and more automatic information extraction systems have been built for different biomedical subdomains using data-driven statistical methods, such as machine learning algorithms. However, diverse syntactic variations still remain as an essential problem to extract semantic information from biomedical text, especially for clinical text, which contains more fragments and ill-formed grammars.

Figure 1. A syntactic parse tree with semantic roles added (ARGs).
One potential solution to this problem is semantic role labeling (SRL) (also known as shallow semantic parsing), which focuses on unifying variations in the surface syntactic forms of semantic relations. Specifically, the task of SRL is to label shallow semantic relations in a sentence as predicate argument structures (PAS). A predicate usually refers to a word indicating an event or a relation, and arguments (ARGs) refer to syntactic constituents representing different semantic roles in the event or relation. For each predicate, arguments representing the most important semantic roles are labeled with numbers, usually from ARG0 to ARG5. In addition, arguments representing modifiers of events (i.e., location, time, manner, etc.) are labeled as ARGMs. Taking the sentence "She should decrease the prednisone by 1-mg weekly" in Figure 1 as an example, the verb phrase "decrease" is the predicate indicating the event; the noun phrase "She" represents the role of ARG0, indicating the initiator/executor of the action "decrease"; the noun phrase "the prednisone" represents the role of ARG1, indicating the receptor of the action "decrease" (i.e. the entity decreased); while the prepositional phrase "by 1-mg weekly" represents the manner of how to decrease the prednisone (ARGM-Manner).

Shallow semantic relations, or PASs are usually applied as features for machine learning algorithms, sentence structural representations in kernel-based models or inference rules in different applications, including question answering, text summarization and information extraction, etc. Especially, PASs have been investigated in various biomedical sub-domains and made positive contributions in semantic information extractions, such as extracting drug-drug interactions from biomedical literature and temporal relations from clinical text.

Generally, a typical SRL system is built by using machine-learning methods based on annotated corpora. Since semantic roles are formed by syntactic constituents, two corpora are needed to build SRL systems, namely a corpus of syntactic parse trees and a corresponding corpus of semantic roles annotated on it. The most widely used large-scale corpora in open domain are the Penn Treebank and the SRL corpus PropBank developed on it. Many state-of-the-art syntactic parsers have been developed and applied to SRL in open domain. Some previous studies attempted to adapt these parsers (e.g., the Stanford Parser) to clinical text using medical lexicons. Recent years have also seen emerging efforts for syntactic annotation guidelines and corpora of clinical text. For example, the MiPACQ corpus (a multi-source integrated platform for answering clinical questions) annotated syntactic trees for 13,091 sentences following the Penn Treebank Style. Furthermore, several SRL corpora were developed for clinical text following the PropBank Style. The available corpora were of different genres and note styles, including operative notes, radiology notes from the SHARP Area 4 project (Strategic Health IT Advanced Research Projects), colon cancer pathology and clinical notes from the MiPACQ corpus and the THYME corpus (Temporal Histories of Your Medical Events). Based on those corpora, studies have been conducted to investigate SRL techniques for clinical text from EHRs. Albright et al. (2013) and Zhang et al. (2014) developed SRL systems on the MiPACQ corpus using dependency parse trees and constituent parse trees, respectively. Wang et al. (2014) built a SRL system on operative notes using an adapted parser.

Given that semantic roles are formed by syntactic constituents in the sentence, an effective parser to first recognize those syntactic constituents is critical for developing a practical SRL system. Furthermore, an effective feature set to describe the syntactic patterns between the predicate and the argument is also essential to SRL. Although previous works have compared different syntactic parsers and representations for biomedical event extraction from literature, there are no formal evaluations and comparisons of state-of-the-art parsers and features for SRL in the medical domain.

In this study, we evaluated the SRL performance of three state-of-the-art constituent syntactic parsers: the Stanford parser, the Charniak parser and the Berkeley parser, using the MiPACQ corpus. We focused on constituent parse trees here because they could be directly converted to dependency parse trees. The purposes of this study were two-fold: (1) to evaluate the SRL performance of existing state-of-the-art English parsers on clinical text, both the original parsers developed on Penn Treebank and parsers retrained on the clinical Treebank were examined; and (2) to validate the effectiveness of state-of-the-art syntactic features for SRL in the open domain on clinical text. To the best of our knowledge, this is the first comprehensive study that investigates the influence of syntactic parsing and features for SRL on clinical text using multiple state-of-the-art parsers.
METHODS

Dataset
This study used the MiPACQ dataset for SRL experiment. MiPACQ is built from randomly selected clinical notes and pathology notes of Mayo Clinic related to colon cancer. Layered linguistic information is annotated in MiPACQ, including part of speech (POS) tags, syntactic Treebank, PASs for SRL, named entities, and semantic information from Unified Medical Language System. The syntactic Treebank annotations in MiPACQ follow the Penn Treebank guidelines, and the predicate-argument structure annotations for SRL follow PropBank guidelines. 13,091 sentences are annotated with syntactic trees. Among them, 6,145 sentences in MiPACQ are annotated for SRL, including 722 verb predicates with 9,780 PASs and 415 nominal predicates with 2,795 PASs.

The basic SRL system

Figure 2. Study design for semantic role labeling of clinical text

Figure 2 shows the study design for SRL of clinical text. Basically, the SRL system can be partitioned into the training stage and the testing stage. In the training stage, gold-standard syntactic trees of the training data set annotated in MiPACQ are used for feature extraction. A SRL task consists of two sub-tasks, the argument identification sub-task and the argument classification sub-task. First, a binary non-Argument vs. Argument classifier is built as the argument identifier on the entire dataset for all the predicates, instead of building one model per predicate. For argument classification, a multi-class classifier is built to assign semantic roles to arguments of all the predicates. In the testing stage, syntactic trees automatically generated by the syntactic parser are used for feature extraction. For each predicate, the argument candidates first go through the argument identifier. If one candidate is identified as an argument, it will go through the argument classifier that assigns the semantic role.

Comparing syntactic parsers and features

Three widely used state-of-the-art syntactic parsers, the Stanford parser, the Charniak parser, and the Berkeley parser are investigated for their influence on the SRL performance in our study. Moreover, state-of-the-art features, most of which are syntactic features, commonly used in open domain and biomedical domain are extracted and compared for use with clinical text.

Syntactic Parsers
Stanford parser: Stanford parser was initially developed based on un-lexicalized probabilistic context-free grammar (PCFG). The lexicalized PCFG parser and the dependency parser shared a factored product model, where the preference of PCFG phrase structures and lexical dependencies are combined by efficient exact inference, using an A* algorithm.
Charniak parser\textsuperscript{24}: Charniak parser is a high-performance lexicalized parser. It achieved an $F_1$ measure of 91.0\% on the Penn Treebank. This parser is constructed by re-ranking the 50-best parse trees generated from a coarse-to-fine generative parser, using a discriminative Maximum Entropy model.

Berkeley parser\textsuperscript{25}: Berkeley parser is also based on PCFG. In addition to local correlations between syntactic tree nodes, this parser learns to capture the non-local correlations between tree nodes using an EM algorithm based model.

Features

Similar to previous work of SRL for biomedical literature\textsuperscript{41,19} and clinical text\textsuperscript{35}, we adopted the common features used in current state-of-the-art SRL systems. The features include baseline features from the original work of Gildea and Jurafsky (2002)\textsuperscript{42}, advanced features taken from Pradhan et al. (2005)\textsuperscript{10} and feature combinations from Xue and Palmer (2004)\textsuperscript{26}.

The features can be categorized into three major groups: (1) basic features include the lexical and syntactic features of the predicate and the argument; (2) context features include features of the syntactic nodes surrounding and the syntactic paths between the predicate and the argument; (3) feature combinations are feature tuples formed of two unitary features from the previous two groups. The complete feature set is described in Table 1. Except for the lemma of the predicate word and the relative position between the argument and the predicate, all the rest of the features are at the syntactic level and need to be extracted from the parse tree. For a more clear illustration, Table 2 lists the specific features extracted for the argument candidate “1-mg weekly” of the predicate “decrease” in the example sentence shown in Figure 1.

Experiments

PASs with at least one argument were used for the experiment. We used the open source toolkit, Liblinear\textsuperscript{43} as implementations of the support vector machine algorithm. For each implemented method, all parameters were tuned for optimal performance.

Experiments and systematic analysis were conducted as follows:
1. Evaluate SRL performance of parsers with their default settings: In this experiment, we directly applied the three parsers to process all sentences of the test dataset. All the parsers were invoked with their default settings and models, which had been trained on the Penn Treebank.

* In the syntactic path feature, ↑ indicates a link from a child node to its parent, and ↓ indicates a link from a parent node to its child.

2. Evaluate SRL performance of parsers re-trained on the clinical Treebank: To assess if the annotation of clinical Treebank could improve the performance of SRL, we applied three parsers retrained on the MiPACQ Treebank. We conducted ten-fold cross validation evaluation for each parser. The cross-validation involved dividing the clinical corpus equally into 10 parts, and training the parser on 9 parts with testing on the remaining part each time. We repeated the same procedure 10 times, one for each part, and then combined the results from the 10 parts to report the performance.

3. Evaluate SRL performance of each syntactic feature: To validate if syntactic features commonly used in the open domain were effective for clinical text, we conducted multiple runs of experiments, adding one new syntactic feature into the feature set for each run. The experimental results were compared to check the effectiveness of each feature.
Evaluation

Precision (P), recall (R) and $F_1$-measure ($F_1$) were used as evaluation metrics for argument identification (AI) and combined SRL task. Precision measures the percentage of correct predictions of positive labels made by a classifier. Recall measures the percentage of positive labels in the gold standard that were correctly predicted by the classifier. $F_1$-measure is the harmonic mean of precision and recall. During the process of argument classification (AC), the boundaries of candidate arguments are already identified by the argument identification step. Therefore, the accuracy (Acc) of the classifier was used for evaluation, which is defined as the percentage of correct predictions with reference to the total number of candidate arguments correctly recognized in the argument identification step. Ten-fold cross validation was employed for performance evaluation.

RESULTS

Table 3 illustrates the performance of semantic role labeling systems, which were trained on the gold standard syntactic trees and tested on the parsing results of Stanford, Charniak and Berkeley, as well as the gold standard syntactic trees, respectively. For these experiments, the whole feature set described in Table 2 was used. The original parsers trained on the Penn Treebank produced relatively lower performance. Charniak got the lowest $F_1$-measure of 61.40%, whereas Berkeley outperformed the other two parsers with a $F_1$-measure of 68.15%. After retraining on the clinical Treebank, the performance of all three parsers increased significantly, with the optimal $F_1$-measure of 71.38% achieved by Berkeley. Testing on the gold standard parse trees yielded a $F_1$-measure of 82.13%.

* AI: argument identification  AC: argument classification

To investigate whether syntactic features commonly used in the open domain are also effective for clinical text, multiple experiments were conducted by adding one new syntactic feature incrementally for each run. Table 4 lists the SRL performance of both the gold standard corpus and the parse results of the retrained Berkeley. As the baseline, the first run adopted all the basic features of predicate, argument and their relative position. Numbers in parenthesis show the changes to $F_1$-measure of argument identification and accuracy of argument classification by adding each new feature. As illustrated in Table 4, all the syntactic features effective in the open domain were also helpful for argument identification of clinical text. The $F_1$-measure was improved consistently from 20.07% and 17.47% to 91.51% and 80.81% for the gold standard corpus and the retrained Berkeley parser, respectively. In addition to the basic features, phrase types of argument neighbors, and the three path features made the most contribution to argument identification. In contrast, for argument classification, the basic features already yielded an accuracy of 86.74% for the gold standard corpus and an accuracy of 83.78% for the retrained Berkeley. Since the path features between the predicate and an argument dropped the accuracy slightly, we conducted additional experiments by removing those features for argument classification, which improved the overall $F_1$-measure of our SRL systems to 82.14% (vs. 82.13%) for the gold standard corpus and to 71.41% (vs. 71.38%) for the retrained Berkeley parser.
**DISCUSSION**

Effective syntactic parsers and features are critical to establish a practical SRL system. This study takes the initiative to make a formal evaluation and comparison of SRL performance on a clinical text corpus MiPACQ, using three state-of-the-art syntactic parsers and common syntactic features used in open domain. Experimental results demonstrate that retraining parsers on clinical corpora could improve the SRL performance significantly, with an optimal F1-measure of 71.41% achieved by the Berkeley parser. Despite the telegraphic type of clinical text, state-of-the-art syntactic features in open domain also proved to be effective for clinical text.
In terms of SRL errors caused by syntactic parsers, a major category was that the parsers did not recognize a large number of syntactic constituents acting as arguments (Original Stanford: 1175, Charniak: 1377, Berkeley: 1262). Nevertheless, retraining parsers on the clinical Treebank reduced such errors greatly (Retrained Stanford: 887, Charniak: 973, Berkeley: 816). Another major type of syntactic problems that caused SRL errors was the essential syntactic structure ambiguities. For example, the sentence “He continues to note the sensation of bilateral leg numbness and pins and needle sensation with walking” contains conjunctive structures linking two phrases “the sensation of bilateral leg numbness”, and “pins and needle sensation”. It’s hard to determine if the prepositional phrase “with walking” only modifies the “pins and needle sensation” or both phrases.

Despite the unique characteristics of clinical text, such as fragments and ill-formed grammars, all the state-of-the-art syntactic features in the open domain contributed positively to clinical text, except for path features that dropped the accuracy of argument classification slightly. One possible reason for the decreased performance is that the specific semantic role of an argument in clinical text is dependent not only on syntactic paths but also on the clinical lexicon and relations. As an example, in the phrase “an advanced breast cancer treated with radiation therapy”, “an advanced breast cancer” is annotated as ARG2 (illness or injury) in the gold standard. However, it was mistakenly labeled as ARG1, because the extracted syntactic path features were similar to those of ARG1 in the corpus.

Our study has the following limitations. In this study, only the SRL performance of pathology notes and clinical notes are investigated. In the future, we plan to extend this study to other types of clinical notes such as operative notes, to assess the generalizability of our findings. In addition to parsers retrained on clinical text, parsers adapted to clinical text using domain lexicons and grammars could also be explored for SRL. Although this study mainly focused on syntactic features, existing clinical knowledge such as semantic types and relations will be further examined as features for SRL in the next stage. Besides, there are other widely used parsers in open domain such as OpenNLP, LingPipe and Gate in addition to the three parsers explored in this study. An extension of our study to other parsers will be conducted in the further, so that to reach the optimal SRL performance on clinical text.

**CONCLUSION**

This study made a formal evaluation and comparison of SRL performance on a clinical text corpus, MiPACQ, using three state-of-the-art parsers, the Stanford parser, the Berkeley parser, and the Charniak parser and state-of-the-art syntactic features from the open domain. Experimental results validated the effectiveness of retraining parsers with a clinical Treebank, with an optimal F1-measure of 71.41% achieved by the Berkeley parser. The results also demonstrated that common syntactic features in open domain could contribute positively to the clinical text.

**ACKNOWLEDGEMENT**

This study was supported by grants from the NLM 2R01LM010681-05, NIGMS 1R01GM103859 and 1R01GM102282. We would like to thank the MiPACQ team for the development of the corpora used in this study.

Abstract

Structured clinical documentation is an important component of electronic health records (EHRs) and plays an important role in clinical care, administrative functions, and research activities. Clinical data elements serve as basic building blocks for composing the templates used for generating clinical documents (such as notes and forms). We present our experience in creating and maintaining data elements for three different EHRs (one home-grown and two commercial systems) across different clinical settings, using flowsheet data elements as examples in our case studies. We identified basic but important challenges (including naming convention, links to standard terminologies, and versioning and change management) and possible solutions to address them. We also discussed more complicated challenges regarding governance, documentation vs. structured data capture, pre-coordination vs. post-coordination, reference information models, as well as monitoring, communication and training.

Introduction and Background

Structured clinical documentation is an important component of electronic health records (EHRs) and plays an important role in clinical care (e.g. dependency for clinical decision support [CDS]), administrative functions (e.g. extracted to support billing, quality assessment and reporting), research activities, and other areas. \textsuperscript{1,2} When well implemented in the context of the clinical workflow, structured documents can save clinicians’ time, assure professional practice standards and clinical thoroughness, and may reduce potential medical errors through clinical decision support interventions. \textsuperscript{2}

Different levels of information aggregation for structured documents are shown in Figure 1. Data elements serve as basic building blocks for composing document templates that are used for generating clinical documents (e.g. provider notes and forms). Appropriate underlying terminologies and information models used to assemble these data elements, closely correlate to the quality of the produced documents, and are keys to a successful implementation. The management of these data elements remains a critical and demanding issue for EHR systems.

Researchers have made significant efforts in developing methodologies for specifying the structure and semantics of clinical documents. Standard development organizations, professional associations and other healthcare organizations have developed standards and models in this area. A few known efforts include: 1) HL7 Clinical Document Architecture (CDA), \textsuperscript{3} which is a document markup standard and specifies an exchange model for clinical documents; 2) HL7 Reusable Information Constraint Templates, \textsuperscript{4} which are used to constrain the structures of a portion of atomic concepts, such as a laboratory report in a CDA document; 3) OpenEHR Archetype Model, \textsuperscript{5} which consists of a domain-level definition in the form of archetypes and templates and allows clinical experts to be able to structure their own data in the way they require it; 4) Intermountain Health Care’s Detailed Clinical Models\textsuperscript{6-9} whose core building block is a “clinical element” represented in a recursive data structure for capturing detailed clinical information; and 5) recent Clinical Information Modeling Imitative by HL7 that aims to create a shared repository of detailed clinical information models and binds the models to standard terminologies. \textsuperscript{4} EHR vendors most commonly use proprietary approaches to structured documentation and template management.

In this paper, we present our experience in creating and managing data elements for different EHR systems, focusing mainly on lessons learned from two legacy systems (a homegrown ambulatory EHR system and a commercial inpatient documentation system) and a newly implemented commercial EHR system. In particular, we
use a basic but nontrivial domain, flowsheet data elements, as an example to illustrate and discuss issues and challenges we encountered.

Case Study Site

Partners Healthcare System is an integrated health care system in the Boston area, founded in 1994 by Brigham and Women’s Hospital and Massachusetts General Hospital. It also includes several community and specialty hospitals, community health centers, and other health-related entities. The Longitudinal Medical Record (LMR) is an internally developed, full-featured, and Meaningful Use-Certified EHR, including primary care and subspecialty semi-structured notes, orders, problem lists, medication lists, allergies, laboratory tests, clinical decision support, quality reporting and other functionalities. It was developed and implemented in early 2000s and used across Partners healthcare network. In 2007, Partners carried out the Acute Care Documentation (ACD) project that aimed to develop highly structured clinical content for the inpatient setting using a vendor system. In 2012, Partners cancelled the ACD project and announced a new initiative, known as Partners eCare, to implement a commercially available integrated EHR system at all its sites. On May 30, 2015, the first site, including Brigham and Women’s Hospital, Partners Home Care, and Dana Farber Cancer Institute, went live with the new EHR system as part of the Partners eCare initiative. In the following, we describe three case studies based on our experience in creating and maintaining data elements for these EHR systems.

Case Study 1: the Longitudinal Medical Record (LMR) System

A Brief History

LMR allows great flexibility for users to create their own data elements and templates at a local level based on their needs. At the early stages of the systems use, data elements were created on an ad-hoc manner based on the specific needs of individual practices and providers and they were generally not shared among users. Because the granularity (level of detail) and presentation of the data elements change over time and vary by domain, by practice, or by user, their reusability is low. The initial design of these data elements applied the “concept-attribute-value (or section-question-answer)” paradigm. Figure 2 demonstrates an example of a data element for lung symptoms developed by a local oncology team. This type of design mixed data and presentation, compromising reuse and data consistency.

In an effort to address these problems, in 2006, the LMR development team and the Partners Knowledge Management (KM) team launched a project that aimed to maximize re-use of data elements and templates, and to support CDS, pay for performance, and quality reporting. A few solutions were proposed and implemented: 1) build an editor that facilitates controlled authoring of data elements and templates; 2) define a shared data element dictionary to manage all elements needed for composing structured clinical documents, where users can create their own data elements or search existing ones; and 3) creation of a limited set of “enterprise” data elements that were flagged and locked (i.e. editable only by authorized KM team members). These solutions did not entirely solve the fundamental limitations of the system. For example, the search function of the editor was relatively simple. LMR Analysts preview existing data elements and templates for new clinical practices and customize as needed. If no existing elements and templates for a specific practice type were found, new ones were promptly created from scratch. In addition, users often expected a high level of customization. Overtime, many similar, or sometimes identical, concepts were added into the data element dictionary. For example, more than 127 same or similar “alcohol use” data elements were created. Compared to a total of 28,400 data elements in 2007, the total number has increased 2.2 times within 3 years to 62,600 data elements in 2010, and continued to grow dramatically in the following years. We coined this phenomenon as the uncontrolled replication of “cancerous” data elements.

Another significant challenge we faced was that these data elements represented concepts from diverse clinical domains, often with duplicate data elements for the same clinical concepts existing and in use in different EHR modules (e.g., problems, medications, procedures, laboratory tests, assessments, and other clinical concepts). For example, a separate “hemoglobin A1c” data element was created specifically for a health maintenance template, but it was not necessarily or directly linked to a patient’s laboratory test or result. It was difficult to define an appropriate scope for a separate set of data elements that are only used in clinical notes and forms, what terminologies (if available) should be used to encode them, and how to link these data elements to other concepts within an EHR.
An Example: Flowsheet Data Elements

Here we use flowsheet data elements as an example to demonstrate in more detail the important issues related to the definition, implementation, and management of clinical data elements. EHR flowsheets allow clinicians to track specific elements of a patient’s health over time and are helpful in identifying trends within these data. As a common method of documenting clinical observations and physiological measurements, flowsheets are an important component of EHRs and are used as a data source for clinical decision support, safety and quality reporting, clinical trials eligibility criteria, and overall data sharing. When well aligned with the user’s clinical workflow, flowsheets can save time and promote consistent documentation, potentially reducing medical errors. However, studies have highlighted the challenges with designing an efficient flowsheet user interface, maintaining the flowsheet ontology, adopting a proper terminology, and measuring compliance in clinician documentation.

Some of the most common data elements of an EHR flowsheet are vital signs, such as height, weight, and blood pressure. In different clinical settings and specialties, flowsheets can be configured to reuse standardized content (such as vital signs and pain scales consistent with quality measures and reportable outcomes), as well as to record more complex data elements. Flowsheets are inherently flexible and analogous to a spreadsheet organized with data element rows and columns that indicate the date and time of recorded observations. This flexibility allows the design and development of flowsheet data elements and templates to meet specific needs of multiple providers, but requires consideration for how data can be standardized and shared among all users of the EHR system. The composite nature of flowsheet data elements and templates requires that the semantic relationships between each component be clearly defined. Figure 3 (left) shows an example of the editor for a flowsheet data element “temperature.” In LMR, each data element can be defined with an identifier, name, abbreviation, result type, and at most two attributes. Each attribute can have a list of value options. Figure 3 (right) shows an example of flowsheet data entry form using a template composed by combining a set of flowsheet data elements. Figure 4 shows a patient’s flowsheet records in a chronological view.

We performed the following analyses on LMR flowsheet data elements. First, we looked at the total number of flowsheet related data elements and found 3,923 in total. Of these, only 36% had distinct names and the remaining were duplicates (exact same name) of existing data elements. The KM team and the Clinical Quality Reporting team at Partners have identified a set of data elements (by grouping data elements with the same meaning) for the purpose of quality reporting, pay for performance reporting, and CDS. We identified that these important data elements accounted for only less than 3% of the total.

Duplicate or cloned data elements have been frequently created in the LMR dictionary. For example, we found 57 data elements for blood pressure, 55 for weight, 42 for pulse, 21 for height, 15 for temperature, 12 for oxygen
saturation, 6 for respiratory rate, and 5 for pain level (0-10). Using weight as an example, 13 of the 55 data elements are synonyms and 2 are abbreviations. The remaining weight data elements were defined using different combinations of attributes (e.g., unit and measure method) and data type (e.g., string or numeric). Table 1 demonstrates the diversity of attributes or properties and their value sets for some of the flowsheet data elements.

In addition, even with customized structured data elements, we found that free-text comments were often used (sometimes as a workaround) in flowsheet data entries. Collins et al found that nurses use free-text comments in flowsheets as a method to communicate concerning events to physicians, and that these data were associated with survival outcomes of cardiac arrest patients. These phenomena needs to be further studied to provide better understanding of current limitations of EHR flowsheet data elements for automated analyses.

Case Summary

As showed above, the underlying design of data elements was rather simple in LMR (i.e., concept-attribute-value format). One of the original objectives was that by using a relatively simple structure it would allow a high level of flexibility for users to create and customize data elements and templates, which would lead to a wide adoption of structured documentation. However, at the early stage, well-defined data governance strategies were not established. There was no formal model or mechanism for structuring data elements, nor an efficient editing tool. Similarly, linkage and mapping to standard terminologies were not created for these elements. As a result, there is redundancy, inconsistency, minimal reusability, and a lack of interoperability of the existing forms and templates, resulting in continuously increasing maintenance costs.

Case Study 2: the Acute Care Documentation (ACD) Project

A Brief History

Partners Healthcare Systems began the “Acute Care Documentation” (ACD) project in 2007 with the goal of configuring structured clinical documentation using a commercial EHR for implementation at BWH and MGH. The documentation templates were intended for use by nurses, physicians, physical therapists, dieticians and other health professionals that care for patients in the acute and critical care settings. The ACD project was ended just before implementation of the system, but the content creation had produced over 12,000 data elements that were used to create more than 1,200 documentation templates. Based on lessons learned from LMR, two major changes were implemented in the ACD project to control the 'neoplastic' behavior of data elements replication to represent clinical topics: 1) a structured naming convention and best practices for data element names, which help standardize structure and usage; 2) a software tool that allows users to create and customize data elements and templates, which helps to capture and share knowledge among clinicians.

practices for data definitions and reuse were defined upfront, and 2) a dedicated team of analysts were the only individuals creating data elements. These analysts were trained in using the defined structured naming conventions leveraging the International Standards Organization/International Electrotechnical Commission (ISO/IEC) 11179 standard. End-users and other clinical stakeholders helped define the documentation templates, but did not have any control in defining or customizing data elements.

An Example – Vital Sign Data Elements

We classified the ACD content in different content categories. A total of 4,188 data elements were classified into 13 categories. Counts for the top 3 categories were: 1,081 wound documentation data elements, 1,440 tube and drain related data elements, and 374 vital sign data elements. Table 2 shows the counts of data elements in the vital signs category. Despite the effort to manage data elements, duplicates and overlap were again present. Some duplicates were unintended and others were “by design” to accommodate system constraints in which a defined data element cannot handle multiple instances of that concept (e.g., multiple arterial blood pressures, multiple wounds). For example, “Blood pressure, diastolic arterial [mmHg]” and “Blood pressure, diastolic arterial 2 [mmHg]” are data fields for measured diastolic arterial blood pressure at a generic anatomical location. These represented essentially the same concept, yet the system requires 2 entries for tracking measurements overtime that take place in two different body locations. This phenomenon repeated for arterial and systolic blood pressure and likely was a factor in the perhaps unintended specification of “Blood pressure, diastolic femoral arterial [mmHg]” and “Blood pressure, diastolic femoral arterial 2 [mmHg]” given that “Blood pressure, diastolic arterial [mmHg]” was already defined. Table 3 shows a set of blood pressure data element names. With this approach a femoral measurement saved in the generic data field, would lead to inconsistent data retrieval.

Case Summary

Based on lessons learned from LMR document template creation, efforts were made to define data elements in the ACD project using a standard naming convention, but also to reuse data elements throughout the system. However, as described above, technical constraints of the system limited the ability to define content according to these identified best practices. This resulted in a data element dictionary with numerous “known” flaws. Such experiences re-confirmed the need to define practical approaches to improve the consistency and reuse of data elements within EHR systems.

Case Study 3: The Partners eCare Project (PeC)

A Brief History

Partners began the “Partners eCare Project” (PeC) in 2012 with the goal of a single patient record across the entire healthcare system using a different proprietary vendor EHR than the ACD project. The PeC project was significantly larger than LMR and ACD projects over a shorter period of time, greatly increasing the complexity of managing data elements. The PeC project went live with its first site on May 31, 2015 and has been in a process of successive implementations since that time. Due to certain functionality, the proprietary system separates structured data elements from flowsheet data elements. At the first went-live site, the total number of structured data elements that have been confirmed to be in use by end users is 15,209. The total number of flowsheet row data elements is 46,575. The project governance was structured based on the EHR system ‘modules’ that corresponded to a variety

</tbody>
</table>
of clinical settings or specialty areas (e.g., inpatient acute care, emergency department, anesthesia, outpatient, and home health). Within each module, reuse and consistent naming of data elements was encouraged; however, reuse across modules was not emphasized as a priority. Problems noted were 1) duplication and overlap of data elements, 2) inconsistent naming convention, and 3) inconsistent data definitions for similar data concepts. During and after initial go-live, efforts were made to implement standardized and consistent data documentation as well as principles and best practices for customized or “local” data elements. We also developed a practical approach to creating reference models for clinical topics that have been determined to be high priority and that should be shared across applications within the EHR (e.g., pain and wound). This effort has been discussed in a previous publication

**An Example – Blood Pressure Documentation**

We extracted all existing data elements within the structured documentation forms and flowsheet records. We then used keyword search to identify data elements related to “blood pressure”. There are 4 data elements used on documentation forms that contained the word “blood pressure”, plus 40 others defined for flowsheets. Examples are shown in Table 4. The multiple data elements with overlapping definitions are partially due to the technical constraints of the system as well as the findings that the EHR configuration was based more upon end-user experience rather than consistent data definitions. The definition of data elements and configuration of the user interface was driven by large groups of subject matter experts (SMEs) and prioritized increasing usability and specialty-specific needs. More often than not, it is assumed that there was little to no search for similar data element definitions used in other modules prior to creating a new data element. The result is the overlapping data definitions that currently exist less than a year after going live with the first site.

**Case Summary**

The lessons learned from our previous experience with LMR and the ACD project did not sufficiently benefit our initial efforts configuring and implementing a vendor-based EHR system. Since those initial efforts, we have established a governance infrastructure and a set of principles and best practices to guide the creation and use of structured data elements and to continuously refine the many inconsistent and duplicate data elements that exist in the system. These inconsistent and duplicate data elements may have been caused by some of the same reasons described in this paper, such as predefined data element structure, the functionality of the editor tool, and constraints for reuse of data elements. We also acknowledge the rapid pace and size of EHR configuration and implementation projects. Our governance infrastructure will continue to remediate and refine structured data elements by focusing on clinical topics that apply across system modules and we have published elsewhere on these processes.

**Discussion**

Structured data elements are important for documenting the care of the patient and for collecting, storing and processing patient care information. In this study, we found that when we develop or implement different EHR systems (either homegrown or commercial products), we encounter various (similar and different) issues and challenges in building clinical data elements and relevant documentation assets used across different clinical settings. In this paper, we mainly used flowsheet data elements as an example, but one can image there are much more data elements needed for building templates and forms to compose clinical documents. Compared to some other coded data in EHRs (e.g., medications or diagnoses), they tend to be more like a “natural” language that contains rich, detailed information with various expressions. Often, they are difficult to be structuralized or standardized across different clinical settings and specialties. Without a comprehensive and efficient strategy, the data elements will grow rapidly to in order cover the diversity.

We faced many challenges to efficiently create and manage clinical data elements in a consistent, reusable, and interoperable fashion. Common themes, requirements, and desirable characteristics for controlled medical
terminologies have been described in previous studies (e.g., Cimino’s Desiderata\textsuperscript{15, 16}). Goossen et al provided a review of related work in the area of detailed clinical models.\textsuperscript{17} Oniki described lessons learned in detailed clinical modeling at Intermountain Healthcare.\textsuperscript{9} We have conducted a series of evaluations of the content created for our clinical systems at Partners Healthcare System and reflected on why the desirable characteristics outlined above have not been realized. Importantly, we consider our organization to be process-driven, motivated, and well-resourced; yet still struggle with these challenges outlined above raising the question: “How extensive is this problem at other organizations?” In the following, we summarize and discuss some key challenges and possible solutions that we have learned from our experience. We don’t intend to propose data element desiderata or comprehensive solutions in this paper. Instead, we start with basic but important challenges and practical solutions (i.e., challenges 1-3), and then move onto issues and solutions that are important and useful (i.e., challenges 4-6), but they may not achieve an expected impact and need to be combined with other approaches. Finally, we discuss more complicated challenges that need more extensive investigation and work in the future (i.e., challenges 7-8). It is hoped that these discussions may be useful in real-world practice for creating and maintaining clinical data elements.

1. Naming Convention, Attributes and Data Types

Well-defined clinical data elements are important to ensure data accuracy, accessibility, consistency and completeness. The institution should create a guideline for naming convention. When specifying the name for a data element, a preferred description may be chosen, for example, based on standard medical terminologies, and other lexical variations are used as synonyms. The design of data elements and attributes should promote reuse in different templates/forms and sharing among different practices. The value set should be generic (including common items) which allows users to choose the items that they need to create customized templates and forms.

EHR systems often have their inbuilt naming conventions and data types. Due the original design of the EHR system, these conventions may not follow the best industry practices. For example, they may tend to use composite terms for naming their data element (e.g., indicating site, specialty, or purpose within the name) and they may have their own predefined limited data types. Institutions, who implement such an EHR system, may consider developing principles and best practice for naming conventions, including how to name a data element, define its attributes and assign appropriate data types. For example, one may consider what components should be included in the name structure given a certain character limit in the naming field and in which order (e.g., if a data element is designed for a specific purpose and should not be used for other purpose, an indicator for an application or specialty may be added). Metadata may include unique identifier, owner, revision history, type, lifecycle state (e.g., draft, approved, retried), creator, date created, date last modified, sources, long name (i.e., descriptive name with more details about the content and intent), short name, reference terminology, etc.

2. Links to Standard Terminologies

Structured data elements need be encoded in computable forms to be used for clinical decision support, reporting, and other analytical tasks. Linking data elements to standard terminologies also has the potential to help identify duplicate, improve search and reuse. Although this is a basic and important strategy, it frequently gets overlooked. Multiple significant challenges for encoding standardized data elements exist. For example, Kim et al. found that SNOMED terminology provided both complete and partial matches of the Intensive Care Unit (ICU) nursing flowsheet data.\textsuperscript{18} The gaps in matching were felt to be mainly due to a lack of appropriate terms used in the original flowsheet and limitations of the concept models.

Manual review and mapping to standard terminologies is tedious and labor intensive. There are many lexical variations (including synonyms, local jargons, abbreviations, misspellings, and other specific symbols) and a lot of data elements have nested structures, thus exact string match or simple algorithms may be inadequate, indicating a need for semi-automated approaches and an efficient tool for mapping (such as the use of natural language processing). Since data elements for structured documentation contains concepts from multiple clinical domains, we need either adopt a comprehensive medical terminology or adopt and combine multiple terminologies at the same time. As mentioned above, similar clinical concept can be defined in both structured data (e.g., problem list) and as a data element for structured documents. This might need to define a scope, i.e., what types of concepts can be created as data elements and what concepts should be reused from other sources. For certain data elements (e.g., flowsheet and health maintenance items), one possible solution might be to keep these separated set of data elements and map them to standard terminologies. For these that are created separately in multiple sources, mapping them to standard terminology may facilitate future data integration and analysis.

3. Versioning and Change Management

Content lifecycle management is a basic and very critical problem. Versioning and change management is important in following the lifecycle of a specific data element. Once a data element is modified (e.g., add an
additional attribute), if the change management is inappropriate, this change may be propagated to every template and structured document using that data element and may potentially break these documents. This requires the system to track state changes (e.g., draft, in review, active, retired) and versions of these knowledge objects. In addition, change management also provides insight for future efforts to see why a particular element was created, the reasoning and thought process into why it was changed, and may provide guidance on when new but contextually related data elements are created. Most editors built within an EHR system often do not have a sophisticated capability for versioning and change management; therefore, additional content lifecycle management and an efficient edit/management tool outside an EHR may be needed.

4. Data Governance

Healthcare institutions should establish a set of principles and processes to ensure that clinical data elements and templates are formally managed throughout the enterprise based on applicable hospital accreditation standards, federal, state and institutional regulations, payer requirements and professional practice standards. The authority and accountability of data and knowledge assets should be clearly defined and enforced. Relevant parties within the organization should reach and follow an agreed-upon model, policies, best practices and guidelines which describe, for example, who can take what actions with what data elements, and when (under what circumstances) and how (using what methods and going through what processes). A committee or team that consists of executive leadership, clinical domain experts, informaticians, application analysts, and data stewards should be allocated, who employs certain methodologies and tools for managing, monitoring and improving data elements across the enterprise. For example, the committee may periodically conduct quantitative and qualitative analyses to check the quality and consistency of existing data elements and gather feedback from application teams and end users, and when necessary, refine data governance policies and procedures. Our PeC project has well-defined data governance strategies, but it has not eliminated all the problems, indicating it should be combined with other strategies such like those approaches mentioned above.

5. Monitoring, Communication and Training

We found that continuous monitoring of the quality and quantity of clinical data elements is needed to make sure that they are useful and reusable, and consistently meet users’ needs. We also found that the existing data elements in our legacy system (although some of them are duplicate and inconsistent) demonstrate the diversity of users’ needs. This resource demonstrating the diversity of users’ needs is now a valuable resource for us to use to create higher quality data elements. For example, we were able to analyze usage rates and aggregate multiple duplicate or similar data elements to create reference data elements.

Based on our previous experience, we found that when the users or analysts cannot easily find a data element that exactly meets their workflow, they tended to create or request a new one. Possible reasons for creating a new (duplicate) data elements include, insufficient time to look up existing content, insufficient tools to look up existing content, or insufficient training to look up existing content and meet best practices for data definitions. Effective communication between different stakeholders and training for data stewards and end users is critical to help maximize data element adoption among clinician users, reduce duplicates and facilitate linking to the standards.

6. Documentation vs. Structured Data Capture and Customization vs. Standardization

Each practice or provider may have their unique requirements or preference when creating a same or similar data element. Data elements should preserve details to some extent in order to capture something unique about the patient, the health problem, the practice, and the doctor. However, if each team works only on their own goals and ignore the needs of others, their silo requirements produces redundant information and functions and make integration with other silos very expensive, if not impossible. In contrast, standardization is critical for data reuse, integration and sharing. It is also important for high quality data capture and collection, and has impact on downstream data dependencies, including reporting, regulatory requirements, and CDS.

To alleviate the tension between documentation (e.g., note generation) versus structured data capture, it is important to build data elements in a more uniform form under a well-defined infrastructure. Development of individual information technology solutions at each practice or provider level with little coordination at the corporate level should be avoided. An enterprise-wide strategy may be established to ensure deeper cooperation and formal coordination among different parties (such as clinicians, application analysts and data stewards). For example, instead of allowing each local application team to create their data element directly into the system, a centralized vetting and management process should be in place. A possible workflow may be that the application team at each site send request to create a new data element to the enterprise committee. The committee will review whether or not a same data element already exists. If not, they will check whether the proposed data element follows the best practices. A management methodology is needed for standardizing the clinical data elements, while leaving
room for flexibility and customization. The effort required to implement this workflow during an EHR configuration is large and requires early engagement, prior to any clinician content validation efforts.

7. Pre-coordination vs. Post-coordination

As mentioned by Oniki et al.,

modeling and creating clinical data elements is not an exact science. A data element builder may face multiple choices when creating a data element, particularly with those that have multiple components. There are pros and cons of each approach and no state-of-the-art rules for deciding when to pre-coordinate and when to post-coordinate. Basically, post-coordination is more structured, so it is easy for computer to process and use for tasks such as information retrieval and clinical decision support. On the other hand, pre-coordinated terms are more like natural language and therefore more user-friendly. Oniki et al has proposed a set of general principles for helping make the decision when to pre-coordinate and when to post-coordinate. Such a decision is often constrained by the functionality that an EHR system provides and the burden created for end-users. For these cases, well-defined naming conventions may be helpful to create useful and consistent clinical data elements.

8. Reference Information Models

There are some existing efforts for structured clinical documentations as mentioned above, such as HL7 Clinical Information Modeling Initiatives, OpenEHR Archetype Model, Intermountain’s Detailed Clinical Models, etc., but there are also challenges and gaps in using these standards in real-world practice. Multiple factors affect the standard adoption, mostly due to the complexity of these models and the limited functionality of the EHR system and informatics expertise within local institutions to implement these models.

One of our endeavors is to create enterprise-wide reference data element models based on usage statistics. That is, we identify highly used clinical topics and convene an inter-professional panel of subject matter experts to vote and validate a reference model for that topic. Based on these activities, we create enterprise-wide reference data element models (e.g., with a comprehensive set of attributes) that specialty areas can customize based on their need (e.g., by selecting specific attributes needed for their purposes).

Summary

As discussed in Lean methodology,

we cannot only rely on clinicians, practice staff, and site analysts that work on a system to adhere with principles from training and generic advice to not create duplicate or inconsistent data elements. Individual institutions need to develop a comprehensive strategy by considering multiple factors. By designing and deploying a documentation system that fits the workflow of clinicians, it may have the potential to save provider’s time for documentation and eventually improve the quality of patient care.

Limitations of This Study

Our study has some limitations. This study was conducted in one integrated healthcare system. Our experiences may not be the same as what others have in other institutions. Our lessons were learned from developing and implementing particular EHR systems.

Conclusion

We presented three case studies of projects within Partners Healthcare to demonstrate the paramount challenges and issues regarding the development and management of data elements for structured clinical documentation in EHR systems. Some of the key challenges faced at Partners were discussed, and we offer some potential solutions to these challenges. It is hoped that our lessons and suggestions will be helpful and useful for institutions who face similar problems when developing strategies for managing their data elements and relevant clinical content.

Acknowledgments

This project was partially funded by the Partners Siemens Research Council. We thank Partners Clinical Informatics team, Acute Care Documentation team, Longitudinal Medical Records and the Partners eCare Structured Data Element Workgroup team for their work and support. We also thank Frank Chang for his suggestions and inputs for this study.

Sharing Patient-Generated Data in Clinical Practices: An Interview Study

Haining Zhu, BS1, Joanna Colgan, BA1, Madhu Reddy, PhD2,
Eun Kyoung Choe, PhD1

1Pennsylvania State University, University Park, PA; 2Northwestern University, Evanston, IL

Abstract

Patients are tracking and generating an increasingly large volume of personal health data outside the clinic due to an explosion of wearable sensing and mobile health (mHealth) apps. The potential usefulness of these data is enormous as they can provide good measures of everyday behavior and lifestyle. However, how we can fully leverage patient-generated data (PGD) and integrate them into clinical practice is less clear. In this interview study, we aim to understand how patients and clinicians currently share patient-generated data in clinical care practice. From the study, we identified technical, social, and organizational challenges in sharing and fully leveraging patient-generated data in clinical practices. Our findings can provide researchers potential avenues for enablers and barriers in sharing patient-generated data in clinical settings.

1. Introduction

Novel technologies have started to provide patients the ability to track their own health data1. Apple’s HealthKit and Google’s Google Fit are just two recently available platforms designed for capturing, storing, and retrieving personal health and fitness data. Startup companies, such as Fitbit2, 3 and Jawbone4, are also offering self-tracking devices. Self-tracking (or self-monitoring) has an extensive history in research and is noted to generally serve either therapeutic or assessment purposes, with assessments relying heavily upon data accuracy5. We build upon this preexisting framework for self-tracking and aim to understand how best to leverage Patient-Generated Data. In this paper, we define Patient-Generated Data (PGD) as health-related data created, recorded, or gathered by patients (or by family members or other caregivers) to help address their health concerns. These data include physical activity, sleep, food, and blood glucose levels. They can be collected using manual journaling, consumer health tracking devices, smartphone apps, or medical devices (e.g., blood glucose meter). In addition, PGD includes any independent lab results or tests ordered by the patients themselves (e.g. ubiome6, 23andMe7, and LabCorp8).

Enabling people to track their own personal health data provides the potential to leverage the data in medical contexts, but to do so requires an effective means of data sharing among patients and clinicians. Moreover, patients who suffer from a chronic disease often find that self-tracking is burdensome and the sharing of data adds to that burden9. Even motivated patients can be hindered by awareness of the disease, the scattered nature of self-tracking tools, and data collection burden, making PGD hard to collect, and thus share10. With the goal of designing technology that allows for effective and meaningful sharing of PGD among patients and clinicians, we conducted semi-structured interviews with both patient and clinician participants to understand how they currently share PGD and to identify what barriers they face. Based on our findings, we suggest design considerations for creating technologies to support PGD data sharing among patients and clinicians.

2. Background

In this section, we provide a background of the Quantified Self movement, patient-generated data, and patient-generated data sharing.

2.1. The Quantified Self Movement

Advancements in mobile and wearable sensing technologies have spawned a movement called the “Quantified Self.”11 Those who practice Quantified Self (Q-Selfers) track data (e.g., food consumption, mood, physical activity) by manual journaling or self-tracking technology for various reasons such as health behavior change and curiosity10. Coupled with participatory health initiatives, big health data, and trends in patient engagement, data provided by Q-Selfers will hopefully be freely exchanged across healthcare sectors and result in personalized preventive medical practices12. The shift to personalized preventive medicine might combat contemporary health challenges, including sleep disorders, mental health issues, and chronic disease management12. Recognizing these potential benefits, we note a growing number of patients who practice Quantified Self as an approach to preventive health or chronic health management10. 13. Barriers and enablers in the Quantified Self movement vary by individual and situation. Q-Selfers might find the inability to customize and add specific tracking parameters to a ready-made tool to be a
barrier; furthermore, ready-made systems that are intended for diagnostic purposes benefit from precision and accuracy to enable reliable diagnoses, while interactive systems require methods of collaboration and communication to enable the relay of contextually relevant data. Despite the increasing number of online services and available platforms (e.g., Electronic Health Records (EHRs), Personal Health Record (PHRs), electronic patient portals), adoption rates of Quantified Self in medical practices are low and the efficacy of these platforms’ abilities to empower Q-Selfers or improve health outcomes remain untested. Thus, we want to understand the barriers patients and clinicians face with the Quantified Self approach and devise ways to leverage the extensive data patients are generating.

2.2. Patient-Generated Data (PGD)

PGD have the potential to lead to novel medical insights and can promote positive changes in contemporary medical practices. For example, data generated by patients using continuous glucose monitoring systems and self-reported surveys have provided insights into complications in hypoglycemia patients, which might have been missed in verbal communication during clinical visits. PGD such as patient status and history have also been successfully utilized in clinical policy decision making, but this decision making would likely improve with the addition of new data categories, such as patient drug combinations, vitals, and blood results. Despite these potential benefits, however, there are inherent limitations to PGD, including the reliability and accuracy of data, forgetfulness of patients, innate attitudes towards technology, and patients’ self-bias. To utilize PGD in medical practices and research, these barriers need to be overcome. One way researchers have addressed these limitations is by suggesting ways to lower the patients’ manual tracking burdens and increase their adherence to tracking. To further lower the tracking burden, automated sensing is commonly embedded in self-tracking technologies (e.g., Lullaby, MyBehavior). In addition, systems that allow users to edit or add to data inferred by devices are more reliable and credible. Thus, innovative technologies and cultural changes related to the Quantified Self movement have allowed for patients to collect more accurate and reliable health data. These changes related to patient self-management and empowerment through tracking are therefore necessitating the creation of successful methods of leveraging PGD in medical applications.

2.3. Patient-Generated Data Sharing

Sharing can occur in many ways, including between a clinician and a patient and amongst patients, with each having unique challenges. Our work focuses on the contexts of sharing PGD between a clinician and a patient. From the patients’ perspective, self-tracking and data sharing can impose extra burden on top of other efforts for managing chronic conditions. Clinicians also have a less than positive view of sharing PGD; they have concerns about large amounts of PGD interfering with their abilities to provide timely and efficient healthcare to their patients. Sharing PGD can also impose privacy burdens on hospitals. Modern medical practices protect patient records with strict laws such as HIPAA. Although PGD is not traditional medical data, it has certain characteristics of it, and thus, there is a growing concern over whether it is subject to HIPAA when the data gets shared with clinicians via mobile devices. However, clear legal standards do not exist. PGD allows patients to actively engage in clinician-patient collaboration; such data can be shared during clinical visits (i.e., synchronous communication) or outside of clinical visits (i.e., asynchronous communication). Asynchronous communication tools, such as patient portals, create secure opportunities for dialogue, but this interaction often loses the benefit of non-verbal communication (e.g., using body language and tone); these tools are most beneficial if they compensate for nonverbal deficiencies and if used by motivated, technologically savvy patients. However, real-time tracking tools (i.e., mobile phone), which can be used for synchronous communication (i.e., in person, telemedicine, phone call), allow for more consistent data recording in patients. These tools might thus mitigate issues of patient compliance, but they often lack support for data sharing. Our work specifically aims to understand what impedes PGD sharing during clinical practices, including technical, social, and organizational challenges.

3. Method

We conducted semi-structured interviews with 21 participants (12 patient participants and 9 clinician participants). We wanted to identify the enablers and barriers inherent to sharing PGD for patient-clinician communication, and to gain insights into design requirements for future technology interventions. The purposes of this study are to help patients become active observers and participants in their care and to inform clinicians of PGD data to enable them to provide better care.
Participants: Participants were recruited by word-of-mouth referrals and advertisements in handouts placed in public locations, hospitals, and online (e.g., university mailing lists). In this qualitative study, we sought diverse perspectives from broad participants. To be eligible as a patient participant, individuals had to (1) have experience collecting PGD (e.g., sleep, diet, exercise) for themselves or for their loved ones (e.g., a parent tracking health data for his or her child); and (2) have experience sharing the collected data with clinicians. Patient participants were not limited to current patients. Patient participants did not require a clear diagnosis to be eligible. We excluded individuals who were minors or non-English speakers. Clinician participants were individuals who (1) regularly consulted with patients (e.g. therapist, physician); and (2) had experience seeing patients who wanted to share their PGD during the visit. Table 1 and Table 2 show our participants’ demographic information.

Study Procedure: We conducted semi-structured interviews. Interviews were conducted either via phone (n = 10), Skype (n = 7), or in-person (n = 4). We also collected screenshots of how PGD was shared, including tracking tools, diary sheets or notes, and visualizations. We designed the interview to guide participants to discuss their firsthand experiences with self-tracking. Interview questions for patient participants included the following: (1) What motivated you to track and share data? (2) How and with whom did you share PGD? (3) What were barriers and enablers to sharing PGD? (4) How did the activity of tracking and the knowledge it provided affect your general life? Interview questions for clinician participants included the following: (1) How do patients typically share PGD? (2) What are some barriers that prevent sharing PGD during clinical visits? (3) How could PGD be utilized to support the clinician and care team? From these interviews, we gained a deep understanding of the key barriers, which inhibit clinical utilization of PGD and ways in which we might mitigate the identified barriers. The research was approved by the Institutional Review Board.

Data Collection & Analysis: All interviews were audio-recorded and transcribed to facilitate analysis. Each interview ranged from 30 to 90 minutes. To ensure the confidentiality of participants, we assigned a unique participant identifier to refer the roles of the participant: C# to denote a clinician participant, and P# to denote a patient participant. Two researchers analyzed each transcript of the individual interviews and used qualitative open coding to note prominent themes that were discovered across the data pool. Once the team agreed on the high-level themes identified, one researcher then iteratively coded the data and updated the coding scheme. The high level

*CI denotes tracking was initiated by clinicians (clinician-initiated), whereas PI denotes tracking was initiated by patients (patient-initiated).
categories we include are as follows: motivations for patients to collect and share health data; motivations for clinicians to adopt PGD; methods and means to share PGD; tensions between clinicians and patients; barriers and drawbacks to PGD sharing; and enablers and workarounds to share PGD.

4. Results

In this section, we present the results from the interview study to report existing gaps in PGD sharing. In particular, we describe the nature of patients’ tracking, address the difficulty in sharing data between patients and clinicians, and report the barriers which inhibit the utilization of PGD—from both patients’ and clinicians’ perspectives.

4.1. Clinician-Initiated versus Patient-Initiated Tracking

In the clinical context, tracking was initiated either by a patient or clinician. In our patient dataset, most of the patients initiated the tracking without any prompting from clinicians (Table 2, last column). On the other hand, all clinicians we recruited had experience initiating the tracking by providing patients with a diary and asking them to track certain items (Table 1). Moreover, most of the clinician participants had experienced patients bringing their data to visits and sharing it voluntarily. We observed that clinicians’ receptiveness to PGD varied depending on who initiated the tracking. When clinicians initiated the tracking, it was often the case that they required PGD for a specific medical reasoning, thereby the value of the data was high. In these instances, patients became a “diagnostic agent” for clinicians, and thus played an active role in personal diagnoses. Patient-initiated tracking, however, was not always welcome by clinicians, which we further describe in the following.

Clinician-Initiated Tracking: Clinicians asked patients to self-track for various reasons. C3 was particularly interested in pushing patients for engagement purposes. C3 said, “…knowing the actual data is less important than just hearing their perspective and knowing where they’ve come from and engaging them on that... if they’re tracking... addressing it is a way to sort of reinforce their engagement.” Clinicians’ authority helped with motivating patients to track, as C5 perceived: “it’s very rare that they [patients] record anything unless you ask them to.” Most of the clinician participants noted it was common to ask patients to provide data such as reactions, side effects, and symptoms when they receive new medications. The practice of asking for data and making decisions based on it was essentially what it meant to be a clinician. Clinician participant C5 suggested that clinicians initiated tracking for the purpose of accurately assessing a patient’s issue: “Maybe for sleep disorders and sleep insomnias, when people complain to that, you try to get them to do a two-week sleep log so you’ll really know how they’re sleeping.” Tracking was most often initiated by clinicians in cases with chronic diseases (e.g., diabetes, hypertension) or persistent symptoms: “Once you diagnose a patient with diabetes, you’ll send them to the diabetic educators, we’ll teach them how to use a glucometer and then go over with them kind of how to keep track of their blood sugar values…” [C8]. Participant P9 also explained that clinicians initiated a tracking regimen after certain medical procedures or during rehabilitation: “After I had heart surgery, I was in a cardiac rehab program for several months and that was a daily or a three times/week tracking.” Finally, C8 explained that PGD is useful for discussing lifestyle changes and barriers preventing patients from achieving their health goals.

Patient-Initiated Tracking: The most common purpose for a patient to initiate self-tracking was to develop self-awareness and self-management skills, with 8 participants offering similarly themed explanations. Patient P11 stated, “…if I’m going to go out and drink… I will expect to have a bad night of sleep. So if I need to be ready to give like a presentation, I’ll just plan for that and not go out. I feel like I know better how things affect me and how long they’re going to affect me. It has helped me optimize myself.” In cases with patient-initiated tracking, another common tracking motivation was individual curiosity—for example, curiosity about how one’s lifestyle affects weight, or whether a treatment works. P8 remarked, “Gathering that information or looking at that information has given me hope…This drug that I have is effective at first but doesn’t seem to be as effective right now… we may discontinue it and start something else.” Patients with medical problems, such as diabetics, often tracked data related to those medical problems. Three patients tracked data so that they could better collaborate with clinicians or answer their questions more effectively. Two other patients stated that they shared data with clinicians to initiate conversations and keep them informed. P9 specifically noted, “I think tracking helps me feel like I am participating in my health and my medical care directly and that I’m being proactive about it. It enables me to have informed conversations with my medical providers that are based on data.” Furthermore, some patients wanted to show the data to collaboratively alter their medications, or to come off medications. P4 noted “…it’s very easy to say, ‘Your cholesterol is too high, take more medicine because we know you’ll go down 10% if you double the dose.’ But by tracking I did, I’m able to say, ‘Hey, if I get my weight down 12 pounds, I will reduce my cholesterol 20 points and do the same thing that way.’” Five patients mentioned this desire to collect data to help change treatment plans. As such, many patients appeared very eager and motivated to be equal partners in the promotion of their health, and the
fact that these patients track multiple factors suggests that some are trying to promote whole health, rather than treat specific symptoms. Lastly, a clinician participant mentioned that patients’ tracking can potentially be due to the patients’ mental health disorder or obsessive behavior.

4.2. How is PGD Shared

Patients track a wide array of health information. In our study, patients tracked factors such as exercise, treatment changes or medically relevant factors, food, alcohol, caffeine consumption, travel and lifestyle, symptoms and ailments, weight, period data, sleep and sleep patterns, test results, general health history, and chronic or persistent health problems (e.g., diabetes, high blood pressure). We examined how data is shared among patients and clinicians by employing the space-time matrix. According to the space-time matrix, PGD sharing can be categorized based on where it occurs (distributed vs. co-located) and when it occurs (synchronous vs. asynchronous) (Table 3).

Table 3. How Patient-generated Data is Shared: Space-time Matrix.

Synchronous Co-located Sharing: Verbal communication during visits was the most common data sharing method in clinical practices. Most participants had shared data verbally during visits, as C5 reported: “[Patient typically shares data during the visit] because that’s the only time we have contact.” Some patients collected their personal data but chose not to share it in any other form but verbally so that they could maximize face to face time with their clinicians: “You get a ton of data, but if you give him all these numbers and stuff to go through, then you’re going to bleed out the time for the visit…” [P4]. There were two cases in which a patient specifically mentioned why they did not use technology to share data with a clinician. Those two instances were specifically the inconvenience of traveling with a laptop and the uncertainty of proper etiquette. P12 noted, “I was worried that he [clinician] might feel annoyed if I pulled out my mobile phone… Normally clinicians don’t want patients to pull it out.” Using a tool (e.g., spreadsheets, images, timelines, videos, data visualizations) was the second most common way of sharing data during visits; the most common tool used by patients was paper. C3 confirmed this by stating, “They may just have a piece of paper with everything they ate for the last 48 hours. Or they might have an ache diary…. It may just be written on a piece of paper.” Information visualizations were thought to be good tools for quickly sharing data to uncover significant insights, especially for those who had the skillset to create visualizations. For example, P11 was a designer who could draw a timeline using Adobe Illustrator, which she printed out and shared with clinicians. P11 expressed, “I think the clinicians have appreciated the timeline format… a visual timeline like a graph, a timeline on a graph would be helpful for sharing (Figure 1).” Patients commonly used data collection tools, such as medical devices and wearable trackers, as data sharing tools, because there were few available tools explicitly designed for data sharing. C8 noted, “Some patients who feel like it’s going to take too much time and efforts for them within their lifestyle will just bring in the glucometer because it’s easier for them to just bring it in.” Patients also presented clinicians data on their mobile phones or desktop applications. Some patients even brought a computer to a clinical visit to demonstrate trends in data. Although any device with the ability to store and present data could potentially be utilized for PGD sharing, clinicians found it especially difficult to manage the data presented by data collection tools. As stated by C8, “…trying to kind of figure out how to maneuver and like data summary of the data from each different app, can be a little challenging and time consuming in an acute visit.”

Figure 1. P11 used Adobe Illustrator to create a medical timeline, and brought the printed version when visiting to a new doctor. The peach color represents gastrointestinal symptoms, and the blue represents Myasthenia Gravis.
Synchronous Distributed Sharing: Phone calls offered a quick and convenient way to share data, especially when other electronic means such as emails could not be utilized or when patients wanted immediate responses but were unable to make an appointment. Furthermore, phone calls provided a benefit over email communications, as they provided important cues such as tone of voice as well as opportunities for clinicians to ask for clarification. The majority of clinician participants asked patients to give a phone call in certain situations: “I get most of my data from the patient during their actual visit…. there will be times when I will ask them like if I make a change in their medication regimen to keep track of their sugars for the following week and call the clinic with those numbers so I can make further adjustments over the phone if necessary” [C8]. Telemedicine offered unique opportunities and drawbacks, and clinician participants had conflicting opinions towards it. Two clinician participants agreed that telemedicine could help them see more patients, and that more patients would benefit from their treatments if clinicians could provide electronic or telephone based communication. Two other clinician participants however questioned the accuracy and reliability of the data shared via telemedicine tools (e.g., phone): “If they’re giving you information over the phone, can you trust that their sugar levels are recordable?... it’s an electronic device that doesn’t transmit it electronically.” Other participants had neutral reactions toward telemedicine but potentially showed a slight preference for email communications. Currently, synchronous distributed sharing is typically uncompensated effort, however, and this significant drawback might have resulted in clinicians being more reluctant to look at PGD and more resistant to using technology outside of clinical visits. C2 explained, “...it’s better that it [PGD] comes to me in an office visit…. I do a lot through like on patient portal and do a lot of management that way but we have no way of compensating that time…. it’s a lot of uncompensated effort on my part… that’s something that I do it because I wanted to be I want them to get better.” Although the work was uncompensated, some clinicians still asked patients to send data via email or phone, took time to look at the data, and offered medical opinions because they believed that it is beneficial to patients.

Asynchronous Distributed Sharing: Asynchronous distributed communication was beneficial in situations where patients and clinicians had conflicts of schedules. Faxes, emails, or patient portals could enable the sharing of data immediately, while allowing for a clinician to respond when he or she has the time to do so. C8 noted, “...via the patient portal, they can actually send a message directly to me if they have any questions or concerns between visits.” Patient P4, who has a software engineering background and is a retired medical doctor, was the most extreme and unique case. He designed and built his own software, which assisted in the sharing of data in an asynchronous distributed manner (Figure 2-c, 2-d): “I just put him [clinician] to my websites... if he just puts in my URL that he can access it from the note, and it’s actually easier for him.”

Figure 2: Example of screenshots that patients shared. (From left to right: P1, P11, P4, P4). P1 and P11 used excel spreadsheets to track their health data, here shown as (a) and (b). P4 created software that generates graphs to show the correlations of certain fitness data, such as Fitbit steps, Aerobic time, and weight.

4.3. Tensions around PGD

Tensions existed between clinicians and patients, which discouraged the sharing of data. Not all clinicians were receptive to patient-generated data. We report major tensions existing in the current medical practice.

Tensions Between Clinicians and Patients: The first tension we observed was the misalignment of the clinician’s agenda and the patient’s expectations; this includes such things as patients recording clinically irrelevant data, or not recording relevant data, and differences of opinion between clinician and patient regarding healthcare needs. C2 noted, “Because sometimes their ideas of why they’re there are different from my ideas of why they need to be there. Then, we have a discussion.” We also observed that patients’ desires to maximize their time with clinicians often created tension between them and clinicians. In many of those cases, clinicians were unable to provide time outside of their visits. One clinician participant expressed, “you don’t have time outside of that [in-person visit]. In
medicine, it has to be as the patient is visiting. Because otherwise, you’re taking time either from somebody else or from yourself” [C5]. Many clinician participants and a few patient participants were concerned that clinicians could be overwhelmed by raw PGD. Many participants specifically expressed concerns about clinicians receiving too much data at once and not knowing how to process it. “If people come in with so much information that you can’t make sense of it, it doesn’t help clarify things...” [C3]. The third tension, experienced by most clinicians, was the issue of the reliability and accuracy of PGD. “It’s not usually accurate because they don’t have all the data to support it so they’re kind of giving you this memory of what they think” [C4]. Concerns regarding data reliability and accuracy were not limited to patients’ data reporting errors. Clinicians also pointed out that uncalibrated machines, improper testing protocols, transcription errors, device errors, or some other unknown factors could result in unreliable or inaccurate data. Thus, clinicians were mistrustful of PGD shared by their patients unless accuracy can be verified. C8 noted, “...people just don’t actually check their blood sugars routinely enough, and if they do they kind of do it sporadically and don’t write down the exact date and time, etc. (...) that can be a little bit more challenging.” Although data collected by a patient could be entirely accurate, and thus reliable, it was not meaningful to a clinician if it did not contain all of the data that the clinician might need.

**Attitude towards using technology:** Clinicians responded differently and sometimes ambivalently to the use of technology for tracking and sharing PGD. About half of the clinician participants expressed preference for paper based data tracking over technology-assisted tracking. C3 noted, “...The electronic stuff is a lot easier to collect, but I think it’s a lot harder to analyze because it’s less common to be able to see everything all on one screen....” However, half of the clinician respondents also reacted favorably to the use of technology for tracking, or negatively to paper based tracking. These groups were not mutually exclusive; there were individuals who both preferred paper methods and reacted favorably to technology-assisted methods. A few clinician participants reacted neutrally towards technology. C3 suggested her reaction was pragmatic, and said, “So whatever method is easiest for them to get you good accurate data.... My patients would lose the piece of paper, if they did something on their phone they would do better with that.” Our data suggests that the clinician’s reaction to technology versus paper-based method is a multifaceted issue; clinicians’ responses to the use of technology likely corresponded to their initial attitudes towards technology in general. Clinicians tended to believe that both paper and technology-assisted method have their own merits and pitfalls as well as niches, which could explain the apparent ambivalence or even neutral responses noted by participants.

**4.4. Barriers and Enablers to Leveraging Patient Generated Data**

Most clinicians consistently noted the difficulty or inability of transferring PGD to EMR as a barrier for data sharing. C4 said, “…it [PGD] doesn’t go into the electronic health record. So unless your clinic is set up where a nurse practitioner or someone else can go through all of that data, set that up, make sure they have it and they give that information to the clinic, it’s not really helpful to anybody else.” A related concern was HIPAA and data security and privacy issues as C5 explained: “We have to send them, ‘We cannot respond to this [PGD], this is a violation of HIPAA. Just go away or go to a secured server’” [C5]. However, it was not clear whether EMR was the right place to store all the patient-generated data collected outside the hospital because (1) there is currently not a good user interface within EMR to upload and view PGD; and (2) the data can be quickly buried in the EMR system. In fact, P4 stated, “…since I have the data, if I get referred to a specialist, I'm not counting on his transfer... I wrote up a little summary with my graphs and charts... [the specialist] said, ‘I just read what you had, it was easier.’” We also learned that storing PGD in the EMR system was not just a data integration issue, but a bigger issue of integrating PGD into clinicians’ workflows, making the data easy to access, use, and transfer. A patient participant noted this challenge: “Patients are self-trapped, when they come in with data that’s difficult for the
doctor to digest and the doctor doesn't like that. (...) The key thing is, that's the work for the patient but it has to create this thing that's so easy for doctor, so that make their life easier too or they'll find a way to ignore it” [P4].

A majority of clinician participants mentioned time constraints as an important barrier impeding data sharing, which was apparent to patients as well. P9 noted, “I have to prioritize what I think is important to share. I’m sensitive that I don’t get a lot of time with them that they have a lot of information to process” [P9]. Participants shared ideas for efficient PGD sharing, for example, sending data to clinicians before visits, as noted by C2: “So if a patient can handle technology and can send the information in preparation for a visit...That would be great.” Likewise, data visualization was noted to have aided efficient data sharing. “I think the visualization is great... So we know there are high levels of innumeracy in patients so figuring out ways to present the data, not just for the patients, but me so I can get a quick overview...” [C4]. We believe that providing insights using visualizations in the context of PGD sharing opens up many possibilities for future research, especially designing a PGD sharing platform that can ensure quick and efficient sharing while providing insights.

5. Discussion

In the previous section, we highlighted a variety of issues related to the sharing of PGD between patients and clinicians. We now turn to four discussion points surrounding PGD sharing. These issues are (1) aligning clinician/patient perceptions about PGD by including clinicians in the early stages of patients’ tracking; (2) integrating PGD into clinical systems; (3) aligning organizational policies; and (4) empowering patients as partners in healthcare.

First, it is important to align the clinicians’ and patients’ perceptions about PGD as closely as possible. Both clinicians and patients are interested in seeing health trends and patterns or documenting treatment efficacy, but the two groups might have very different perceptions about the type and value of the data. One of the primary motivations for patients to collect PGD was to gain an as in-depth picture as possible of their health, which they can then share with their clinicians. Based on our interviews, however, we learned that when patients initiated tracking, clinicians often ignored the data collected and did not find the data useful, especially when it was either incomplete or irrelevant to the current issue. For clinicians to leverage the data, clinicians must know that data is accurate, reliable, and aligned with their agenda. We therefore see opportunities in making the PGD more useful and relevant by involving clinicians early on to provide guidance to patients on how and what data to collect and to help patients understand why such data is important. With such guidance from clinicians (e.g., what to track, how often to track, what format to use), patients might be able to collect more clinically relevant data, thereby making clinicians more likely to leverage that data in their clinical practice. Likewise, if patients could provide contextual information regarding their testing and data collection, clinicians might be more accepting of PGD.

Second, although PGD could have immense value for patient care, clinicians cannot effectively use this data until it is integrated into the clinical systems. The integration will require the development of a technical infrastructure to transfer the information from the patient to the clinician. Although patient portals have started to be used for sharing patient information with clinicians, it is not being used for PGD data sharing, especially the synchronous co-located manner, which was the most prevalent way of sharing PGD. Data visualizations, analytics, and summarization techniques will play an important role in making PGD valuable for clinicians and patients, helping them quickly gain critical insights and reflect on the data.

Third, clinicians need to be incentivized to incorporate PGD into their everyday workflows. While the technical challenges of integrating PGD into clinical systems are important, it will be just as important to re-align organizational policies to incentivize clinicians to utilize PGD. It is unclear at this point whether sharing PGD will lead to more patient encounter time (if sharing is done inefficiently) or even less patient encounter time (if sharing is done efficiently) than what is currently allocated for patient encounters for clinicians. The effectiveness of sharing would depend on how a PGD sharing platform is designed and how well the data is presented to the clinicians.

Lastly, clinicians need to understand and adapt to the cultural shift in healthcare, in which more patients are attempting to make healthcare a collaborative endeavor. The patient participants we talked to wished to alter their treatment plans and create conversations with their clinicians; they wanted to be equal partners in healthcare and careful observers of their bodies, as opposed to traditional passive patients. Furthermore, some of these patients promoted their whole health through employing tracking for preventive purposes, rather than to treat an illness, thus changing the current paradigm of receiving healthcare. Patients are also motivated by clinicians; they will engage in their healthcare more if clinicians welcome their involvement. One way of inviting patients into the care team is through encouraging patients to start tracking their data in a way that can help clinicians.
6. Limitations and Future Directions

Our study’s limitations include the small participant sample size and purposive sampling towards receptive patients and clinicians due to our inclusion criterion of requiring prior PGD collecting and sharing experience. The study results are therefore unlikely generalizable to the entire population. However, our goal was to discover current practices and barriers in patient-clinician data sharing, and we argue that our inclusion criteria are necessary to gain meaningful data, as we were looking for initial insights into existing phenomena. Our findings could be used to create an in-depth study of PGD sharing behaviors, by creating a prototype intervention and testing it with a representative sample. We also selected participants from multiple localities and medical subdivisions, and with various health conditions to recruit a diverse population, because we were interested in the coverage of various issues. We also note that the patient participants were not necessarily the clinician participants’ patients; this is why most of our patient participants indicated that they had initiated their tracking (patient-initiated, or PI), but all of our clinician participants indicated that they initiated the tracking (clinician-initiated, or CI) or both CI and PI. Therefore, our patient participants might have been particularly motivated in collecting and sharing PGD whereas our clinician participants might have actively encouraged patients to track. In the future, we are planning to study patient and clinician pairs, so that the selection bias may be reduced. The findings of this study will help us design a future platform for PGD sharing to enhance patient-clinician communication.

7. Conclusion

In this study, we described the current practices of PGD sharing among patients and clinicians. We particularly examined the differences between tracking initiated by clinicians versus patients. We then employed the space-time matrix to analyze various PGD sharing practices. After describing tensions between clinicians and patients, we identified barriers and enablers to PGD sharing. Many of the barriers were related to the lack of infrastructural support for data integration, but this was not merely a technological issue; a bigger challenge was how PGD sharing could be incorporated into clinicians’ workflow. Most of these barriers can compound to further inhibit clinician-patient communications. Understanding a clear picture of how PGD is currently shared and its associated challenges are important for the design of systems that can leverage PGD and integrate the data into clinical practices. This initial study provides new opportunities to study PGD sharing between patients and clinicians with better focus on the significant issues we identified. We are particularly interested in how information visualization can be designed to aid efficient data sharing. With the ever-increasing growth of personal health mobile applications and wearable sensors, patient generated data will only increase. We are only starting to understand the challenges that we need to address to integrate this data into the healthcare process.

Clinical Decision Support to Detect High Risk Patients with QTc Prolongation

Christopher A. Aakre, MD, J. Martijn Bos, MD, PhD, Gyorgy Simon, PhD, Robert F. Tarrell, Michael J. Ackerman, MD, PhD, Pedro J. Caraballo, MD
Mayo Clinic, Rochester, Minnesota

Abstract
Prolonged QTc is a risk factor for sudden cardiac death. To identify patient at risk, we implemented clinical decision support integrated in the electronic health record to detect new QTc prolongation of 60ms and alert clinicians to implement corrective measures. We reviewed our experience and identified technical challenges. We propose changes to decrease the number of alerts and alert fatigue without jeopardizing patient safety.

Introduction
Prolonged QT is an independent risk factor for Torsades de Pointes (TdP), a ventricular arrhythmia and a cause of sudden cardiac death. Prolonged QTc is defined as a QTc >470 milliseconds (ms) in men and >480ms in women. For both sexes, QTc >500ms is very abnormal and is associated with a 2- to 3-fold higher risk for TdP. Additionally, an increase of QTc of 60 ms over baseline is considered highly torsadogenic. Prolonged QTc can be congenital (long QT syndrome) or secondary to several medications, electrolytes abnormalities and comorbidities. Because of these risks, national guidelines recommend the use of electronic systems to detect potentially arrhythmogenic QTc prolongation in hospitalized patients. Mayo Clinic has developed and implemented several clinical decision support interventions to identify these high risk patients. In this work, we discuss methods and pitfalls of automated identification of QTc prolongation of >60ms in two consecutive electrocardiograms (ECG).

Methods
A clinical decision support (CDS) rule integrated with the electronic health record (EHR) was implemented to screen all new ECGs to identify an increase in QTc interval >60ms in consecutive ECGs. If QTc prolongation was identified, a semi-urgent alert was sent to the inbox of the ordering provider or primary hospital service. The CDS rule also identified any ECG with QTc >500ms and sent a semi-urgent alert. The generated alerts suggested patient specific modifiable risk factors that may be associated with the QTc prolongation, such as medications and electrolytes. We reviewed all alerts generated by the CDS system related to QTc prolongation > 60ms from 1/1/2010 through 12/14/2015.

Results
The system generated 6,798 alerts in 6,039 unique patients (52.2% male, mean age 60.1 years, SD ± 19.5). Alerts were sent to 6,434 unique providers. The time interval between consecutive ECGs was highly variable: 27.35% of alerts with interval less than 2 days, 23.4% between 2 to 7 days, 34.25% between 8 to 365 days, and 15.0% between 1 year to 5 years. The figure shows the distribution of the alerts based on the QTc intervals of the previous ECG (y) and current ECG (x). Approximately, half of the alerts (46.1%) occurred when both QTc intervals were between 360 and 500ms (B). Few alerts occurred when both QTc intervals were at extreme values (<360ms and >500ms), both low (A=0.1%) or both high (C=2.6%). However, 47.3% of all alerts (C=2.6%+F=44.1%+E=0.6%) occurred with a current QTc >500ms, which would trigger the second alert regardless. Manual review of a sample of ECGs with extreme QTc measurements revealed both accurately and inaccurately measured QTc intervals. Most erroneous measurements observed were attributed to low T-wave amplitude in several leads.

Conclusion
Our preliminary analysis suggests that close to half of the alerts for QTc prolongation >60ms occurred at the same time the current QTc interval was >500ms. Clinically, these patients might be at higher risk of complications and require special attention; however quantification of this potential increased risk requires further study. Two separate alerts may not convey combined risk, if it exists, and may contribute to alert fatigue and alert override. Additional analysis is needed for extreme QTc values found in our samples to identify technical difficulties measuring the QTc interval and implement corrective measures to avoid false positive alerts.
Introduction: In May 2015, Brigham and Women’s Hospital (BWH) transitioned from an electronic health record (EHR) system called the Longitudinal Medical Record (LMR) to an Epic EHR. Both systems provide clinical decision support for drug-drug interactions (DDIs), but each system uses a different knowledge base (KB), user interface, and workflow. The LMR uses a highly-tailored KB to provide only clinically relevant alerts as determined by a panel of experts; the implementation of Epic at BWH uses a commercial KB with minimal customization. In LMR, DDIs are alerted at the time of medication selection; in Epic, DDIs are alerted at the time of order signing after all drugs have been selected. Both LMR and the implementation of Epic at BWH sort drug interaction pairs into three tiers of severity (where Tier 1 is the most severe), although the drugs in each tier differ according to the KB. In LMR, Tier 1 alerts are interruptive hard stops that require the user to cancel one of the interacting drugs, Tier 2 alerts are interruptive alerts that require the user to provide a reason when opting to override an alert, and Tier 3 alerts are passive and provide in-line text that there is a DDI. In the implementation of Epic at BWH, all three tiers of alerts were initially interruptive but could be overridden and providing a reason for the override was optional. After March 1, 2016, in response to concerns about alert fatigue, Tier 3 alerts were filtered so that they are only displayed to users on request.

Methods: Retrospective data was analyzed for the final six-month period in which LMR was in use and for the initial six-month period in which Epic was in use to evaluate alert burden and acceptance rate in each system. Additionally, DDI alert data from Epic was collected for the three months before and after Tier 3 alerts were filtered, in order to measure whether decreased alert burden would increase alert acceptance rates. For each system and time period, all DDI alerts that fired in the outpatient setting were collected, as well as the severity of each alert and the action taken by the user when presented with the alert. Historical medication orders transferred to Epic were excluded, as were orders on test patients.

Results: In LMR, there were 1.1 interruptive DDI alerts per 100 orders. The implementation of Epic had a much higher alert burden, with 10.4 DDI alerts per 100 orders. More concerning, the acceptance rate for drug interactions fell from overall 28.6% to 6.6%. Tier 1 alerts in LMR were accepted 100% of the time (since the system did not allow users to override the alert), but such alerts were accepted only 9.08% of the time in Epic. Tier 2 alert acceptance fell from 27.29% in LMR to 7.81% in Epic. Tier 3 alert acceptance was 5.44% in Epic – there was no comparable figure in LMR, as Tier 3 alerts were informational only and could not be accepted. We also compared the five most frequently alerted interactions for each severity tier in each system and found that acceptance rates fell a large amount for every drug pair compared.

Given the substantial drop in acceptance rates for DDI alerts, the BWH CDS committee hypothesized that the increased alert burden, particularly of Tier 3 alerts, was causing alert fatigue, leading to lower acceptance of Tier 1 and Tier 2 alerts, and decided to filter the Tier 3 alerts. After the change, alert burden fell by 51%, which led to a small increase in acceptance rates. Tier 1 alert acceptance rose from 8.8% to 12.4%, while Tier 2 acceptance rose from 7.0% to 8.8%. Though slight, this difference was statistically significant using Pearson’s chi-squared test for independence in both tiers (P = 0.011 for Tier 1 and P < 0.001 for Tier 2).

Discussion: There are about ten times as many DDI alert firings in Epic as in LMR, and acceptance rates in Epic are much lower than in LMR. There are several possible explanations for the disparity in rates. Each system uses a different KB, and there may be more interactions in the Epic KB that rarely warrant discontinuation of a drug. However, when we limit our focus to specific drug pairs, the difference in acceptance rates persists, suggesting that the difference in KB does not fully explain the difference in acceptance rates. Another possibility is that the increased alert burden in Epic causes alert fatigue. However, our findings show that cutting the alert burden by 51% only caused a small increase in acceptance rates, not nearly enough to make up the decrease in acceptance rates after switching from LMR to Epic, suggesting that alert fatigue may play a role but is not the sole factor. A third possibility is that the greater differentiation between severity tiers in LMR is more effective at convincing users to discontinue drug orders (for good or bad) than the equivalent in Epic.

Conclusion: Analysis of DDI alert data shows higher acceptance rates in LMR than in Epic that are not fully explained by a difference in KB and alert fatigue, suggesting that severity tiering and other workflow differences may be important factors.
Mining EMR Data to Hypothesize Causal Associations for Depressive Disorders

Orhan Abar, M.S. and Ramakanth Kavuluru, Ph.D.

1Division of Biomedical Informatics, Department of Internal Medicine, University of Kentucky
2Department of Computer Science, University of Kentucky

Introduction: Mining electronic medical records (EMRs) to identify potentially meaningful and novel clinical associations has been gaining popularity in the medical informatics field. However, it is well known that associations do not necessarily indicate causal relationships owing to confounder variables. If confounders are known, stratification and matching approaches [1] exist that can account for the effect of confounders. In general, identifying confounders is often time consuming and involves significant domain expertise giving rise to automated approaches for identifying and controlling for such variables [2]. We employ such approaches to mine diagnosis and medication data and hypothesize causal associations for depressive disorders using a large EMR dataset of all patient visits (∼ 3.25 million) to the University of Kentucky’s medical center and affiliated clinics during the ten year period 2004-2013. We chose depressive disorders given they form one of the most common mental disorder group, especially among adults.

Methods: To handle sparsity with large numbers of unique codes, we employ grouping techniques. For diagnoses, we use ICD-9 code classes developed by the AHRQ’s Healthcare Cost and Utilization Project (HCUP). These classes group related codes resulting in 282 classes for the 11,877 codes in our dataset. We rolled-up the Multum medication codes using their class hierarchy which resulted in 150 classes (e.g., Penicillins) from a total of 1064 unique medication codes. In each patient visit transaction, we then replaced the codes with the corresponding HCUP and Multum classes resulting in a total of 432 unique variables populating 3.25 million transactions. The depressive disorder HCUP class has a total of sixteen ICD-9 codes representing all variants of depression in ICD-9-CM and occurs in EMRs for 54,923 visits. We first identify and rank potential confounder variables for the HCUP depressive disorder group using L1-regularized logistic regression based feature selection because it has been shown to be comparable to the manual expert propensity score based approach [2]. We repeat this process for all items that have a 95% confidence interval based odds ratio lower bound ORLB > 1 with regards to the depressive disorder group as the outcome variable. That is, we identify potential confounders for all variables that are known to have statistically significant associations with our outcome variable. For each of these variables, we rank-aggregate (using Borda count) to rerank potential confounders in the intersection (given confounders ought to influence both antecedent and outcome variables) of the corresponding sets for the variable and the depression HCUP class. We then build the corresponding so called “fair dataset” [1] that matches patient visit transactions where the top k (for k = 5, 10, 20) confounder variables take on the same set of values and compute ORLB on the fair dataset for the particular antecedent variable. We have also added the well known age-group (based on NLM’s MeSH classification) variable as an additional confounder regardless of whether it was included based on the automated analysis.

Results: We rank-aggregated the antecedent variables that had an ORLB > 1 computed with their corresponding fair datasets by averaging ORLBs from the three scenarios with k = 5, 10, and 20. We had a total of 48 variables remaining after excluding those with support less than the minimum support of 100 co-occurrences with depressive disorders. We hypothesize these variables as having causal associations with depressive disorders (within the scope of the variables, medications and diagnoses, we considered). The top variable (based on the average ORLB rank) is the class of drugs sulfonamides typically used to treat bacterial infections. This is followed by disease group non-Hodgkin’s lymphomas and drug class bronchodilators. There were a total of 313 antecedent variables with support ≥ 100 and ORLB > 1 with depression as the outcome variable when ORLB is computed across the full dataset (that is, before accounting for confounders). This means only 48/313 ≈ 15% of the full set of statistically significant associations can be hypothesized to be causal based on our analysis. Furthermore, out of the top 20 associations from the list of 313, only the drug class of CD52 monoclonal antibodies also occurs as a causal association. Suicide, self-inflicted injury, personality, dissociative, anxiety disorders that have high ORLBs did not end up in the causal variable list after accounting for confounders.

Abstract
While poor oral health impacts overall health, care coordination and integration of medical-dental practices can better address this issue. This study aimed to understand the challenges of implementing clinical decision support alerts (CDS-A) to support care coordination of patients with diabetes at medical and dental centers.

Introduction
It has been established that diabetes has a deleterious effect on gum disease. Evidence is growing regarding the impact of periodontal health on diabetic control. In primary care it is a routine practice to conduct periodic foot and eye exams for patients with diabetes and refer them to the specialist if required. However, conducting regular oral exams for patients with diabetes and referring them to dentists is not standard practice. One out of every four patients with diabetes is unaware of the condition and dental visits can be utilized for screening. The objective of this study was to pilot the implementation of CDS-A within an integrated Electronic Health Record (EHR) to facilitate better care coordination of patients with known/unknown diabetes at the medical and dental centers.

Methods
Two medical and two dental practices at the Marshfield Clinic Health System were targeted for the pilot implementation of the CDS-A. At the medical center, the study team developed a CDS-A which would remind the primary care providers (PCP) of the need to conduct a visual oral examination for their patients with diabetes. The CDS-A would trigger in the EHR for the patients with known diabetes based on the following rules: If a patient was partially dentulous and has not been to a dentist in more than six months; OR If a patient was completely edentulous AND has not been to a dentist in more than 12 months. At the dental center, the study team developed a CDS-A which would inform the dental providers that their patient may be diabetic and a chair-side blood glucose screening is needed. The CDS-A would trigger in the EHR for patients with undiagnosed diabetics based on the following rules: If a patient presents with a Body Mass Index (BMI) > 35; OR If a patient presents with a BMI >30 AND age >60 years. The following data from the pilot sites was evaluated: number of CDS-A triggered (medical and dental sites), number of visual oral examination conducted (medical sites), number of blood glucose tests conducted (dental sites), number of advice provided to see the dentists/PCPs, and number of referrals made to the dentists/PCPs.

Results
During the one year data collection period from the medical sites, there were a total of 2,120 unique patients for whom the CDS-A triggered indicating the need for an oral examination. Of this, 1,455 patients received a visual oral examination by the PCPs, 266 patients were advised to see a dentist, and 77 patients had referrals made to dental providers. The pilot at the dental centers was stopped after a period of 5 months as a result of Clinical Laboratory Improvement Amendments certification issues with the glucometers used. During data collection, there were a total of 160 unique patients for whom the CDS-A triggered indicating the presence of diabetes. Of this, 157 patients received a blood glucose test at the dental center. One patient was referred and two were advised to see a PCP.

Discussion
There was provider and operational reluctance to changes in clinical workflow. The medical center pilot yielded valuable information to continue our efforts toward a system-wide implementation of the CDS-A. The dental center pilot identified several challenges which call for further investigation before system-wide implementation.

A National Survey Assessing How Many Records Providers Are Allowed to Open at Once in Electronic Health Records in Hospitals and Ambulatory Sites

Jason Adelman, MD, MS1; Matthew Berger, MD2; Amisha Rai, PA2; William Galanter, MD, PhD3; Gordon Schiff, MD, PhD4 David Vawdrey, PhD1; Robert Green, MD, MPH1, Hojjat Salmasian, MD, PhD1, Ross Koppel, PhD5; William Southern, MD, MS2

1Columbia University Medical Center/NewYork-Presbyterian Hospital; 2Montefiore Medical Center; 3University of Illinois at Chicago; 4Brigham and Women’s Hospital; 5University of Pennsylvania

Background: Placing orders on the wrong patient occurs frequently, as exemplified by one hospital that reported over 5,000 wrong-patient orders in one year (a rate of 58 wrong-patient orders per 100,000 orders).1 Some safety experts argue that Electronic Health Record (EHR) systems that allow multiple patient records to be open at one time increase the risk of wrong-patient errors. However, little is known about the number of records hospitals and ambulatory sites allow their providers to open at once. To address this knowledge gap, we conducted a national survey of Chief Medical Information Officers via the American Medical Informatics Association (AMIA) and the Association of Medical Directors of Information Systems (AMDIS) listservs.

Methods: We conducted an electronic survey of CMIOs to assess the number of records hospitals and ambulatory sites allow clinicians to open at one time. In March 2014, we posted the survey on the AMIA and AMDIS listserves, followed by three reminder postings per listserv spread throughout the month. Respondents were asked to identify their EHR vendor, their facility’s location, the maximum number of records their organization allows providers to open at once, and the rationale for this decision.

Results: 112 surveys were completed, of which 79 organizations had both inpatient and outpatient EHR systems, 25 organizations had only inpatient EHR systems, and 8 organizations had only outpatient EHR systems. Of the 104 inpatient EHR systems, 91 allowed multiple records open; and of the 87 outpatient EHR systems, 76 allowed multiple records open. The inpatient and outpatient EHR systems vendors included: Epic (60), Cerner (48) Allscripts (15), Meditech (12), McKesson (9) Siemens (9) and General Electric (7). The healthcare organizations were from around the country, including 25 organizations from the South, 16 from the West, 32 from the Midwest, and 32 from the Northeast. 44% ±5% of organizations allowed the maximum number of records open, while 38% ±4% restricted providers to one record open at a time (Table 1). Some examples of the rationales provided for how many records organizations allow open at once are given in Table 2.

Table 1. The number of records providers are allowed to open at once by healthcare setting.

Table 2. Survey respondents’ explanations for the number of records providers should be allowed to open at once.

<table>
<thead>
<tr>
<th>Comments from those who allowed three or more charts open.</th>
</tr>
</thead>
<tbody>
<tr>
<td>“The efficiency benefits are such that this is justified. There are other ways to prevent wrong patient errors.”</td>
</tr>
<tr>
<td>“Within our EHR, there are certainly efficiencies associated with having multiple patient charts open at once. It allows the clinician to quickly move between patient charts. We have had very little issues with documentation of orders in the incorrect chart. Thinking back to the paper record, there is really no higher risk than gathering multiple patient charts to complete rounds or documentation.”</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Comments from those who allowed only 1 charts open at a time</th>
</tr>
</thead>
<tbody>
<tr>
<td>“My organization chooses to allow only one EHR open at a time to decrease potential documentation errors by staff documenting on the wrong record, as well as treatment errors by staff reviewing orders and/or results on the wrong patient. We feel, as do the organizations we polled, that multiple records open by the same person is not good practice and is an error waiting to happen.”</td>
</tr>
<tr>
<td>“Totally against having more than one record open at a time for patient safety reasons. I have been at a previous organization that allowed multiple records open and have seen wrong-patient errors occur. It MAY be more efficient - I have no proof of that - but for patient safety the limit should be just a single patient chart open at a time.”</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Comments from those who hedged at two charts open at a time</th>
</tr>
</thead>
<tbody>
<tr>
<td>“Two seems to represent the sweet spot between efficiency and safety as long as training is present to mitigate the risks.”</td>
</tr>
<tr>
<td>“Have to balance efficiency and chance for error (even occurred on paper charts). For ED I think the number should be 4 and 2 for all other venues.”</td>
</tr>
</tbody>
</table>

Discussion: The results of our survey demonstrate there is no consensus on the number of records that should be allowed open at the time of placing orders. In fact, the proportion of organizations that allow the maximum number of records open (44%) is not significantly different than those who restrict providers to accessing only one record at a time (38%) (p=0.32). Interestingly, 17% ±3% of organizations aim to balance the risks of wrong-patient errors and the benefits of increased efficiency by hedging with two records open at once. These results are not surprising, as there is currently no evidence to support a best practice. We are conducting an AHRQ-funded study to assess the relationship between the number of records concurrently and the risk of placing an order on the wrong patient (AHRQ 1R21HS023704).

Introduction

Electronic prescribing promises to reduce legibility and transcription errors during the prescribing process. However, electronic prescribing can also introduce new kinds of errors. When prescribing medications in the Partners Healthcare outpatient Longitudinal Medical Record (LMR), practitioners have the option of writing additional information in one of two fields: “Special Instructions” and “Comments”. Text written in “Comments” usually contains notes to providers and is not viewable by the pharmacy or patient; text written in “Special Instructions” is transmitted to the pharmacy or printed on the prescription. This presents the potential for dangerous errors: providers could mistakenly write important information intended for the patient or pharmacy in “Comments”, thinking that they are communicating with the pharmacy or the patient. We investigated the prevalence of providers inputting information meant for the pharmacy in “Comments” and analyzed what information these comments contained.

Methods

LMR medication record data were requested for Brigham and Women’s Hospital ambulatory care patients from 1/1/2000 to 5/31/2015 (20,123,881 records). From this database, we extracted orders that were electronically sent to the pharmacy where the “Comments” field did not match the “Special Instructions” field or was not auto-populated by information found in the Partners Medication Dictionary (6,060,272 medication orders). From this database of medication orders, a random sample of 10,000 prescriptions were reviewed and manually coded by a research assistant, with results verified by a pharmacist.

Results

10,000 randomly selected comments were reviewed, and 862 (8.6%) of those comments appeared to have been meant for the pharmacy. Examples include: “Pharmacist, please do not fill this rx, it has been changed to lotrimin, thank you” and “please write instructions in Spanish”. We coded these comments using five categories, shown in Table 1. Additionally, we found that 82 (9.5%) of the comments contained information that conflicted with the rest of the prescription and 71 (8.2%) comments contained redundant information.

Table 1. Categorization of comments that were meant to be sent to the pharmacy.

<table>
<thead>
<tr>
<th>Categories</th>
<th>Count (n = 862)</th>
<th>%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dose instructions/clarification</td>
<td>273</td>
<td>31.7</td>
</tr>
<tr>
<td>Other instructions to pharmacist</td>
<td>194</td>
<td>22.5</td>
</tr>
<tr>
<td>Warnings and other instructions to patient</td>
<td>153</td>
<td>17.7</td>
</tr>
<tr>
<td>Substitution information</td>
<td>108</td>
<td>12.5</td>
</tr>
<tr>
<td>Formulation and quantity</td>
<td>95</td>
<td>11.0</td>
</tr>
</tbody>
</table>

Conclusion

While the majority of comments in the LMR “Comments” field are meant for other providers, 862 (8.6%) of analyzed comments appear to have been meant for the pharmacist. This suggests that some providers may not realize that the “Comments” field is not transmitted to the pharmacy and include important information in this field. The system should be reconfigured to ensure that providers know where to put information that is meant to be seen by the pharmacy when sending electronic prescriptions.
The Super Annotator: A Method of Semi-Automated Rare Event Identification for Large Clinical Data Sets

Abstract

Detecting rare events in an electronic medical record (EMR) can be like searching for a needle in a haystack. Automated methods like natural language processing (NLP) and manual methods like chart review can be used, but when events are rare and the patient population is large, manual annotation may not be feasible and NLP alone may not be able to reach acceptable levels of performance. We propose a semi-automated method for NLP-assisted retrieval of relevant documents and manual review of the resulting instances. This method was developed to identify medication-related adverse events among patients receiving care in the U.S. Department of Veterans Affairs.

Background

Success in detection of an adverse drug event (ADE) using EMR depends not only on how often the medication is used relative to how often an ADE occurs, but also on frequency of medication mentions in notes, which defines the search space size, relative to frequency of ADE documentation. For example, given a medication that is 1) administered twice a month, 2) prescribed to 1,000 patients, 3) observed over a one-year period, and 4) associated with an ADE published to occur in 1% of patients, there may be only 10 mentions of ADEs among 24,000 mentions of medication administrations documented in the clinical notes. Creation of a knowledge base sufficient for a fully automated solution requires manual annotation of documented cases. However, the number of clinical documents where ADEs can potentially be mentioned may be too great for manual review of a random set.

Methods

We propose a semi-automated method of identifying drug-related adverse events from the EMR with the following steps: 1) Using relevant drug administration codes from structured data, identify patients who received the target medication during the selected study period. 2) Create a clinical document corpus that contains clinical notes found on the day of administration or with keywords relevant to the medication. These documents potentially have a mention of an ADE. 3) Develop an initial list of keywords or phrases that could identify the ADE of interest and flag documents in the selected corpus that contain one of these patterns. At this point, the majority of mentions may involve drug label warnings, patient instructions, and other instances that do not represent a patient actually having an ADE. 4) Use other relevant words in the flagged examples to expand the list of ADE keywords and phrases. 5) Use the flagged examples to determine a heuristic of how close ADE related keywords have to be to medication-relevant keywords to be associated with the target medication (for some examples, presence of an ADE keyword in the document may be enough). 6) Create candidate snippets of text from the flagged examples and group snippets that contain the exact same phrase. Order the snippet groups by descending frequency and review to eliminate patterns that do not pertain to the patient experiencing an ADE. Reviewing these snippets as groups allows hundreds of instances to be manually reviewed at the same time and potentially excluded as irrelevant from any future iterations of this process. As each snippet group review accomplishes the work of many otherwise individual manual review tasks, it comprises the “super” annotator function. 7) Snippets with lower frequencies or those that cannot be determined as irrelevant without reviewing their individual context can be assigned to the normal manual review process. 8) As ADEs are discovered, any new potentially relevant terms can be added to the ADE keyword and phrase list and steps 4-8 can be repeated until the number of instances is small enough that a detailed manual review of all remaining candidate phrases becomes feasible.

Discussion

Using an NLP-assisted, semi-automated method for detecting rare ADEs can help overcome the combination of having a limited knowledge base to train a fully automated method and having too many documents for manual review. Future work includes applying this approach on a clinical use cases to test its time saving relative to the traditional approach of chart review or natural language processing.

Approaches for using temporal and other filters for next generation phenotype discovery

David Albers, PhD, Adler Perotte, MD MA, and George Hripcsak, MD MS
Department of Biomedical Informatics, Columbia University, New York, NY

Introduction

There are two processes that contribute to health data, human biology and the noisy measurement process, caused by the healthcare process. Additionally, these systems are not static in time; when we account for time, even the measurement process is infinitely dimensional and difficult to manage. Because of these complexities, inferring useful information from electronic health record (EHR) data is difficult, opaque, and yet is necessary. To make the inference more transparent we formulate the relationship between the humans being cared for and the process of observing them explicitly to understand what choices these processes impose about our inferences and to appreciate the consequences our inference choices have on what is observable given an inference method. Specifically, when we attempt to infer a feature about patients given their data, we have four choices, (i) we can transform the data using clinical and biological insights into a targeted form (e.g., a median) and input that into a machine learning algorithm, (ii) we can input raw data directly into a machine learning algorithm, (iii) we can impose clinically and biologically motivated constraints on the machine-learning–optimization-system–identification machine, or (iv) we can try to infer the measurement process, undo its effects, and input the transformed data into a machine learning algorithm. Here we will formulate an explicit framework for the generation of healthcare data and then demonstrate how the projection options (i)-(iv) can impact what we can observe.

Methods

We have two goals, formalizing the EHR-data generating process and demonstrating how inference choices affect what is possible to observe. This framework, motivated by stochastic filtering and inverse problems, explicitly defines the relationship between the data we collect and the underlying true human state we would like to study. Moreover, we use this framework to conceptualize different methods of representing laboratory variables for use in high-throughput computing applications such as phenotyping and cohort identification. Then, to explicitly demonstrate how the different inference pathways (i-iv) can affect what we can infer about the true human state given the data biased by the healthcare measurement process, we apply several analyses including lagged correlations, principle component analysis, Bayesian networks, and Kalman filters to data from the Columbia University Medical Center.

Results

We begin with the framework and follow with inference examples constrained by the framework. Consider for individual i the state, \( x_i \), the biology and environment that map the state forward in time, \( x_i(t+dt) = f_i(x_i,t) \), and the measurement process, \( m \), with noise, \( n \), \( y_i(T+dt) = m(f_i(x_i,t)) + n(m(f_i(x_i,t),t) \), generating all the measurements for an individual, \( \{y_i\} \), or for a population \( Y = \{y_1, y_2, \ldots, y_N\} \). Next introduce a diagnostic function, \( d(y_i) \), such as the median of a patient’s data. Healthcare bias is generated by \( m() \) and \( n() \). Ideally, \( m() \) would be the identity and \( n() \) would be small and independent of \( m() \), but when they are not, what we can derive from data, \( d(y_i) \) may have no relationship to the truth, \( d(x_i) \). In this case, it is very difficult to infer \( f_i \) from raw data. Pathway (i) requires selecting an intermediate diagnostic function \( h(y_i(T)) \) using either clinical knowledge of \( m() \) and \( n() \) or a modeling technique targeted at a reducing a problematic feature of \( m() \) and/or \( n() \) to minimize the bias imposed by \( m() \) and \( n() \) on \( y_i \). Explicitly, we choose \( h() \) such that \( d(h(y_i(T))) \) is very similar to \( d(x_i) \) or captures a desired feature of \( x_i \) effectively reducing the dimensions or bias for inferring a feature of \( f_i \). Examples include removing outliers generated by \( n() \) that can confound \( d() \) or capturing important temporal pairwise relationships between variables. We then use the de-biased output of \( h(y_i) \) in a machine learning algorithm to infer features of \( f_i \). This method could be iterative. Pathway (ii) requires applying machine learning to relatively raw healthcare data, either \( \{y_i\} \) or \( Y \), attempting to directly infer \( f_i \) from the data while ignoring \( m() \) and \( n() \). Pathway (iii) is pathway (ii) with constraints imposed on the data or the model. Pathway (iv) directly attempts to infer \( m() \) and \( n() \) given data and then uses our understanding of these processes to de-bias \( y_i \). To verify the observable effects of choosing one inference pathway over another we compare the resulting analysis of lagged correlations versus Kalman filter, Bayes nets, and PCA. We find many differences. For example, lagged correlations (i) between laboratory variables reveals intervariable relationships, e.g., sodium’s relationship to magnesium that do not appear in the Kalman filter or PCA analyses (ii). Nevertheless, the Kalman filter and PCA reveal interesting intervariable relationships and effectively reduced the dimensions by revealing the most important laboratory measurements that account of the most variance.

Discussion

We show how relationships embedded in data are differently extractable and represented when we make different choices regarding the path to inference. We cannot include every possible data element and encoded temporal relationship because we have neither the data nor the computational power to do so. Because the analysis of a variable affects what we can infer about it, we have make choices about the form of variables included in our analyses. Here we show some of the generalizable effects of different inference pathways, helping to inform goal driven choices when applying data science methods to EHR data.

Heteroscedastic Omics Data Analysis: Distance-Based Multivariate Approach

Alexander V. Alekseyenko, PhD

1Program for Human Microbiome Research; The Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC

Abstract

Permutational non-Euclidean analysis of variance, PERMANOVA, is a highly effective test for exploratory analysis of multivariate data. This approach however suffers from loss of power and control of type I error when data are heteroscedastic and unbalanced. We provide several solutions to this problem. We demonstrate the desirable type I error and power characteristics of the new tests and develop a R-Shiny package for data analysis with these novel methods.

Introduction

Permutational non-Euclidean analysis of variance, PERMANOVA, is routinely used in exploratory analysis of multivariate datasets to draw conclusions about the significance of patterns visualized through dimension reduction. This method recognizes that pairwise distance matrix between observations is sufficient to compute within and between group sums of squares necessary to form the (pseudo) F statistic. Moreover, not only Euclidean, but arbitrary distances can be used. The PERMANOVA is highly effective in testing the omnibus hypothesis in data with uniform multivariate spread across factor levels. This method, however, suffers from loss of power and type I error inflation in the presence of heteroscedasticity and sample size imbalances. Under some conditions, PERMANOVA is unable to make any rejections or the test rejects all or most of the times without discrimination.

Methods

We develop several solutions to overcome the issues with PERMANOVA in unbalanced heteroscedastic conditions. First we propose, a sub-sampling approach which stabilizes type I error at the cost of reduced power. Next, we derive a pairwise distance-based computation for the Welch t-statistic, which accounts for unequal variances. Finally, we develop a general distance-based multivariate analysis of variance approach statistics for arbitrary k-level factors. We evaluate these methods on simulated data spanning a wide range of possible sample sizes and multivariate spread. In addition, we demonstrate the performance of the methods on sample sizes typical of a discovery type experiment or a small clinical study.

Results and Conclusions

We demonstrate empirically the desirable type I error and power characteristics of the new tests. Specifically, the novel approaches control the type I error at the prescribed rejection level, and do not exhibit anomalous power loss associated with the PERMANOVA. We compare the performance of PERMANOVA and the new methods in reanalysis of two existing microbiome datasets, where the methodology has originated. In these analyses, we demonstrate how the use of PERMANOVA may result in erroneous conclusions, while the new approaches do not. We develop a package using R-Shiny to enable visualization and multivariate analysis of microbiome datasets using PERMANOVA and the newly developed approaches.
Creating electronic clinical decision support tools for management of obese GERD patients in an outpatient setting.
Olga Alexeeva, BS¹, Rena Yadlapati, MD¹, Raj Keswani, MD¹
¹Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Abstract: The aim of this quality improvement initiative was to design and implement a real-time electronic clinical decision support workflow to improve weight loss and symptom score outcomes in obese GERD patients, and to solicit feedback on the effectiveness of this intervention from physicians and patients.

Introduction: The aims of this quality improvement initiative were 1) to design and implement a real-time electronic clinical decision support (CDS) workflow for providers seeing obese GERD patients to encourage referral to a 6-month weight loss counseling program, 2) to assess the impact of the workflow on physician and patient satisfaction and on patient outcomes, and 2) to solicit feedback from physicians on the efficacy of the workflow and intervention.

Methods: We are conducting a prospective pilot study at a single academic medical center targeting obese outpatients with GERD in internal medicine (IM) and gastroenterology (GI) clinics. Over a six-month period (3/15-9/15), an inter-disciplinary team including GI physicians, NM CMIO, health educators, a dietician, IT staff, a nurse practitioner, and a medical student designed an electronic CDS workflow in Epic to identify at-risk patients and automate referral to a targeted weight management program. Patients are identified via a BestPractice Advisory (BPA) utilizing criteria of documented BMI (≥ 30), ICD-9/10 diagnosis code of GERD, and an active PPI prescription. Education for the GI and IM department providers was provided via e-mail in August, and the workflows went live in both clinics in September. Patient enrollment in the weight loss counseling program initiated on 9/15/15 and is ongoing. Patients are also enrolled in a PPI monitoring program with tapered PPI withdrawal and/or PPI optimization as appropriate; data is not yet available on outcomes of the PPI monitoring program.

Results: An interdisciplinary approach to design and implementation of a CDS workflow targeting obese GERD patients for referral to a targeted weight loss program was successful (go-live date: 9/15/15). Unforeseen interference of our BPA workflow with existing workflows in the IM department necessitated adjustments to the BPA and workflow and expansion of our interdisciplinary team to include IM physician stakeholders. Over a 5-month period, 76 obese GERD patients were identified via the BPA and referred to the weight management program; 36 were successfully contacted; 16 enrolled and are participating (44% successful enrollment). Analysis of workflow impact, physician satisfaction, patient satisfaction, and physician feedback is ongoing and expected to be complete by August 2016.

Conclusion: This pilot study demonstrates that an interdisciplinary team-based approach is effective in developing and implementing an electronic CDS tool. Further analysis will reveal the impact of the tool on physician satisfaction, patient satisfaction, and patient outcomes.
Investigating How Health IT Solutions Responded to Information Needs for Fall-Risk Management: A Case Study

Dari Alhuwail, PhD and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, Maryland, USA

Motivation: Managing falls is particularly challenging for home health agencies and affects the outcomes of many patients. As identified in earlier research, home care clinicians are challenged throughout the episode of care by the lack of relevant information critical to fall-risk management (FRM) in the Physiological, Care Delivery, Educational, Social, Environmental, and Administrative domains. Therefore, it becomes important to investigate how health information technology (IT) can better support FRM by addressing the information needs and management issues.

Aims: (a) Understand how the currently adopted IT solutions responded to the FRM information needs. (b) Identify opportunities to customize and modify the currently adopted IT solutions as well as adopting other solutions to better support FRM.

Methods: After obtaining the institutional review board’s approval, a case-study approach was followed in one suburban not-for-profit Medicare-certified home health agency (HHA) with three branches in Maryland. The HHA is a part of a healthcare network including a number of hospitals, physician practices, and rehabilitation centers. The case-study was appropriate because the phenomena of interest were inseparable from their context. A diverse sample of full-time nurses, physical therapists, and occupational therapists participated in semi-structured interviews (n=20) and four focus groups (n=15). The interview and focus group transcripts were analyzed using the Framework method.

Results: To support FRM, the clinicians mainly used (i) the electronic health record (EHR) and (ii) a separate fall reporting application (FRA). (iii) The evidence also highlights opportunities for other IT solutions that are not currently adopted. (i) The EHR was helpful in capturing, processing, and reporting most information in the Physiological, Care Delivery, and Administrative domains such as the patient’s musculoskeletal disorders, brief medical history, and insurance information. However, the EHR sparsely provided information about the patients’ functional status, weight-bearing status, or caregiver contact information. The referral documents received by the HHA and entered into the EHR were mostly faxed, often illegible, and did not have any of the information Social, Environmental, or Educational domains such as caregiver availability, clutter in the home, or patient educational level. (ii) The FRA provided comprehensive information in the Care Delivery, Social, and Environmental domains such as fall-risk assessments, caregiver involvement, and the home organization. Because the FRA was not integrated with the EHR, the clinicians manually entered into the application the relevant Physiological information related to the incident after reviewing numerous screens and notes in the EHR. (iii) The clinicians reported that health information exchange (HIE) solutions can improve the communication of the relevant information in all the domains between the HHA and the referring organization by exchanging Continuity of Care Documents (CCDs). However, it should be noted that presently CCDs have no specific placeholder for patient culture, language barriers, or home environment hazards. Home and body sensors can help gather the patients’ Physiological information about activity levels or perform non-invasive fall-risk assessments and report them on a regular-basis to the EHR for the clinicians to review. The clinicians reported that physician portals can be useful for obtaining Physiological and Care Delivery information. Using physician portals, the clinicians can clarify and obtain further information on FRM-related orders or follow-up on requests for additional services. Telemedicine can assist the clinicians to share and exchange Care Delivery and Educational information with the patients and caregivers such as FRM goals or explaining how a newly prescribed medication affects fall-risks. Telemedicine can also assist in the Social domain by involving the caregivers in the communication of the patient’s progress in care. Patient portals can aid in alerting the clinicians timely to take actions to reduce fall risks when the patients or caregivers self-report negative changes in health conditions or functional status. Patient portals also aid the clinicians in the Educational, Social, Environmental, and Administrative domains by capturing, reporting, and sharing information with the patients and caregivers such as how a health condition affects fall risks, caregivers’ availability, the dangers of clutter in the home, and updates to the patient or caregiver contact information.

Conclusion: To better support FRM, HHAs need to evaluate the current and potential IT solutions’ ability to address the information needs, capacity to store information in a logical manner, and capability to exchange information with other IT systems. Without doing so, health IT solutions may not support FRM.

Heuristic Evaluation of a Novel Inpatient Patient Portal
Sana Ali, MPH, BDS, Baria Hafeez, MS, Lisette Roman, BA, Jessica S Ancker, MPH, PhD
Department of Healthcare Policy & Research, Weill Cornell Medicine, NY, NY

Background: The patient portal is a secure online website (1) through which patients can view their medical records and perform tasks such as request medication refills (2). Portals must be well-designed before patients are likely to use them (3). Others have noted that portals may present usability barriers (4), and these barriers might be contributing to the known socioeconomic disparities in adoption rates (5).

Objectives: Contributing to the known socioeconomic disparities in adoption rates (5).

Methodology: We employed a heuristic assessment checklist by Zhang et al (6) to gauge the usability of the patient portal. Three study team members with training in informatics and human-computer interaction examined the portal functionalities, identified usability problems, and assigned a severity score (range: 1-4) to each problem. Agreement was reached in a consensus meeting. Recommendations to improve portal functionalities and suggestions for innovation were conveyed to the development team. The same evaluators conducted a second round of evaluation after selective implementation of the recommendations. The heuristic evaluation was the first phase of a larger project in which patients will be invited to pilot test the site.

Results: The patient portal had an attractive, minimalist appearance and offered an array of potentially useful functionalities, including large quantity of personal medical data and access to family members’ records. In the pre-implementation evaluation, amongst the usability issues identified, the most severe was Failure to use patients' language with a severity score of 4. A striking example of this was that instead of inviting patients to create a report of their medical information, the website invited patients to click a button labeled “CCD export.” Three heuristics, Consistency and Standards, Match between System and World and Prevent Errors each received a severity score of 3. Of the remaining heuristics, 50.0% received a severity rating of 2 and 50.0% a severity rating of 1, indicating minor usability problems and cosmetic problems respectively. The most severe potential error was the availability of an option for patients to accidentally delete the entire medical record within the portal. After implementation of the recommended changes, the heuristic with the highest severity rating i.e., 4 was Failure to use patients’ language. Among the rest of heuristics, 78.5% received a severity score of 1 or 2 and 14.3% received 3. Although the development team followed some of our usability recommendations, they simultaneously implemented new functionality, which introduced novel usability challenges. For example, a new cardiovascular disease module was added to the portal. As a result, the total score remained almost unchanged.

Recommendations: Some of the recommendations made are listed below:

- Reorganize and re-label the navigation menu in a hierarchical way into groupings based on their conceptual underpinnings. A new organization for the navigation scheme was created.
- Rename report creation options with self-explanatory labels and organize the options for report in a thematic/alphabetical order.
- Notify users that any information that they add to this record is not automatically pushed to the hospital EMR and therefore would not be viewed by the physician.

In addition to these, suggestions were also made for improvement and innovation. For example, organizing information by encounter, displaying medications, diagnoses, and other information in a timeline format, creating progressive levels of complexity to make onboarding easier for first-time users.

Conclusion: Heuristic evaluation yielded valuable information to inform the design and development team. The findings underscore the fact that usability evaluation must be done iteratively and concurrently with the rollout of new functionalities. Otherwise the overall patient experience will continue to be impacted by usability barriers.

A Toolkit that Standardizes Data Retrieval across Multiple Perioperative Data Sources

Frank Aline, BS1, Maxim A. Terekhov, MS, MBA1, Teus H. Kappen, MD, PhD1, Karen Y. McCarthy, MS1, Hongjuan Z. Blazer, PhD1, Stephen P. Baker, AS1, Jesse Ehrenfeld, MD, MPH1-4, Jonathan P. Wanderer, MD, M.Phil.1,2

Departments of Anesthesiology1, Biomedical Informatics2, Surgery3, and Health Policy4
Vanderbilt University Medical Center, Nashville, Tennessee, USA1

Introduction

The increasing utilization of Electronic Medical Record (EMR) yields an abundance of clinical data that can be leveraged in a healthcare setting. Combining patient data within the EMRs can answer various clinical research and quality assurance questions1. While some hypotheses can be tested with data retrieved through EMR reporting systems, data to address more complex questions are typically retrieved through unstandardized, custom-built queries. However, research projects2 may share a similar ‘data pipeline’, which can result in unnecessary analytic work, which is time-consuming and costly. Moreover, each custom query varies per developer, which may compromise reproducibility.

The toolkit framework

We standardized information retrieval through a data pipeline implemented in a toolkit using Microsoft Visual Studio Ultimate 2012, Visual C# 2012 and SQL Server Management Studio (Microsoft, Redmond, WA). This application enables the process of translating a question into a query to retrieve the research data in an automated way. The toolkit allows external data to be imported with a high degree of flexibility into the pipeline. The toolkit then uses the external information to select an appropriate patient cohort (Figure 1). The logic determines whether or not procedural or hospital-encounter information is requested. Depending on which common identifier(s) are presented in the initial cohort, the toolkit will then find and validate other identifiers that link patient demographics to hospital-encounter and procedure information. The next step is a selection process where the user can choose additional variables for retrieval (e.g. comorbidities, drugs, fluids, etc.) and aggregation if applicable (minimum, maximum, average, etc.). Finally, a summary report and a log of applied standardized queries are generated.

Comparing the toolkit to the previous approach, the differences were subjectively noticeable, but were not objectified.

Figure1. Workflow visualization of the Toolkit.

Conclusion:

Implementing a standardized interoperable toolkit, that leverages various sources, permits for the use of a uniform approach. This may reduce tedious and costly efforts towards repetitive data requests.

Identifying Discrepancies in Diabetes and Diabetic Foot Ulcer ICD-9 Codes Via Administrative Data in a Veteran Population

Latricia L. Allen, DPM, MPH, Eni Njoh, MPH, Gail Powell-Cope, PHD, Tatjana Bulat, MD, Dezon K. Finch, PHD
HSR&D Center of Innovation on Disability and Rehabilitation Research, James A. Haley Veterans Hospital, Tampa, FL

Introduction
Diabetes and associated comorbidities have been ranked the 7th leading cause of death. Prevention programs have been noted to reduce the likelihood of limb loss but unfortunately are not widespread. Thus, amputations and other adverse events related to diabetes is still prevalent. Diabetic foot ulcer may pose a safety risk for adverse events. The number of undiagnosed cases of diabetes is so prevalent, thus we conducted an evaluation to determine the prevalence of adverse events related diabetes and diabetic foot ulcer in a local Veteran population.

Methods
A sample of all patients with diabetes and diabetic foot ulcer ICD-9 codes during the years of 2009-2014 were examined and from those patients with diabetic foot ulcers we checked to see if diabetes was coded. 41,324 patients were noted to diabetes diagnosis code, 3200 patients were noted to have a code for diabetic foot ulcer with diabetes, and 2783 patients with diabetic foot ulcer did not have a diagnosis code for diabetes. Adverse event data are still being currently collected for this project.

Results
41,324 patients were noted to have a diagnosis code for diabetes, 3200 patients were noted to have a code for diabetic foot ulcer with diabetes, and surprisingly 2783 patients with diabetic foot ulcer did not have a diagnosis code for diabetes. The number of patients with diabetic foot ulcer without a diabetes diagnosis code brings questions to mind such as possible false positive or false negatives for diabetes as well as diabetic foot ulcer coding in this patient population.

Conclusion
The data set from this project will be further examined in a chart extraction study to determine any variation in documentation of diabetes and diabetic foot ulcer in the electronic medical record and ICD-9 codes. This information may prove valuable in possibly improving EMR accuracy as well as improve management of patients with diabetes.

Towards Automated Selection of Patient-Specific Education Materials in Ambulatory Care Settings

Fatemah M. Aloudah, MS, Janusz Wojtusiak, PhD, George Mason University, Fairfax, VA

Introduction

In the era of personalized health and patient-centered care, providing personalized education materials to patients becomes vital especially for patients with chronic diseases where self-care management is highly required for successful health outcomes. However, during an office visit, fully educating and informing patients is not feasible due to several factors, including short visit time, patients’ varying health literacy levels, and complexity of the information needs to be delivered to patients. Information systems, including certified EHR systems, may be able to remedy this situation by aiding providers in the selection of the education materials to be distributed to patients during or after discharge. One of the effective ways to engage patients in their health, trigger a behavior change or improve compliance to a treatment regimen is by providing personalized education materials. We propose to personalize education materials along five patient-specific dimensions: demographics, diagnoses, prescriptions, health literacy level, and preference of material delivery method/media.

Methods

We reviewed available literature and investigated leading EHR systems to explore what options are available for selection of patient education materials. In the description below we purposefully left out names of vendors. Literature Review: A number of papers have been published since 1990s in regards to generating tailored education materials to patients. Mainly, these earlier initiatives were not implemented in clinical settings, but some were tested in controlled clinical trials. The literature varied between reporting on new systems, case studies and system evaluative studies. Current EHR approaches: We have reviewed options available in five leading EHR systems as part of demonstrations given by the vendors. While the systems differ in how the education materials are selected, there is no real individualization of selected materials. All of the systems allow for selecting materials based on diagnoses for a given patient, and don’t seem to consider wider patient context. The systems either search available resources by keywords defined by ICD-9/ICD-10 diagnoses, or link directly to pre-defined resources for these diagnoses. Sources of education materials: EHR systems link to publically available materials, such as Medline Plus, or to sites of commercial content providers. Among the reviewed EHR systems, one included selection of basic built-in materials, and additional ability to link to more advanced ones by an external provider. Some of the content providers offer materials in multiple languages (mainly English and Spanish, but also others), with varying availability of specific topics. Additionally, some content providers specialize in multimedia content, or in mobile delivery format.

Proposed Solution

The selection of education materials can be done in an automated fashion, with only final approval by clinicians. Artificial Intelligence can be used to match patient characteristics with specific content to be provided, and embed the materials into patient’s context, not simply provide diagnosis-specific information. Such a system should allow for full individual customization of materials based on the 5 dimensions: demographics, diagnoses, prescriptions, health literacy level, and preference of material delivery method/media. The solution requires creation of education materials in small modules that can be assembled in multiple ways to match patient’s characteristics and preferences.

Conclusion

The main identified issue with the current approach is that education materials are not patient-specific, but rather diagnosis-specific. The use of patient information should allow for selection of truly individualized education materials, and narrowing the gap between currently used approaches and what is possible.
Complexity Reduction and Visualization of RDF Knowledge Networks for Precision medicine

Zainab Al-Taie, MS¹, Nattapon Thanintorn, MS², Ilker Ersoy, PhD², Richard Hammer, MD², Dong Xu, PhD ¹,³, Trupti Joshi, PhD ¹,³,⁴, Dmitriy Shin, PhD ¹,²,³

¹Informatics Institute, ²Department of Pathology and Anatomical Sciences, ³Department of Computer Science, ⁴Department of Molecular Microbiology and Immunology, University of Missouri, Columbia, MO, 65211, USA

Introduction
Precision medicine is one of the most rapidly emerging areas of research and development, proving to be crucial for improving patient care, but there is a lack of a comprehensive set of tools that are easy to use for analysis and incorporating genomic data into clinical decisions. In our study, we attempt to reconstruct interrelationships among biomarker proteins, diseases, and signal transduction pathways for individualized treatments. Towards this, we have developed a suite of tools, which can shed some light on tumorigenesis and genomic changes taking place in individual patient.

Method
We have developed a suite of tools for visualization and curation of KEGG pathway data to incorporate it into precision medicine. The curated pathways have been converted into Resource Description Framework (RDF) to create a knowledge base network¹. Our Complexity Reduction and Visualization (CRV) tool reduces the complexity of the knowledge network by finding the more relevant paths among a set of start and end genes. This tool creates three different networks from cohort patients; the first network is created from non-metastatic cancer data, the second network is created from regional metastasis cancer data, and the third one is created from distance metastasis cancer data. The start and end genes list for each network differs; for the non-metastasis network, they are the surface receptors as start genes, and differentially expressed genes in cancer patient as end genes. In the regional metastasis network, they are differentially expressed genes in cancer patients with non-metastatic cancer as start gene set, and differentially expressed genes in regional metastatic cancer after excluding the genes that exist in the start gene set as end gene set. In the distance metastasis network, they are the differentially expressed genes in patients with regional metastatic cancer after excluding the genes that exist in non-metastatic cancer as start genes, and differentially expressed genes in distance metastatic cancer after excluding the genes that exist in the start gene set as end genes set. For individual patient, a network can be created from these three networks in order to get most relevant network to a particular disease. Patient’s disease network after mapping to the three networks can be used by pathologists to predict if a particular patient may develop metastasis. The resulting networks have been visualized using d3.js.

Results
The tool will find the shortest paths among the set of start and end genes to create less complex network than the input network. We have applied this to Lung Adenocarcinoma (LUAD) samples. From the patient cohort dataset, we have found 90 genes and 15 pathways such as focal adhesion, mTOR, and ErbR signaling pathway that have a role in transforming the cancer from non-metastatic cancer to be a metastatic cancer. This set of tools can be applied to answering diverse questions including getting a better understanding of genomics mechanisms that play a role in metastasis vs. non-metastatic cancers and finding the genes that can cause the cancer to metastasize in an individual patient.

Conclusion
Our study represents a novel computational method in pursuing the understanding of interplay between pathways in metastatic cancer and how primary tumor will develop metastasis. The CRV Tool can help in finding key genes, and hypothesis generation. The two major components of CRV which are the complexity reduction and visualization provide pathologists a simplified network of relevant genes and pathways for the individual patient.

Designing an evaluation methods course in health informatics
Jessica S Ancker, MPH, PhD, Stephen Johnson, PhD
Weill Cornell Medical College/Weill Cornell Graduate School of Medical Sciences, NY, NY

Background: Health informatics is a multidisciplinary field, integrating aspects of engineering, computer science, medicine, statistics, epidemiology, social sciences, and cognitive science. As a result, health informatics graduate programs may feel fragmented for students, who may encounter multiple perspectives with little sense of a unifying framework. Educational research demonstrates that learning, particularly among adults, is facilitated when students clearly understand instructional goals, relevance, and relationships within the curriculum. Although much excellent discussion has focused on what should be taught in an evaluation methods course, it has not to date focused on the best way to sequence instruction to avoid the perception that the course is a laundry list of methods.

Objective: To propose a unifying framework for an evaluation methods course, which can help students understand the rationale for, relationships between, and appropriate ways to apply a variety of evaluation methods.

Course design: Hierarchical sequencing is a highly effective curriculum design approach; in this approach, knowledge and skills introduced early in training are built upon as more complex competencies are introduced later. However, it is impossible to develop a simple hierarchical sequence for a multidisciplinary curriculum that incorporates methods from several disciplines. Instead, we propose a content relationship structure after a content analysis of evaluation methods. We based the structure upon the Delone and McLean model of information systems success. The structure allows us to group and sequence theories and methods according to underlying constructs.

Course content and competencies: Because the DeLone and McLean model recognizes that information quality, system quality, and service quality are important precursors to information system success, we begin our course with an information quality module focusing on evaluating data quality and related constructs. The module introduces measurement theory and evaluation competencies including test characteristics, information retrieval metrics, and expert rater approaches.

The DeLone and McLean model progresses to user satisfaction, intent to use, and system use. The evaluation course therefore progresses to a users module, which introduces behavioral theories of use such as diffusion of innovation and task-technology fit, as well as evaluation competencies such as survey design, survey data analysis, and psychometric methods.

The next module on human-computer interaction focuses on DeLone and McLean’s system quality, use, and user satisfaction constructs. This module exposes students to cognitive and information processing theories along with methods such as cognitive walkthroughs and usability analysis. A sociotechnical module orients students to the subjectivist perspective and develop competencies in qualitative methods including conducting interviews and focus groups and analyzing qualitative data.

The course concludes with an outcomes module focusing on the DeLone and McLean net benefits construct. This module introduces theories and methods appropriate for assessing benefits as well as unintended consequences, in terms of healthcare quality, patient safety, and cost. One important focus is on approaches drawn from health services research that are useful for informatics interventions, including randomized trials, retrospective cohort studies, and interrupted time series analyses. The other focus is on approaches drawn from engineering such as such as iterative design and evaluation cycles.

Conclusions: Evaluation methods are critical components of graduate informatics training, but the heterogeneity of health informatics makes it challenging to select and sequence competencies. Our curriculum provides context for evaluation methods via a well-validated model of information system success. This curriculum helps students understand the relevance of the methods, how to select methods to address particular questions, and how all methods support the long-term goal of developing effective informatics tools. Furthermore, by introducing methods in the context of this model, we reinforce the applicability of theoretical models to guide research, design, and implementation in health informatics. In our program, we offer the evaluation methods course in the first semester of the master’s program, concurrent with introductory courses on health informatics, biostatistics, and the healthcare system.

Configurable Permissioning to Address Diverse Data Collection Needs

Beth Anderson, PhD¹, Charles Tirrell¹, Henry Agnew¹, Frank Farach, PhD¹,
Leon Rozenblit, JD, PhD¹

¹Prometheus Research, New Haven, CT, USA

Abstract

Multi-study research clinical data repositories (CDRs) require complex permissioning schemes to meet IRB and HIPAA requirements. CDRs that push permissioning configuration into menu options increase administrative overhead and the risk of process and quality errors. We describe how analyst-configurable workflows and permissioning structures, instead of one-size-fits-all approaches, can simplify tasks and improve data quality.

Introduction

Organizations that manage multiple studies within the same clinical data repository (CDR) must meet the permissioning and regulatory requirements of HIPAA and their local IRB. Rules for data sharing often differ even between departments within the same institution, requiring complex permission-management capabilities. Lab-specific workflows such as using a central recruiter versus direct study enrollment are common. Research CDRs such as REDCap² handle this variability by providing over a dozen study level permission options.

Methods

In 2015, Prometheus Research restructured their open source research CDR, RexStudy, to take advantage of newer technologies. As part of this restructuring, RexStudy 4.1¹ permissions were initially broken into 10 different options (e.g., enroll participants, enter data, reconcile data, explore data) where users could be granted permission to zero or more of the options. Several RexStudy clients found their workflows were hampered by being broken into too many discrete permissions and requested customizations to have our technology match their internal workflows, each of which differed slightly. Prior research suggests matching computer and human workflows enhanced acceptance of the technology.³ To better understand the most common client needs, we analyzed permission combinations for 243 users of RexStudy across 14 studies in 6 different labs and 3 different sites.

Results

Of the over 3 million possible unique permission combinations available in RexStudy 4.11, clients used only 20. The four most common were: 1) lab admin only (18.5% of users) which allows adding other users to the lab, creating studies, and assigning study permissions; 2) day-to-day study operation permissions (14.8%) which included recruiting, enrolling, entering data, reconciling and exploring data; 3) lab admin plus day-to-day study operation permissions (10.7%); and finally 4) no permissions (11.5%). Based on these results, it was clear users do similar tasks via different workflows and permission restrictions. To improve the permissions and workflows in RexStudy 4.12: (1) analysts can now define roles and (2) assign a workflow to one or more roles. In the one-size fits all approach of RexStudy 4.11, the workflows were disjointed with each task and permission utilizing a different workflow. Using RexStudy 4.12, a semi-technical business analyst can configure a workflow to include all necessary tasks enhancing data integrity by minimizing the chances of missing a step and improving researcher productivity.

Conclusion

Breaking up workflows across permission boundaries can result in a disjointed user experience in a research CDR and may increase the chance of data collection and/or entry errors. By defining the locally-recognized roles needed for a specific research environment, and by connecting role permissions directly to workflows, our new approach minimizes the chance of errors, and improves the overall user experience.

Log File Analysis of User Engagement with Maternity Information Access Point

Adriana Arcia, PhD, RN\textsuperscript{1}, Eva Rose Asaan Warner, BS, BA, RN\textsuperscript{1}
\textsuperscript{1}School of Nursing, Columbia University, New York, NY

Abstract

Maternity Information Access Point (MIAP) is a mobile-ready, web-based patient education platform populated with curated, evidenced-based, multi-media content for maternity care. It is the research version of Care Guide™ by Maternity Neighborhood™. The purpose of MIAP was to evaluate the feasibility and acceptability of the platform for Medicaid-enrolled women. In this study we sought to gain insight from users’ browsing behaviors by analyzing log files.

Introduction

Maternity Information Access Point (MIAP) is a mobile-ready, web-based patient education platform populated with curated, evidenced-based, multi-media content for maternity care. It is the research version of Care Guide™ by Maternity Neighborhood™. The purpose of MIAP was to evaluate the feasibility and acceptability of the platform for Medicaid-enrolled women. In this study we sought to gain insight from users’ browsing behaviors by analyzing log files.

Methods

Platform users were 16 English- and Spanish-speaking Medicaid enrolled women in the second or third trimester of pregnancy. Users were provided with a mobile hotspot with unlimited data to ensure Internet connectivity. Users were invited to log in to MIAP as frequently as desired over the course of four weeks with a request that they do so at least once a week. Users were also invited to message the researchers (as a proxy for their care provider) with any pregnancy health questions they had. Links to site resources were sent via email once a week to promote engagement.

We examined log files of the activity of the users. Interactions with the site were sorted by user and grouped into sessions (clusters of activity). We analyzed: a) number of sessions, b) number of messages sent, c) total number of resources accessed, d) average number of resources per session. Planned analyses include the relationship of the user’s gestational age to the types of resources accessed.

Results

Users logged between zero and seventeen sessions over the course of their participation. Most sent no messages; the remainder sent only one or two. The total number of resources accessed ranged from 0 to 55. Of the users who accessed resources, their average number of resources per session ranged from 1 to 3.8.

Discussion

Users varied substantially in their engagement with the platform. Avid users logged in repeatedly and accessed numerous resources. However, messaging with the nurses running the study was a poor proxy for messaging with the care provider and there was very little uptake of this option.

Conclusion

Analysis of log files can yield valuable insights about users’ engagement with a site. Potential future research includes comparison of popular versus unpopular resources in an attempt to identify structural factors that affect browsing behavior.

Nursing Documentation Redesign: A Collaborative Approach

Deborah Ariosto, PhD, MSN, RN
Vanderbilt University Medical Center, Nashville, TN

**Background:** In response to staffing ratio changes, a team of clinicians and industrial engineers were deployed to observe and interview nursing staff to identify opportunities to save nursing staff time. Top priorities identified by staff nurses were unnecessary/redundant documentation, finding equipment, and better communication with the care team. In 2014, executive leadership endorsed the formation of cross enterprise clinical workgroups to address these priorities. This presentation focuses on the methodology applied to a highly successful documentation reduction initiative.

**Methodology:** Over fifty clinical staff from acute and critical care in both the adult and pediatric hospitals was challenged to standardize and simplify nursing documentation. Exclusions included Obstetrics, Neonates, and Psychiatry. A representative core group of nurses met weekly to shape a common documentation model using a terminology framework that reflected professional nursing practice endorsed by the American Nurses Association\(^1\).

The Clinical Care Classification System\(^2\) (CCC) was used to organize nursing care concepts into 15 Care Categories to create a high level framework for nursing centric problems (e.g., acute pain), interventions (acute pain control), and goal setting. SNOMED CT\(^3\) concept matching was used for signs and symptoms and intervention detail. Free text narrative statements captured the overall patient response to care and communication/event notes.

Other strategies included a modified charting by exception approach and elimination of most copy/paste functions. Assessments auto-populated the plan of care and easily visualized the daily progress toward problem resolution. Documentation that did not reflect professional practice or support high value decision support was discouraged.

**Outcomes:** Several pre/post evaluation approaches were utilized. These included timed classroom simulations and real-time clocked documentation times on pilot units. Timed studies showed on average, > 25 fewer minutes spent documenting and a 30% decrease in charted elements overall.

Staff has had an overwhelmingly positive response in that they have more time to spend with their patients and take needed breaks. Rounding during implementation reassured leaders of the value of their investment in staff time and resources and gave staff an opportunity to show their work and tell their stories. One poignant story shared was: “I now had time to give my patient a foot rub when morphine didn’t work”.

**Conclusions:** Providing nurses with a nursing terminology framework that they could shape and own was key. While the informaticists knows the value of standards for data re-use, interoperability, decision support, and system stability, the clinician knows their own practice and unit needs. Working together, documentation redesign achieved both goals.

Technological Barriers to Situational Awareness in Laboratory Testing

Argus Athanas, BS; Molly Kantor, MD; Meghan Sebasky, MD; Robert. El-Kareh, MD, MS, MPH
University California San Diego; San Diego, CA

Introduction
Laboratory testing involves many team members and is an integral part of clinical care in the hospital. Ineffective information flow can lead to poor situational awareness amongst team members regarding the status of previously ordered tests as well as unnecessary repeat testing and loss of samples. Motivated by specific concerns raised by clinicians in our hospital, we sought to characterize the entire laboratory testing process with the goal of highlighting areas of breakdown and providing context to improve the effectiveness and efficiency of clinical care.

Methods
We interviewed team members from one hospital at UC San Diego Health System, including physicians, nurses, phlebotomists, a lab director and IT staff. We mapped the laboratory testing process from end-to-end (Figure 1), which allowed us to identify several barriers to effective information flow.

![Figure 1. Clinical laboratory testing process and information flow diagram](image)

Results
We identified several steps of the laboratory testing process that created barriers to situational awareness. These barriers included: limited ability to update test status in the EHR, obstacles to correct erroneous collection modes, multiple methods of collection, nursing work-arounds that increase risk of mislabeled specimens, and limited support for handoffs from one care setting to the next.

Conclusions
A thorough mapping of our entire laboratory testing process provided important insights into system-level improvements that can be implemented to improve situational awareness amongst team members and improve the safety and reliability of our testing process.
Standardization of FDA Adverse Event Reporting System to the OHDSI Common Data Model

Amelia J. Averitt, MPH1, Adler Perotte, MD, MA1
1Columbia University, Department of Biomedical Informatics, New York, NY, USA

Abstract

Adverse drug events (ADEs) are responsible for hundreds of thousands of injuries and deaths every year. The FDA Adverse Event Reporting System (FAERS) is a database for the collection of ADEs, but the data is unstandardized and inaccessible to most. To facilitate research with this data, we developed a methodology to extract, transform, and load the FAERS data into a standardized data model developed by the Observational Health Data Science and Informatics (OHDSI) collaborative.

Introduction

Post-marketing adverse drug events have shown that pharmaceutical agents can be harmful or fatal to consumers, despite rigorous clinical safety testing.1 The Food and Drug Administration (FDA) created an adverse event reporting system (FAERS), to capture possible post-marketing AEs and the potential causal drugs. Though the FAERS data is available to the public and accessible through the FDA website, the data requires substantial preprocessing and is unstandardized, making mapping to medical terminologies arduous and research results difficult to reproduce. The Observational Health Data Sciences and Informatics (OHDSI) is an international, interdisciplinary collaboration to support large-scale data analytics. Data standardization is a principal concern of OHDSI, as a common data model and standardized vocabularies necessarily underlie successful collaborative research. The Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) provides standardized tables for observational health domains including condition occurrences and drug exposures among others. The CDM has previously been utilized to transform and house administrative claims and EHR data, but has not yet been applied to spontaneous reporting data, such as the FAERS data. The transformation of the FAERS data into the OMOP CDM would facilitate research of drug-adverse event relationships and may further support collaborative research that would employ this data.

Methods & Results

The data was standardized according to the OMOP Common Data Model using an extract, transform, and load (ETL) procedure. FAERS data from 2013-2015 was downloaded from the FDA Adverse Event Reporting System website. This data is organized into several files, and consists of seven domains - Demographic, Drug, Reaction, Outcome, Reporting Sources, Therapy, Indication - reported quarterly for every year. The primary unit of observation for each of these tables is the caseid, which represents a single individual, with potentially more than one adverse event, and multiple drugs that may be responsible. After the initial extraction, the data was processed to combine like-tables across all years and quarters. To populate the OMOP CDM, the FAERS data associated with each domain required a series of transformations. The FAERS Demographic table required the least data transformation where birth_year was calculated from the FAERS' reported age at event and event date to populate the OMOP Person table. For the purpose of this ETL, we assume that each caseid represents an individual with a single visit. Therefore, the Demographic table was also mapped to the OMOP Visit_Occurrence table, which captures the time frame of the potential adverse event. The raw data from the FAERS Reaction and Indication tables are recorded as MedDRA concepts, and both tables were mapped to the OMOP Condition_Occurrence table, with the drug indications recorded as primary conditions (58.7% distinct conditions mapped), and the adverse events recorded as secondary conditions (50.8% distinct AEs mapped). The principal challenge of this ETL was the successful mapping of the raw FAERS drug data to systematized concepts. This process was complicated by the free-text entry of the users’ drug use, which was subject to inconsistencies in preferred drug name, dosage, and misspellings. In this exercise, FAERS Drug data was mapped to the OMOP Drug_Exposure table using the NLP tool, MedXN, to process the free-text drug names to RxNorm codes (69% match rate). NLP tools are a frequently utilized when mapping FAERS drug data, but to our knowledge, this is the first utilization of MedXN for this task.

Conclusion

The FAERS data is an important resource for data-mining for adverse events. An ETL of this data into the Common Data Model is a useful standardization of the data, which will support analytics into drug-adverse event relationships. Though this process only addressed the most recent FAERS data, future work will extend this process to all available FAERS data and improve the completeness of concept mapping.

Lessons learned from adopting RTLS(Real-Time Location System) based asset tracking system in a tertiary hospital

Hyunyoung Baek, Seok Kim, MPH, Eunhey Kim, Eunja Jung, Rongmin Baek, Hee Hwang, MD, PHD, Sooyoung Yoo, PHD
Center for Medical Informatics, Seoul National University Bundang Hospital, Korea

Abstract

This study aims to share insights and considerations of adopting Real-Time Locating System (RTLS)-based asset tracking system in a medical environment, based on our experience of implementing and operating it in a tertiary hospital setting.

Introduction

The health care industry has seen robust adoption of RTLS technology, generally for tracking medical staff, patients and assets to improve patient safety and efficiency.

Methods and Results

We developed an asset tracking system and an application that is conducive to tertiary hospitals. Bluetooth sensing beacons and tracking tags utilized in the system were also tailor-made. The entire project, from product design to implementation, lasted 13 months starting from November 2013. Five types of devices (i.e. iPad, Patient Monitor, Bladder Scan, Infusion Pump, Oxygen Holder) expected to benefit the most from the system due their high mobility were identified. 4 iPads, 160 Patient Monitors, 15 Bladder Scans, 200 Infusion Pumps, 21 Oxygen Holders were attached with active tags for tracking location. The existing Wi-Fi infrastructure was used for recognizing the asset’s location in the general wards, whereas, the new Bluetooth beacon with higher accuracy in locating asset position were used in the Emergency Center.

A questionnaire was designed to survey user perception of the RTLS-based asset tracking system 3 months after initial implementation. The user satisfaction scale consisted of five factors: information quality, system quality, device type, expected outcome and overall satisfaction. The survey was disseminated to the nurses of 3 general wards, 3 ICUs and the ER and 117 responses were collected. The score of the overall satisfaction ranged from 2.7-3.4 out of 5, indicating that most nurses were satisfied with the service. Most nurses responded positively scoring 3 or higher out of 5 for the helpfulness and their desire for continued use of the service. There were suggestions regarding the adjustment of tag size and the need for facilitating user training programs.

The following are issues and considerations in terms of development and usability of the said system.

1) Scope of asset tracking: Adequate discussion should precede development to accurately define end-users and target assets to drive needs. 2) Locating & positioning: Proper sensing techniques matching the target asset and area should be selected since Wi-Fi and Bluetooth techniques are generally known to have margin errors of 10m and 5m, respectively. 3) Design of Active Tag: The needs of onsite staff and policy guidelines of the organization should be appropriately balanced when designing and adopting a tag frame. 4) System functionality & Usability: User-friendly interface meeting the needs of end-users should be developed. 5) Education & Operation Support: Education is necessary for end-users to use the system smoothly. Supporting or maintenance staff for the continuous operation of the system should be considered (e.g. changing batteries of beacons and tags periodically).

Conclusion

The successful adoption of a RTLS-based asset tracking system in a hospital setting requires accurate identification of targets (both user and asset) based on their work environment analysis. Moreover, technical aspects such as availability of smaller RFID tags and enhancement of sensor accuracy is equally important and necessary.

End-user Customization of Electronic Medical Record System Provides Measurable Improvements in Documentation Compliance

Anindita Bagchi, M.Sc., RHIA, Jayne Mitchell, ANP-BC, Jiri Sklenar, Ph.D., James O. Mudd, M.D.
Knight Cardiovascular Institute, Oregon Health and Science University, Portland, Oregon

Abstract
A commercially available EMR was optimized for documentation and delivery of evidence-based care for heart failure patients using American College of Cardiology (ACC) heart failure performance measures. The new workflow resulted in an increased frequency of clinical documentation for ACC heart failure performance measures.

Introduction
Current EMRs provide technical means for optimization to specific local needs. Such modifications, to be successful, require a coordinated effort of clinicians and IT specialists.

Hypothesis
Practicing evidence-based medicine in heart failure patients requires clinicians to consider, and subsequently record, a well defined set of variables, e.g. the seriousness of the disease, or whether recommended therapies were provided to the patient. We hypothesized that consolidation of relevant data elements from several locations into one intuitive, interactive form will result in increased documentation compliance.

Results
We observed consistent increase in reporting frequency for each performance measure (Figure 1) after the form was activated

Conclusion
Commercially available EMRs can be incrementally improved in response to specific local needs. Using this tool we improved clinical documentation practices. We enabled this new form initially only for heart failure providers, and developed a road map to include all cardiology providers in Phase 2, and internal medicine and family medicine providers in Phase 3. We expect the new tool will result in better clinical documentation, enhanced use of evidence based heart failure therapies, and reduce variation in heart failure care throughout the organization.

Figure 1. An example of data visualization of frequency with which “ACE/ARB Prescribed” therapy was reported over time demonstrates the impact of system changes.
On the Predictive Potential of Graph Patterns for Biomedical Relation Extraction

Gokhan Bakal, M.S. 2, Sergei Wallace2, and Ramakanth Kavuluru, Ph.D.1, 2

1Division of Biomedical Informatics, Department of Internal Medicine, University of Kentucky
2Department of Computer Science, University of Kentucky

Introduction: Biomedical relation extraction (BRE) is a crucial information extraction task where binary relations are used to encode potentially novel processes/interactions between biomedical entities. Several existing BRE efforts focus on natural language processing (NLP) approaches that look at specific sentences for linguistic phenomena that are typically used to manifest/express different relations. In this effort, we demonstrate the potential of a complementary approach that employs graph patterns and instead models the prediction problem at a global level to output probability estimates of whether a pair of entities participates in a particular relation. Our models are trained with graph pattern features over the graph of predications from SemMedDB [1], a database of relations connecting UMLS entities with predicates, most of which are relation types, from the UMLS semantic network. We first introduced this approach [2] for the treats predicate and here we report improved results for both treats and causes predicates. Additionally, we report on the coverage provided by the top few patterns from the trained logistic regression (LR) models.

Methods: Given any two biomedical entities (as UMLS CUIs), our goal is to predict whether the entities participate in a treats or causes relation. For example, given Tamoxifen and Breast Cancer, our model for the treats predicate should output a positive decision as it is a well-known treatment relationship. The features we use are based on all simple paths of length ≤ 3 connecting both entities in the SemMedDB graph. We take each path and replace the nodes with their UMLS semantic type sets (given an entity can have more than one type) while keeping the predicate labels as they are. This essentially “lifts” specific paths to semantic patterns between the input entities. We call these patterns compound patterns [2] as each node is replaced with its semantic type set. A conventional LR model is trained with these patterns as features. In this effort, we also experimented with what we are terming “primitive” patterns where each compound pattern is expanded into multiple simpler patterns by replacing the semantic type sets with constituent individual items. Additionally, we also identified the coverage (recall) provided by the top few patterns when they are ranked based on LR model coefficients (which are log-odds ratios for the corresponding features).

We used 7000 treats and 2918 causes hand-curated relations from the UMLS Metathesaurus for our experiments and removed any existing treats and causes edges between the corresponding pairs from the SemMedDB graph when building the corresponding models (to ensure fair assessment of our approach). We derived negative examples from pairs that are not connected via the corresponding predicates in the Metathesaurus or the SemMedDB graph but are nevertheless allowed by the semantic network. We computed performance measures over 100 distinct 80%–20% train-test splits of the datasets to compute confidence intervals over F-scores with a positive-negative imbalance of 1:10 in the test set to model realistic scenarios. We varied the imbalance in the training datasets to see the corresponding effect on test set performance.

Results: For both treats and causes, models with compound pattern features outperformed their counterparts trained with primitive patterns although primitive patterns were superior when balanced training datasets were used. The training datasets with the most positive-negative skew (1:10) yielded the best performances in both cases. The 95% F-score confidence interval for the treats predicate is 98.03 ± 0.06. The corresponding interval for causes is 88.56 ± 1.8. For treats, we had over 423,000 unique compound pattern features in the model, but the top 100 patterns (based on model coefficients) cover 43% of the 7000 instances. Similarly, for causes we had over 197,000 unique compound patterns and the top 100 connect 25% of the full dataset. This shows that our method is also able to identify high-quality patterns that can be used to query knowledge graphs for generating new hypotheses.

Establishing Value of Health Information Exchange Content
Gina B. Baker, MSN1, Sidney N. Thornton, PhD1,2
1Intermountain Healthcare, Salt Lake City, UT; 2University of Utah, Salt Lake City, UT

Abstract
Health Information Exchange (HIE) has been proposed as a value added system to the expensive and complex healthcare problem of information silos and segmented patient treatment. Differing opinions of HIE success are circulating based on possible barriers, success stories and its promised potential. In an attempt toward objectivity, patient summaries within the CCDA format were evaluated for content and value added with respect to the current encounter. The ultimate usefulness of data can be defined by its inherent content and by the situational context to a provider at the point affecting care.

Introduction
Despite millions of dollars invested into health information exchange technology, questions of value and usefulness remain in regards to HIE systems. In a recent review Eden et al.1 identified the three main barriers for HIE as information completeness, organization, and workflow technology matching user needs. Beyond connectivity, questions remain about the information actually available for providers through health information exchange and whether the information is relevant. Information contained in a health information exchange depends on the architecture of the health information exchange, consent structure (opt-in or opt-out) and participating providers1. Once information is actually available in the HIE the problem becomes one of filtering the data according to its value or usefulness for the provider in the specific situation. In a study by Kierkegaard, Kaushal and Vest providers reported that they cannot find any patient information about 30% of the time and really only find what they are seeking about 5% of the time2.

Methods
Patient summaries from the community were reviewed against current visits for an internal medicine clinic. Data were analyzed based on the length of the summary, number of sources, data sections and types populated, whether the data was recent within the past six months and data completeness. A clinician evaluated the data points in addition to the scheduled visit reason compared to available HIE data context to determine if available external reason would be valuable to the current encounter. The HIE data was then categorized by its potential to alter the course of treatment.

Results and Discussion
Similar to the study by Kierkegaard, Kaushal and Vest2 patient clinical information was found from community HIE sources for 62% of the internal medicine visits. Patient summaries were generally three pages in length with an average of three external clinical sources. Patient results of any type were found 90% of the time while results within the last six months were noted 60% of the time with 25% being new information from the last visit at the internal medicine facility. Encounter information occurred 70% of the time in patient summaries followed by laboratory at 40% and radiology notes at 33%. Treatment course changing results were seen in the external data for only 1% of the visits.

Conclusions
Content of HIE will continue to grow as participation grows. Giving providers a snapshot of data content found in the exchange can help with provider acceptance and the ultimate rate of usage. Once information is readily available, the technology and clinical workflows need to consider data presentation, filtering and usability to aid the provider based on the specific encounter, specialty and the individual patient. Additional evaluations of HIE data in current visit context by multiple clinicians is recommended.

Introduction

The HIV/HCV/STD Clinical Education Initiative (CEI) provides continuing medical education to healthcare providers and is funded by the New York State Department of Health AIDS Institute (AI). In 2009 CEI diversified its portfolio with the addition of online education. To date we have offered more than 280 multimedia learning modules, over 100 online accredited courses, 14 interactive case simulation tools (ICST) and other informational materials to support continuing medical education among clinical providers. All these resources are delivered through various platforms: website (www.ceitraining.org), Android and iOS apps, social media and email newsletters. In 2013 we started offering interactive case simulations to healthcare providers as a fast and easy access tool to decision diagrams based on the latest AI guidelines.

The objectives of this paper are to describe the development of ICST, analyze the usage of these tools, and evaluate the tool based on the feedback from our users.

Method

The time period of this study is June 2013 to February 2016. The analysis from google analytics data on demographics and geographical distribution of users, total/new/returning users, mobile devices used, traffic sources and network referral indicated the ICS usage. Descriptive statistics and time series were used to examine all these variables and, whenever appropriate, correlations were also determined. To determine the merit of ICST, we considered the feedback received from users through our online survey.

Results

Simulation tools have been used by 17,345 users; 36% were returning users, 73% were in the 18-45 year age group, and 58% were female. Users accessed the simulation tools primarily from mobile devices (85%) compared to only 15% on computers. While targeted to New York State providers only half of the users (52%) came from the US; other countries included Tanzania (6%), India (5%), Kenya (4%), South Africa (3%), Brazil (2%), United Kingdom (2%), Ghana (1%), and Canada (1%). The most popular simulation tools were the HIV testing and PrEP. The interactive decision diagrams inside the tool are designed to offer step by step approach in different case scenarios.

The simulation tools were found to be easy to use and helpful in the process of medical decision making, providing a convenient and useful way to offer clinical education.

Conclusions

All ICST were developed based on the NYSDOH AI guidelines, using a new technology-enhanced simulation training approach to deliver up-to-date medical knowledge to healthcare providers. The survey data revealed that the majority of clinicians found the ICST easy to navigate and very useful in the process of medical decision. In addition, the tool is being used around the globe, especially in countries impacted by the HIV epidemic.
Constructing Diagnostic CT Exam Lists for Sites across an HIE

Anton O. Beitia, MD¹, Tina Lowry MS¹, Daniel J. Vreeman, PT, DPT, MSc², Bradley N. Delman, MD¹, Benjamin H. Slovis, MD¹, George Loo, DPH¹, Frederick Thum III, MD¹, Jason S. Shapiro, MD¹
¹Icahn School of Medicine at Mount Sinai, New York, NY; ²Regenstrief Institute, Indiana University School of Medicine, Indianapolis, IN; ³Department of Biomedical Informatics, Columbia University, New York, NY

Introduction

Duplicate computed tomography (CT) imaging may cause increased health care costs and unnecessary exposure to ionizing radiation. Since duplicate CT imaging often occurs because providers lack prior patient health information from other clinical sites, a prior CT alerting system based on results from a health information exchange (HIE) may reduce avoidable CT imaging. Such an alerting system requires decision rules that operate against a list of CT exam codes and corresponding descriptions across HIE sites. Radiology master files typically mix codes for all modalities within the same file, and also contain various administrative and billing codes. Since diagnostic CTs, rather than procedural/interventional CTs, are the most likely duplicate exam types, we propose a method for constructing lists of diagnostic CT exams from facilities within an HIE in order to focus resources on the most pertinent exam types.

Methods

Our overall approach was to query HIE server data with word stems to identify potential CTs and then apply filters to create separate lists of diagnostic, procedural and post-processing/administrative CTs. Radiology data from exam description fields contained on local HIE “edge” servers of sites participating in Healthix (New York City area HIE) were queried with strings likely to indicate CT exams (e.g., CT, CAT). For our study, we created three sets of terms that each contained all exams from 10 sites: a training set, a preliminary test set, and a final test set. For the training set, a user with domain knowledge extracted all non-CT, procedural CT, and administrative/post-processing CT exam descriptions and segregated them into separate tables. Following the removal of these non-diagnostic exams, by exclusion the CTs remaining on the original list were diagnostic studies. The lists of non-CT, procedural, and administrative/post-processing CT exam descriptions were analyzed to determine high occurrence strings that could serve as tokens for filtering exams into the three categories. Examples of strings used for filtering include laet and oetreo for non-CTs, biopsy and guidance for procedural CTs, and multiplanar, recon, and consult for post-processing and administrative CTs. We then applied these filters to the preliminary test set. One of the authors (AOB), a board certified radiologist with domain expertise, manually reviewed the resulting diagnostic CT list for false negatives (i.e., non-CTs, procedural CTs, and administrative/post-processing CTs that were included in the diagnostic list) and analyzed the non-CT, procedural, and administrative/post-processing CT lists for false positives (i.e., diagnostic CTs incorrectly excluded). Preliminary test set results were used to further refine the word stem filters, which were then applied to a final test set of potential CTs from 10 other sites. We calculated sensitivity and specificity of the filters for non-CTs, procedural, and administrative/post-processing CTs applied to the final test set.

Results

A total of 11,115 potential CT exam descriptions from 30 Healthix sites were obtained for the training, preliminary test, and final test sets. In the training set there were 3,034 potential CT exams of which 1,758, 777, 471, and 28 were diagnostic, non-CTs, procedural, and administrative/post-processing CTs respectively. In the preliminary test set there were 3,663 potential CT exams of which 2,357, 864, 392, and 50 were diagnostic, non-CTs, procedural, and administrative/post-processing CTs respectively. For the final test set, there were 4,417 potential CT exams of which 3,017, 1021, 333, and 46 were diagnostic, non-CTs, procedural, and post-processing/administrative CTs respectively. Sensitivity of the non-CTs, procedural CTs, and post-processing/administrative CTs refined filters applied to final test set were 0.98, 0.99, and 0.91 respectively. Specificity of these filters were 0.99, 1.00, and 0.97.

Conclusion

Our method of constructing CT exam lists from HIE sites produced diagnostic, procedural, and administrative/post-processing CT exam lists with a high sensitivity and specificity. Application of these filter methods may facilitate constructing HIE-wide and site-specific exam lists which can be used for terminology mapping, crossover analysis, and as the basis for a previous exam alerting system.
Categorizing Clinical Data to Make It Easier for Patients to Indicate Their Data Sharing Preferences

Elizabeth Bell, MPH, Diana Guijarro, Hyeon-eui Kim, RN, MPH, PhD, Alexander Richardson, Jina Huh, PhD, Shuang Wang, PhD, Lucila Ohno-Machado, MD, MBA, PhD
Health System Department of Biomedical Informatics, UC San Diego, La Jolla, CA

Introduction and Background
The informed CONsent for Clinical data and biosample Use for Research (iCONCUR) project aims at (1) studying patient data sharing preferences and (2) developing innovative web-based tools to facilitate the informed consent process. We previously developed a web-based tool prototype, iCONCUR v.1, which allows patients to make choices about which parts of their medical record they want to share with different categories of researchers. The choices are saved in a database that is checked before data are released to researchers. The choice taxonomy available to patients was based on interviews with healthy volunteers and analyses of the clinical data requests from the researchers in our institution. Our goal for the final system is for the data sharing options to cover the data items most commonly used in research, and for each item to be properly placed under an intuitive category that is easily understood by patients. To inform the taxonomy design for the final system including the categorization of data sharing options intuitive to the patients, we are conducting 4 focus groups, each consisting of 3~5 participants. This abstract reports on the process of developing data categories and results of the first focus group with 3 HIV+ patients.

Methods
To identify the medical data items to review in the focus group session, we examined 22 reference articles about informed consent and 192 nursing and clinical trial study papers. We identified more than 1,800 data items from these articles, which were later condensed to 1,100 unique items. Two readers collaboratively reviewed the 1,100 items and identified additional data items and categories that could potentially be included in the iCONCUR system. These articles helped us determine categories of clinical data that should be considered for the data sharing options. The information obtained from the articles was compared against the iCONCUR data to create a condensed version with 17 category labels (Table 1) to be used in the focus groups. The three participants of the first focus group performed a card sorting activity, sorting 67 medical data items into groups based on perceived similarities. After sorting all cards, they constructed category names for each group, informed by our 17 category labels. Letting the participants first sort the items and add category names later (as opposed to being presented with category names to sort the items into) allowed us to start to understand how some participants naturally group data items.

Results and Discussion
The participants developed 6 groups and sorted the items in unexpected ways. For instance, Neighborhood and Number of Pregnancies were grouped together under the category Family History, which these participants perceived as a category that would encompass any data item relating to their families. Additionally, patients did not place data items relating to sensitive topics such as drug use, mental health, or sexual history in a separate category. They also had a hard time considering more than two items in a group—i.e., in choosing which group an item should be included, these patients looked in each group for an item that was similar to the pending item, rather than considering multiple items in the group. These “anchor” items seemed to be those that the participants remembered more clearly because either they were easy to understand (e.g., height) or they had experience with it (e.g., urine sample). In future work, we plan to investigate how different card sorting or alternative procedures might have an impact on patients’ decisions. More focus groups with a larger number of patients from different clinics will give us insights to patients’ mental models on personal medical data categories. This will guide the development of iCONCUR v2.

Acknowledgements
This project is supported by NIH grants from NHGRI (R01HG008802 and R00HG008175).

NASA’s GeneLab: Phase I Results and Plans

Daniel C. Berrios, MD MPH PhD\textsuperscript{1,2}, Jon D. Welch, BA\textsuperscript{2}, Homer W. Fogle, MS\textsuperscript{2}, Michael Skidmore, BS\textsuperscript{2}, Oana Marcu, PhD\textsuperscript{2}

\textsuperscript{1}University of California, Santa Cruz, CA; \textsuperscript{2}NASA Ames Res. Ctr., Moffett Field, CA

**Purpose**

GeneLab is currently being developed by NASA to support “open science” biomedical research in order to enable the human exploration of space and improve life on earth.\textsuperscript{1} Phase I of the four-phase GeneLab Data Systems (GLDS) project emphasized capabilities for submission, curation, search, and retrieval of genomics, transcriptomics and proteomics data from biomedical research of space environments. Key challenges included: 1) selecting and tailoring the platform for Phase I; 2) designing optimal data set curation procedures including metadata representation and generation, and quality control); and 3) balancing GLDS accessibility with user engagement and tracking capabilities.

**Design**

For GLDS Phase I, we deployed a project-management and file-sharing software platform developed by NASA, deemed the most expedient path towards democratizing data access to space life science research data. For metadata representation, the project surveyed a wide variety of options, and chose the ISA-Tab specification\textsuperscript{2} for its broad applicability to all kinds of biological experimental data, conceptual and practicable use of formal knowledge representation structures (i.e., ontologies), and availability of open-source metadata acquisition and translational tools.

**Results**

Open access to Phase I of the GeneLab Data Systems was implemented in April 2015. Usage of the system has steadily grown (see Figures 1, 2), mirroring the growth in curated data file collections (from 22 to 47 data sets as of Feb. 2016). Growth was observed despite limited end-user capabilities of the Phase I system (rudimentary data set browsing and search by metadata, limited metadata display). The majority of Phase I-curated data were transcriptomics investigations already housed in other repositories (a validation of data acquisition, storage and curation processes); four never-before-released, multi-omics spaceflight investigations (using Mus musculus and Arabidopsis thaliana), were added in late 2015, leading to an exponential increase in download volumes (Fig. 2).

**Conclusions**

The Phase I system download volumes indicate strong interest of the scientific community in these data. Phase II of the GLDS will focus on enhancing search capabilities, including search of federated repositories like the NCBI GEO/SRA and EBI PRIDE archives. We anticipate challenges in the areas of federation flexibility, federated search performance, and metadata representation mapping. More powerful search, data and metadata visualization functions, and more automated data submission processes may increase usage dramatically. The project is currently evaluating how best to include these capabilities, including evaluating alternative software platforms for Phases II-IV.

Toward Honoring the Values of Patients With Multiple Chronic Conditions: Insights from a field study

Andrew B. L. Berry, MS¹, Catherine Lim, MDes¹, Tad Hirsch, PhD¹, Andrea L. Hartzler, PhD², Edward H. Wagner, MD, MPH², Evette Ludman, PhD¹,², James D. Ralston, MD, MPH¹,²
¹University of Washington, Seattle, WA; ²Group Health Research Institute, Seattle, WA

Introduction
Older adults with multiple chronic conditions (MCC) face competing demands for care, which can impede self-care among patients and their family caregivers¹. Furthermore, patients and their healthcare providers often disagree on priorities for care—providers tend to focus on managing individual conditions while patients often focus on their ability to engage in meaningful activities². It is important that patients and providers set care priorities together. Patients’ values—things that are important to them in the context of their daily lives—influence their priorities, but previous work has defined patients’ values inconsistently³. Therefore, we sought to clarify and expand the definition of patients’ values with the ultimate goal of understanding how their values affect their priorities for care.

Methods
We conducted 24 home visits with patients who receive care at a large integrated healthcare system in Washington state. Home visits involved a semi-structured interview, aided by photo elicitation, and a home tour. The goal was to understand what is important to patients in their daily lives, and how they relate what they value to their illnesses and self-care. We recruited adults with diabetes and at least two of the following: osteoarthritis, depression, and coronary artery disease. Our analysis of interview transcripts was guided by constructivist grounded theory.

Results
Five themes about what patients value emerged (Table 1). Participants often described relationships among values, such as tensions and synergies. For example, P2 expressed tension between her volunteer work providing food for the homeless and her desire to avoid pain and fatigue: “The first thing I’m going to have to give up is, unfortunately...I hate to even verbalize it...is [volunteering]. That’s the most strenuous part, and the most risky, that [as] an 85-year-old may not be the best position for me to be in...when I go to Costco, and lifting all that stuff in the car, my shoulders, pain, you know?” P2’s volunteer work represents a valued activity, but also reflected other values, including principles, emotions, and social relationships. To continue volunteering, P2 scheduled days off to rest and read in her recliner, reflecting her value of comfort. Findings illustrate different things patients value and suggest that clinicians should strive to understand relationships among patients’ values and demands for care.

Conclusion
We characterize what patients with MCC value and relationships they perceive among those values. Findings establish a foundation for future work to understand how patients’ values shape their care priorities, how patients and providers communicate about values, and how to design systems to promote shared priorities for care.

Acknowledgments: Study procedures were approved by Group Health Research Institute IRB. We wish to thank the Agency for Healthcare Research and Quality for their generous support (R01 HS022364) and valuable contributions of Linda Kiel, Zoe Bermet, and Luesa Jordan.

Transmission of ELR messages To Improve Public Health Reporting

Samar Binkheder, MS, PhD Cand1, Brain E. Dixon, PhD2,3, Shaun Grannis, MD, MS3,4
1Indiana University School of Informatics and Computing, Indianapolis, IN; 2Indiana University Richard M. Fairbanks School of Public Health, Indianapolis, IN; 3Regenstrief Institute Center for Biomedical Informatics, Indianapolis, IN; 4Indiana University School of Medicine, Indianapolis, IN

Introduction

The notifiable condition detector (NCD) receives more than 350,000 Health level 7 (HL7) messages daily for public health reporting (1). The NCD system showed the lowest sensitivity 38.0% for free-text (Methicillin Resistant Staphylococcus Aureus (MRSA)), 70.2% for discrete (Influenza), and 97.1% for numeric (Lead) (2).

Methods

First, we manually evaluated a previously extracted set of 100 HL7 microbiology messages for their compliance with HL7 rules, and patterns of errors of electronic laboratory reporting (ELR). Second, we performed a descriptive analysis of the received HL7 messages (including non-microbiology test results) for one month (August 2015) for percentages of microbiology results, LOINC, and SNOMED. Text processing and descriptive analysis were performed using Python language regular expressions and SAS.

Results

The analysis revealed several patterns. For example, free-text results (e.g. MRSA) were written in multiple ways for 22% of messages. In addition, multiple results or organisms were written as one result in HL7. Moreover, even though some of the results were in numeric format, they were reported as a text format. Additionally, some irrelevant information was found within the result, such as address or person’s name.

During August, 2015 the NCD has successfully identified a total of 31,831 (excluding neoplasms) notifiable conditions. We found that microbiology-related totally 8,656, which is 27.2% of the notifiable conditions. “Staphylococcus, Methicillin-resistant” was the most prevalent (N=2950; 9.3%) microbiology-related condition. In order to learn about the reportable conditions in free-text format, LOINC codes were extracted only for the reported free-text format results. There were a total of 150,622 LOINC codes (27.2%) represented in the data set. For all of the one-month income messages, adoption of SNOMED CT codes was low with only 1323 codes (1%).

Conclusion

This work is still in progress. Even though the NCD has successfully identified notifiable conditions from text data, it is still important to analyze the non-reported conditions to increase the sensitivity and specificity of detection. Results from this work will identify message problems and compliance with standards. In addition, our results will facilitate the identification of methods that improve transmission of ELR messages, and increase the use of structured data. Future work will also seek to apply machine learning and natural language processes techniques that have proven useful in analyzing text documents in other biomedical informatics application spaces.

Comparison of Approaches for Heart Failure Case Identification from EHR Data

Saul Blecker, MD, MHS1, Stuart D. Katz, MD, MS1, Leora I. Horwitz, MD, MHS1, Gilad Kuperman, MD, PhD2, Hannah Park, MS1, David Sontag, PhD3
1NYU School of Medicine, New York, NY; 2New York-Presbyterian Hospital, New York, NY; 3New York University, New York, NY

Background: Heart failure (HF) is a common cause of hospitalization and a focus of readmission reduction efforts. Accurate, real-time case identification is needed to target interventions to improve quality and outcomes for hospitalized patients with HF. Problem lists may be useful for case identification, but are often incomplete. Machine learning approaches may improve accuracy of case identification, but may be limited by complexity. We developed five algorithms of increasing computational complexity to identify hospitalized HF cases.

Methods: We performed a retrospective study of hospitalizations at a single academic medical center in 2013-2015 using electronic health record (EHR) data. Using a development set comprised of a random sample of 75% of hospitalizations, we developed 5 algorithms for HF identification at the second midnight of hospitalization: 1) HF on problem list; 2) presence of at least one of three characteristics: HF on problem list, any inpatient diuretic use, or brain natriuretic peptide≥500 pg/ml; 3) logistic regression of 30 clinically relevant structured data elements; 4) machine learning approach using L1-regularization logistic regression with unstructured notes and imaging reports; 5) machine learning approach using both unstructured data and 30 clinically relevant structured data elements. For algorithms 3, 4, and 5, we calculated areas under the receiver operating curves (AUCs) as well as sensitivity based on setting a positive predictive value (PPV) at 0.9. Model validation was based on physician review of selected charts from the 25% validation set.

Results: Of 47,119 hospitalizations, 6,549 (13.9%) had a discharge diagnosis of HF. Inclusion of HF on the problem list (algorithm 1) had a sensitivity of 0.40 and PPV of 0.96 for HF identification in validation. Algorithm 2 improved sensitivity to 0.77 at the expense of PPV of 0.64. Algorithms 3, 4, and 5 had AUCs of 0.953, 0.969, and 0.974, respectively (Figure). With PPV of 0.9, these algorithms had associated sensitivities of 0.68, 0.77, and 0.83, respectively.

Conclusion: The problem list is insufficient for real time accurate identification of HF hospitalization cases. Although analysis of free text using machine learning had the highest predictive accuracy, less computationally-intensive approaches using structured data may be adequate depending on clinical need.

Figure. Receiver operating curves (ROCs) for three algorithms to classify patients with heart failure: logistic regression of structured data (algorithm 3), machine learning of unstructured data (algorithm 4), and machine learning of a combination of structured and unstructured data (algorithm 5).
Characterizing the semantic composition of the UMLS Metathesaurus over time

Olivier Bodenreider, M.D., PhD and Lee Peters, M.S.
U.S. National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA
{olivier.bodenreider|lee.peters}@nih.gov

Motivation. The UMLS Metathesaurus has grown dramatically over the past fifteen years. From 2002 to 2015, the number of concepts has increased from about 777,000 to 3.1 million, a 4-fold increase. It is difficult to infer the semantic composition of the UMLS from the list of its sources. While some source vocabularies contribute concepts from a single semantic category (e.g., anatomical entities in the Foundational Model of Anatomy), others reflect a wide range of semantic categories (e.g., SNOMED CT). Moreover, the integration of a given term from a source vocabulary does not always result in new concepts, since this term may end up as a synonym for an existing concept. In this investigation, we leverage the semantic groups to characterize the semantic composition of the UMLS Metathesaurus and its evolution over time.

Methods. Each Metathesaurus concept is assigned at least one of the 127 semantic types. Semantic types are grouped into fifteen semantic groups, which represent broad subdomains of biomedicine, such as Anatomy, Chemicals and Drugs, and Disorders. The UMLS semantic groups have been used to create semantic profiles for source vocabularies, but can also be applied to the Metathesaurus as a whole. For each edition of the UMLS (2002-2015), we compute the distribution of the Metathesaurus concepts with respect to the 15 semantic groups.

Findings. As shown in Figure 1, the proportion of a few semantic groups has changed markedly between 2002 and 2015. Chemicals & Drugs. The composition of the early Metathesaurus versions was heavily dominated by chemical concepts, especially from MeSH. Although the number of chemical concepts has almost doubled during this period, it has grown at a slower pace than that of other groups. Living Beings. This group mostly represents organisms (mainly from the NCBI taxonomy) and has grown from 30,000 to nearly 1M concepts. It is the fastest growing group and now represents 30% of all Metathesaurus concepts. Disorders and Procedures. The integration of a single large and fine-grained vocabulary can be responsible for major shifts in composition. The growth of disorder concepts between 2009 and 2011 is attributable to the integration of two large and fine-grained vocabularies, MEDCIN (2009) and ICD10-CM (2011). This is also the case for procedure concepts in 2009, when ICD10PCS was added. In contrast, the integration of SNOMED CT in 2003-2004 is silent, because, although extensive and detailed, its content was already largely represented by SNOMED International and the Read Codes.

For information about the UMLS semantic groups, see: https://semanticnetwork.nlm.nih.gov/.

Acknowledgments: This work was supported by the Intramural Research Program of the NIH, National Library of Medicine.

Identifying Missing Finding Site Relations in SNOMED CT

Jonathan P. Bona, PhD\textsuperscript{1}, Werner Ceusters, MD\textsuperscript{1},
\textsuperscript{1}Department of Biomedical Informatics, University at Buffalo, Buffalo, NY

Introduction

Every concept in SNOMED CT comes with descriptions, including a Fully Specified Name (FSN). FSNs typically end with a semantic tag in parentheses to disambiguate from other concepts with similar descriptions. However, some things that are not semantic tags appear in parentheses as parts of FSNs, and some FSNs have more than one tag, so it’s sometimes hard to know by looking at an FSN exactly what its tags are. We will call words within parentheses in FSNs apparent tags if it’s not obvious that they are not tags. “(bullous edema is not sufficient evidence to classify a tumor as T4),” appears in an FSN but is clearly not a semantic tag.

SNOMED CT’s concept model includes associative relations between concepts used to formally specify their meanings. For example, 10000006 | Radiating chest pain (finding) is associated via 363698007 | Finding site (attribute) with 51185008 | Thoracic structure (body structure). Formally specified and query-able relations between concepts enhance the completeness and usefulness of an ontology, and increase its utility for organizing and retrieving data, e.g., as part of structured EHRs, especially when combined with the Is-a hierarchy and subjected to logical inference. SNOMED CT’s main finding concept 404684003 | Clinical finding (finding) has many thousands of sub-concepts. Here we examine the use and disuse of finding sites in finding concepts related to cancer staging (specifically, some of the 1038 concepts under 385356007 | Tumor stage finding (finding)). For those lacking finding sites, we use apparent tags in the FSNs to find body structure concepts that should be associated with those findings.

Method

We first found all Tumor stage finding concepts that lack finding site relations to any body structure, and identified 170 candidate semantic tags in their FSNs. These were manually filtered for likely body structure tags: apparent tags that name anatomical entities. We focused on the 47 simplest body structure tags and omitted tags with longer phrases (e.g., “liver, including intrahepatic bile ducts”), and 36 short “tags” like “pT1-pT4, pM1” that are codes for different components of tumor staging. Each of these 47 body structure tags was manually matched to the best fit body structure concept. Starting again from the full set of Tumor stage findings, we used the body structure tags and matching concepts to generate a list of suggested finding sites for any of the 1038 concepts that used those tags.

Results

The result is a list of suggested candidate finding sites for 369 concepts (out of 1038) that do not have associated finding sites. These were manually verified as coherent and plausible finding sites for the relevant concept. Each concept was then marked with its nearest anatomically-specific TNM finding ancestor concept (e.g. 397092003 | Gallbladder TNM finding (finding)) where applicable. Almost all had anatomically-specific TNM ancestors. Of the 17 concepts without such ancestors, 6 have the apparent tag “appendix.” Unlike other body structures (Bone, Thyroid, etc) there is no TNM finding concept for Appendix. 4 out of 17 are pN (regional lymph nodes) or pM (distant metastasis) breast cancer findings. Another was for a primary tumor that cannot be assessed. Since none of these is about things located in the breast, they might need no finding site relation with Breast (body structure). The prevalence of anatomically-specific TNM finding concepts here suggests another technique to efficiently add finding sites for many of the tumor stage concepts: such concepts (Ampulla of Vater TNM Finding, etc) should be directly associated with the relevant body structures (Structure of ampulla of ...) -- relations that will apply also to their descendants (pT1: Tumor limited to ampulla of Vater ... ) after classification.

Conclusion

Our preliminary investigation of the use of finding site associations in a small section of the SNOMED hierarchy reveals an important gap that limits the usefulness of the relevant concepts for representing and reasoning about cancer staging and its relation to patients, parts of their bodies, their health, and so on. We have used the presence of apparent semantic tags that name body structures to align approximately one third of the target concepts with body structure concepts suitable to serve as their finding sites.
Pre and Post Knowledge Self-Assessment in a Flipped Classroom: Analysis of Students in an Introduction to Health Informatics Course

Suzanne A. Boren, MHA, PhD\textsuperscript{1}, Iris Zachary, PhD, MS, CTR\textsuperscript{1}, \\
\textsuperscript{1}Department of Health Management and Informatics, University of Missouri, Columbia, MO

Abstract

Self-assessment of knowledge by students is an important tool for course design, learning, and assessment in a flipped classroom. The students in an introductory health informatics course completed knowledge self-assessment surveys covering the full content of the course at the beginning and end of the course. The self-assessment served as an outline of the learning objectives for the course, a resource for students to understand their learning, and a measure of their gains in knowledge.

Introduction

The purpose was to evaluate the pre and post knowledge of master of health administration and master of health informatics students enrolled in an introduction to health informatics course taught in residential and executive formats. Education models continue to move to student-centered learning. Adopting methods for understanding student learning must be utilized as part of a comprehensive assessment system. In addition, formative assessment and feedback should be used to empower students as self-regulated learners.

Method

Students were invited to complete a self-assessment exercise of their health informatics knowledge at the beginning and end of the course. Sixty-eight (68) students were enrolled in the course and participated in the pre and post knowledge self-assessment. One hundred thirty-four (134) knowledge areas were selected from the chapters of an introductory health informatics textbook. The students rated each knowledge area on a five point scale with the corresponding anchors: no knowledge (1), very limited knowledge (2), limited knowledge (3), moderate knowledge (4), great knowledge (5). The data was collected, de-identified, organized, and analyzed to calculate the change in knowledge between the beginning and end of the course. The pre and post knowledge self-assessment means were calculated for each student to evaluate how each individual benefited, as well as the class as a whole. Following this, the pre and post knowledge self-assessment means were calculated for each chapter. Each of the 134 areas was also linked to a level of Bloom’s Taxonomy.

Results

Overall, there was a pre knowledge mean of 2.0 (limited knowledge) and a post knowledge mean of 4.3 (moderate knowledge). The pre assessment overall mean for each student ranged from 1.0 to 3.3. The post assessment overall mean for each student ranged from 2.8 to 5.0. Four of the 68 students reported post assessment knowledge scores of 5.0 indicating great knowledge in all areas. The overall difference between pre and post knowledge self-assessments ranged from 0.5 to 3.7. The pre knowledge overall mean for each chapter was an average of 2.0 and the post knowledge overall mean was an average 4.0.

Conclusion

The knowledge gained during the semester of an introductory health informatics course was quite satisfactory and moved 2.3 points on a 5.0 point scale from limited knowledge to moderate knowledge. While a pre and post knowledge self-assessment surveys cannot be used solely to determine a student’s learning, they can certainly be used as part of a comprehensive assessment plan for validation of learning. Implications for educational practice include a greater awareness by students and instructor of course content requiring additional emphasis.
Evaluation of Safety Heuristics Applied to a Mobile Medication Reconciliation Application

Elizabeth M. Borycki, RN PhD1, Andre W. Kushniruk, MSc PhD FACMI1
1University of Victoria, Victoria, British Columbia, Canada

Abstract

There is a need to evaluate the ability of safety heuristics to identify potential technology-induced errors in mobile health (mhealth) applications. In this work we evaluate the ability of safety heuristics to identify potential technology-induced errors in mhealth applications.

Introduction and Background

The safety of health information technology (HIT) has emerged as an important issue for the modern healthcare organization. New technologies are being developed that can improve the quality and safety of health care, yet, along with the introduction of these new HIT there has also emerged new types of errors (i.e. technology-induced errors) 1. Researchers have developed a number of differing methods for identifying technology-induced errors among them safety heuristics2. Safety heuristics have been used to evaluate software applications such as EHRs that are accessible via desktop and laptop computers. Less research has been done on the assessing the safety of mhealth applications using safety heuristics2,3. In this poster we describe our pilot work in applying safety heuristics developed for traditional EHRs available via desktop and laptop computers to mhealth applications.

Methods

There exist a number of mhealth applications that health professionals and consumers have identified as being supportive of patient safety. One type of application that has been identified by consumers and safety organizations as being of value is the mobile medication reconciliation application (mMedRec app)4. Many safety organizations recommend using mMedRec apps to help patients remember the medications they are taking, remind them to take the right medication, the right dose of the medication and at the right time. To assess the ability of published safety heuristics to evaluate the safety of an mhealth MedRec application, an analyst stepped through the user interface of a MedRec app using safety heuristics developed by Carvalho et al for EHRs2,3.

Results

It was found that many of the safety heuristics developed by Carvalho et al2,3 could be used to evaluate an mMedRec app. The safety heuristics are subdivided into four safety areas: workflow, content, safeguards and function. Workflow, content and safeguard heuristics helped to identify mhealth application safety issues (i.e. those associated with user interface design and workflow)2,3. Several “function” heuristics focused on interoperability and integration of mhealth applications with EHR software2,3. The application studied indicated problems regarding integration and exchange of data with EHRs. This work suggests that interoperability and exchange of data between mhealth apps and EHRs is a key aspect of mhealth and patient safety especially for mMedRec applications.

Conclusion

The work identifies that there is a need for heuristic evaluation of mMedRec apps. In particular there is a need for further study of the integration and exchange of data between consumer mMedRec apps and traditional EHRs and their implications for patient and technology safety.

Opioid-Related Side Effects and Adverse Reactions: Mining of Patient Secure Messages

Lina Bouayad, PhD1,6, Robert D. Kerns, PhD2, William Becker, MD2,3, Thomas Houston, MD, MPH4, Stephen L. Luther, PhD1, Stephanie Shimada, PhD4,5, Balaji Padmanabhan, PhD6

1James A. Haley Veterans’ Hospital, Tampa, FL; 2Yale University, New Haven, CT; 3VA Connecticut Healthcare System, New Haven, CT; 4Bedford VA Medical Center, Bedford, MA, 5Boston University, Boston, MA; 6University of South Florida, Tampa, FL

Introduction

Extensive data about opioid-related side effects and risk factors to predict opioid-associated adverse events are stored in the EHR in coded fields and progress notes. Research indicates the structured data in EHR are incomplete and inconsistent. Prior literature has targeted mining of clinical documents written by providers. Yet, Patients’ data extracted from unstructured progress notes contains provider-reported information only. Recently, secure messaging has been developed as a tool that provides patients with convenient and fast access to healthcare providers regarding non-urgent health concerns. As of October 2015, an exponential growth in SM adoption was reported among veterans with more than over 1 million SMs sent. This suggests that SMs represent an important new resource that was previously inaccessible for clinical care or research.

Patient-reported side effects and adverse events can be extracted from secure messages (SMs). Data extracted from SMs could be integrated into the EHR (as structured fields) to (1) enhance predictive risk models for opioid-related adverse events, and (2) improve time of responses by health care providers for patients with pain.

To our knowledge, this would be the first study to use analytics to explore the content of SMs. If successful, the method could be applied to other high-frequency, high-risk, and/or high-cost conditions.

Methods

This retrospective study looked at cohort of Veterans who 1) have been diagnosed with pain, 2) have been prescribed opioid therapy during FY12-FY13, and 3) have used SM to communicate with clinicians. Analyzing our sample data, we identified 1,300,885 unique Veterans who were prescribed common opioids (hydrocodone, oxycodone, morphine, codeine, tramadol, methadone, and hydromorphone) between FY12 and FY13. We then searched for keywords indicating opioid-related side effects and adverse events within the secure messages associated with that cohort of patients (exceeding 2 million). Then, Machine Learning was applied to identify the different topics documented in the selected secure messages. Topics identified through machine learning will be presented at the conference.

Results

Using secure messages’ data (through the VA Informatics and Computing Infrastructure (VINCI)), we able to complete two preliminary investigations. Results indicating the prevalence of keywords indicating opioid-related side effects and adverse events are listed in Table 1. Results also indicate that terms used by patients to describe health concerns in SMs can be different than the ones used by clinical providers. Therefore, future text mining work on SMs needed to be adapted to include commonly used patients’ terms. Co-occurrences of symptoms identified through data mining will be presented at the conference.

Conclusion

In the present study we assessed the presence of opioid-related side effects and adverse events in patients’ secure messages. Our future work intends to use text mining and machine learning algorithms to extract symptoms related to opioid therapy from SMs which will enable (1) comparison between patient- and provider-reported data and (2) integration of patient-reported symptoms into structured fields for further analysis.

Home3D -- Virtualized Home Environments in the EHR
Markus Broecker, PhD, Patricia Flatley Brennan, PhD, RN
Living Environments Lab, University of Wisconsin-Madison

Problem
Patients’ homes play an increasingly important role in health care, from being a place for self-care and disease management to a source of health hazards or barriers and facilitators of living healthy. However, there is little space and no formalized way to capture in the electronic health record the typical ways clinicians learn about homes: verbal reports from the patient, still photographs, videos, or home visits. It is difficult to gain a shared understanding by listening to verbal reports or viewing images, and it is cost-prohibitive to make visits to the home of every patient who might benefit from this. Our team has developed a way to capture high fidelity 3D images of home interiors and display them in immersive virtual reality (VR) platforms in a way that enables rich understanding and sharing of perspective. Yet to make these visualizations clinically useful it is critical to find a way to integrate them into the workflow and generate entries in the EHR of the home images and of the decisions based on them.

We have partnered with a local medical center (UW Health) and a major electronic health records vendor (Epic) to demonstrate how to access and explore full 3D images of a patient’s home, annotate the images, and store them in a clinical record. Other members of our team are adapting existing standard terminologies to label specific objects in the home. During this one-year proof of concept project we will 1) refine a web-based application that enables omni-perspective viewing of point cloud data; 2) integrate this web viewer application into the Epic clinical interface; and 3) evaluate through focus groups of patients and clinicians the relevance and practicality of being able to access and explore a full scale model of a patient’s home. This strategy will be useful for those patients with complex self management needs, those at risk for household hazards, and those with discharge planning needs.

Approach
Figure 1 depicts the workflow. In step A, a point cloud of the home is generated and processed (currently using a $40,000 LiDAR scanner; future work anticipates generating point clouds simply and cheaply via smartphone-captured video). Because of the very large file size (> 1Gb) of the point cloud the storage in Step E must be external to the EHR using existing DICOM standard. Our project focuses on the clinical informatics challenges noted in Steps B, C, and D. At the appropriate time after a point cloud of a patient’s home is available, the clinician and patient can review the patient’s anticipated home patterns using any 3D visualization platform (e.g. VR head-mounted display, such as the Vive). Together they can make annotations of relevant spaces, for example where dressing changes can be done easily or where medication can be stored safely. Screen-scraped annotated images are created (C) and only those images sent to the electronic health record (D).

Current Status
Using HTML5 and WebGL standards we developed prototype web viewer application, which will be accessed via ‘tab’ from the EHR screen displayed on any platform or through immersive VR platforms. The existing data pipeline will be optimized to create data optimized for server-side storage and asynchronous file transfer. The current version of the code is available from github (https://github.com/broecker/PointCloud-WebGL).

Anticipated Challenges
We anticipate two key issues: 1) technological challenges, such as guaranteeing interoperability with existing data types and implementation details; and 2) integration into the existing clinical workflow, such as training to personnel to use the viewer and analyze the data, determining the correct patient population for which such information might prove useful or providing guidelines addressing privacy concerns of patients.

A Systematic Review of The Types And Causes Of Prescribing Errors Generated From Using Computerized Provider Order Entry Systems in Primary and Secondary Care

Clare L. Brown, MPharm, Helen L. Mulcaster, Katherine L. Triffitt, BSc, Dean F. Sittig, PhD, Joan Ash, PhD, Katie Reygate, MPharm, Andrew K. Husband, PhD, David W. Bates, MD MSc, Sarah P. Slight, PhD

1School of Medicine, Pharmacy and Health, Durham University, U.K.; 2Newcastle upon Tyne hospitals NHS Foundation Trust, U.K.; 3The University of Texas Health Science Center, School of Biomedical Informatics at Houston, TX, USA; 4Oregon Health & Science University, Portland, OR, USA; 5Health Education KSS Pharmacy, U.K.; 6The Center for Patient Safety Research and Practice, Division of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, USA; 7Harvard Medical School, Boston, MA, USA; 8Harvard School of Public Health, Boston, MA, USA.

Abstract: Computerized provider order entry (CPOE) systems have been shown to reduce the occurrence of prescribing errors. However, reports have also emerged that these systems have contributed to new types of errors. We conducted a systematic review of the literature to understand the different types and causes of prescribing errors associated with CPOE systems. We identified eight key themes in which improvements could be made.

Introduction: CPOE systems with clinical decision support (CDS) have been shown to reduce the occurrence of prescribing errors. However, a study by Koppel et al. in 2005 sought to identify and quantify the role of CPOE in facilitating prescription errors. Since then, many more studies have provided rich insights into the types and causes of these CPOE related prescribing errors. We conducted a systematic review of the literature to understand the different types and causes of these errors, and recommend improvements in these systems.

Methods: Our review was conducted according to PRISMA guidelines. We searched the literature published between January 2004 and June 2015 using three large databases: the Cumulative Index to Nursing and Allied Health Literature (CINAHL), Embase and Medline, and terms relating to ‘CPOE’ and ‘Errors’. Three authors reviewed titles and two authors reviewed all abstracts and full texts. Studies that reported qualitative data about the types and causes of these errors were included. Three authors read and re-read all full text articles and key recurring themes and sub-themes were identified iteratively from the data.

Results: We identified 1,185 publications, of which 34 were included. We identified eight key themes related to the causes of different types of prescribing errors associated with CPOE systems: computer screen display, drop-down menus and auto-population, wording, default settings, non-intuitive or inflexible ordering, repeat prescriptions and automated processes, users’ work processes and alerting. For instance, the layout of the computer screen display affected how users viewed patient information. Displaying an incomplete list of a patient’s medications on the computer screen contributed to a drug overdose being prescribed for a patient. Intravenous medications may not be displayed in the area of the screen where the patient’s other medications were, and thus users were less likely to consider these medicines when prescribing. Lack of system flexibility also resulted in users employing error prone workarounds, such as the addition of contradictory free-text comments, and CDS alerts generated inappropriate prescribing recommendations. Misinterpretation of the terminology used to describe data labels was also linked with the occurrence of prescribing errors.

Conclusions: This review highlighted how there is still much to be done to improve the safety of these systems. Human factors and user-centred design is key across all of these eight areas and should be prioritized by developers. Drop-down menus should be designed with safeguards to prevent selection errors. A crucial development will be the production of more patient specific and better worded alerts to reduce the impact of alert fatigue and erroneous suggestions.

An outcome-weighted network model for quantifying and measuring collaboration in a hospital cardiology unit

Matthew B. Carson, PhD1, Denise M. Scholtens, PhD1, Conor N. Frailey, PhD1, Stephanie J. Gravenor, MS1, Emilie S. Powell, MD, MS, MBA1, Amy Y. Wang, MD1, Gayle S. Kricke, MSW1, Faraz Ahmad, MD1, R. Kanna Mutharasan, MD1, Nicholas D. Soulakis, PhD1

1Northwestern University, Chicago, IL

Introduction: Shared patient encounters form the basis for collaborative relationships, which are crucial to the success of complex and interdisciplinary teamwork in healthcare. Quantifying the strength of these relationships using shared risk-adjusted patient outcomes provides insight into interactions that occur between healthcare providers in a hospital setting. A network-based approach to quantify teamwork quality could characterize clinical processes, facilitate quality improvement (QI), and become an important tool in learning healthcare systems.

Objective: To establish a generalizable, graph-based framework for calculating and measuring the Shared Positive Outcome Ratio (SPOR), an objective composite measure that quantifies the concentration of risk-adjusted positive outcomes for each pair of providers over a set of shared patient encounters.

Methods: We extracted patient encounter data from a cardiology unit over a three-year period from the Northwestern Medicine Enterprise Data Warehouse (NM EDW). For each encounter, we identified a list of associated healthcare providers along with an outcome indicating the patient’s satisfaction and an acuity measure that we used for risk-adjustment modeling of the encounter outcome. Next, we created a provider-encounter network and used this to identify providers who shared encounters. Finally, we evaluated the SPOR by constructing a network model to assess pairwise collaboration and compared each SPOR in the cardiology collaboration network to SPORs for corresponding edges in 1000 randomly permuted networks.

Results: From a network of 334 providers and 3,453 relationships, we identified 188 pairwise collaborations resulting in significantly high patient satisfaction rates (p ≤ 0.05). To examine high-scoring collaborative relationships more closely, we identified the providers who had 1) ≥ 10 collaborations involving ≥ 6 encounters, and 2) ≥ 10% of their total collaborative interactions with a significant SPOR. Twenty-six providers matched these criteria, indicating potential top performers in terms of patient satisfaction. Though providers in the high- and low-scoring groups had the same average number of associated encounters (41), those in the high-scoring group had a higher percentage of total encounters with positive outcomes than those in the low-scoring group (78% vs. 64%).

Conclusions: We identified extreme high- and low-scoring relationships over a set of shared patient encounters and quantified high variability in collaboration between providers. Our study shows that a healthcare collaboration network can be structurally evaluated to gain insight into the collaborative interactions that occur between healthcare providers in a hospital setting.

Figure 1. An example provider collaboration network showing 22 providers and 30 SPOR relationships. Properties associated with the highlighted edge (yellow) including the SPOR rank, an indication of the significance of the SPOR coefficient (pval), the SPOR coefficient, and the number of shared patient encounters between the two providers (num_collabs), are shown in the bottom left. The proximity of nodes to each other is based on the SPOR coefficient, with high-scoring relationships being shorter in length and low-scoring relationships being longer.
Extending Informatics Education to Home Care

Gail R. Casper RN, PhD¹, Paula A. Jarzemsky RN, MS¹, Jennifer D. Athanas RN, MS¹, Patricia Flatley Brennan, RN, PhD¹

School of Nursing, University of Wisconsin-Madison, USA

Background

Investments by ONC to develop the informatics workforce largely focus on preparing health professionals and informatics specialists to develop, deploy and evaluate information technologies within health care institutions that are familiar and readily accessible, in which their work responsibilities are well-known. As health care increasingly takes place in homes, lay people join professionals as essential health care workers; thus preparing informatics professionals for these less-formal, less accessible health care environments is needed. Patients and their families are required to manage unfamiliar health care demands and technologies in their homes. Critical aspects of the home such as the size, layout and condition are often unknown to those who prepare patients for discharge, prescribe requisite care or provide direct home care. Patients and families need guidance in planning and integrating their health care within their homes’ physical spaces; yet most health professional students lack curricular opportunities to master these skills. While the research on the effectiveness of simulation in clinical care is growing, these studies focus on clinical competencies such as communication, psychomotor skill acquisition and decision-making without risk in formal care settings¹. The home is a site of care, and simulated practice in the home has not been studied.

As part of the vizHOME project (www.vizhome.org; HS R01HS022548) our team captured and rendered full, 3D replicas of the interiors of 20 homes. We now use these replicas to enable health professional students to experience and understand the range and variability of such intimate personal spaces, and to enable them to generate guidelines about the location, use and expected benefits of computer and information technologies in the home.

Methods

Health professional trainees first experience a 3D home replica in a single point-of-view video exploration of an actual home with its characteristic “lived-in” look – a look that has not been successfully created in previous virtual “worlds.” In this “insitu” training, we guide the students to design, implement and evaluate a variety of simulated informatics challenges in home care situations (e.g. placement of devices/technologies, locating cues or reminders).

The primary goal of the videos is to provide opportunities to view and explore homes whose residents are not known to them. More than just providing experiences with home hazard assessment, these videos will be used to enable assessment of the home for such things as placement of mHealth technologies, planning for accommodations in the home that are needed to support self-care and rehearsing communication and demeanor when encountering a home that may be very cluttered or very different from the environments to which they are accustomed. Videos also provide visual cues that prepare the trainees to better participate in telehealth encounters with patients, because the trainees will better understand varied home environments.

In a pilot test, student trainees reviewed a video and case scenario; an important and unexpected barrier was their visceral response to the varying degrees of clutter and disarray. Evaluation of the simulations based on the virtual home videos will focus on several aspects including: feasibility and satisfaction with the simulation (student and course faculty), fidelity of the experience (Witmer’s Presence Questionnaire), workload (NASA-TLX) and impact.

Conclusion

This project is the first step in a modular approach to the design of many simulated home care experiences for health professional students to learn about how both health professionals and lay people use computer and information technologies in home-care and self-management. The ultimate goal is to provide easy-to-use tools to address a variety of learning needs for use by clinical experts. The pilot trial of a video supports the need to afford such guided opportunities to practice communication, priority-setting and decision-making in the home setting.

Modeling Information Behavior over Time: A Colorectal Cancer Screening Case Study

Caitlin Champion, MD¹, Gonzalo G. Alvarez, MD, MPH¹, Ewan Affleck, MD², Craig Kuziemsky, BSc, PhD¹

University of Ottawa, Ottawa, ON, Canada, Northwest Territories Health and Social Services, Yellowknife, NT, Canada

Purpose

Existing modeling approaches are limited in their ability to capture the complexity of health system problems such as limited colorectal cancer screening access in a rural and remote environment¹. A combined Collaborative Information Behavior (CIB)/continuity of care framework for health care process modeling was developed and applied to identify and describe the complex health system factors contributing to screening access.

Methods

Transcripts from interviews with health care providers across the Northwest Territories, Canada (N=29) were analyzed using a combined CIB/Continuity of Care framework for qualitative content analysis²,³. Exploratory process models applying the combined framework to depict colorectal cancer screening access were developed.

Results

Within the combined modeling framework, CIB categories identified and described health care system components, while continuity of care categories were used to model care processes in screening access over time (Figure 1).

Figure 1. Process model applying combined CIB/Continuity of Care modeling framework

Information behaviors were identified as foundational to colorectal cancer screening access, and gaps in these behaviors contributing to access problems were identified and described, including siloed information systems and gaps in results reconciliation and recall, in combination with influential rural and remote contextual factors.

Conclusion

A combined CIB/Continuity of Care modeling framework can be applied to qualitative modeling of complex health system problems such as colorectal cancer screening access, identifying crucial information behaviors and system gaps where targeted informatics solutions may improve screening access and cancer outcomes. These findings may be applied to modeling of similar complex problems and inform improvements in rural and remote screening access.

Knowledge Management of Drug Indications – Complexities and Challenges

Christine M. Cheng, PharmD and Jeff Bubp, PharmD
First Databank Inc, South San Francisco, CA

Abstract

Health information systems use medication indication information for various applications, e.g., identifying FDA-approved and appropriate unapproved “off-label” uses for a medication, associating a drug order with an indication, indications-driven claims adjudication, patient problem list augmentation, prior authorization, and indications-based prescribing. Each use case requires consideration of many factors. We will present some of these considerations and challenges in detail and propose constructs for indications that attempt to account for these factors.

Introduction

Health information systems use medication indication information for a variety of applications. Examples of use cases for indications include identifying FDA-approved and appropriate unapproved “off-label” uses for a medication, associating a drug order or prescription with an indication, consumer labeling of prescription vials, indications-driven claims adjudication, patient problem list augmentation, prior authorization, and indications-based prescribing.\(^1,2\) Each of these use cases requires consideration of many factors, including role of therapy (e.g., treatment, prevention, diagnosis, symptom management) as well as the patient population (e.g., gender, age group, comorbidities, genomic factors) and place in therapy (e.g., first-line, second-line, adjuvant, etc.). Medication indications can also be described in multiple ways that seem divergent from one another. For example, the FDA regulatory approval (e.g., “skin and soft tissue infection” for an antibiotic) may differ from standardized terminologies (ICD-10, SNOMED CT) describing the same condition. Health care providers may use a different vernacular for use in their daily work (e.g., “cellulitis”). New terms may replace older terms (e.g., “juvenile idiopathic arthritis” instead of “juvenile rheumatoid arthritis”) in guidelines and in the literature. In addition, consumer-facing terms for indications may differ from terms used by health care providers. A knowledge base that represents the nuances and complexities of medication indication information may help support the different use cases for indications.\(^3\)

Data model requirements

We define the following model requirements: (1) ability to associate a highly granular drug indication (e.g. a patient population is specified as part of the indication) to a higher level disease concept (e.g. roll-up term), (2) ability to attribute selected drug indications with therapy intent (e.g. empiric vs definitive, preventative vs. maintenance, etc.), (3) ability to associate drug indications with patient population criteria (e.g. age, gender, disease genomics, stage of disease, etc.) when listed as part of the drug indication, (4) ability to associate the indication with standardized terminologies. Examples of drug indication modeling using different constructs will be described.

Technology Usage and Preferences during Pregnancy

Sai Chennupati¹, Marian Dorst¹, Shilo Anders, PhD², Gretchen P. Jackson, MD, PhD.²
¹Vanderbilt University, Nashville, Tennessee; ²Vanderbilt University Medical Center, Nashville, Tennessee

Introduction

During pregnancy, prospective mothers and their caregivers have numerous information needs related to the upcoming birth of the child, many of which are unmet. A growing number of technologies and resources are available to support pregnant women and their caregivers. The goal of this study was to determine the technologies used by pregnant women and caregivers and their willingness to use emerging technologies to support their health.

Methods

This project was conducted as part of an ongoing longitudinal study of the information needs and information management practices. Adult pregnant women and their caregivers (e.g., spouses) seen in an advanced maternal fetal care and group prenatal care practices at Vanderbilt University Medical Center were eligible. Participants were queried about their use of text messaging, automated telephone calls, video calls, social media, and online forums, and their willingness to use these technologies to communicate with health care providers or to support their health.

Results

Twenty six individuals have been enrolled in the study. 18 pregnant women and 8 caregivers. Pregnant participants had a mean age of 32 years; caregivers, 35 years. Thirteen participants (50%) were White; 8 (31%), Black; 2 (8%), Asian; and 3 (12%), other. The mean gestational age was 24.4 weeks. The usage of and willingness to use technologies among pregnant women and caregivers are shown in Figures 1 and 2, respectively.

Conclusions

In our study, most pregnant women and at least half of caregivers used text messaging, automated calls, video calls, and social media. Over one third had used some of these technologies to communicate with their providers, but fewer had used them support their health in other ways. Over half were willing to communicate with providers and support their health through text messaging and video calls. Fewer were willing to use automated calls, social media and online forums to support their health and communicate with providers. Discrepancies between actual usage and willingness to use technologies may provide innovative ways to meet information needs during pregnancy.

Informatics Tools to Support Family Caregivers’ Pain Management in End-of-life Care: Current Evidence and Opportunities
Nai-Ching Chi, PhD Candidate, George Demiris, PhD, FACMI
University of Washington, Seattle, WA, USA

Background: In 2014, more than 1.6 million terminally-ill Americans received hospice care and most of them needed their family caregivers to assist with daily activities or clinical care. In 2015, an estimated 43.6 million U.S. adults served as informal caregivers for a family member. Pain management has been identified as the most challenging task by family caregivers in end-of-life care. Many argue that informatics tools such as telehealth may prove useful in assisting with pain management especially for rural and isolated caregivers. Recommendations on the design and implementation of such tools and documentation of their effectiveness are limited.

Purpose: To identify opportunities for the use of informatics tools to support family caregivers in pain management.

Methods: We conducted this study in three phases. In the first phase, we aimed to understand the magnitude of pain management challenges caregivers experience, and for that purpose we conducted a theory-driven thematic analysis of secondary qualitative data obtained from a larger clinical trial with 514 hospice caregivers. The participants were included in the analysis only if they discussed pain management difficulties with the interventionist in their interview. Two coders coded all transcripts thematically using Kelley’s “Informal hospice caregiver pain management concerns” framework. The different themes between two coders or newly identified themes against Kelley’s framework were resolved through discussion. In the second phase, we conducted a systematic review of the literature to identify existing informatics systems and applications that have been designed to target supporting family caregivers. In 2014, we searched studies from the Embase, CINHAL, Cochrane and PubMed databases using the following keywords: “telehealth”, “telemedicine”, “telecare”, “telemonitoring”, “caregiver” and “family.” We reviewed studies that described a telehealth-based intervention or application with a focus on family caregivers’ outcomes in all settings, life stages and clinical conditions. Studies were included if they used any telehealth interventions and focused on family caregivers’ outcomes. Studies were excluded if they were not published in English. In the third phase, we mapped existing interventions to identified challenges to explore existing or new ways to utilize informatics to support caregivers. In other words, we identified which of the caregiver needs had been addressed by specific interventions and if what these interventions were, as well as searched for those challenges that do not seem to have been addressed by any informatics based intervention to date.

Results: In the first phase, 15 family caregivers’ interviews were included. The prominent themes emerged from the interviews including caregivers’ physical and psychological limitation or burden, caregivers’ belief system (fear, religious belief, ethical belief or moral belief), caregivers’ inability to accurately assess pain, and ineffective communication between caregiver and healthcare provider. The results in the first phase showed that family caregivers need structured education and healthcare providers’ support in pain management. In the second phase, we conducted a systematic review of studies that employed telehealth interventions to support family caregivers. The initial search found 4205 articles. After applying inclusion and exclusion criteria, a total of 65 studies was included in this review: 52 experimental studies, 11 evaluation studies, 1 case study and 1 secondary analysis. The types of technologies utilized included video, web-based, telephone-based and remote monitoring. More than 95% of the studies found that interventions delivery through technologies significantly improved the family caregivers’ outcomes. In the third phase, mapping existing evidence to caregiver needs highlighted various areas where informatics has already played or can play a role. These include pain management education, cognitive behavioral interventions (coping, problem-solving strategies), overall support, and oversight by clinical staff (e.g. remote observation of caregiver administering pain meds).

Conclusion: Family caregivers do not receive formal clinical training but they are asked to manage patients’ pain and administer pain medications for their loved ones. Our study showed that a lack of adequate pain management knowledge as well as misperceptions about pain management prevent caregivers from managing pain effectively. Telehealth brought significant improvements to the caregivers’ outcomes, and caregivers were satisfied with the telehealth technologies. Our study results suggested that informatics technology is a promising tool to support family caregivers to be successful in pain management.
Card Sorting of Symptom Self-Management Strategies to Inform the Development of a mHealth App in underserved Persons Living with HIV

Hwayoung Cho, MSN, RN, Lena M. Milian, BSN, Rebecca Schnall, PhD, MPH, RN-BC
School of Nursing, Columbia University, New York, NY, USA

Introduction

As advances in HIV treatment have increased survival, HIV has largely become a chronic disease. At the same time, persons living with HIV (PLWH) are confronted with persistent symptoms related to HIV infection, medication side effects and comorbidities. Effective management of symptoms is essential, since it has been shown to support adherence to antiretroviral medications, improve quality of life and increase engagement with healthcare providers. In response to this need, Holzemer developed a paper-based symptom management manual with self-management strategies for 21 common HIV-related symptoms (T32NR0007081), and the manual was founded to be efficacious in a 775-person RCT over 3 months. To facilitate uptake, a web-based patient-centered tailored symptom management tool, video information provider (VIP), was developed and the feasibility of the use of the system was demonstrated in a 3 month pilot study (P30NR010677-03S1). Nonetheless, subsequent use of the symptom strategies has been very limited. The use of mobile technology has the potential to improve communication, access, and information delivery to racial/ethnic minorities. Thus, mobile health (mHealth) applications (apps) have the potential to be effective channels to disseminate the manual of symptom management in underserved PLWH. Prior to developing a mHealth app which incorporates the self-management strategies from the symptom management manual, we employed user-centered design methods to guide the information architecture of the mHealth app for symptom self-management.

Methods

We recruited 20 PLWH aged 18 and older from 1 HIV Medicaid clinic and 4 community based organizations in NYC between Dec, 2015 and May, 2016. Demographic characteristics were obtained by self-report. A reverse card sorting technique was conducted to inform the development of a mHealth app for PLWH. Users were presented with a pile of cards representing symptoms and self-management strategies. 152 self-management strategies for 13 symptoms were included in the card sorting exercise. Symptoms included: fatigue, depression, dizziness, anxiety, neuropathy, insomnia, fever, cough/breath shortness, forgetfulness, skin problem, weight loss, nausea, and diarrhea. Participants were asked to select an index card of symptoms they experienced in the past 7 days, and then place index cards of self-management strategies in priority order. Descriptive data for demographics were analyzed using SPSS. A hierarchy analysis was conducted for establishing the rank order of symptoms and self-management strategies.

Results

Our sample included 20 participants between 38-64 years of age. 12 (60%) participants were female and 8 (40%) were male. 11 (55%) participants self-identified as African American and 8 (40%) self-identified as Latino. Participants identified the following symptoms which they experienced during the past 7 days. The most frequently reported symptoms and the top 3 self-management strategies for each symptom are listed in Table 1.

Conclusion

As ensuring the needs of underserved PLWH via a participatory design process, findings from this study will be incorporated into the information architecture of a prototype of mHealth app for supporting symptom self-management. The information collected in this study will inform app navigation, hierarchical menus, and the priority order of self-management strategies.

Why patients in online communities report not taking SSRIs

Jason H.D. Cho, M.S.1, Marina Shah, B.S. 1, Roxana Girju, Ph.D. 1
1University of Illinois at Urbana-Champaign, Urbana, IL

Abstract

Patients often post on online forums to discuss their health or their prescribed medications. We focus on why depressed patients are not taking Lexapro, in particular, why they are hesitant to take it and why they have stopped taking it. We find that while the most common reason for not taking the medication is aversion to side effects, other reasons, such as price or a previous negative experience, are also contributing factors.

Introduction

72% of patients discontinue antidepressant use within 90 days1, in spite of the literature showing that SSRIs are effective treatments. This is in spite of the literature showing these medications are effective in treating the given symptom. Motivated by this study, we leverage online communities to investigate why depressed patients are not taking medications. Researchers have utilized online communities to discover adverse drug reactions2 or to detect epidemics. In particular, we focus on one medication, Lexapro, in the context of depression treatment, and ask two research questions: First, why do patients discontinue prescribed medication? A previous study3 showed that patients stop taking psychiatric medication because 1) they experience loss by use of medication (adverse drug reactions), 2) personal meanings associated with taking medication, 3) feelings evoked by the process of taking medication and 4) perceived changes in payoff matrix (efficacy of medication). However, this was a small-scale study based on interviews. In this research we investigate whether data from online communities reflects similar patient concerns. We also investigate reasons patients are hesitant to begin taking a given medication.

Dataset and Analysis

We crawled www.healthboards.com, an active online health support community. For the purpose of this study, we looked into Lexapro, a very popular antidepressant, and took opening posts mentioning the medication from the Depression forum. There were 1,490 mentions of the drug. We sampled 300 of the mentions, and two annotators labeled forums in two ways. First, we labeled whether a forum post has mentions of ceasing to take Lexapro. Next, we looked for posts with mentions of patients' hesitancy to begin taking Lexapro. The Kappa agreements were 0.67 and 0.64 respectively. Labelers then analyzed posts on which they had disagreed, and decided on the final label.

We found 73 posts in which patients mentioned why they had stopped taking Lexapro. Of these, side effects were the single biggest reasons why they stopped taking the medication (35 posts). Ineffectiveness of medication followed, with 18 posts that mentioned this reason. Patients also indicated a desire to wean off the medication in eight of these posts. Six posts were due to changes in prescriptions, and four posts mentioned price or insurance reasons. There were other reasons, such as feeling better, or simply having no mentions on why they stopped.

There were not as many mentions (25 posts, ~10%) on why patients were hesitant to start taking medication. The predominant reasons were fear of side effects (10 posts), or previous negative experiences with Lexapro or other medications (4 posts). 8 patients mentioned searching for the best option as a reason for not taking Lexapro, and other reasons include price and uncertainty about the helpfulness of Lexapro. We see from our preliminary studies that while fear of adverse drug reactions is a big reason why patients either stop or are hesitant to take medication, perceived efficacy of the drug, and even the desire to not be on medications were also big factors. For future works, we intend on investigating an NLP technique to automatically filter out why people have stopped, or are hesitant to take medications which would allow us to scale our study to a bigger number of medications and symptoms.

A Single-Item Stress Scale for mHealth Interventions

Wonchan Choi, PhD¹, Sherry L. Pagoto, PhD², Edwin D. Boudreaux, PhD², Bengisu Tulu, PhD¹

¹Worcester Polytechnic Institute, Worcester, MA; ²University of Massachusetts Medical School, Worcester, MA

Introduction

Stress is associated with increased risk for obesity and cardiovascular disease¹. Mobile technologies could be an effective platform to monitor and manage stress continuously without interrupting daily routines. However, stress measurement instruments are typically lengthy and not suitable for the mobile platform. The goals of our project are (1) to develop and validate a single-item stress scale optimized for mobile delivery, and (2) to design an mHealth app interface that facilitates frequent stress data input in a timely manner with accuracy and minimal effort.

Our scale has six anchors with numerical values and visual indicators (faces that represent different levels of stress) corresponding to the six anchors. We used the item wording of a validated measure of stress symptoms, which includes a definition of stress in it: “Stress means a situation in which a person feels tense, restless, nervous or anxious or is unable to sleep at night because his/her mind is troubled all the time. Are you experiencing this kind of stress currently?”²

Methods

We recruited participants with experience in using a touchscreen-based smartphone from a university located in the northeast of the United States (n = 8, as of March 4, 2016 – study is ongoing). The study consists of two phases. In Phase I, participants answer an online survey where they match six different visual indicators (faces) we created with six anchors of stress. This task is designed to examine whether the visual indicators and participant’s perceptions of different levels of stress are aligned. Participants are then asked to list up to ten stressful events they were experiencing in their daily lives. Later, they are asked to rank the self-identified stressful events in the order of intensity of stress and rate them using the stress scale. In Phase II, we test four different mobile app user interfaces (UIs) we designed for frequent stress data input: (a) Tap-Vertical, (b) Tap-Horizontal, (c) Slide-Vertical, and (d) Slide-Horizontal. Participants are asked to input a given level of stress across different UIs as quickly and as accurately as they could using our test phones running the mobile app we developed for this experiment. After this task, they fill out a questionnaire that captures their perceptions of easiness and usability of the four UIs they tested.

Results

In our Phase I sample, a majority of the participants (7 out of 8; 87.5%) successfully matched the six faces to the corresponding levels of stress as intended. Participants identified 37 stressful events in total. A Spearman’s rank-order correlation was run to determine the relationship between the rank orders of and the ratings on the 37 stressful events. There was a statistically significant, strong negative correlation between the rank orders and ratings (r_s = - .64, n = 37, p < .001), which implied a good concurrent validity of the single-item stress scale under development.

The preliminary findings from Phase II showed that the tap-based mobile app UIs required less time for data input than the slide-based version (Tap-UIs = 2555.94 < Slide-UIs = 2747.75 milliseconds, on average). The participants rated the tap-based UIs higher than the slide-based UIs (Tap-UIs = 4.34 > Slide-UIs = 3.84 out of 5, on average) in terms of usability.

Conclusion

We will continue to collect data from a wider range of user groups to validate our stress scale. The findings from this study will provide useful insights for mHealth interventions targeting stress management in addition to other mHealth interventions involving frequent data input tasks in various contexts.

Crowdsourced Evaluation of Medical Texts Simplified by Medical Trainees

Yong Choi, MPH¹, Anne Turner, MD, MLIS, MPH¹, Katrin Kirchhoff, PhD¹
¹University of Washington (UW), Seattle, WA, USA

Introduction

With the drive towards greater patient engagement in healthcare, more and more medical texts (doctor’s notes, discharge summaries, etc.) are becoming available to patients. However, medical notes are complex and generally not written with patients and caregivers in mind. Medical notes are likely to include specialized medical language that is not easily interpretable by a lay person, especially those individuals with low health literacy. To address this problem, one German non-profit project has created a service for lay individuals whereby medical text is simplified into plain language by volunteer medical students [1]. Their pilot study demonstrated that the written communication skills of the students who translated medical documents on the website were enhanced. We explored whether medical trainees in the U.S. have sufficient expertise to be able to convert medical reports into understandable everyday language. The goal of this project was to determine to what extent text simplifications provided by medical trainees can improve lay persons’ understanding of medical text.

Methods

Four medical fellows and students at UW, who had completed at least one year of medical training, were recruited for the study. The medical trainee participants were given five short (5-10 sentences) excerpts from five different medical reports of various types (e.g. surgical note, procedure note, discharge note, clinic note) and were asked to express the same information in simpler, more understandable, language (e.g., 8th grade reading level). No further training was provided. We collected a total of 20 simplified texts from 5 original medical excerpts. We obtained UW IRB approval prior to initiating the study. Because the text simplifications varied greatly in their length and level of simplification, we decided to investigate which of the “translated” simplified texts were easier to understand by lay readers. To measure actual text comprehension, we created two 3-answer multiple-choice comprehension questions for each of the five original excerpts. We recruited lay participants through Amazon’s Mechanical Turk (mTurk) crowdsourcing platform. The mTurk Participants were each asked a total of 10 comprehension questions (2 questions for each of the 5 texts). The participants were randomly assigned to read either the original text or one of the simplified versions, and then asked to answer the questions. Eligibility: participants had to be 18 years or older, native English speakers, and connected to a U.S. IP address. We collected basic demographics and health literacy scores using the Brief Health Literacy Screen (BHLS) tool.

Results

179 mTurk participants completed the study. The recruited participants had a mean age (SD) of 37 (12) years old and 56% were female. The majority of the participants had at least some college education or higher (90%). The BHLS median (IQR) score was 13.0 (12.0–15.0) and the mean (SD) was 12.8 (2.1). Among the participants 167 (93.3%) had a BHLS > 9, and 12 (6.7%) had low health literacy score (BHLS ≤ 9). The percentage of correct answers was 74% for the original texts and 85.6% for the simplified texts (P=0.018). Among total 40 comprehension questions associated with the simplified texts, the correct answer rate was higher in 31 questions (77.5%) compared to the original texts. Out of the 31 questions, 20 questions showed over 15% increase in understanding but 9 questions showed less than 5% increase in understanding. Simplified versions showed lower levels of understanding by the participants in in 9 out of 40 questions (22.5%).

Discussion

Overall, the findings of this study indicate that simplifications of medical notes by medical trainees led to better understanding of medical texts. This was despite the lack of explicit task-specific training of students, and despite the fact that most mTurk participants had a fairly high literacy level. In the few cases where the simplified texts performed worse than the original texts, we found that the simplified versions either omitted critical information or contained errors. For instance, one simplified version incorrectly translated a medical jargon ‘q.d.’ on prescription (meaning one a day) to ‘twice a day’. Although improved lay person understanding can be provided through text simplification by medical trainees, training and oversight on medical simplification is recommended to ensure accuracy and consistency.

The Design of a Patient-Centered Personal Health Record with Patients as Co-Designers

Arlene Chung, MD, MHA, MMC,¹ ² Haiwei Chen,¹ Grace Shin, MS,¹ ² Ketan Mane, PhD,³ Hye-Chung Kum, PhD⁴

University of North Carolina at Chapel Hill School of Medicine,¹ Carolina Health Informatics Program,² Kaiser Permanente,³ Texas A&M University⁴

Introduction. The promise and potential of connected personal health records (PHRs) has not come to fruition. This may be, in part, due to the lack of user-centered design and of a patient-centric approach to curating personal health data for use by patients. Co-design with end-users could help mitigate these issues by ensuring the software meets user’s needs, and also engages patients in informatics research. Our team partnered with patients with multiple chronic conditions to co-design a patient-centric PHR. This poster will describe our experience with the co-design process, highlight functionalities desired by patients, and showcase the final prototype.

Methods. We conducted three design sessions (90 minutes per session) with patients as co-designers and employed an iterative process for software development. Patients were recruited from Chapel Hill and surrounding areas. The initial design session laid the foundation for future sessions, and began with brainstorming about what patients thought their ideal version of an engaging connected PHR would look like in terms of features and functionalities. After each software iteration, our entire design team, including our patient co-designers, was shown the prototype during a subsequent design session. Once the final prototype was developed, usability testing was conducted with patient participants. Our team then conducted a final design session to debrief about the final prototype.

Results. We started with an initial group of 12 patients (6 males) who all had diabetes and an additional comorbidity such as hypertension and hyperlipidemia. Age of participants ranged from 30-77 years with an average age of 56. The majority of participants were Caucasian with one Asian and two African Americans. Hemoglobin A1c values ranged from 6.0-9.2% with approximately half having A1c values less than the goal of 7.0%. Half the patients were aware of PHRs, majority had smartphones, and all participants had access to the Internet and used email. Two of the patients were retired engineers who had prior experience with software design. The other sessions had between 7-8 participants at each session, and 7 patients completed the 90-minute usability testing session. There was a core group of 7 patients who were engaged in the design and testing sessions throughout the entire 9-month study.

Key features of the PHR that emerged from design sessions included the following: 1) allow for annotation of data by patients (particularly important for lab values like glucose or for physical activity); 2) calendars, to do list, and reminder functions should be linked so that an entry in one of these allows for auto-population of this data within the other sections; 3) notifications whenever new data from the electronic health record or other sources are pushed to the PHR account; 4) allow for drag and drop of photos of pills/medications taken via smartphone or from other sources so that medication list has photo of actual pills or pill bottle; 5) allow for patients to customize the order of sections in the PHR dashboard so that the sections most important to the individual patient can be displayed more prominently; 6) allow for notifications from pharmacies to be pushed to the PHR (e.g. confirmation of receipt of prescription requests or alert that prescription is ready to pick up); and 7) graphical display of trends over time (patients would like to select the measures and time frames to plot for display). Patients cited the importance of data provenance so that patient-entered data vs. provider or electronic health record data could be easily differentiated. Patients also highlighted the importance of having this PHR be a “one-stop shop for all their health data” and to have meaningful data dashboards for the different types of information needed to comprehensively manage their health. Patients wished for a single PHR that could easily bring together data from multiple patient portal accounts to avoid having to manage multiple accounts and passwords. They felt that heat map displays such as those used on popular fitness tracking websites were not intuitive and that the color-coding made interpretation challenging. Participants noted that engagement in the design process made them feel that they contributed towards developing software that could not only positively impact them individually but others as well. Every patient indicated the desire to participate on future design projects. Of the 19 tasks evaluated during usability testing, only 5 tasks could not be completed (e.g. adding exercise to the calendar, opening the heat map, etc.). Patients felt that the overall PHR design was clean and aesthetically pleasing. Most patients felt that the site was “pretty easy to use” (6 out of 7). The majority of participants would like to use this PHR in the future (5) and would recommend this PHR to their friends/family to use (6).

Discussion. Involving patients directly in the design process for creating a patient-centric connected PHR was essential to sustaining engagement throughout the software life cycle and to informing the design of features and functionalities desired by patients with diabetes and other comorbidities.
Assessment of the Heterogeneity of Outcome Measurements for IT Interventions in Health Care

Tiago K. Colicchio¹, MBA, MS, Julio C. Facelli², PhD, Guilherme Del Fiol¹, MD, PhD, Debra L. Scammon², PhD, Watson A. Bowes III¹,³, MD, MS, Scott P. Narus¹,³, PhD

Introduction

Adoption of Electronic Health Record (EHR) systems has significantly increased in the U.S. partially due to financial incentives provided by the CMS Meaningful Use program. Despite substantial research on the impact of EHR adoption in health care, our understanding of how IT tools contribute to improving health care outcomes is still limited. A significant contributing factor to this gap is the lack of standardized measurements that could be used to compare different studies. In the present study, we analyze and categorize the measurements reported in evaluations of health IT interventions. We also identify potential ways to create a common set of measurements that could facilitate comparison among future studies.

Methods

We screened 236 studies from a previously published systematic review [1]. To create an inventory of measures that could be used in future studies we performed the following steps: (1) identified all measures used as a dependent variable and identified the targeted population; (2) conducted a bottom-up analysis grouping the measures by similarity into less specific measures (as determined by the expert opinion of the authors), creating a hierarchy that excluded unique measures that were used in only one study or could not be grouped into other more general measure; and (3) grouped the measures from the highest level of the hierarchy into categories that represent the types of measurements.

Results

From Step 1 above we identified 429 unique measures and from Step 2 we excluded 239 (56%) unique measures, leading to the inclusion of 190 measures at the most specific level of our hierarchy. The 190 measures were grouped into 66 less specific measures in the highest level of the hierarchy, and then further grouped into 15 types of measurements. The most common types of measurements were “test or procedure ordered as preventive care”; followed by “optimal care documented in the patient’s EHR” and “appropriate use of pharmacotherapy”. Figure 1 provides an example of the hierarchy for one measure: “appropriate use of antibiotics”.

Discussion

Our analysis demonstrates that the measures used in health IT adoption research vary substantially, creating obstacles to the comparison of health IT outcomes. Our hierarchy was used to create a taxonomy of commonly used measures that may help researchers to identify measures and gaps in their measurement approaches. The taxonomy will be published in a separate study; its first version can be accessed at https://goo.gl/EiwyKR. The use of a previous systematic review is a limitation to the identification of measures. We expect to address this limitation by eliciting more measures from informatics experts and report our results in a future study.

A Qualitative Analysis of Electronic Clinical Quality Measures Development and Data Validation

Nicholas V. Colin, MA, Raja A. Cholan, BS, Shelby J. Martin, MS, RD, Bhavaya Sachdeva, MPH, David A. Dorr MD, MS
Oregon Health and Science University, Portland, OR, United States

Introduction. Electronic Clinical Quality Measures (eCQMs) are tools to measure and record the quality of care being provided by healthcare professionals. The precise implementation of eCQMs can identify care gaps and produce accurate reports for incentive programs such as Meaningful Use or the Physician Quality Reporting System. However, it can be difficult to determine whether eCQMs are implemented accurately, as storage, retrieval, and processing of key data varies substantially by practice and provider. We utilized a six step process for developing and validating eCQM reports (1. identifying needs/assessing requirements for the measure, 2. initial code/concept mapping, 3. team code review, 4. implementation of non-validated measure in test environment, 5. validation and revision, and 6. implementation as validated measure). This allowed us to improve our implementation and increase trust of the data. Our objective is to describe our approach to help improve accurate eCQM implementation for others trying to do this work.

Methods. Our group used prior work to encode the six step process during the development and implementation of three eCQMs (Aspirin use when appropriate, CMS164v4; Controlling High Blood Pressure, CMS165v4; and, Cholesterol management, CMS347v0) as outlined in Table 1 below. First, we identified the need and assessed requirements for each measure by reviewing the official measure specifications from the National Quality Forum, and compared the criteria to any previous versions of the measure. Next, we coded the necessary logic and mapped aggregate concepts, reviewed the code, implemented the measure in a test environment, and validated the measure by conducting chart review of patients’ records who were returned in the denominator/numerator.

Results. Table 1 highlights the process and changes by measure. Review of the aspirin code identified an error in the numerator coding in which medications were mislabeled as antithrombotic. Validation and revision of the patient charts from the blood pressure denominator revealed an error in the lookback period for most recent blood pressure recording. Review of the cholesterol measure code identified missing criteria making the denominator too broad; this correction lowered the count of patients in the denominator from 3,903 to 1,565. No coding changes were recorded for step 1 (identifying needs/assessing requirements for the measure) or step 6 (implementation as validated measure) for any of the three eCQMs (Aspirin, Blood Pressure, and Cholesterol).

Table 1. Six steps of eCQM development and number of coding changes documented

<table>

Discussion. We codified the six step process for implementing and validating eCQMs; we found following and documenting this process improved implementation. The validation process provides an opportunity to identify areas for improvement including coding errors, gaps in care that exist in current workflows, and value set discrepancies used in measure definitions for eCQMs. Through this process, we were able to identify errors affecting the accuracy of our eCQM implementation. We were able to improve the overall performance and accuracy of the eCQMs, and once corrections were implemented we were able to validate against patient-level data to improve our trust and confidence with the data.
Usage of Electronic Online Care Process Models for Learning at the Point of Care

David A. Cook, MD, MHPE1,2,3 Laurie J. Pencille, CCRP1, Kristi J. Sorensen, MS1, Deborah J. Rhodes, MD1,2

1Knowledge Delivery Center, Mayo Clinic College of Medicine, Rochester, MN; 2Department of Medicine, Mayo Clinic, Rochester, MN; 3Mayo Clinic Online Learning, Mayo Clinic College of Medicine, Rochester, MN

Introduction

Clinicians constantly seek and apply new information in response to patient-focused questions.1 Electronic clinical decision support systems and knowledge resources help to efficiently answer these questions.2 AskMayoExpert is a novel multifaceted knowledge resource, integrated with the electronic medical record, providing concise information on >1700 clinical topics and >140 care process models (CPMs).3 CPMs reflect institutionally-approved evidence-based standards for managing common clinical problems. These are implemented as flowchart-like interactive algorithms highlighting key decision points. At each decision point, the CPM provides relevant information about the problem (e.g., disease classifications and risk factors), suggests additional information to be obtained (e.g., interview questions, exam elements, or laboratory tests), and recommends next actions. All CPMs are developed and approved by a committee of topic experts who employ state-of-the-art evidence and clinical guidelines. Generalist clinicians may find CPMs particularly useful.

We sought to determine how often clinicians (physicians, residents, nurse practitioners, and physician assistants) access CPMs; the relative usage by generalists vs non-generalists; and how often clinicians return to the same topic.

Methods

We determined usage from January 2014 – June 2015 using computer logs. We compared usage rates for generalists vs non-generalists using the Wilcoxon rank-sum test, and enumerated the number of recurrent views of the same topic by a single user.

Results

We have developed 142 CPMs. Over the 18-month period, 4076 clinicians (61% of approximately 6700 clinicians with access) viewed CPMs a total of 81,853 times. Usage varied from 1 to 809 views per person, and from 9 to 4621 views per CPM. We were able to determine the clinical specialty for 2754 clinicians. Among these, generalists (N=1415) used CPMs much more often (median 7, mean 31.4 views) than non-generalists (N=1339; median 2, mean 6.9; p<.0001). 2116 clinicians (52%) returned to the same CPM topic more than twice, with an average of 7.8 views per topic (maximum 195). 733 clinicians revisited the same topic more than 5 times, and 168 revisited more than 20 times. Generalists revisited topics more often than non-generalists (mean 8.8 vs 5.1 views; p<.0001).

Conclusion

Electronic care process models are highly used, particularly by generalists. A subset of clinicians uses them with very high frequency. Clinicians commonly revisit the same topic. Whether revisiting a topic is desirable (i.e., reflecting high perceived utility) or undesirable (i.e., reflecting failure to retain information) merits further study. We are now developing and evaluating additional specialist-focused content.

An Automatic Data Mining Approach Using Linked Data Technologies
Brett F. Cropp MS\textsuperscript{1}, John B. Coles PhD\textsuperscript{1}, Karen M. Meess\textsuperscript{1}
\textsuperscript{1} CUBRC Inc., Data Science and Information Fusion Group, Buffalo, NY

The traditional relational database structure loses value when working with high volume, multi-dimensional data derived from multiple sources. Misalignment of data is exacerbated due to proprietary structures that do not adhere to common data models or standards, and through several iterations of schemas, typical in the healthcare industry. One of the most significant challenges with large disparate datasets common to healthcare research and operations is that valuable information is difficult to identify, contextualize, and analyze. Techniques in the healthcare domain using broad technical data mining or the Knowledge Discovery in Databases (KDD) paradigm have been shown to provide immense potential and value\textsuperscript{1}. One particular approach for iteratively mining data, called Sample, Explore, Manipulate, Model, and Assess (SEMMA), has been used to investigate medical conditions, including healthcare-acquired infections\textsuperscript{2}. However, this approach is difficult to implement for large, dissimilar datasets\textsuperscript{2} and thus requires solutions that are both data source agnostic and scalable.

We implemented a multi-stage, automatic data mining approach that leveraged Linked Data technologies. Treating data as an interconnected web by using an ontological framework provides the ability to search information across sources while maintaining key details about an entity (e.g., individual, group, or agent of interest). Our approach used Resource Description Framework (RDF) and built upon a carefully designed and extensible mid-level ontology to align and semantically enhance data across multiple domains. In RDF, all information is represented as triples (\textit{Subject, Predicate, Object}), each of which represents a statement or assertion about something. Such NoSQL databases are flexible by having a single data representation, rather than constraining data to table models. This also allows for flexible data storage methods, as highlighted by integration with open single-instance (Apache Jena) and cluster-based (Rya with Accumulo) triple stores. By removing dependencies on traditional table models and specific sources, and applying an extensible programmatic workflow, we built an analytic framework that was shown to be generalizable across multiple domains and use-cases, with an initial focus on healthcare applications.

Our mechanism identified key information related to a base RDF graph pattern constructed in SPARQL. This pattern may represent a patient condition, particular event, relationship, or any combination thereof (e.g., patients having a diagnostic code for diabetes mellitus type II). Subsequently, the network surrounding this base graph was sampled using near-graph searches, with connected resources (e.g., John Doe) and literals (e.g., John Doe’s HbA1c test result) undergoing automatic data-type identification, classification, and contextualization. This information-agnostic near-graph search and sampling technique was then applied to different cohorts of individuals, who were compared using a predefined set of standard descriptive and inferential statistical procedures for pairwise or group comparison. Each statistical comparison was weighed by a significance factor and the cumulative discrepancy between groups was calculated using Bayesian inference, isolating a similarity metric for each information object. Finally, a threshold or confidence level was set for automatic feature selection into multivariate models including logistic regression, clustering (\textit{k}-means) and supervised learning techniques (support vector machines).

This approach was applied to several data sources, including clinical and claims. We ingested protein biomarker (nuclear translocation) data derived from allogeneic hematopoietic cell transplantation (allo-HCT) patients to identify correlations with the acquisition of acute graft-versus-host disease (GvHD). We also partnered with an insurance company to parse several million claims records, isolating correlates of case management outcomes among patients with high-risk diseases and informing patient-specific interventions and risk modeling.

Future work includes implementing time-series based resolution to identify common patterns that occur in sequence or within a particular time period. Medical data sets can be enhanced by linking to outside sources, such as social media and purchasing activity, to gain a more complete picture of individual behavior and environmental factors. A limitation with a naive approach to data mining is that certain information requires further contextualization and classifiers should be developed to provide higher-level computed information, where appropriate.

Developing Analytics for Wheelchair Sensors to Improve User Health

Rui Song\(^1\), Dorothy W. Curtis, M.Sc\(^1\)
\(^1\)Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA, USA

Abstract

Why can’t wheelchairs be more intelligent? This was the rationale behind integrating a contact-free sensor system with a wheelchair and subsequent deployment at The Boston Home. We are analyzing the resulting data for both long-term trends and real-time alerts. Applications include prevention of heat stress and pressure sores, and detecting sleep apnea by analyzing information from environmental sensors, accelerometers, and respiration waveforms. This has the potential to improve user health and autonomy.

Introduction

Common issues faced by long-term wheelchair users include inactivity-induced pressure ulcers, irritation from dermal sensors, and undetected sleep apnea; a comfortable and intelligent wheelchair could solve these issues. Dorothy Curtis of MIT CSAIL’s Assistive Devices for Healthcare Group and Diego Arias, Professor Esteban Pino and Professor Pablo Aqueveque from Universidad de Concepcion built a contact-free sensor system for a wheelchair to collect environmental information, motion data, and vital signs [1]. The system was deployed at The Boston Home, a care facility for patients with multiple sclerosis and other neurodegenerative diseases. The first phase of this project evaluated whether valid data could be collected while minimizing patient discomfort. Now we are developing algorithms and visualization methods for the collected data to create a retrospective summary of trends in user activity and health, and a real-time alert system.

Technical Approach

The first objective was to compile a user’s historical data into a concise summary of the following parameters: outdoor activity, general motion, pressure ulcer prevention activities, and heart rate abnormalities. The wavelet method was used to separate the ballistocardiogram signals into respiratory rate and heart activity, and remove noise generated from patient movement [2]. For each week of data, statistical baselines were established for every parameter. The summary then displays these baselines for the user-selected week along with the daily value of these parameters. The summary can also display trends in parameters over a period of several weeks. The primary user of this summary visualization is the caregiver, who may leverage this information to recommend treatments. The second objective was to collect vital-sign and environmental information to create a real-time alert system. The first application of the alert system is to alert the user to possible heat stress situations and remind the user to tilt to avoid pressure ulcers. Analysis of the respiratory and cardiac signals can give the caregiver and the user information about a potential sleep apnea episode, and, possibly other heart rate abnormalities, through the use of machine-learning classification algorithms [3].

Conclusion

The overall objective is to improve upon an existing contact-free wheelchair sensor system by providing powerful vital signs, environmental and motion data analysis and visualization. In the next phase we will evaluate the effectiveness of this method in improving wheelchair user health and autonomy by enabling them to avoid heat stress exhaustion, reduce the incidence of pressure sores, and be alerted to potential sleep apnea episodes.

Integrating Electronic Death Registration with Electronic Health Records Systems: Results of a Trial Use of the VRDR Profile

Vira Danak MS¹, Glenna Gobar DVM MS¹, Michelle Williamson², Michael Hogarth, MD¹
¹UC Davis Health System, ²Center for Disease Control and Prevention

Abstract
The collection of death related information is a long-standing process in society. Vital statistics derived from this process have been critical in characterizing jurisdictional mortality for over 300 years. The evolution toward electronic vital record systems and the increasing adoption of electronic health record systems have created an opportunity to dramatically decrease the latency of vital event reporting through integration of EHRs and death registration systems. This research studied the feasibility of using the Integrating the Healthcare Enterprise (IHE) Vital Records Death Reporting (VRDR) profile in successfully enabling EHR-based capture of medical certifier sourced data into an electronic death registration system (EDRS) as well as jurisdictional reporting of death events to the National Center for Health Statistics (NCHS).

Introduction
We report early results of a pilot in which the IHE VRDR profile was used to integrate the California Electronic Death Registration System (CA-EDRS) with a broadly used enterprise level EHR (Epic Corp, Verona WI) to facilitate the capture of medical information for death certificates in CA-EDRS, as well as the submission of death certificate information to NCHS.

Methods
We developed a module in our EDRS system that provides a secure data collection web-window that is provided to an EHR user within the EHR client. The VRDR profile involves an EHR user triggering a request to an external system using the IHE Remote Form for Data Capture (RFD) profile. This request includes an attached death information clinical document architecture (CDA) XML file. Our EDRS system responds by creating a new record with the received CDA file information, and responding with a private record-specific URL that is rendered by the EHR client, thus providing a data entry form to the medical certifier who is using the EHR. Subsequent to the successful completion of the death certificate and registration by the state, a process is triggered with CA-EDRS that constructs an HL-7 v2.5.1 message using the VRDR profile specification and immediately submits this message to the NCHS using an on-premises PHIN MS node.

Results
We found that the VRDR profile, as currently specified, was able to support the medical certifier data capture workflow as well as the jurisdictional reporting to NCHS. This was satisfactorily validated by the IHE at the 2016 IHE Connectathon (Cleveland,OH). We found that an EHR user with limited experience could complete the medical portion of the death certificate in as little as 10 minutes.

Conclusion
The IHE VRDR profile is a key specification in the integration of EHRs and EDRS and can reduce the latency of mortality reporting. Improving the exchange of death information using national standards will strengthen the vital statistics infrastructure for public health reporting and public health surveillance.

Analysis of Heparin and Aspirin Administration on Acute Ischemic Stroke from International Stroke Trial (IST)
Yifang Dang, Sahitha Gajjala, M Pharm, Craig W. Johnson, PhD
The University of Texas Health Science Center at Houston (UTHealth), School of Biomedical Informatics, Houston, TX.

Introduction
The original study done on the IST dataset\(^1\) reported that early administration of aspirin is not effective in decreasing death in acute ischemic stroke (AIS). Our specific aim was to test, via secondary analysis of the dataset, the research hypothesis that; by statistically controlling and testing for age groups (below and above 70), gender, and countries; aspirin, as well as heparin, would be found to be effective on recurrent AIS or death rate within 14 days.

Analysis Procedure

![Hierarchical Binary Logistic Regression Diagram]

Results
The total IST database sample contained 19,435 patients. Binary hierarchical logistic regression analyses converged for 19,117 patients in the analysis on recurrence of ischemic stroke within 14 days and 19,340 patients in the analysis on death within 14 days. Odds of recurrence of ischemic stroke within 14 days were multiplied by 0.541, 95\%CI = (0.439, 0.667) for aspirin and 0.74, 95\%CI = (0.605, 0.905) for heparin administration, controlling for age, gender, and countries. Odds of death within 14 days were multiplied by 0.861, 95\%CI = (0.784-0.946) for aspirin and 0.983, 95\%CI = (0.895-1.080) for heparin administration and by 2.20, 95\% CI = (1.97, 2.45) for age above 70, controlling for age, gender, and countries. Aspirin by heparin interactions were not statistically significant. Countries were significantly associated with both AIS recurrence and death but gender was associated with neither recurrence nor death.

Conclusion
In contrast to results of the original study showing aspirin administration not significantly associated with reduced deaths within 14 days, we observed significant association of aspirin administration with both AIS recurrence and death within 14 days, while statistically controlling gender, countries; and testing and controlling for age above/below-70. Furthermore, age above 70 was a significant risk factor for death within 14 days. For heparin administration, which had significantly reduced AIS recurrence at doses 5000 IU and 12,500 IU, but not likelihood of death within 14 days, our results were similar to those of the original study.

Assessing Healthcare Workforce Training Needs for Health Information Technology-Enabled Healthcare Transformation

Raven David, MPH1; Morgan Moy, MPH1; Virginia Lorenzi, MS, CPHIMS, FHL71,2; Andrew Flatgard1; Angie Lee1; Bruce Forman, MD1,2; Lucy Appert, PhD1; Jennifer Ringler, BS1; Gilad J. Kuperman, MD, PhD1,2; Victoria Tiase, MSN, RN2; Rita Kukafka, DrPH, MA, FACMI1; 1Columbia University, New York, New York; 2New York-Presbyterian Hospital, New York, New York

Problem

Our nation’s healthcare system is changing at a rapid pace accelerated by the American Recovery and Reinvestment Act (ARRA) and the Affordable Care Act (ACA). Transformative health care delivery programs depend heavily on health information technology (HIT) to improve and coordinate care, maintain patient registries, support patient engagement, develop and sustain data infrastructure necessary for multi-payer value-based payment, and enable analytical capacities to inform decision making and streamline reporting. Additionally, EHR technology is now available to over half of the nation’s eligible providers participating in the Meaningful Use program. The accelerated pace of change from new and expanding technology will continue to be a challenge for preparing a skilled workforce. Therefore, we seek to investigate what does the healthcare workforce need to know to enable healthcare transformation as health information technology and healthcare delivery systems evolve.

Purpose

As part of the U.S. Department of Health and Human Services’ efforts to create an interoperable learning health system that achieves better care, smarter spending, and healthier people, the Office of the National Coordinator for Health Information Technology (ONC) funds programs in workforce training. As one of the awardees for this two-year program, Columbia University has performed a training needs assessment to inform the design of a training curriculum for incumbent healthcare workers for the rapidly changing landscape of healthcare and HIT.

Methods

We conducted 14 interviews with 16 key informants that are senior leaders in their respective organizations and serve on our advisory board. These informants represent a broad expertise across population health, care coordination and interoperable health IT systems, value-based care, healthcare data analytics, and patient-centered care. These interviews were transcribed and a qualitative coding and analysis was performed. A quantitative survey to complement qualitative findings is being administered to managers and their workforce to obtain ground-level data to inform tailored content and delivery of training. This protocol was approved by Columbia University IRB.

Results

Preliminary results from the qualitative surveys indicate that the trainings should contextualize why and how healthcare workers’ actions and responsibilities have macro-level effects. For example, it is important for a physician to understand how their interactions with individual patients relate to population health and payment initiatives. Respondents also expressed a need for training that clearly conveys how an individual worker’s job functions and responsibilities are interconnected with other healthcare jobs. With a paradigm shift towards team-based care, it is important for a nurse to understand how a community health worker can contribute valuable patient information, for example. Respondents also expressed that with this paradigm shift and the blurring of roles, training should be tailored to job function rather than credential (e.g., nurse, physician, etc.). Insight was provided on which roles should be targeted for training, what should be trained, and how training can be disseminated.

Conclusion

There is an enthusiastic demand from senior leadership for highly targeted HIT training for the healthcare workforce in this new era of healthcare. The quantitative survey currently being administered will further identify specific areas of training for various types of healthcare workers. With a dynamic landscape of healthcare, a challenge is to forecast what future training needs will be and balance them with the current needs to train the workforce. Additional analysis of the qualitative and quantitative surveys is being conducted and will be reported.
Automatic Extraction of Maximum and Recommended Drug Dosage Information from DailyMed Database

Lalindra De Silva, MS\textsuperscript{a,c}, Olga V. Patterson, PhD\textsuperscript{a,b}, Scott L. DuVall, PhD\textsuperscript{a,b}

\textsuperscript{a}VA Salt Lake City Health Care System; \textsuperscript{b}University of Utah, Salt Lake City, UT

Abstract
Medication dose depends on a range of factors, including drug class, drug form, patient age and weight, and frequency of administration. Detailed information on different dose requirements for each drug is described in the drug label. Due to its complexity and variability across a large number of drugs and manufacturers, this information is stored as unstructured text in public and proprietary sources. We developed a two-layered approach to extract recommended and maximum dosage information for a large number of drugs by: 1) retrieving drug information from a public database, and 2) applying a rule-based Natural Language Processing (NLP) pipeline to perform extraction.

Background
Medication data quality issues can have a lasting detrimental impact on accuracy of computerized decision support and potential research studies that utilize prescription records in modeling patients' state of health. The incorrect dose of the prescribed or administered drug is one of the potential types of errors. A simple but very effective way of detecting erroneous entries in large databases is to identify outliers using recommended and maximum doses. Detecting the individual maximum and the usual recommended dosages for a given drug is challenging because it depends on whether the drug is administered to a child or an adult, the form of the drug (i.e., tablet, capsule vs. liquid), the dosage of an individual unit (200mg tablet vs. 400mg tablet), etc. Using absolute doses that disregard variability across individuals is a potentially effective alternative to individual doses in identifying outliers. Previous studies\textsuperscript{1} have explored related approach using proprietary full-text drug monographs. We present a methodology where a publicly available database is used to extract dosage information for a large number of drugs.

Methods
We utilized the NIH DailyMed drug database (http://dailymed.nlm.nih.gov/dailymed/index.cfm) through RESTful web service to collect 50,028 drug names using the RxNorm mapping files. For each drug, we queried the web service and retrieved an HTML response. The response was parsed using the Jsoup Java library and the free text under the “Dosage and Administration” section heading was extracted. This resulted in free text entries for 47,088 drug names, leaving out the ones, which did not contain the aforementioned section heading.

We developed a dose extraction NLP pipeline using Leo architecture based on Apache UIMA framework that takes in the free text entry for each drug and identifies mentions of several dosage annotation types.\textsuperscript{2,3} The NLP system annotates free text using three dosage annotations: 1) SimpleMention, 2) RecommendedDosage and 3) MaximumDosage. The SimpleMention type identifies phrases of dosage mentions using regular expression patterns anchored around terms such as “capsules, tablets, doses”, quantifier terms such as “mg” and temporal terms such as “daily, weekly” (e.g., ‘100mg a day’). The remaining two annotation types augment these mentions, looking for modifier phrases around the context of SimpleMentions such as “maximum”, “max”, “do not take more than” for maximum dosages, and “recommended”, “usual” for recommended dosages. The system detected 139,453 mentions, of which 15,769 were MaximumDosages, 12,629 RecommendedDosages, and 111,055 SimpleMentions.

Discussion
The dose information resulted from this work can be used for as the initial filtering criteria to detect erroneous medication entries in electronic medical records. Additional development is needed to extract dosages at a more granular level, relating them to patient characteristics (age, weight) and medication variables (form, administration frequency). Since most publicly available drug information repositories are geared toward individuals (clinicians or consumers), the developed system bridges the gap and makes dosage information available for data quality auditing.

Effects of Meaningful Use of EHRs on ED Clinical Workflow

Courtney Denton, BA1, Gloria Nimo, MSN2, Jason Shapiro, MD2, Thomas G. Kannampallil, BA3, & Vimla L. Patel, PhD1
1The New York Academy of Medicine, New York, NY; 2Mount Sinai Medical Center, New York, NY; 3University of Illinois at Chicago, Chicago, IL

Introduction
While electronic health records (EHRs) have had positive impacts on clinical practice, research has also highlighted challenges regarding their use including usability issues1, increased operation and maintenance costs2, and limited integration and support for clinical workflow activities3. To encourage widespread adoption, financial incentives have been offered to healthcare providers for the “meaningful use” (MU) of certified EHRs as they document and manage patient care information. We report on the impact EHR usage and MU criteria compliance has on clinical workflow in the emergency department (ED).

Methods
Participant observations and semi-structured interviews were conducted at Mt Sinai Medical Center and NewYork-Presbyterian Hospital EDs. During two 10-day periods, 16 physicians and 12 nurses were shadowed during their clinical shifts to capture clinician interactions and clinical activities involving EHR use using field notes. Twenty semi-structured interviews with ED clinicians were conducted to gather perceptions of EHR use and the impact of MU criteria compliance on efficiency, quality and safety of patient care. Clinical workflow-based MU considerations for EDs included door to diagnostic evaluation time and admit decision time. Clinicians were specifically asked how these MU criteria supported (or did not support) their clinical work. Interviews were transcribed, and, in collaboration with clinician collaborators, responses were coded by two researchers using Nvivo software. All coding disagreements were discussed and resolved to generate a more standardized coding scheme.

Results and Discussion
Shadowing data highlighted the sequence of steps, and the interwoven nature of EHR use during clinical workflow at two sites, where different EHRs are used. Three main themes emerged during analysis of interviews: (a) nature of EHR use, and its primary role as an information seeking and documentation tool in ED practice, (b) the influence of EHR usability on the inefficiencies in the workflow, and (c) lack of clinician awareness surrounding MU criteria compliance.
While some clinicians were aware of potential effects of MU in increasing efficiency, others merely referred to the positive aspects on EHR use and workflow, where access to a more comprehensive patient history in improving accuracy of care and tracking the status of patient care were considered important. At both academic hospitals, more physicians identified the positive rather than problematic aspects associated with EHR and MU. Clinicians’ reliance on the use of heuristics to circumvent problems in dealing with EHRs has implications for potential threats to patient safety and to the quality of care.

Conclusions
Compliance to MU criteria impacts clinical workflow. In two academic environment studied, clinicians perceive the impact to be more positive with less awareness of negative effects across two different platforms. Literature reports the opposite findings from small primary care practices. To what extent the perceived advantages correlate with the real work in the ED is under further investigation.

Methods to Measure and Improve the Quality of Large Scale Health Data: An Application in Public Health Surveillance

Brian E. Dixon, MPA, PhD1,2,3, Jon Duke, MD, MS,2 Shaun J. Grannis, MD, MS2,4
1Indiana University Richard M. Fairbanks School of Public Health, Indianapolis, IN; 2Regenstrief Institute Center for Biomedical Informatics, Indianapolis, IN; 3Center for Health Information and Communication, Health Services Research & Development Service, Veterans Health Administration, U.S. Department of Veterans Affairs, Indianapolis, IN; 4Indiana University School of Medicine, Indianapolis, IN

Introduction

Nearly all of the myriad activities (or use cases) in clinical and public health (e.g., patient care, surveillance, community health assessment, policy) involve generating, collecting, storing, analyzing, or sharing data about individual patients or populations. Effective clinical and public health practice in the twenty-first century requires access to data from an increasing array of information systems, including but not limited to electronic health records. However, the quality of data in electronic health record systems can be poor or “unfit for use.” Therefore measuring and monitoring data quality is an essential activity for clinical and public health professionals as well as researchers.

Methods

Using the Health Data Stewardship Framework [1], we will extend Automated Characterization of Health Information at Large-scale Longitudinal Evidence Systems (ACHILLES), a software package published open-source by the Observational Health Data Sciences and Informatics collaborative (OHDSI; www.ohdsi.org) to measure the quality of data electronically reported from disparate information systems. Our extensions will focus on analysis of data reported electronically to public health agencies for disease surveillance. Next we will apply the ACHILLES extensions to explore the quality of data captured from multiple real-world health systems, hospitals, laboratories, and clinics. We will further demonstrate the extended software to public health professionals, gathering feedback on the ability of the methods and software tool to support public health agencies’ efforts to routinely monitor the quality of data received for surveillance of disease prevalence and burden.

Results

To date we have mapped key surveillance data fields into the OHDSI common data model, and we have transformed 111 million syndromic surveillance message segments pertaining to 16.4 million emergency department encounters representing 6 million patients for importation into ACHILLES. Using these data, we are exploring the existing 167 metrics across 16 categories available within ACHILLES, including a person (e.g., number of unique persons); and observation period (e.g., Distribution of age at first observation period). Syndromic surveillance (SS), however, is driven largely by monitoring patient stated chief complaints (non-standard free text clinical data) in addition to coded diagnoses. Consequently, ACHILLES must be extended to maximally support use in analyzing SS datasets.

Conclusion

This work remains a work-in-progress. Over the coming year, we will not only explore existing ACHILLES constructs using real-world public health data but also introduce new functionality to explore 1) patient demographics; 2) facility and location (e.g., emergency department where care was delivered); and 3) clinical observations (e.g., chief complaint). The design and methods for examining these aspects of surveillance data will be included on the poster, and they will be made freely available for distribution with a future instance of the ACHILLES software. We ultimately envision these tools being available for use on platforms such as the CDC’s Biosense – open to all local and state health agencies as a one-stop portal for surveillance data analysis – or research environments where they can be used to examine and improve the quality of data output from informatics systems.

Proposal of Automatic Patient Authored Text Analysis to Measure Patient Engagement

Gabriel N. Ribeiro, BSc¹, Marcia Ito, PhD²
¹IBM Software Laboratory, São Paulo, SP, Brazil; ²IBM Research, São Paulo, SP, Brazil

Introduction

Chronic diseases cause more deaths than all other causes combined, and are projected to increase from 38 million in 2012 to 52 million by 2030¹. Treatment requires behavior change, and patient engagement in chronic diseases continues to be one of the main concerns in the healthcare field worldwide². Evidences suggests that patients who are engaged tend to use fewer health care resources, make better decisions and have better health outcomes³. Measure non-engagement behavior and analyze its causes are important to identify patient in a group-risk and to develop specific interventions²³.

Assessment of Patient Engagement

Patient engagement is explained by models of behavior change. These models have in common the patient's perceptions, such what they think about their doctors, disease, treatments or themselves². First step of our method is to choose one appropriated model of behavior change. Then, data from one patient is collected from a variety of data sources (e.g: social medias, online health communities, etc) and classified according to the patient's perceptions and polarity (as positive or negative to engagement), using pre-trained machine learning models. The system uses the classified data to calculate the engagement degree for the patient. The calculation is the difference of all positive and negatives classified perceptions, with an optional weight factor for each perception for adjustment purposes, according to its relevance for engagement. Negative perceptions of this patient are associated with all available strategies to address non-engagement behavior, such as health literacy or self-efficacy intervention. The winner strategy is the one with more negative perceptions. Patient data is also used in this calculation to adjust each case, considering age, sex or any other relevant variable.

In the final step, the system presents a quantitative engagement degree with the top-N negative perceptions and possible strategies that can maximize the intervention outcomes for the patient. All the classified data, engagement degree and calculated strategies are stored on engagement database, linked to the patient on patient database.

Conclusion

Our method proposed a solution to assess patient engagement and present a calculated intervention strategy. This method can speed up engagement diagnosis because it's independent of medical consultation. Also, it does not depend on an individual and biased doctor evaluation, can be cheaper than sensors or mobile solutions Future research focuses on clinical trials to compare this method efficiency against traditional engagement assessment methods.

GWAS Finder: Search Engine for GWAS Datasets in Biomedical Literature

Xiao Dong, M.D., M.S.1, Yaoyun Zhang, Ph.D.1, Hua Xu, Ph.D.1
1School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

Introduction

Building a new technical infrastructure for researchers to efficiently find and cite datasets is important. The aim of this study was to develop a scalable approach that can automatically scan millions of scientific publications and identify dataset mentions. In order to fulfill this final goal, we started our study by searching literature using attributes representing the underlying datasets. Genome-Wide Association Studies (GWAS) was chosen as a case study. A corpus of biomedical literature from GWAS catalog was annotated with essential attributes that are most representative of GWAS datasets, on the basis of which an automatic attribute identifier was built. Identified GWAS literature was then indexed with their dataset attributes, in order to establish a search engine, GWAS Finder, for GWAS datasets in literature.

Method

300 GWAS abstracts randomly selected from GWAS Catalog were annotated with eight essential attributes of datasets, including trait, platform, source, ethnicity, stage, sample size, case size and control size. A hybrid named entity recognition model was generated by combining conditional random fields and heuristic rules. Then a total of 13,196 GWAS abstracts collected from PubMed and GWAS Catalog were indexed using their identified dataset attributes, upon which the GWAS Finder was built for searching GWAS datasets in literature.

Results

We evaluated the performance of GWAS Finder by comparing the search results from GWAS Finder to those from GWAS Catalog and PubMed. Each performance was the average score of ten randomly selected queries. The comparisons between GWAS Finder and PubMed are shown below in Table 1, and the comparisons between GWAS Finder and GWAS Catalog are illustrated in Table 2. PubMed does not provide a search function for case size so we didn’t evaluate the performance of PubMed using “Trait + platform + case size” combination as the query type.

Discussion

There are different ways for users to search for biomedical datasets. Searching literature for biomedical datasets, which this study aims to address, is an important aspect of data discovery process. Our future work would include efforts towards another direction, searching datasets from data repositories using similar strategies with which we used in this study and building final linkages between literature and data repositories. This switch indicates the broad uses of text mining methods in building data discovery index.

Conclusion

Our study demonstrates the potential application of text mining methods in building the data discovery index. It can create a better index of literature linked with their underlying data sets, thus improving data discoverability.
Utilizing a State-level, Integrated, Discharge Database to Monitor the Trend in Potentially Preventable Hospitalizations for Congestive Heart Failure

Riddhi P. Doshi, MBBS, MPH1, Gregory Matthews, PhD2, Garth Graham, MD,MPH3, Robert H. Aseltine Jr., PhD1

1University of Connecticut Health Center, Farmington, Connecticut, USA; 2Loyola University Chicago, Chicago, Illinois, USA; 3 Aetna Foundation, Hartford, Connecticut, USA

Introduction

The Agency for Healthcare Research and Quality (AHRQ)-sponsored researchers identified ambulatory care sensitive conditions as conditions (ACSCs) for which hospitalizations can be prevented through primary care interventions. Prevention quality indicators (PQIs) measure the preventable hospitalizations for these conditions. Congestive heart failure accounts for a large proportion of hospitalizations due to chronic ACSCs. Affecting over 37 million individuals globally, congestive heart failure results in over a million hospitalizations annually.1,2,3

Methods

The state of Connecticut’s Acute Care Hospital Inpatient Discharge Database (HIDD) is maintained by the Connecticut Department of Public Health (CT DPH). Inpatient discharge data is submitted by acute care hospitals every six months to the Office of Health Care Access (OHCA)-approved vendor in January and July of each year. After clarifications with the source and addition of diagnostic codes, the vendor merges an annual file. The HIDD contains demographic, clinical, and billing data for discharges from all acute care hospitals in the state.4 This database was screened to obtain information regarding discharges for adult patients (>=18 years old) with the ICD-9 codes for congestive heart failure (PQI #8) during CMS fiscal year 2010 through 2012. The population rates of Prevention Quality Indicators (PQI) were calculated using the technical specifications from the AHRQ. We fit generalized estimating equations (GEE) to the 2012 data, in order to determine the effects of age, sex, race/ethnicity, payer status and median zip-code level income on the outcomes.

Results

A total of 26,894 CHF discharges were recorded during the study period. There was a net increase in the crude population rate for preventable hospitalizations due to congestive heart failure in Connecticut increased from 314.1 per 100,000 in 2010 to 322.6 per 100,000 in 2012. Upon stratification by sociodemographic variables, the rates were found to be higher for men, individuals older than 65 years, African Americans and Medicare enrollees. Multivariate analysis revealed that Medicaid enrollees (OR: 11.46; 95% CI: 10.25-12.82) had the highest odds of hospitalization due to CHF followed by Medicare enrollees (OR: 5.12; 95% CI: 4.67-5.61). African American (OR: 1.81; 95% CI: 1.68-1.94) and Hispanic (OR: 1.12; 95% CI: 1.02-1.22) race also demonstrated significantly increased odds. Men had 50% higher odds of hospitalization.

Conclusions

This study demonstrates the efficacy of an integrated state-level discharge database in monitoring ambulatory care sensitive conditions using a standardized approach. Over the long term, this tool could be used in identifying areas with low access to primary care and direct healthcare policies.

Improving quality of care for heart failure patients in a home care setting: what feedback information do nurses need?

Dawn W Dowding, PhD, RN1,2, Nicole Onorato, BS2, Jacqueline Merrill, PhD, RN1, David Russell, PhD2

1Columbia University School of Nursing, New York, NY; 2Visiting Nurse Service of New York, NY

Introduction

Providing performance feedback to clinicians is an important factor in improving health care quality1 and is a key component of the IHI Triple Aim initiative2. However it is unclear how best to deliver feedback to clinicians, especially in the home health setting. The objective of this study is to identify existing quality performance measures related to the care of patients with congestive heart failure (CHF) that are relevant to home care nurses, and that are actionable (i.e. under the control of the home care nurse), from the nurses’ viewpoint.

Methods

6 focus groups with home care nurses (N=61) working in a large not for profit home care agency in the Northeast region of the United States were conducted between November 2015 and February 2016. The number of groups was chosen to include nurses across all geographical regions of the agency. Focus groups were led by a member of the research team (DD or DR) with another member of the team taking notes (NO).

Focus group participants were provided with a list of 23 statements derived from existing evidence based practice guidelines on the management of patients with heart failure and what feedback on that item might contain (e.g. monitor weight and weight changes daily and notify MD if weight gain of 3lb overnight and over 5lb in 7 or fewer days. Feedback would provide indications of how weight has changed over time). Participants were asked to identify the top 5 statements that they felt were a priority in terms of receiving feedback and rank them from 1 (top priority) to 5 (least priority). The focus group discussion then explored the rationale for priority rankings and how a dashboard could be designed to provide that feedback. All focus group discussions were audio-taped and transcribed. Priority rankings were used to calculate a score (the higher the score, the greater the priority) for each statement. Qualitative data were analyzed using a framework approach, with codes assigned to the text inductively and deductively.

Results

Providing feedback to enable the tracking of vital signs, symptoms and weight changes was the highest ranked statement by nurses for receiving feedback (score =219). The second highest ranked statements related to providing feedback on what educational goals the patient had achieved (score = 75). Analysis from the focus group discussions identified that nurses wanted the feedback to be available in ‘real time’ when the opened the patient’s record in the agency EHR, and that it should be summarized in an accessible, visualized format (e.g. a line graph that displays trends over time).

Conclusion

This study has identified specific elements of care provision for heart failure patients that home care nurses would find valuable to receive feedback about, in order to improve care provision. These aspects of care are exclusively at individual patient level, and are required by nurses in real time. This is in contrast to more traditional approaches to providing feedback on care quality using dashboards, which are often aggregated data across patients (e.g. re-hospitalization rates) and rarely in real time, in a home care setting. The results of this study will be used to develop dashboards to provide feedback on quality outcomes to home care nurses, in real time, at the point of care.

Preliminary Evaluation of a Multi-Component Intervention Prior to Discharge to Reduce Pediatric 30-Day Readmissions

Amie J. Draper, MS1, Andrew Urbach, MD2, Roger Day, PhD1, Fereshteh Palmer, MS, RN2, Srinivasan Suresh, MD2, Fuchiang (Rich) Tsui, PhD1

1Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA
2Children’s Hospital of Pittsburgh of UPMC, Pittsburgh, PA

Abstract: We performed a preliminary evaluation of a 4-component intervention (MAPS) to reduce 30-day readmission rates in a pediatric hospital. We distributed a survey to care providers and compared pre-and post-implementation readmission rates to assess impact on users, the discharge process and readmission rates. No definitive conclusions were made, but intervention improvements were identified. We plan to expand the evaluation by tracking compliance rates, examining user actions in the EHR, workflow analyses, and stakeholder interviews.

Introduction: On July 1, 2015, the Children’s Hospital of Pittsburgh (CHP) of UPMC, a 315-bed children’s general facility with 13,000+ annual admissions, completed deployment of a hospital-wide program called MAPS-to-discharge. The program helps ensure completion of specific pre-discharge care steps through formal, centralized documentation in a designated page within the electronic health record (EHR). The steps are organized into 4 components: 1) reconciling discharge medications (M), 2) scheduling future appointments (A), 3) completing patient education (P), and 4) providing appropriate social worker/care manager services (S). As prior studies have shown that similar multi-component interventions can improve 30-day readmission rates1, 2, we hypothesized that reduced 30-day readmission rates would be a by-product of implementing the program. In this study, we performed a preliminary evaluation of the MAPS program to determine its impact on users, the discharge process and 30-day readmission rates.

Methods: We performed both qualitative and quantitative evaluation. We sent out an 8-question survey to 1400 care providers within CHP. The survey was designed to get feedback on the following aspects of the MAPS documentation page: 1) usage and reasons for use, 2) quality of information, and 3) perceived impact on care processes and workflows. We then extracted month-level data from all in-patient EHRs for visits to CHP during 2012-2015. We compared 30-day readmission rates from July-December in 2015 to aggregate and individual rates from 2012-2014 over the same time period.

Results: Our survey response rate was 17%, with only 37% of respondents reporting that they use the MAPS documentation page. The most common use of the page was to prepare/review patient discharge instructions (81% of users), while the least common use was to take steps to prevent patient readmission (11% of users). Although 48% of users reported valuable information displayed on the MAPS page, few users reported it having an impact on care decisions or readmission risk assessment (16% and 11% of users, respectively). From open-response questions, we learned that users currently perceive an increased workload due to redundant documentation between systems during the transition to MAPS and missing information on the MAPS page. We also learned that not all users understand how to best utilize the MAPS page according to their clinical position. Readmission rates from July-December in 2015 were borderline significantly better than aggregate rates from 2012-2014 during the same months (p-value = 0.01); however, we observed no significant differences and borderline significant differences when comparing to individual rates for 2012, 2013, and 2014 (p-values = 0.63, 0.43, 0.01 respectively).

Discussion and Conclusion: Based on our preliminary findings, we could not make any definitive conclusions regarding the MAPS-to-discharge program. The findings indicate that the intervention may be valuable for the discharge process and might impact 30-day readmissions rates, but further analysis is required to confirm these findings. We plan to continue our evaluation by (1) correlating MAPS compliance rates (i.e. completion of each intervention component) to readmission, (2) correlating user actions within the EHR (via user log files) to readmission, (3) performing workflow analyses to understand user interactions with MAPS, and (4) perform interviews with care providers and patients (families). We will perform these evaluations after implementing the following recommended improvements: (1) promotion/education of MAPS program use for specific clinical roles, (2) embedded readmission risk score from a predictive model, and (3) indicator and alert system for MAPS component completion for each visit.

Evaluation of Clinical Score Usefulness to Guide Development of Automated Score Calculation for Hospitalized Patients

Mikhail A. Dziadzko, MD, PhD, Christopher A. Aakre, MD, Vitaly Herasevich, MD, PhD
Mayo Clinic, Rochester, MN

Abstract

Hundreds of clinical scores have been created, but relatively few are useful to clinicians in their routine clinical practice. We aim to identify the clinical scores deemed useful by hospital-based clinicians to prioritize development of automated scoring algorithms (calculators) within the electronic medical record.

Introduction

Clinical scores have been created to establish disease severity, to predict risk of specific outcomes, to estimate diagnostic probabilities, to be used in research settings, and to aid in clinical decision making. Of the scores that have been externally validated, it is unclear how many are clinically useful in practice. Many scores have been translated into clinical calculators and now are available online. These calculators need manual input – requiring clinician time for data collection and manual data entry. Therefore, automated score calculation within the electronic medical record provides an opportunity to save clinician time. To determine which clinical scores should be targeted for automated score calculation, we performed an exploratory multispecialty survey of hospital-based clinicians to determine the usefulness of evidence-based clinical scores.

Methods

109 readily available clinical calculators based on externally validated clinical scores for hospitalized patients were identified from the medical literature and online medical calculator repositories. Calculators were mapped to clinical specialties based on the age of the target population and the disease of interest. A web-based survey was created and distributed to a convenience sample of attending physicians at Mayo Clinic in Rochester, Minnesota. Respondents received surveys with calculators tailored to their specialty and were asked to rank each score on a 3-point scale: “Don’t need”, “Nice to have”, and “Very important”. Responses were weighted as follows to generate a proportion of clinicians that deemed each score useful:

\[ P = \frac{(\# \text{Very important}) + 0.5 \times (\# \text{Nice to have})}{(\# \text{Very important}) + (\# \text{Nice to have}) + (\# \text{Do not need})} \]

Scores with a proportion > 0.5 were classified as useful. Scores with 2 or fewer responses were not included in the final analysis.

Results

23 clinicians responded to the survey with specialties as follows: 15 anesthesia/critical care, 7 pediatric, 3 general surgery, 3 emergency medicine, and 7 internal medicine and subspecialties. 11 providers had multiple affiliations. 15 calculators were excluded (2 or fewer responses). 25/109 (22.3%) calculators were identified as useful (Table 1).

Table 1. List of useful clinical calculators identified by respondents.

</tr>
</tbody>
</table>

Conclusion

Fewer than one quarter of clinical calculators based on externally validated clinical scores were classified as useful in our analysis. Most of the scores classified as useful in Table 1 are used for diagnosis and prognosis of acute illness, which may reflect the anesthesia/critical care or internal medicine backgrounds of the majority of respondents. Our findings are consistent with previous observations on the rejection of prognostic models by clinicians(1), but should be replicated in a multicenter study before committing resources to automate calculation of the most useful scores. Similar multicenter studies in ambulatory settings may be useful to determine useful scores in outpatient practice.

Analyzing Electronic Health Record Interactions to Capture Resident Work Hours

Adam C. Dziorny, MD, PhD; Evan Orenstein, MD; Robert B. Lindell, MD; Nicole A. Hames, MD; Bimal Desai, MD, MBI
Department of Pediatrics, The Children’s Hospital of Philadelphia, Philadelphia PA

Introduction: Recording and monitoring of resident duty hours is a program mandate from the ACGME to prevent resident burnout and avoid medical errors. Annual review of rotations with duty hour violations provides room for program improvement. Self-report of duty hours is onerous, frequently leading to under- or over-reporting and associated challenges with compliance. Residents constantly interact with the electronic health record (EHR) while on inpatient services. EHR access logs provide an opportunity to capture the minimum hours of resident work in a non-intrusive but quantitative manner. In our large academic medical center with approximately 145 pediatric residents, our EHR, EPIC, stores time stamps of interaction events (e.g. open list, view results, sign order) for all users. We have developed an algorithm to convert these time stamps into shift start and end times.

Objectives:
- To characterize frequency of events, and intervals between the EHR time stamps for residents of different training levels working in differing inpatient roles.
- To compare EHR time stamp generated shift estimates to scheduled resident shifts.

Methods: For the purposes of analyzing EHR interactions, pediatric residents were characterized into one of three inpatient roles: intern; “resitern” or senior resident acting as a front line ordering clinician; and senior supervising resident. EHR time stamps were retrieved from the EHR database system, matched to scheduled resident shifts, de-identified and analyzed. Time stamp intervals between events were computed and binned in Excel. Assumptions of continuous shifts were made based on the measured time stamp intervals, and shift times were estimated from raw time stamp data using custom software. Estimated shift times were compared to scheduled shift times and percent agreement was calculated as overlapping hours divided by total hour span.

Results: On a per-day basis, interns and “resiterns” interacted the most with the EHR, generating the most logged events [Interns: 3153 (SD 876); Resiterns: 3434 (SD 764) interaction events per day] compared to our senior supervising residents [1938 (SD 35) events per day]. Time interval histograms demonstrated that among interns, 100% of the time intervals between events were either < 120 minutes or > 8 hours. Intervals among “resiterns” showed 0.001% (1 interval out of approximately 96000) between 120 – 180 minutes with the remainder either < 120 minutes or > 8 hours. Senior supervising residents demonstrated multiple intervals between 120 – 480 minutes (6 total intervals out of ~ 27000) and required different cutoffs when calculating shift times. Estimate shifts overlapped with scheduled shifts 91% (SD 6%) among interns, 87% (SD 12%) among “resiterns” and 91% (SD 5%) among supervising seniors. Patterns of non-overlap include “resitern” estimated shifts consistently ending earlier than scheduled (mean: 53 minutes earlier) and senior shifts starting later than scheduled (mean: 14.8 minutes later).

Conclusions: Residents in a large academic children’s hospital interact frequently with our electronic health record. Those residents providing front line care to patients interact more frequently than supervising residents. From our sample data, in a typical shift, front line ordering residents are rarely away from the EHR for more than 1 hour, and never away for more than 3 hours. Shift times estimated from EHR access logs demonstrate good concordance with scheduled shift times for all trainee roles. Patterns suggest that “resiterns” stop interacting with the EHR earlier than scheduled, and senior supervising residents do not interact with the EHR as early as expected in a given shift. These differences may reflect the actual shift times the residents worked, as is likely in the case of “resiterns” who typically leave when work has been completed for the day. However the differences also may reflect that not all resident workflow requires EHR interaction, as is likely the case with senior supervising residents.

Accurate shift times generated by interaction with EHR systems provide useful, quantitative means to assess work hours. Future work involves using estimated shift times to determine duty hour adherence based on ACGME requirements and rotation-based analysis to look for areas of residency program improvement.
An Analysis of Readmission Events over Time in Patients with Type 2 Diabetes
Dara L. Eckerle Mize, MD1,2, Mia Levy MD, PhD1,3, Shubhada Jagasia MD, MMHC2, Colin Walsh, MD, MA1,4
1Department of Biomedical Informatics, 2Division of Diabetes, Endocrinology & Metabolism; 3Division of Hematology & Oncology; 4Division of Internal Medicine, Vanderbilt University Medical Center, Nashville, TN

Introduction
Financial penalties have been imposed on healthcare systems which fail to meet accepted quality standards for excess hospital readmissions. Patients with diabetes account for 25-30% of the hospitalized population. Diabetes is even more common among the most common conditions requiring readmission within 30-days of hospital discharge. The best approach for implementing safe care to diabetic patients across the continuum remains unknown. We hypothesize that trends in readmission diagnosis change over time in patients with type 2 diabetes. Identified variation in readmission diagnosis can be used to improve the utility of readmission risk prediction models when compared to traditional all-cause, 30-day readmission risk prediction models.

Methods
Subjects included all adults admitted to Vanderbilt University Medical Center (VUMC) between October 1, 2010 and September 15, 2015 with a diagnosis of T2DM at the time of hospital discharge and >1 admission during the study period. We obtained data from the Vanderbilt Research Derivative (RD), a database of clinical and related data derived from VUMC’s clinical systems. Descriptive statistics were used to summarize the discharge and readmission rates of patients with T2DM and to analyze variation in readmission diagnosis of patients with T2DM over time. Data visualization techniques temporally stratified trends in the variation in readmission diagnosis.

Results
As shown in figure 1, distribution of readmission diagnosis varies within each time period. Over time, the number of readmissions decrease but these preliminary results do not support a clear cutoff at 30 days as is currently used to judge quality over the continuum of care. Additionally, readmission diagnoses do not change consistently over time. For example, figure 2 demonstrates that congestive heart failure (CHF) is the most common reason for readmission in every time period except the first week after discharge. A larger dataset demonstrates that CHF accounts for 20-25% of readmissions and remains the most common readmission diagnosis 12 months after discharge. In contrast, renal failure and infection appear to account for a greater proportion of readmissions the first few weeks after discharge and decrease over time. Statistical analysis on a larger dataset is underway.

Conclusions
Using a data-driven approach to the development of a hospital readmission risk prediction model, we identified variation in the readmission diagnoses of diabetic patients over time. Readmission risk prediction models which take readmission diagnosis into consideration may outperform traditional all-cause models and inform the allocation of resources to reduce readmission risk.
A Maximum Entropy Model of Follow-up: Using Cancer Registry and Insurance Data to Identify Encounters for Breast Cancer Surveillance

Kathryn S. Egan, MS¹, Gary H. Lyman, MD, MPH¹,², Karma L. Kreizenbeck¹, Catherine R. Fedorenko¹, April Alfiler¹, Heather Noble¹, Tracy Kusniir-Wong³, Ada Mohedano³, F. Marc Stewart, MD²,³, Benjamin E. Greer²,³, Scott D. Ramsey, MD, PhD¹,²
¹Fred Hutchinson Cancer Research Center, Seattle, WA; ²University of Washington, Seattle, WA; ³Seattle Cancer Care Alliance, Seattle, WA

Introduction

National guidelines recommend that women who have undergone curative treatment for breast cancer do not receive surveillance testing¹. We have begun collecting data at a regional oncology clinic to measure adherence to this recommendation in the first year of surveillance. However, because follow-up visits for breast cancer are not specified in insurance data or the cancer registry, determining if and when a patient undergoes surveillance has required intense manual abstraction of clinical records. To reduce the need for abstraction, we developed a statistical classifier that identifies follow-up visits for eligible patients with 88% sensitivity and 91% specificity. The classifier identifies patients in their first year of surveillance with 100% sensitivity and 86% specificity.

Methodology

We extracted insurance billing data at a regional oncology clinic for patients with one or more clinic visits in 1/1/2012-12/31/2014 with a code for breast cancer and no code for treatment (4203 patients). We used the clinic’s cancer registry to filter for breast cancer patients who had stage I-IIIA disease, no prior history of cancer, no concurrent non-breast cancer, and had undergone treatment with curative intent (584 patients). Dates of end of treatment and routine breast cancer follow-up were abstracted for the first 200 patients, alphabetical by medical record number. We trained a maximum entropy classifier on 180 randomly selected patients, one vector per discharge date per patient. Twenty patients were held out for testing. Vectors were uniformly weighted and consisted of a boolean indicating whether the encounter was pre- or post-end of treatment, and all billing codes for that encounter, labeled by type (e.g. first ICD-9 diagnosis code). End of treatment dates for the model were calculated using the cancer registry: surgery date, chemotherapy start date + 90 days, or radiation start date + 30 days, whichever came last (90 and 30 days produced optimal sensitivity to follow-up visits in training).

Results

Against abstracted data, classifier sensitivity and specificity for individual encounters were 88.2% and 91.0%, respectively (Table 1). Out of the 20 test patients, 13 experienced routine follow-up for breast cancer in the first 13 months after end of treatment. The model identified all 13 of these patients with only one false positive (Table 2).

Discussion

The classifier has several limitations: abstracting alphabetically may have introduced bias; we excluded patients receiving initial diagnosis or treatment elsewhere and transferring to the current clinic for surveillance; the model is untested at other clinics (although regulation of registry and insurance data suggests it is transferrable); small sample size; and abstraction of breast cancer follow-up visits was subject to interpretation. Nonetheless, the classifier can play a crucial role in quickly and accurately evaluating clinic-wide adherence to national guidelines.

Identifying SNOMED Concepts Relevant to CHA₂DS₂–VASc and HAS-BLED Scores¹

Peter L. Elkin, MD, Edwin Anand, MD, Chris Crowner, MS, Sina Erfani, BS, Grégoire Ficheur, PhD, MD, and Daniel R. Schlegel, PhD
Department of Biomedical Informatics, University at Buffalo, Buffalo, NY, USA

Introduction

The CHA₂DS₂–VASc¹ and HAS-BLED² scores are used to assess the risk of stroke in patients with atrial fibrillation, and risk of major bleeding due to oral anticoagulants used to treat atrial fibrillation, respectively. Our eventual goal is to build a reasoning model to calculate these scores automatically. In this study we identify a list of SNOMED concepts which are relevant to the generation of these two scores.

Methods

Two clinicians, EA and GF, familiar with CHA₂DS₂–VASc and HAS-BLED used the IHTSDO SNOMED CT Browser to find concepts relevant to the clinical use of those scales. The clinicians examined all SNOMED concepts which were found when searching for terms the clinicians thought were relevant to each criteria in the two scales. They examined all descendants of relevant concepts to ensure they are also relevant, and noted if they were not. A consensus³ was formed with the help of an adjudicator (PLE). A Cohen’s κ score could not be calculated because the (potentially very large) set of SNOMED concepts which both clinicians found to be irrelevant is unknown, and an estimate could yield an artificially high κ score. Instead we report the further three variables in the contingency table. We computed these three values both at the top level (the one selected by the clinicians) and including descendants.

Results

Of the 106 concepts identified by the clinicians, only 13 (12%) of them were common to both. Including the descendants the intersection was just over 47%. The variability in depth of the tree under selected terms can be seen in Figure 1 – GF selected 36 concepts which EA did not, but including descendants only added 42 concepts to the total, while the 57 which EA selected that GF did not added 5,862. The final consensus included 47 concepts, indicating a rather large amount of culling during arbitration was performed.

Discussion

The overwhelmingly majority of issued resolved during arbitration was the removal of concepts for which an ancestor had already been identified. This accounts for 36 of the 59 concepts excluded during arbitration. In other cases a category was chosen which was too broad – this happened twice and accounts for many of the descendants EA captured but GF did not. Other issues resolved during arbitration had to do with whether to include items which have low probability of indicating the criteria, e.g., Endocrinologist for renal disease or Respiratory crackles for congestive heart failure. It was decided that these should be excluded. Finally, some clinical decisions had to be made. For example, it was decided during arbitration to include Chronic liver disease instead of Disorder of liver, which one clinician had identified, since the scales are about longer term effects, rather than short-lived diseases.

A Bespoke Big Data/Visual Analytics Solution for Treatment Pathway Analysis and Visualization Using Healthcare Data

Sergio Eslava, MD, MMI¹, John Cai, MD, PhD¹, Saar Golde, PhD², Fei Yang²
¹Celgene Corporation, Summit, NJ, ²Knowledgent, Warren, NJ

Introduction

Multiple areas of drug development require a detailed understanding of how drugs are prescribed by healthcare providers and used by patients outside the controlled environments of clinical trials, and for a long time the industry has used healthcare databases (EMR, Claims, Registries, etc) for that purpose.

However, to extract drug utilization patterns from those data sources and present them in an intuitive manner that facilitates decision making, standard analytical methods need to be supplemented with Visual Analytics¹.

Methods and Results

We custom built an interactive Visual Analytics solution using only Open Source analytical tools (R, RStudio, Shiny and D3.js) on top of a Hadoop/AWS cluster, with the following functionality:

- Ingest patient level data from an administrative claims database (Truven’s Marketscan) and build disease-specific patient cohorts from standardized phenotype definitions
- Extract sequential events (diagnoses, prescriptions, procedures, providers) and reconstructs treatment pathways from those events using pre-defined business rules
- Present those patterns to end users using customized data visualizations at the population level (lines of therapy visualization using Sankey diagrams²,³) and at the patient level (individual patient timelines) (Fig 1)
- Summarize and display patient characteristics (demographics, comorbidities), cost and healthcare resource utilization, duration of treatment and time to next treatment in relation to different pathways

![Figure 1. Left: Line of therapy visualization for Chron’s Disease using Sankey Diagrams. Right: Individual Patient Timeline for a Chrohn’s Disease patient](image)

Discussion

Our solution has been used in diverse disease areas including Crohn’s disease, AML and Psoriasis, where it has proven effective in helping to understand the patterns of care for a disease-specific patient population.

Future directions include the incorporation of additional data sources including EHR and integrated EHR/Claims data to help overcome some of the limitations of using claim databases alone.

A Multi-Institutional Honest Broker in the Cloud
Claudiu Farcas, PhD, Tyler Bath, Paulina Paul, Antonios Koures, PhD
Lucila Ohno-Machado, PhD, MD, MBA
University of California, San Diego

Abstract
The cloud paradigm is permeating scientific advancements, yet it brings its own challenges for human-subjects research. We introduce a novel honest broker system to aid investigators in safe management and exchange of Protected Health Information (PHI). Our approach takes advantage of the private iDASH HIPAA CLOUD and its associated PHI repository. Our system integrates institutional policies that govern data exchange.

Introduction
Current research practices involving data from multiple research institutions depend on human-in-the-loop processes for creating the appropriate request forms for each institution, specifying the data of interest, performing the extracts from the available EHR systems, transferring the data to the institution originating the request, etc. Some of these processes can be highly automated, others require intensive human intervention (e.g., IRB reviews and approvals). To address these challenges, we developed a prototype system that acts as a broker to mediate the end-to-end processes, including the physical delivery of data, and keeps the researcher and relevant staff from several institutions in a continuous communication loop with regard to each study and their progress. It leverages the private IDASH HIPAA Cloud, developed as part of the NIH NCBC program, to store sensitive data in a secure isolated repository on behalf of the requesting party and institutions involved in each study.

The Honest Broker
Our prototype matches (1) a technological solution to safely request, extract, aggregate and compute on human-subjects data in a secure environment, with (2) a legal and organizational framework, including handling of data-use agreements and IRB approvals across institutions. It gives participating institutions full control over who has access to the data and for what purpose. At the same time, it aims at reducing the administrative and technical burden on investigators and supporting staff. The legal framework encompasses the handling of data sharing agreements between relevant parties, with support for de-identified, limited, or fully identifiable information, along with specifications on authorized use by investigators. The system translates these restrictions into computer actionable items, such as access rights onto specific repositories, folders, and files, and automates the collection of data request parameters, notification of the appropriate staff at each institution participating in a study, estimated completion dates and progress reporting, and data transfers to a secure repository.

This work addresses some of the Findability + Accessibility + Interoperability + Reuse (FAIR) aspects of biomedical research that are currently hampered by siloed data, unsafe computing practices, inadequate tools and poor documentation

![Legal Framework Diagram](Image)

**Figure 1.** The Honest Broker combines a legal and technical solution to streamline the end-to-end data access
Interoperability among Prenatal EHRs: A Formal Ontology Approach

Fernanda Farinelli, D.S.I.S.1,2,3, Mauricio B. Almeida, PhD1, Peter Elkin, MD2, Barry Smith, PhD2,3

1 Federal University of Minas Gerais, Brazil; School of Information Science
2 Department of Biomedical Informatics and 3 Department of Philosophy, University at Buffalo, USA

Introduction

Gathering information from EHRs connected to different information systems is a challenge and involves the adoption of interoperability solutions(1). To overcome this interoperability failure among prenatal EHRs our strategy is to develop an ontology in the obstetric and neonatal domain (OntONeo(2,3)). Such ontology will be able to join different standards and terminologies adopted by information systems that deal with prenatal EHRs. OntONeo has the potential to contribute to interoperability of information among EHR from different specialties. In addition, the definitions of OntONeo will facilitate the understanding of how information can be organized in EHRs for purposes of healthcare.

Methodology

We adopted Basic Formal Ontology (BFO) as the top-level ontology of OntONeo, the methodology of ontological realism(4), and we are also following the Open Biomedical Ontologies (OBO) Foundry(5) principles.

Partial results

We built a formal definition to specialties found in EHRs on OntONeo domain (Figure 1). We identified a set of basic types of information that are common across different EHRs independently of specialty (e.g. demographic data and vitals). Moreover, each medical specialty has specific information about the care provided.

Figure 1. Part of OntONeo that deal with the basic information common in EHRs.

Conclusion

We presented how OntONeo ontology represents the EHR data involved in the care of pregnant women. This is an on-going project, and the current version can be found at http://ontoneo.wordpress.com.

Why is Natural Language Processing so Difficult to Generalize?

Jeffrey P Ferraro1,2, Peter J. Haug, MD1,2, Michael Wagner, MD, PhD3
1Intermountain Healthcare, Salt Lake City, Utah; 2University of Utah, Salt Lake City; 3University of Pittsburgh, Pittsburgh, Pennsylvania

Introduction
Clinical natural language processing (NLP) systems are becoming an integral component of systems that relay on information contained within unstructured and semi-structured clinical notes. These systems include disease surveillance systems and predictive diagnostic modeling systems to name a few1,2. Some of these systems such as disease surveillance require portability and ease of deployment across geographical regions and include natural language processing tasks for critical information mining.

The information contained within unstructured clinical notes takes many forms and differs in content and structure within institutions as well as across institutions. To some degree, natural language processing tools must be resilient to these local differences if they are to be effective in providing critical information while supporting system portability.

Methods
As part of a natural language processing compatibility study to support disease surveillance we evaluated some of the difficulties that arise in developing a generalizable NLP solution. The goal was the extraction of 70 clinical findings associated with Influenza at two large healthcare institutions in North America. We analyze ED encounter clinical notes at each institution to determine the distributional characteristics of the language used to describe each of these 70 clinical findings. For example, for the clinical finding “chest wall retractions - present” one institution may describe it as “was using his accessory muscles for respiration” while the other institution may describe it as “does have some abdominal breathing and moderate subcostal and mild to moderate suprasternal retractions”. We confirm the statistical validity of distributional differences between institutional languages by applying Fisher’s Exact Test for Homogeneity performed on the word frequency describing each clinical finding.

Results
P-value significance was adjusted for multiple comparisons testing using the false discovery rate method. Seventy percent (n = 49/70) of the clinical findings had statistically significant (adjusted p-value < 0.05) differences in language used to describe the clinical findings between the institutions.

Discussion
It is common to find language differences in clinical notes describing clinical findings among institutions. Even within institutions, dictation styles and linguistic expression may vary among clinicians. This is one of the most difficult challenges faced in generalizing modern NLP systems today. Whether rule-based or statistically based, NLP systems are developed from training sets providing samples of phrases and linguistic expression to draw upon in developing extraction rules or statistical extraction methods. Systems that show reasonable generalizing characteristics have typically done a good job at incorporating unseen-case heuristics into their extraction algorithms in anticipation of variance seen in practical application. In information extraction, it is challenging to develop good unseen-case guessing heuristics because there is typically over-fitting caused by the institution-dependent lexical scope of relevant phrases. This applies to the phrasal components used to express clinical concepts as well as to the extraction rules derived to recognize them. It is also difficult to develop general extraction methods to address synonymy at a complex phrasal level.

These are some of the reasons why it is so difficult to generalize natural language processing tasks such as information extraction. Our poster presentation will elaborate on these challenges, provide illustrative examples of typical, location-dependent, textual variation, and discuss existing and proposed approaches to dealing with this ubiquitous problem.

Review and Evaluation of the State of Standardization of Computable Phenotype
Stephanie Feudjio Feupe, MSc, Ko-Wei Lin, PhD, Tsung-Ting Kuo, PhD, Chun-Nan Hsu, PhD, Hyeon-Eui Kim, PhD
Department of Biomedical Informatics, UC San Diego, La Jolla, USA

Abstract
Inadequate standardization of phenotype data in biomedical database and electronic medical record (EMR) has created challenges in data reuse for patient care, quality improvement, new scientific discovery, and validation of existing knowledge. We conducted literature review on this topic published in the past 10 years to assess the efforts on phenotype standardization and rendering phenotype computable. We summarize the findings here.

Introduction
According to the medical encyclopedia, a phenotype is an observable or measurable characteristic or trait in an organism. In the clinical domain a phenotype can be a disease or condition, a symptom, a biomedical process or a measure of physical characteristic. The ever growing need to investigate the associations among phenotypic data and other types of data such as genetic, pharmaco-genetic, environmental, psycho-behavioral data makes it crucial to have standard for phenotype representation across databases. While the availability of phenotype data in the EMR, clinical databases and other supporting sources bring new opportunities for large scale data driven research such as genome wide association studies and cohort discovery; the lack of clarity in phenotype definitions and the idiosyncrasies in data representations make it a non-trivial task to render phenotype data interoperable and sharable. Given the significance of phenotypic data and the growing efforts to make phenotype data computable, we reviewed and analyzed published literature to access current state of the research in order to understand what efforts have been done, to identify potential gap and unexplored areas for developing further research focus on this topic.

Methods
We searched articles from both PubMed and Web of Science (WoS) using the following queries respectively.
- PubMed: Phenotype[MeSH] AND (standardization OR "vocabulary, controlled"[MeSH] OR "terminology as topic"[MeSH]) AND Published year: past 10 years AND Language: English AND Abstract available AND Human studies
- WoS: TOPIC: (Phenotype OR "computable phenotype") AND TOPIC: ("standardization, definitions" OR "vocabulary, controlled" OR "terminology as topic") AND YEAR PUBLISHED: (2004-2015) AND Language: English

The searches yielded 611 and 440 papers respectively; a total of 918 papers after duplicate removal. Using our predefined inclusion and exclusion criteria, we selected 48 articles. To be included, articles had to focus on phenotype standardization with an informatics-based method for standardization and suggest or present some evaluation of their approaches. We further screened the 48 articles by reading the full-text papers. Articles related to establishing clinical guidelines, papers that dealt with diagnostic criteria as opposed to phenotype description were removed. Fifteen relevant articles met our eligibility criteria, thus included in our review. The articles were summarized using a standardized review form, which is designed to capture study characteristics such as study author, year, phenotype target domain, study goal, data source, research methods, results, open sources, evaluation methods, and limitations of each paper.

Results and conclusion
Phenotypes are considered computable and integrable when they can be described to a more granular level as possible. Methods for such representation ranged from annotation by human, to standardization based on computerized from structured and unstructured data sources. In the past year, efforts like eMERGE, PhenX, HPO have attempted to standardize phenotype data from omics research databases; whereas, the combination of information models and terminology system like UMLS and SNOMED-CT has been used to assure EHR interoperability and phenotype identification. While most methods for rendering phenotype computable in these studies seemed to be informative, the majority of the work we reviewed focused on specific types of phenotype or the data from a single data repository, which can be considered a potential threat to generalizability.

Number of patients included in randomized controlled trials versus observational studies in three reference journals over 20 years

Grégoire Ficheur MD-PhD, Daniel R. Schlegel PhD, and Peter L. Elkin MD
Department of Biomedical Informatics, University at Buffalo, Buffalo, NY, USA

Introduction
Empirically, many informaticians have noted an increase in clinical research networks and data warehouses which have as part of their purpose to serve observational research needs. It is unknown whether this empiric trend has led to an increase in the size of studies in terms of number of participants recruited in trials or in observational studies. Our objective was to estimate the number of patients included in randomized controlled trials versus observational studies in three reference journals from 1995 to 2014.

Methods
The structured abstracts from the New England Journal of Medicine, the Lancet and the Journal of the American Medical Association we extracted from MEDLINE for the period 1995-2014. Abstracts including a Methods section were retained. Two lists of patterns were built by an expert in order to automatically analyze the Methods section then classify the abstracts into the two categories randomized controlled trials (RCTs) or observational studies (OS). A list of regular expressions was then used to automatically extract the number of participants included in each study from the Methods section. Four successive periods of 5 years were defined and the median was computed for each of these periods. The corresponding boxplots were constructed without the potential outliers.

Results
The analysis included 13,377 abstracts. For the four successive periods of interest, the medians of the number of participants were respectively 289, 436, 668 and 512 for the RCTs. For the same periods, the medians were respectively 446, 558, 1338 and 2067 for the observational studies. The corresponding boxplots are presented in Figure 1.

Discussion
Contrary to RCTs, the number of patients included in observational studies has increased strongly over the last 20 years. The move towards dematerialized electronic medical records and the reuse of this data for epidemiology seems a reasonable hypothesis to explain this observation.
Using Machine Learning to Improve Sentence Detection

Dezon K. Finch, PhD\textsuperscript{1}, Stephen L. Luther, PhD\textsuperscript{2}
\textsuperscript{1}HSR&D Center of Innovation in Disability and Rehabilitation Research.
James A Haley Veterans Hospital, Tampa, FL

Introduction

Medical progress notes in the Veterans Health Administration have proven to be challenging for standard sentence splitters due to the presence of semi-structured data and because free text is often not written in grammatically correct sentences. This makes it difficult for Natural Language Process systems to accurately extract concepts from the text. Sentence splitters either split sentences apart because of the new line characters (\texttt{\textbackslash n}) left in the text or they find it very difficult to identify the ends of sentences because punctuation is absent.

Methods

100 progress notes were sampled from an existing study corpus such that each note was unique based on the standardized title. A Python script was developed to sample text strings in two ways. First, the samples were taken with the new line character at the center with 10 characters on each side and a large span of 20 characters on each side. Second, samples were taken such that characters that are expected at the end of sentences were at the center, such as periods, question marks, exclamation points and quotations. Each character of each string was coded with the character type as the value of a variable that indicated its position in the string. Each string with the new line character in the center was hand labeled as True when break was within the boundary of a sentence and False when it was not. Refer to Table 1 for illustrative examples. The `|` denotes `\texttt{\textbackslash n}` character in the text.

</tbody>
</table>

The strings with end of sentence characters were labeled True when it was a sentence boundary and False when it was not. The 20 character strings were left in their raw text form for the labeler to reference. Two separate machine models were developed using C5 rule induction and 10 by 10 cross validation. The trained models are converted to executable code to be used in a pre-processing program that would extract the strings from a note, code the characters in the string, determine if a join should be made by changing the `\texttt{\textbackslash n}` to a space and whether candidate sentence ends should be split, by inserting a changing a space to a `\texttt{\textbackslash n}`.

Results

The model developed for identifying sentence splits (n=18,600) achieved an overall accuracy of 98.5% while the model for identifying joins (n=48,900) achieved an accuracy of 98.9%. The split detection model was able to distinguish recognize typical abbreviations like “Dr.” and in cases where sentences ended with quotation marks, split on the quotation rather than the period. There were some cases where text was written in all caps that were missed. The joins classifier accurately identified cases where some text was indented and overcame multiple leading spaces in the gap. However, in cases where text was deeply indented it was not able to properly identify the break in sentences due to the limitation of the length of the string sample. Some of this was overcome by reducing the amount of leading white space before extracting the string samples.

Conclusion

The tool produces note with each sentence complete and on a single line which will make parsing algorithms in NLP perform more effectively. We will test the effect on parsing accuracy in future efforts and make the final version in Java available to the public for use NLP pipelines. More complete examples provided in the poster.
Informatics Challenges in Working with "Big Data" – A Use Case in Identifying Predictors of Constipation

Fern FitzHenry1,2 Svetlana K. Eden1,2 Jason Denton1,2 Robert J. LoCasale3 Hui Cao3 Aize Cao1,2 Ruth Reeves1,2 Nancy Wells1,2 Michael E. Matheny1,2

1Tennessee Valley Healthcare System, Veterans Affairs Medical Center, Nashville, TN; 2Vanderbilt University Medical Center, Nashville, TN; 3AstraZeneca Pharmaceuticals, Gaithersburg, MD

Introduction

Large datasets just by virtue of their size can present problems in data convergence. The electronic health records of the Veterans Health Administration (VHA) presents a rich use case of a large dataset, studying the risk factors for developing constipation in opioid naïve veterans. When dealing with large observation cohort data, study design is complicated by computational resources required and model convergence challenges. We sought to describe some of the analytic challenges in the use of “Big Data” within the use case of opioid-associated constipation.

Methods

We selected a national cohort of veterans receiving care from 1-2008 to 5-2013 with opioids for 30 days or more (any formulation/dose) and at least one encounter in each of the previous 2 years, but with no opioid exposure or cancer diagnoses in the year prior. The analysis was a Cox Regression studying the association of subject characteristics measured in the year prior to the opioid exposure with the development of constipation. The outcome, time to constipation, was defined as time to constipation related diagnosis, procedure, or new/changed laxative treatment. Out of 162 available variables, 82 variables with a prevalence <1% or >99% were excluded to allow convergence of the model. The final model adjusted for the remaining 80 variables. The analysis was performed in statistical language R.1

Results

The number of veterans meeting the criteria for inclusion/exclusion was 861,422 with 11.42% developing constipation. The top 14 significant variables (7 positive and 7 negative) associated with the development of constipation are presented in Figure 1. Although the number of events (98,360) was large enough to include all 162 variables, some variables had to be excluded because the full model would not converge. After identifying and removing variables causing computational singularity, the model still produced an aberrant 3 digit effect size. Further investigation showed that the reason for singularity and the aberrant effect size was that some binary variables were very sparse (for example, a rare medication taken by a single patient who developed constipation). Removing sparse variables with a prevalence <1% or >99%, an a priori defined threshold, solved the problem of convergence. The modeling showed clinically plausible associations with a C-index of 0.676 (95% CI: 0.676, 0.678).

Conclusion

A careful understanding of the data and methods are required to execute analyses in “Big Data." Exploring non-linear functional forms of association between the explanatory variables and the outcome might help improve discrimination ability of the model.

Counting Knowledge Objects – Estimating How Many Discrete Knowledge Artifacts are described in the Biomedical Literature by Type

Allen J. Flynn, PharmD1,2, Charles P. Friedman, PhD1,2,3
1School of Information, 2Medical School, 3School of Public Health, University of Michigan, Ann Arbor, MI

Abstract

Some knowledge artifacts are intended for routine use. These include calculators, scales, algorithms, checklists, flowcharts, guidelines, pathways, protocols, and templates. Bibliometric data from PubMed were used to estimate quantities of these types of “knowledge objects.” Since 1970, about 47,000 articles have described such objects.

Introduction

In a Learning Health System, publication of knowledge artifacts must be followed by their routine use.1 To understand the scope and scale of the knowledge management and implementation challenges that need to be overcome to achieve a Learning Health System, an estimate of the number of potentially useful knowledge objects is needed. This estimate informs ongoing work to develop a digital library system within which to represent, store, curate, manage, and make accessible biomedical knowledge artifacts as digital objects.

Method

Nine coordinated PubMed database article title queries were performed and analyzed using NCBI’s Entrez E-utilities2 and PERL (v.5.12.4). First, a query for ‘calculator’ was run and every article found was manually reviewed so that all clinical calculators could be counted. Second, a Boolean logic query for ‘scale’ and (‘clinical’ or ‘treatment’ or ‘management’ or ‘practice’) was run with keyword exclusions (e.g., ‘pay’). Finally, seven more queries were run to find and count relevant article titles with ‘algorithm’, ‘checklist’, ‘flowchart’, ‘guideline’, ‘pathway’, ‘protocol’, and ‘template.’ To avoid duplicates, each successive query excluded all previously queried artifact types. PERL scripts organized and counted results. Results are limited to publications indexed in PubMed.

Results

From 1970 through 2015, guidelines are featured in 27,268, protocols in 9,652 and algorithms in 3,552 articles, respectively. Taken together, another six knowledge artifact types are featured in 6,342 articles. Accounting for some duplication but also allowing that some articles discuss more than one artifact, it is estimated that since 1970 about 47,000 articles in PubMed describe one of these nine types of artifacts. This number is increasing.

Conclusion

An estimate of the number of discrete knowledge artifacts described in articles indexed in PubMed since 1970 has an order of magnitude in the tens of thousands, not the hundreds or the millions. This number is rapidly increasing.

Towards Large-Scale Predictive Drug Safety: A Computational Framework for Inferring Drug Interactions Through Similarity-Based Link Prediction

Achille Fokoue, MS, Ping Zhang, PhD, Oktie Hassanzadeh, PhD, Mohammad Sadoghi, PhD
IBM T.J. Watson Research Center, Yorktown Heights, NY

Introduction

Drug-Drug Interactions (DDIs) may happen unexpectedly when more than one drugs are co-prescribed, causing serious side effects. Discovering and predicting DDIs will not only prevent life-threatening consequence in clinical practice, but also prompt safe drug co-prescriptions for better treatments. In this study, we propose a computational framework that takes in various sources of drug-related data and knowledge as input, and provides as output a list of potential DDIs along with an explanation for each DDI.

Methodology

We obtained a set of 12,104 drug pairs (among 1,197 drugs) already known to interact from DrugBank. By exploiting information originating from multiple linked data sources (e.g., DrugBank, UMLS, and CTD), we created 13 drug similarity measures to compare two drugs such as chemical structure similarity, pathway based similarity, and metabolizing enzyme based similarity. The resulting similarity metrics are used to build features for a large-scale and distributed logistic regression model to predict the existence of DDIs while efficiently coping with skewed distribution of DDIs and data incompleteness. The overview of our similarity-based DDI prediction approach is illustrated in Figure 1. In the experiment, we compared our method with a baseline that either assumes all drugs are known in advance during training or fails to account for skewed and rare events. Furthermore, we have developed a number of novel similarity measures that goes beyond the state-of-the-art approaches.

Results and Discussion

To fully evaluate our DDI prediction framework, we performed two types of experiments. Using the standard 10-fold cross-validation, our method achieved an average F-Score of 0.74 (vs. 0.65 for the baseline) and area under PR curve of 0.82 (vs. 0.78 for the baseline) for the newly developed drugs scenario (i.e., we held out all the DDIs associated with a fixed percentage of the drugs, rather than holding out DDIs directly). Additionally, we conducted a novel retrospective analytics to further demonstrate the effectiveness of our approach in DDI prediction. Our method correctly predicted up to 68% of the DDIs discovered between January 2011 to December 2014 by using only DDIs known before January 2011 as positive examples in training. This demonstrates our ability to discover valid, but yet unknown DDIs.

More details of our methodology and experimental results are presented in http://ibm.biz/adrtechreport.
Priorities for health-related use of personal data trails: Patients’ perspectives

Jacqueline Fontaine, MH1, Evette Ludman, PhD2, James Ralston, MD MPH2, Andrea L. Hartzler, PhD2
1University of Michigan, Ann Arbor, MI; 2Group Health Research Institute, Seattle, WA

Abstract

As the adoption of personal technologies grows, use of “personal data trails” from these tools promises to provide significant insight for research and care delivery. Yet use of patient-generated health data raises ethical, social, and legal concerns. Through focus groups, we investigated patients’ perceptions about sharing personal data trails for different health-related uses. Findings highlight concerns about personal autonomy, recipient trust, sharing costs and benefits, data quality, technological barriers, and limitations to law and policy.

Introduction

Widespread adoption of personal technologies, including smartphones, Internet, wearables, smartcards, and other ubiquitous devices, is accelerating the volume, type, and speed at which patient-generated health data spreads1. Personal data trails – digital footprints captured through our use of technology – carry insights into our characteristics and activities. This data also reflects our health, including what food we buy, how we exercise, and with whom and how much we openly interact. In this study we engaged patients to examine ethical, legal, and social issues surrounding the health-related use of personal data trails, including priorities of users who generate personal data (“generators”) when sharing their data trails with “recipients” in exchange for personalized services.

Methods

We conducted six 90-minute focus groups with 48 patients from Group Health Cooperative, a healthcare system in Washington State. Participants were adults who had actively used “MyGroupHealth”. Group Health’s Epic-based personal health record. Majority of participants were female (57.4%), White (77%), and well-educated (74.5% had a Bachelor’s degree or higher), with an average age of 59.8 (SD=16). Focus groups led participants through a series of scenarios that described how a fictitious patient “Susan” shared her personal data trail. Scenarios varied the personal data trail data types and recipients to explore differences in participant priorities in deciding when and with whom they share their data. Data types were expanded from Wood’s conceptualization of patient-generated health data and included lifestyle, online behavior, and retail data.2 Scenarios depicted this data shared purposefully with “primary recipients” and captured by third parties for secondary use. We coded transcripts using a codebook developed from initial qualitative themes, which were refined iteratively through collaborative coding among co-authors. Each transcript was independently coded by two researchers and compared for agreement. A third researcher coded transcripts to resolve disagreements. Any further coding discrepancies were resolved by discussion.

Results

Qualitative themes that emerged from the focus groups included general orientations towards sharing as well as costs and benefits of sharing and trade-offs when deciding to share. Foundational concerns that cut across these themes included the desire for personal autonomy and recipient trust. Other concerns were limitations of data quality, technology, and traditional laws and policies that do not necessarily safeguard health-related use of personal data trails outside the healthcare system. We are using findings to inform a conceptual framework to depict patients’ priorities for sharing across personal data trails across data types, recipients, and sharing pathways.

Conclusion

Patients provide a critical voice about the health-related use of their personal data trails. Themes about patients’ priorities depicted by our conceptual framework provides a foundation for future work that leverages patient-generated health data and informs thoughtful design and spread of personal health technologies.

Deriving the “Number Needed to Treat” from PubMed Structured Abstracts

Paul Fontelo, MD, MPH; Fang Liu, MS
National Library of Medicine, Bethesda, MD

Abstract
The Number Needed to Treat (NNT) indicates the number of patients needed to treat to prevent one unfavorable outcome. In some IMRAD-formatted abstracts, the Results section may contain adequate data of interventions to estimate the NNT. We developed a Web interface that automatically calculates the NNT after the table is manually populated with clinical trial results. A link is provided to the fulltext article if the abstract is insufficient.

Introduction
The Number Needed to Treatment (NNT) is an indicator of the effectiveness of a drug or intervention in preventing one adverse event in a patient population. Lower numbers are better. PubMed now has more than 16 million citations with abstracts and 3.1 million (19.8%) are structured abstracts. 406,000 are randomized controlled trials (RCT) and 51% of them are structured abstracts. Abstracts of some RCTs may provide enough information to calculate the NNT.

Methods
The PubMed for Handholds (PubMed4Hh) Web app algorithm was modified. Modifications involved two sets of vocabularies: the first set included identifying terms which indicate possible NNT terms, such as, “treated”, “control”, “intervention”, etc. The second set includes more accurate phrases, like, “treated group”, “control group”, “intervention group”, etc. RCT was set as the default publication type but other publication types are kept as options. Citations retrieved are scanned for the vocabularies in order and search terms are highlighted (left panel, Table 1). Citations with set 1 terms are marked with a star and those found by set 2 are marked with 2 stars, denoting that these sentences may contain data useful for completing the the NNT table. An NNT calculator in JavaScript is embedded in every abstract. Users manually complete the requisite data from the abstract on a 2x2 table. The NNT tool will calculate the Experimental Event Rate (EER), Control Event Rate (CER), Absolute Risk Reduction (ARR) and the NNT.

Result
The tool was tested on a set of 10 clinical queries. The tool performed as designed and citations correctly identified the terms in both sets (Table 1, right panel). Limitations include the requirement to manually complete the 2x2 table and that abstracts may not contain the data needed to complete the table. A link to the fulltext article is provided if the abstract does not include the data needed. The resulting values from the NNT calculator were the same as those from published manual methods.

Conclusion
An NNT calculator embedded in PubMed4Hh might be useful for some healthcare professionals to determine the NNT at the point of care. Development to automatically populate the table and use odds ratios are ongoing.
Factoring near-field chemical exposure into personalized medicine
Henry A. Gabb, PhD and Catherine Blake, PhD
University of Illinois at Urbana-Champaign, IL, USA

Introduction
Personalized medicine considers many factors (e.g., diet and genetics) affecting how a patient responds to treatment. However, the effect of long-term chemical exposure from consumer products is not typically taken into account. Though not acutely poisonous in normal usage, long-term exposure is potentially harmful and could exacerbate existing medical conditions and could affect how medication is metabolized\(^1\),\(^2\). For example, the fragrances and parabens in consumer products can exacerbate asthma. Roughly 80,000 chemicals are currently registered under the U.S. Toxic Substances Control Act. Most have not been subjected to toxicological risk assessment and fewer have been studied for potential drug interactions.

Materials and Methods
A database of 38,975 consumer products and their ingredients was compiled from online retailer sources\(^3\). Ingredient names were normalized using PubChem\(^4\) and the Unified Medical Language System\(^5\) in order to account for chemical synonymy and homonymy\(^6\). Product ingredients were compared to four authoritative lists of potentially harmful chemicals (Tox21, HSDB, EDCDB, and DODSON)\(^2\),\(^6\) to gauge their prevalence and distribution.

Results
Twenty-two of the 10,921 unique chemicals are shared in all four lists (Figure 1). Of these, 12 appear in the consumer products database: octinoxate, benzophenone, and benzophenone-3 (UV filters); octamethylcyclotetrasiloxane (cyclosiloxane); acetyl methyl tetramethyl tetralin (fragrance); diethyl phthalate and di-N-butyl phthalate (phthalates); triclosan and triclocarban (antimicrobials); and butyl, ethyl, and methyl paraben (parabens). The prevalence of these chemicals within five broad product categories indicates that the potential for exposure is high (Figure 2), though exposure duration and likely dosage must be taken into account before considering health outcomes. Parabens, suspected endocrine disruptors with estrogenic and allergenic potential, are in all categories; particularly skin care, cosmetics, and hair care products. Antimicrobials are also found in every category, though they are not as common as parabens because they are being phased-out of consumer products over similar health concerns. The paraben and antimicrobial compounds are associated with asthma severity due to immune sensitization\(^7\).

Conclusion
In addition to genomics, a patient’s product usage profile, or “productome,” could affect treatment outcomes. The list of potentially harmful chemicals is long but the results above suggest that exposure via consumer products could be used to prioritize the chemical-treatment combinations that should be further explored and considered in personalized medicine.

Developing a predictive model for discharge delay in the Post-Anesthesia Care Unit

Rodney A. Gabriel, MD, Jihoon Kim, MS, Lucila Ohno-Machado, MD PhD
University of California San Diego, La Jolla, CA

Abstract
We developed a predictive model using logistic regression to identify patients at risk for prolonged post-anesthesia care unit length of stay. The final model contained 7 predictor variables with an area under the ROC curve value of 0.765 (95% CI [0.741, 0.788]) on the training set and 0.764 (95% CI [0.729, 0.799]) on the validation set. This model may be beneficial from both a cost and patient satisfaction perspective.

Introduction
A predictive model that can identify patients who are at an increased risk for prolonged post-anesthesia care unit (PACU) stays could help optimize resource utilization and staffing needs. Although previous studies based on hospital stays identified some predictors, there is not a model that utilizes various patient demographic and preoperative comorbidities that may affect PACU length of stay in the ambulatory surgery setting.1-3

Methods
We collected 4,151 cases requiring care from an anesthesiologist in the ambulatory surgery PACU at a single institution. The binary outcome was the occurrence of prolonged PACU length of stay, defined as admission lasting more than one standard deviation above the mean recovery room time. A total of 20 predictor variables were obtained from electronic health records. The presence of a comorbidity was based on the existence of corresponding ICD9 codes extracted from each patient’s record. The dataset was split randomly into a training set (67%; n=2,782) and a validation set (33%; n=1,369). A logistic regression model was built on the training set using a combined method of forward selection and backward elimination based on the Akaike Information Criterion (AIC). The trained model was applied to the validation set. Model performance was evaluated with the area under the ROC Curve (AUC) for discrimination and the Hosmer Lemeshow (HL) test for goodness-of-fit.

Results
The final model had 7 predictor variables that included: primary anesthetic type, surgical subspecialty, obstructive sleep apnea, hypertension, congestive heart failure, history of postoperative nausea/vomiting, and scheduled case duration. The model had an AUC value of 0.765 (95% CI [0.741, 0.788]) on the training set and 0.764 (95% CI [0.729, 0.799]) on the validation set, with no significant differences in AUCs between them (p=0.980). The model had good calibration for the data in both the training and validation set as indicated by HL p-values of 0.52 and 0.14, respectively.

Conclusion
Several predictive models have been used in anesthesia1-3. This is the first model that utilizes patient factors that are identifiable in the preoperative setting as predictors for prolonged PACU length of stay specifically in the ambulatory surgery suite. The predictive model using logistic regression utilizes variables that may be predetermined prior to surgery (i.e., known comorbidities such as hypertension or sleep apnea). By developing a model using this type of data, future systems can automatically identify at-risk patients before surgery and aid in the allocation of staffing and resources in the surgical suite. This may prove to be beneficial from both a cost and patient satisfaction perspective and will be studied in future work.

The Use of a mHealth Decision Tree Support Program for Epinephrine Auto-injector (EAI) Administration Training of Adolescents

Joel Gallagher, MD¹, Robert Rivera, MS², Asriani Chiu, MD¹, Tanvir Roushan, BS³, Golam Ahsan, MS³, Cheng Wen, MPH⁴, Christina Eldredge, MD², and Shiekh Ahamed PhD³

1. Medical College of Wisconsin, Department of Asthma, Allergy, and Immunology, Milwaukee, WI, USA; 2. Medical College of Wisconsin, Department of Family and Community Medicine, Milwaukee, WI, USA; 3. Marquette University Ubicomp Laboratory, Milwaukee, WI, USA; 4. University of Southern California, Keck School of Medicine, Los Angeles, CA, USA

Introduction: Anaphylaxis is a potentially fatal allergic reaction which requires immediate treatment with an epinephrine auto-injector (EAI). Adolescents make up a disproportionately large percentage of anaphylaxis fatalities – 53% of the subjects in one study (1). Knowledge alone was unlikely to persuade adolescents to use EAI when needed (2), and only prior usage correlated with increased comfort with future EAI administration (3). Compounding this problem is the risk-taking nature of the adolescents (5). Encouraging EAI carriage without any other intervention is ineffective in ensuring that EAI are appropriately used (7). Current methods of teaching EAI administration utilize didactic sessions. However, it has been shown in various settings that skills wane as time since the session increases (9-13). There also exists a notable disparity in training between urban and rural settings (14). Therefore, novel interactive training modalities that are easily scalable to audience size and geographic setting are needed.

To address this gap in education, our mHealth decision tree support program focuses on training with the use of case-based scenarios and an interactive decision support mobile health application. The ultimate goal is to engage adolescents at a deeper level in decision making, therefore providing improved anaphylactic emergency preparedness. The mHealth decision tree support program creates a novel interactive virtual learning environment that allows for repetition using life-like scenarios. Repetition without focused responses has been shown to be ineffective in the successful retention of skills (15, 16). In contrast, our simulation concept results in continuous reinforcement of concepts and provides prompt feedback, allowing users to learn from their failures in a safe environment and nurturing the skills to successfully manage real life anaphylactic events. Current anaphylaxis training tools lack this level of interaction and decision support.

Methods: During the summer of 2016, our IRB approved trial will use a 3-arm, parallel, randomized group pre-intervention and post-intervention study design with a Control Group, Intervention A Group, and Intervention B group. All subjects will first undergo a simulation with a series of scenarios as measurement of their baseline performance. Then, we will provide each group with their respective training modalities. The Control Group will receive the standard of care only (an EAI demonstration via a clinician educator in conjunction with pamphlets describing anaphylaxis). The Intervention A Group will receive the standard of care plus training via the mHealth decision tree support program, while the Intervention B Group will receive the standard of care plus training via an application available to patients by a prominent EAI manufacturer. Each participant will be asked to complete a survey of anaphylaxis knowledge, self-efficacy, and health-related quality of life, before and after their respective interventions. Each participant will be introduced to their respective training modality and allowed a one week “run in” period to utilize their respective modalities. After one week, they will undergo another simulation with a series of comparable scenarios.

Conclusions: Current training modalities for teaching EAI use are insufficient and inadequately prepare food-allergic adolescents for anaphylactic episodes. We anticipate that our intervention will provide a viable and valuable alternative, increasing EAI carriage rates as well as increasing food-allergic adolescents’ health quality of life through improved self-efficacy and an increased feeling of safety. Results will be reported in our Fall 2016 presentation. In addition, our mHealth decision tree support program has the potential of reaching adolescents in a variety of geographic settings, therefore providing rural telemedicine support.
Comparison of Emergency Department Throughput Visualizations

Swaroop Gantela, MD1, Todd R. Johnson, PhD1, Nnaemeka G. Okafor, MD, MS1,2, David J. Robinson, MD1, Brent R. King, MD3, Amit M. Mehta, MD1, Nathan R. Hoot, MD, PhD1, Charles L. Maddow, MD1, Vickie Nguyen, MS1, Adriana Stanley, MS1, Amy Franklin, PhD1

1The University of Texas Health Science Center at Houston, Houston, TX; 2Memorial Hermann Health System, Houston, TX; 3Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE

Introduction

Increasing importance is being placed on hospital throughput metrics1, creating an opportunity for situation awareness dashboards to play a supportive role. We discuss the use of visualizations of Emergency Department (ED) throughput data to provide cognitive support for real-time comprehension of the current state of the ED. Three visualizations were examined for their ability to assist in tasks ranging from global searches for bottlenecks to focused identification of individual patients whose metrics require attention.

Methods

The same dataset was used for all visualizations. The data represent a snapshot of all patients in a simulated ED and contain the length of time each patient has spent in their current stage of care. Three visualizations are presented: (1) the distribution of pending times for each stage of care, (2) bar chart for each stage, each bar a patient with the height being the pending time, and (3) a jump plot showing transitions across set checkpoints of care where each curve is a patient, the deviation from the midline is the difference from the median, and positive deviations are to the right.

Discussion

The distribution charts allow for comparison of absolute medians across stages, convey bottlenecks with increased density, give salience to outliers, but are hindered by overplotting. The bar charts allow for easy comparison of total count in each stage, allow for easy height comparison of patients within a stage, but are not as easy for comparing medians across stages. The jump plot is a new style of graph requiring some learning to interpret, but it allows for easy comparison across stages by setting the median of each stage on the common midline, emphasizes the position relative to the median, emphasizes outliers, and reduces overplotting.

Conclusion

No one chart served all purposes, but each chart had strengths in different contexts, and a combination of charts may provide utility in ED status assessment. The distributional chart aided absolute comparisons, the bar charts aided in count comparisons, and the jump plots aided in global views, highlighting outliers, and finding bottlenecks.

Documentation of Patient Strengths in Electronic Health Records

Grace Gao, RN-BC, DNP1, Madeleine Kerr, RN, PhD1, Ruth Lindquist, RN, PhD, ACNS-BC, FAAN1, Karen A. Monsen, RN, PhD, FAAN1
1School of Nursing, University of Minnesota, Minneapolis, Minnesota

Abstract

A strength-based model with a whole-person perspective aligns with person-centered care practice and documentation. A systematic review was conducted to determine the current state of patient strengths documentation in electronic health records (EHRs). Clinical information in EHRs is typically structured by problem-based diagnoses, however, there is emerging documentation of formalized strengths attributes using the Omaha System, which may promote a holistic approach to clinical practice and documentation using a person-centered ontology.

Purpose

Effective health management of individuals calls for a holistic, person-centered approach in clinical care and documentation. A whole-person representation captures not only patient problems but also patient strengths.1 Strengths are an integral part of well-being that involves physical, mental, and social dimensions.2 Studies suggest that patients want their strengths and inner resources to be utilized by care providers.3,4 To better understand and inform practice of person-centered care and documentation, a systematic review was conducted of the current state of patient strengths documentation in the EHRs.

Methodology

The data, information, knowledge, and wisdom (DIKW) informatics framework was employed to develop this systematic review.5 Three scientific databases were used to conduct a systematic or advanced search: CINAHL, Ovid Medline, and PubMed. The following search terms were used: strength*, problem*, whole-person, wellbeing, electronic health record*, personal health record*, EHR*, and PHR*. The inclusion criteria were to include literature related to utilization and documentation of patient strengths and/or problems in EHRs and/or personal health records (PHRs). The exclusion criteria were to exclude literature written in a language other than English or published before 2000. 384 articles were returned with different combinations of designated search terms. All articles were screened through review of titles, abstracts, or full texts. 20 articles were selected for this review.

Findings

The vast majority of articles focus on problem-based diagnoses and practice. However, one emerging trend appears to expand problem-oriented EHRs to include a person-centered ontology with the use of standardized terms to capture both needs-focused and strengths-based care and documentation. Early reports of strengths documentation were found using a standardized interface terminology and ontology, the Omaha System. Results of two studies demonstrated the feasibility of using the Omaha System for whole-person documentation to capture perception of both problems and strengths.1,6 Findings illuminate the merits of a strength-based approach in chronic illness management and well-being.

Conclusion

Clinical information in EHRs is typically structured by problem-based diagnoses, however, there is emerging documentation of formalized strengths attributes using the Omaha System, which may promote a holistic approach to clinical practice and documentation using a person-centered ontology.

An Examination of Provider Satisfaction with Telemedicine

Robert Garcia, MS1, Adelakun Olayele, PhD1, Wencui Han, PhD2
1DePaul University, Chicago, Illinois, United States of America; 2University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States of America

Introduction

For many organizations medical providers serve as the gatekeepers to adoption and their satisfaction is critical to the success of telemedicine projects (1). While satisfaction remains a complex process understanding the factors that influence it can help influence the design and implementation of projects (2). The goals of this research are to identify common constructs used for examining provider satisfaction with telemedicine. These will be used for the creation of an instrument for measuring provider satisfaction with telemedicine.

Literature Review

Although patient satisfaction with telemedicine has been commonly studied there remains a need to study provider satisfaction (3). Factors that influence patient perspectives of telemedicine may not apply similarly to providers (4). Yet there remain methodological challenges in examining telemedicine satisfaction such as deficiencies in construct development and issues with the meaning of “satisfaction” (3).

Methodology

A survey of the literature was conducted on the United States National Center for Biotechnology Information’s PubMed database for the keywords “telemedicine satisfaction”. 167 studies that included empirical measures and used previously validated instruments were examined. 6 instruments with a total of 106 questions were identified that were used to measure provider satisfaction. A 10 step procedure using a grounded theory approach was used to identify common constructs from these questions (5, 6). The resulting constructs were then matched to similar concepts identified in the literature.

Results and Discussion

Few of the studies examined measured provider satisfaction using previously validated instruments. In some cases, provider satisfaction was measured using instruments previously validated for patient satisfaction or other types of systems. In total 16 categories were identified. These include: Overall satisfaction, treatment, workflow effectiveness, patient-provider relationship, time, cost, information availability, system quality, ease of use, usefulness, reliability, security, relative advantage, facilitating conditions, re-use and recommendation. While there is support for some of these constructs in the literature there are others that need further defining. Although several categories were identified, there may be other factors that contribute to provider satisfaction but were not evaluated in any of the instruments examined.

Conclusion and future work

Future work will expand on the number of instruments tested and attempt to identify additional constructs. These constructs will be further defined using methods described in the literature (5, 6). These constructs will be used to develop an instrument for measuring provider satisfaction that will then be validated and tested at a partner institution.

A Feasibility Study of Answering Clinical Questions Using askMEDLINE at the Point of Care

Kyungsook Gartrell, RN, PhD1, 2, Gwenyth R. Wallen, RN, PhD2, Caitlin W. Brennan, PhD, APRN2, Cheryl Fisher, EdD, RN-B, PhD2, Paul Fontelo, MD, MPH1
1National Library of Medicine, Bethesda, Maryland; 2National Institutes of Health/Clinical Center Nursing Department, Bethesda, Maryland

Introduction
The Internet plays an increasing role as a resource for answering questions in clinical practice. However, the availability of trusted resources and lack of time are known factors that hinder the use of technology at the point of care. Wireless mobile devices may mitigate barriers to access and delivery of reliable clinical information needed to support clinical decision-making among clinicians at the point of care.

PubMed for Handhelds (PubMed4Hh) is a mobile application from the National Library Medicine (NLM) for finding health information from biomedical literature. It features TBLs ("the bottom line" summaries), abstracts, and links to full text articles accessible anywhere the Internet is available. askMEDLINE, one of its features, allows the clinician to search using free-text queries of PubMed. PubMed4Hh is available for iOS and Android devices. The purpose of this study was to test the feasibility of answering clinical questions posed by clinicians using askMEDLINE during clinical rounds at the Clinical Center (CC) of the National Institutes of Health (NIH).

Methodology
This is a collaboration between the Lister Hill National Center for Biomedical Communications, NLM and the NIH CC Department of Nursing’s Research and Practice Development section. This observational study was carried out by a postdoctoral research fellow shadowing clinicians during rounds for one month in the following units: Oncology/Hematology, Oncology/Surgical, Pediatrics, Medical and Surgical Telemetry, and Intensive Care Unit. To simulate real-time conditions, clinical questions raised during rounds were searched using askMEDLINE using an iPad. Search results were evaluated by reading TBL summaries or the abstract, and the most relevant “answers” were selected. Search terms were highlighted in the TBL and abstract for convenience. The process was done independently and the results were not shared with clinicians, hence, not used in clinical decision-making. The clinical questions and search results were recorded electronically on a server at the NLM. No personally identifiable information on the clinicians, patients or CC units were captured. This study was exempted from Institutional Review Board review and approved by the Office of Human Subjects Research Protections of the NIH.

Results
Sixty-six questions were collected during the study period. The average number of questions per day was 3.7 (range: 1 to 8). The majority of questions (90.9%) collected were generated by physicians and 9.1% were from nurse practitioners. Physicians included residents, fellows, and attending physicians in various specialties. More than three-quarters (77.3%) of questions were from the Intensive Care Unit team. More than two-thirds of questions (65.2%) were answerable from the results obtained at the point of care. Almost 35% of questions were not answerable because of lack of time to read the search results, and/or the need to revise the questions when the initial search outcomes were not satisfactory. Reading search results and modifying search terms and resulted in the resolution of about 26% of the initially unanswerable questions. More than half of questions (60.6%) were related to information about medication or treatment, while 21% were questions regarding diagnosis, and 12% were specific to disease entities. The least frequently asked questions (6%) were related to information on patient data or information on instructions for the patient.

Conclusion
Our results show that real-time search and retrieval of reliable and potential useful information for clinical decision-making is feasible at the point of care. Since the information found was not used for clinical decision-making (i.e., the search was done independently by the researcher and not shared with the clinicians), the next phase is to make the search results available to clinicians, and assess its usefulness.
Using Electronic Health Records to Create Morbidity Based Epidemiological Profiles: Closing the Local Morbidity Surveillance Gap in Public Health

Becky Gawelek, MPH¹, Chris Kippes, MS¹, David C Kaelber, MD, PhD, MPH²,³
¹The Cuyahoga County Board of Health, Parma, Ohio, ²School of Medicine, Case Western Reserve University, Cleveland, Ohio, ³Center for Clinical Informatics Research and Education, The MetroHealth System, Cleveland, Ohio

Background
Chronic diseases, including: heart disease; cancer; stroke; diabetes; and arthritis, are the most common and costly of all health problems but they are the most preventable.¹ Population based morbidity data (along with associated risk factors) is one of the largest information gaps that confronts local public health (PH) departments. The purpose of the project is to determine the feasibility of utilizing electronic health records (EHR) for local PH surveillance.

Methods
Through a partnership between a large county health department and a large county hospital system in northeast Ohio, electronic health records (EHRs) (Epic Systems, Verona WI) were used as the primary data source. Inpatient and outpatient records from 1999 to 2014 were initially considered. Select demographic information were used in the generalizability assessments comparing the EHR based population within the county with the 2010 U. S. Census Bureau population statistics for the county. To conduct these assessments, we considered any patient that had an encounter between 2008-2012. Records were geocoded (ArcGIS 10.2.2, Redlands CA) to assign a zip code to the patient. Comparisons in proportions were made between EHR and Census populations with respect to 18 different standard age groups (0-4 years old, 5-9 years old, etc…), two gender groups (male, female), two race groups (white, black), and 51 zip codes. Statistically significant differences were assessed using chi-square analysis (IBM SPSS 23, Armonk NY) and a p-value of 0.001. Given the large sample size (over 300,000 patients), absolute differences of greater than 1.0% were considered to be of interest.

Results
Despite statistically significant differences (p < 0.001), absolute differences of greater than one percent were only found in nine of the possible 36 different age-gender groups (see Figure 1) and nine of the 36 possible age-race groups (data not presented). Zip code level comparisons and disease specific morbidity measures are pending.

Discussion
With multiple healthcare (HC) systems in our community, some baseline differences were anticipated. However, we were encouraged with the number of comparisons that had less than a one percent absolute difference. While optimistic, additional work remains to understand the full or limited value of using this type of data to close the PH morbidity surveillance gap.

Conclusion
EHR records can be a useful tool for local PH surveillance especially for morbid conditions. To help increase generalizability, attempts should be made to include all health system records through the use of health information exchanges. Furthermore, partnerships of this nature between local HC systems and public health can provide valuable experience for public health staff to gain proficiency with working with large datasets. Additionally, it serves as a resource for HC systems that need assistance with non-traditional analysis.

RDF-Based Method to Uncover Implicit Health Communication Episodes from Unstructured Healthcare Data

Pericles Giannaris, MS¹, Zainab Al-Taie, MS¹, Nattapon Thanintorn, MS², Ilker Ersoy PhD², Chi-Ren Shyu, PhD¹,³, Richard Hammer, MD², Dmitriy Shin, PhD¹,²,⁴

¹MU Informatics Institute, ²MU Department of Pathology and Anatomical Sciences, ³MU Electrical and Computer Engineering, ⁴MU Department of Computer Science, University of Missouri, Columbia, Missouri

Abstract

We present an informatics pipeline to discover healthcare communication episodes from unstructured healthcare reports. Our methodology is based on Resource Description Framework (RDF), ontological modeling, and description logic inference for uncovering and quantifying implicit communication episodes. We conclude that inferring these episodes helps to re-engineer healthcare communication structures important for exchanging amplified information.

Introduction

Healthcare communication includes transaction of specimen and medical records, oral interactions, etc. However, not every healthcare communication episode is formally recognized risking inefficient healthcare services, finding these episodes mitigates that risk. Here, with a proof-of-concept study, we propose a method to infer implicit communication episodes from free text pathology reports. The preliminary results show that our method reveals implicit communication both as information and artifact exchanges.

Method

Our informatics pipeline (Figure 1) includes the following components: (i) Ontology, (ii) Vocabulary, (iii) RDF Triplifier, (iv) RDF Store, and (iv) RDF Inferencer.

Ontology: The ontology provides classes and object properties describing the specific relations of terms in unstructured medical text. The classes are Communication Episode; Actor: an entity that serves as a sender or receiver of healthcare communication; and Object: any entity of healthcare communication representing Information or Artifact.

Vocabulary: The vocabulary serves as the basis of the ontology with a domain-specific set of selected terms found in surveyed unstructured pathology reports. These terms represent instances in the ontological classes.

The RDF Triplifier: The RDF triplifier parses with natural language grammatical and syntactical techniques unstructured pathology reports to terms that abide by the ontology and the vocabulary. These terms are semantically marked and encoded to RDF subject, predicate, and object (SPO) triples representing healthcare communication networks.

RDF Store: The RDF Store keeps triples that represent healthcare networks; each node is either an actor or an object linked by arcs symbolizing predicates of communication activity.

RDF Inferencer: The RDF inferrer checks the consistency of the RDF statements with a reasoning engine and infers implicit communication episodes from the RDF statements. For instance, given two RDF statements S₁ - P₁ - O₁ and O₁ - P₂ - S₂ the RDF inferrer collapses these statements to one and infers S₁ - P₃ - S₂. In general, the RDF inferrer uncovers implicit communication episodes by computing paths between actors in RDF networks.

Uncovered Communication Episode: It represents the output of the RDF pipeline: S₁ - P₃ - S₂

Results and Conclusion

We processed a sample of fifty unstructured pathology reports and our methodology uncovered five implicit healthcare communication episodes. For instance, one of the communication episodes that has been uncovered by the RDF pipeline is PathologyDepartment Send ExcisionalBiopsy, ExcisionalBiopsy ReviewedBy Dr.InConsultation; by collapsing the statements it infers that PathologyDepartment Send Dr.InConsultation. Therefore, we conclude that our RDF informatics pipeline infers healthcare communication that is not formally recognized and represented as acyclic communication networks.

DeBakey VA Medical Center, Houston, TX and Section of Health Services Research, Department of Medicine, Baylor College of Medicine, Houston, TX; ²School of Biomedical Informatics, University of Texas Health Science Center, Houston, Texas

Introduction

A recent Department of Health and Human Services rule now gives patients direct access to their completed laboratory test results.¹ Additionally, Meaningful Use prioritizes patient online access to health information. While patient portals are now being implemented to provide patients access to their health information, little is known about patients’ needs when accessing their test results via the portal. Test result access is of high interest to patients and provides an opportunity to involve patients in preventing abnormal test results from being missed, a common patient safety concern. We conducted a mixed-methods study to explore patients’ experiences when accessing their test results via patient portals.

Methods

We recruited eligible participants (adults who viewed a test result in their portal) at four settings: an academically affiliated private general practice, a primary care community clinic, a network of private-practice physicians and an urban Veterans Affairs facility. We posted fliers at each site and a research coordinator approached patients in each clinic for potential recruitment. To boost sample size, we obtained a list of all portal users at one site and sent recruitment letters to a random sample of 450 patients (data collection is ongoing). Interviews were transcribed and then coded independently by the first and second author using content analysis. Descriptive statistics were used to summarize the survey data.

Results

Thus far, we have conducted five semi-structured interviews, three observations, eight structured interviews, and 33 surveys with patients. Our sample consists of 50% women and is 51.6% white, 28.1% black, and 12.5% Hispanic. Nearly two-thirds (65.6%) had one or more chronic illness and 57.8% were 50 years or older. In interviews and observations, use of the portal for viewing test results emerged as one of the dominant functionalities. While respondents valued access to their test results, many indicated that they needed additional contextual information to understand what the result means for their health and specific instructions for next steps for both normal and abnormal results. The majority of survey respondents were aware as to why the test was conducted (27.3% for routine visits and 57.6% for a specific health condition). To determine if the result was normal or abnormal, 40.0% looked at the range, 25.7% received the result from a clinician before they saw it in the portal, 6.1% saw a visual cue such as flag or highlight, and 6.1% were already familiar with the test. Although 81.8% indicated they understood the result upon viewing it in the portal, most sought additional clarification through online search (66.7%) and/or contacting their doctor by phone or secure message (51.9%). About one-third indicated feeling negative emotions, such as confusion or anxiety, after receiving the test result in the portal for both normal and abnormal results.

Conclusions

Our study, to our knowledge, provides one of the first mixed-method studies examining a new area of research, patients’ experiences of receiving test results through the patient portal. Providing patients access to their test results via portals should be accompanied by strategies to help patients interpret and manage results received. Additional work must devise strategies to leverage this technology to improve patient understanding of their overall health and next steps.

An Adaptive Conjoint Survey to Select Potential Features of a Technology Based Self-Management Intervention

Bryan S. Gibson, DPT, PhD1, Ana Sanchez Birkhead, PhD2, Elisa Amador, BSN2, Nancy Allen, APRN, PhD2

1University of Utah Department of Biomedical Informatics, Salt Lake City, UT; 2University of Utah College of Nursing, Salt Lake City,

Background: In order to maximize the effectiveness of technology based behavioral interventions, designers must ensure that the system’s features promote adoption and long-term engagement. Currently, the features included in most behavioral interventions are based on designers’ expertise or preferences, or qualitative input from potential end users. The goal of this project was to determine whether the adaptive conjoint survey method, which captures individuals’ relative preferences for features and attributes, could be used to inform design decisions in developing a technology-based self-management intervention.

Methods: To develop the list of potential intervention features, we held via a series of six focus groups with Hispanic community members with Type 2 Diabetes Mellitus (T2DM). In these meetings, attendees told their “diabetes stories.” The group then collaboratively identified common problems that people face in dealing with T2DM and discussed potential solutions. These solutions were then mapped to potential intervention features (including both well-established and novel functionalities).

We then developed an adaptive choice-based conjoint survey to determine which features were most desired and the modality by which people preferred they be delivered. The survey began with a “build your own” (BYO) section in which users chose the features they might be interested in (e.g., “something to keep track of my diet,” “something to monitor my activity levels,” etc.). Of the features that individuals chose, the adaptive survey then presented different possible configurations of the system using different modalities (e.g., reminders using text messages vs. email vs. phone calls). The survey was administered on a tablet computer in either English or Spanish.

In analyzing the data, we first calculated the mean importance for each potential intervention feature and then ran bootstrapped market simulations to ascertain the ideal (preference maximizing) configuration of features.

Results: 176 individuals initiated the survey and 135 provided complete data. Participants largely self-identified as Hispanic (98.5%), completed the survey in Spanish (94.7%), were mostly female (62.9%), middle aged (mean age 51 years, SD=13.3) and had limited access to healthcare: only 35.5% reported having health insurance. However, they had high ownership of TVs (97.7%), Smartphones (81.5%) and computers (63.7%).

The figure below depicts the mean importance for each potential intervention feature, notably TV ad replacement was the preferred amongst potential novel intervention features that our group is considering developing.

The market simulation, estimated that the ideal configuration of our potential system would address the preferences of 72.4% of potential end users. Most importantly, these simulations showed that whenever possible participants preferred functions via a smartphone.

Conclusion: Adaptive Choice Based Conjoint analysis provides a means to quantify end user preferences to drive system design decisions. In this project it helped to prioritize development of a novel intervention feature.
VIP: A Framework for Mining Clinical Concepts Using Knowledge Author Ontologies and Apache UIMA

Thomas Ginter, BS\textsuperscript{a,b}, Lalindra De Silva, MS\textsuperscript{a,b}, Olga V. Patterson, PhD\textsuperscript{a,b}, William Scuba, BS,\textsuperscript{b} 
Wendy W. Chapman, PhD\textsuperscript{a,b}, Scott L. DuVall, PhD\textsuperscript{a,b} 
\textsuperscript{a}VA Salt Lake City Health Care System; \textsuperscript{b}University of Utah, Salt Lake City, UT

Abstract
Mining domain-specific concepts from large collections of clinical text is an increasingly common task that facilitates many clinical studies. While existing Natural Language Processing (NLP) systems allow concept extraction, not many of them enable the full spectrum of domain-specific concept definition and concept extraction. To this end, we present a framework where clinical concept definition is handled through a sophisticated clinical ontology definition tool and the concept extraction is provided through an integrated Apache UIMA NLP pipeline.

Background
Extracting domain-specific concepts from large collections of clinical corpora is frequently needed for many clinical studies. Common approach is to define a set of domain-specific concepts, which is often carried out by domain experts, using a domain ontology creation tool. While many of these tools cover broad domains, it is often beneficial to work with more domain-specific tools that can exploit external clinical resources in the concept definition phase. Knowledge Author\textsuperscript{1} (KA) is one such tool that enables easy definition of domain-specific clinical concepts and allows users to augment their concept ontologies using existing resources. However, KA does not include the capability for a downstream NLP application to extract instances of these concepts from large corpora.

Methods
In this work, we present a framework named VIP, which facilitates mining of KA-defined clinical concepts in large text collections. The general architecture of our framework is presented in Figure 1. The input to our framework is a KA-authored clinical ontology in OWL format. KA allows concepts to be augmented with synonyms, abbreviations, CUI codes, etc. using the UMLS Metathesaurus. The VIP Decipher module extracts concept variables and relationships from the OWL representation. It then serializes these variables into a Leo service definition file that is used by VIP to create an NLP pipeline utilizing Leo framework based on Unstructured Information Management Architecture Asynchronous Scaleout (UIMA AS).\textsuperscript{2,3} The Leo service defines a series of UIMA annotators using the resulting service in UIMA AS for processing of the clinical data. A Leo client is executed from the command line to pull data for processing and provide reporting and output functions once the service completes data processing.

Figure 1: VIP Workflow

Knowledge Author also allows the users to qualify and quantify the clinical concepts and their associated contexts. For example, a user can define the clinical concept fever, attach it to UMLS concept C0015967 fever and create a complex variable, which includes attributes, such as experiencer [patient or other] and temporality [historical, present, etc.]. To enable extraction of the concept instances that satisfy these contextual attributes, we also implemented ContextAnnotator – a UIMA annotator based on the Context\textsuperscript{2} algorithm - to filter and retain only the desired instances.

Conclusion
In this work, we presented a framework for integrating the process of defining clinical concepts with the process of mining those concepts in large text collections. Our framework exploits the benefits of Apache UIMA for creating NLP pipelines that can process large text collections and we highlighted its capabilities in retaining relevant concepts.

Migration to Electronic Documentation – Benefits Seen at a Community Hospital

Derek Goodyear D.O.
East Liverpool City Hospital, East Liverpool, OH, USA

Introduction
The past decade has seen a huge increase in the use of electronic health records (EHRs) in the US. The goal is primarily to improve patient care and safety, but also to save hospitals money\(^1\). This may occur through reducing the need for transcription services and by improving communication to patient care teams. Our goal was to see if using our EHR instead of a transcription service would show any such benefits.

Methods
Over the last year, East Liverpool City Hospital, a 110 bed community hospital in Eastern Ohio, has undergone a transformation in their transcription process. Until June 2015, all reports (H&Ps, consultations, progress notes, discharge summaries, etc.) were recorded through a phone dictation service. Starting in June 2015, a transition was made to electronic notes within the Meditech EHR. This was initially rolled out to the hospitalist service followed by general surgery and then to other specialties.

Training led by Information Services and myself was provided to the physician staff to assist in this process. During this time, there were multiple sessions where staff physicians would document on mock patients and decide on what was important to include in the Review of Systems, Physical Exam and other sections. Over a 3 month trial period, progress, operative and post-op notes were migrated from transcription to electronic notes, followed by H&Ps and discharge summaries.

![Figure 1. Total Line Count Use in 2014 and 2015](image)

Results
Records were kept of how many total lines were being dictated and there was a significant drop after the change. The total cost to the hospital also decreased, saving over $30,000 in a period of 6 months. Because of this cost savings, a renegotiation was made with the transcription vendor. Now the electronic documentation is being rolled out to more providers and departments within the hospital. With the new documentation procedures, the primary service and all consulted specialists know exactly what each other are thinking right after they submit their notes. Time spent by physicians contacting each other for status updates was perceived to have decreased without compromising patient care, although this was not specifically recorded.

Conclusions
EHR documentation leads to immediate publication of records to facilitate physician communication and improve patient care; in comparison, the dictation system can take up to 72 hours, delaying important communication between physicians. We also found that electronic documentation can save hospitals a significant amount of money each year.

The Impact of Emergency Department Census on the Decision to Admit

Jillian K. Gorski, BS¹, Robert J. Batt, PhD, MBA², Erkin Otles, BS³, Manish N. Shah, MD, MPH³, Azita G. Hamedani, MD, MPH, MBA³, Brian W. Patterson, MD, MPH³
¹University of Wisconsin School of Medicine and Public Health, Madison, WI; ²University of Wisconsin-Madison, Wisconsin School of Business, Madison, WI; ³University of Wisconsin-Madison, BerbeeWalsh Department of Emergency Medicine, Madison, WI

Introduction

The Emergency Department (ED) serves as a “gatekeeper” for inpatient services. Hospital admissions rose 4% from 2003 to 2009, and EDs were responsible for almost all of the rise in admissions¹. It is known that ED physicians’ decision to admit or discharge patients has a significant impact on treatment costs². Furthermore, as ED utilization rises, the phenomenon of crowding - the operation of the ED beyond its resource capacity - can be observed. As an impact of the Affordable Care Act, increasing attention is being directed to system-level outcomes, while physician responses to crowding factors, such as whether admission decision are affected, remain less well characterized. The electronic health record (EHR) stores a wealth of operational data, and this information has not previously been used to examine this relationship.

Methods

We utilized a novel operational dataset built from event times recorded in the electronic health record to determine the effect of ED crowding on admissions decisions made by ED physicians. We performed a retrospective analysis using 49,487 adult patient encounters taken over an 18 month time period at a Level 1 trauma center. Waiting room census and physician load were calculated at the time of physician assignment. Univariate and multiple logistic regression models were created to assess the association between these census variables and the disposition decision, controlling for potential confounders.

Results

Of the encounters included in the analysis, 37% resulted in a hospital admission. Both census measures showed a statistically significant positive association with admission; the OR (odds ratio) per patient increase for waiting room census was 1.011, (95% CI: 1.001-1.020), and the OR for physician load census was 1.010, (95% CI: 1.002-1.019). Table 1, below, shows the output of the regression model at increments of patient census, illustrating the combined effect of waiting room census and physician load on likelihood of admission.

Table 1. Predicted likelihood of admission at given census values in the combined multiple logistic regression

<table>
<thead>
<tr>
<th># of patients</th>
<th>Waiting Room Census</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>0</td>

<td>35.3%</td>
</tr>
<tr>
<td>8</td>
<td>36.6%</td>
</tr>
<tr>
<td>16</td>
<td>37.9%</td>
</tr>
</tbody>
</table>

Conclusion

Our results indicate that increased crowding may result in potentially avoidable ED admissions. This suggests that disposition decisions in the ED are influenced not only by objective measures of a patient’s disease state, but also by workflow related concerns. Further, we were able to study this relationship exclusively utilizing data retrospectively abstracted from the EHR.

Electronic Messaging During Patient Care Coordination

Erika Green, MD¹, John T. Finnell, MD MSc FACEP¹, Emily C. Webber, MD FAAP²
Regenstrief Institute for Biomedical Informatics, Indianapolis, Indiana; ²Riley Hospital for Children at Indiana University Health, Indianapolis, Indiana

Introduction
Many communication tools are used in healthcare with a mix of benefits and limitations. Paging systems are neither efficient nor secure, EHR Messaging tools are not universally available, phone/callback cycles disrupt workflow. Text messaging has become a popular choice for fast communication in private and business settings, and is also increasingly utilized by medical staff during patient care.¹ But despite the variety of tools available, healthcare communication continues to experience a significant tug of war between efficiency and security. This study seeks to 1) describe the communication tools used currently by team members involved in patient care coordination and 2) find provider attitudes toward the efficiency and security of each.

Methods
Web-based, anonymous, IRB approved survey was distributed to physicians and advanced care practitioners, pharmacists, and case managers at a 19 hospital health system with multiple ambulatory centers.

Results
704 (31% of all invited) team members responded to our survey. When contacting medical staff, pagers are used predominantly by all groups. Phones are the most common tool to communicate with other team members. Staff working in an outpatient setting utilize EHR Messaging twelve times as often as the inpatient group (26.25% vs 2.20%, p=0.05), while the inpatient group prefers to use text messaging (15% vs 8%, p=0.05) and pagers (52% vs 21%, p=0.05). Staff in outpatient setting also finds EHR Messaging to be the most efficient and secure tool. Overall, twice as many respondents chose text messaging to be most efficient (202, 34%) compared to EHR Messaging (109, 18%) or phones (118, 20%), however, overwhelming majority perceived EHR Messaging (300, 50%) to be the most secure available tool. Because communication best practices are still under development at this institution, the results reflect employee’s unguided use and preferences.

Table 1. Communication tool utilization and attitudes on security and efficiency.

</tr>
</tbody>
</table>

*Substantial vote (at least 2x the response rate of the next highest vote)
** Overwhelming vote (at least 3x the response rate of the next highest vote)

Conclusion
Most of the communication tools utilized by inpatient team during patient care today are perceived to be neither efficient, nor secure. There is a significant gap in the inpatient environment between efficiency and security that may be narrowed by evaluating the role of secure text messaging. Efficiency and utilization may also be improved by clarifying standards for best use for each communication method.

Automatic Workflow Extraction Using Sequential Pattern Mining and Electronic Medical Record Usage Data

Tim A Green¹, Michael Phinney², Chi-Ren Shyu, PhD¹,²,³,⁴
¹Informatics Institute, ²Department of Computer Science, ³School of Medicine, ⁴Department of Electrical and Computer Engineering, University of Missouri, Columbia, MO

Understanding sequences of events is paramount to developing a picture of how clinicians interact with Electronic Medical Records (EMR). Applications for EMR workflow include measuring productivity to help target training, and dynamic EMR experiences based on predicted actions. Common methods of assessing clinical workflow include video recording, direct observations, or directed user experience testing in a controlled environment. Computational methods can also be applied, such as sequential pattern mining [1], workflow mining [2], and graph-based mining [3]. To apply these methods, reliable sources of trace data that mirror clinician behavior within the EMR must exist. Often this trace data can be collected from debugging log files of computer systems. Benefits of computational workflow discovery include elimination of the observer effect, a potential for greater amounts of data for analysis, and the ability to include timestamped data from other ancillary systems in observed workflows.

The EMR at University of Missouri Health generates log data that is suitable for use in computational workflow discovery. We developed a system that extracts meaningful frequent sequential patterns from a combination of EMR log data and Admit, Discharge, and Transfer (ADT) data. One day’s worth of EMR log data from the middle of the month, and one months’ worth of matching ADT data for outpatient clinic visits were used, consisting of approximately 1.25 million records. EMR and ADT data were collated into 14,219 sequences that mirrored a physician’s interaction with the EMR. We looked for patterns indicating a predilection for use of the EMR before or after a patient visit to a clinic. ADT records were tagged with categorical timing information as it related to EMR interaction (Table 1). ADT time categories were 1) within 24 hours, 2) one to seven days, and 3) greater than seven days before or after EMR use. Sequential pattern mining running on Apache Spark [4] produced 14,990 frequent patterns, with a minimum support threshold of 0.20. There were many interesting frequent patterns identified that show the most commonly occurring EMR modules used, and in which order. We focused on three meaningful workflow patterns that included an element related to ADT (Table 1). We discovered that all frequent patterns over the support threshold included use of the EMR after a patient arrived at clinic. No frequent patterns emerged showing EMR use before clinic arrival, indicating that using the EMR as a preparatory tool may not be occurring frequently, or by physicians.

In this preliminary work, we have demonstrated that this system is capable of identifying commonly occurring patterns of EMR use. Future work will include generation of workflow graphs based on discovered sequences using sequential pattern mining, and use of sub graph mining techniques to look for more complex workflow patterns.

A Scalable Dataset Indexing Infrastructure for the
bioCADDIE Data Discovery System

Grethe, PhD1, Burak Ozyurt, PhD1, Hua Xu, PhD2, Xiaoling Chen, PhD2, Ruiling Liu, MS2, Anupama Gururaj, PhD2, Hyeon-eui Kim, RN, MPH, PhD1, Yueling Li, PhD1, Claudiu Farcas, PhD1, Alejandra Gonzalez-Beltran, PhD3, Philippe Rocca-Serra, PhD3, Ian Fore, DPhil4, Ronald Margolis, PhD4, George Alter, PhD5, Susanna-Assunta Sansone, PhD3, Lucila Ohno-Machado, MD, PhD1

1Univ. of California, San Diego, CA; 2Univ. of Texas Health Science Ctr. at Houston, TX; 3Univ. of Oxford, UK; 4National Institutes of Health, Bethesda, MD; 5Univ. of Michigan, Ann Arbor, MI

Abstract
The biomedical and health care Data Discovery Index Ecosystem (bioCADDIE) is an NIH funded Big Data to Knowledge (BD2K) project which is building a prototype (DataMed; http://datamed.org) for data discovery analogous to PubMed. A core component of DataMed is a scalable dataset indexing infrastructure that aggregates metadata from federated repositories and community aggregators.

Introduction
The development of bioCADDIE was started in 2015 with three primary goals: 1) Help users find sharable data; 2) Build a prototype (software system) for Data Discovery, called DataMed to reflect the analogy with PubMed; and 3) Engage the community and interoperate with other systems. The indexing infrastructure of DataMed maps disparate metadata from the diverse data sources into a unified specification provided by various working groups organized by bioCADDIE and related communities. This pipeline involves an automated component that provides controlled translation and curation of metadata using special tools such as a transformation language and JSON-Path.

Overview of the bioCADDIE Dataset Indexing Infrastructure
Since many indexing projects already exist and many repositories are already maintaining detailed metadata about the data sets they host, our goal was to leverage all this work and build a cross-repository, cross-indices index. This umbrella system was designed to interoperate with these indices and repositories, and not to replace them. The overall infrastructure (see Figure) consists of the following components:
• A data and metadata extraction system that is able to connect to various repositories and data aggregators. All metadata information is converted to JSON documents for each dataset being described and stored in MongoDB.
• A messaging infrastructure, utilizing Apache ActiveMQ, distributes dataset description documents from MongoDB, and depending on their status value, dispatches them to persistent point-to-point queues.
• A collection of multiple concurrent consumers retrieve documents from MongoDB, process them, update the job status and save them back. Consumers can be written using the STOMP protocol. Documents are transformed, to align with the bioCADDIE metadata model, and processed by a collection of modules that enhance the metadata records.
• Fully processed documents are then exported to an ElasticSearch endpoint that serves the dataset indices via RESTful services.

Current Status
The indexing pipeline for DataMed currently contains dataset description documents for 649,055 datasets from 23 different repositories that include 10 different data types. Work continues to incorporate new repositories to expand the content as well as on validating, testing and improving the metadata descriptions.

Acknowledgements
bioCADDIE is funded by NIH U24AI117966 and has many more team members and collaborators than would fit the author list for this abstract. They are listed in our web site at http://biocaddie.org.
Evaluating Google Translate for Facilitating Survey Translation from English to Mandarin

Jia-Wen Guo, PhD, RN
University of Utah College of Nursing, Salt Lake City, Utah, U.S.A.

Abstract
This study evaluated the translation quality of Google Translate in translating a survey from English to Mandarin. A 33 item survey was used as an example to evaluate the outcome from Google Translate. An acceptable Google Translate outcome can be used a starting point for researchers although the translation quality was not highly satisfied. Cultural difference and the region where the language is used contribute to challenges in the translate process.

Introduction
A great need exists to translate surveys into the language of the culture being studied. The task of translation is not simply to translate word for word from one language to another. The main challenges are to produce a translated surveys that is the linguistic and cultural equivalent of the original and to find experienced and well-qualified translators within limited project time to complete the repeated forward–backward translation procedure. Machine translation systems can be used to support the iterative and time-consuming translation process. Google Translate, a free online machine translation tool, has been tested in clinical and research for facilitating the translation work, but it was unclear how it can support in survey translation.

Purpose
The purpose was to evaluate the translation quality of Google Translate in translating a survey from English to Mandarin.

Methods
This was an observation study from both quantitative and qualitative perspectives. The Pain Care Quality Surveys (PainCQ), a valid survey for measuring the quality of pain care with 33 items published in U.S. English,1,2 was used as testing material. The quality of translation including intelligibility of translations, structural accuracy, and usefulness of the translation was quantitatively evaluated by two nursing researchers (one from Taiwan and one from Mainland China—both fluent in English and Mandarin). Regarding the qualitative evaluation, three nursing researchers provided the feedback of the use of Google Translate.

Results
The Google Translate outcome showed the average level, 3 out of 5, on intelligibility of translations, structural accuracy, and usefulness of the translation. The number of word per question, the sentence complexity, and readability of the sentence did not show a statistically significant influence on the translation quality of Google Translate. However, the Google Translate outcome still can be used a starting point for researchers although it does not have a satisfied result of the translation quality.

Discussion
The challenges of translating the instrument from one language to another are complicated. A sentence with a few or many words may have the same challenge to Google Translate and human translators. Cultural difference and the region where the language is used contribute to challenges in the translate process.

Roudebush VA, Indianapolis, IN; 2Department of Medicine, Indiana University School of Medicine, Indianapolis, IN; 3Regenstrief Institute, Indianapolis, IN; 4Department of Biostatistics, Indiana University School of Medicine, Indianapolis, IN; 5Fairbanks School of Public Health, Indiana University, Indianapolis, IN; 6Northwestern University School of Medicine, Chicago, IL

Introduction: If health information exchange (HIE) has enough reach into the population, HIE programs may improve coordination of care through the sharing of medical information across health care systems. The VA/DoD Virtual Lifetime Electronic Record (VLER) program is an HIE program administered in cooperation with community partners, including the Indiana Health Information Exchange (IHIE). By sharing data collected about hospital admissions across different health care systems, HIE has the potential to improve post-discharge care. By sharing data about outpatient care, HIE has the potential to reduce ambulatory-care sensitive hospitalizations.

Methods: The study population included all Veterans who were seen at least once in the year prior to HIE implementation at a tertiary VA medical center in Indianapolis. Among these patients, all VA and non-VA (IHIE) hospital admissions were measured for 1 year before and 1 year after implementation of the HIE program. Using this information, we first identified the data source (VA and/or non-VA) identifying each hospitalization, and then summarized admissions at both the hospital and patient level because a single patient could be hospitalized more than one time. We also compared the rate of hospitalization for ambulatory-care sensitive (ACS) conditions among those who were and were not enrolled in the VLER program, before and after HIE implementation, using a “difference-in-differences” zero-inflated Poisson model.

Results: More than a third of Veterans’ hospital admissions were identified at both the patient and hospital level using non-VA data (Table 1).

The difference-in-differences in the rates of ACS hospitalization (per 100,000 population) was not statistically significant among patients who were enrolled in the VLER program (4,694 before vs. 4,633 after implementation) compared to those who were not enrolled in the VLER program (3,090 before vs. 3,184 after implementation).

Conclusions: The high proportion of Veterans’ hospital admissions that can be detected using data from a regional HIE suggests the potential for care coordination after discharge. Making use of shared electronic data, pro-active health care teams may be able to improve medication reconciliation, completion of follow-up tests, and other post-discharge coordination activities across health care systems. However, the impact of HIE use in primary care upon ambulatory-care sensitive conditions was not detectable within the first year of program implementation.
Exploratory Analysis of Marketing Vs. Non-Marketing Tweets on E-Cigarettes

Sifei Han, B.S. and Ramakanth Kavuluru, Ph.D.

1Division of Biomedical Informatics, Department of Internal Medicine, University of Kentucky
2Department of Computer Science, University of Kentucky

Introduction: The broad topic of electronic cigarette (e-cig) use has become a major fault line among clinical, behavioral, and policy researchers who work on tobacco products. There are arguments on either side given their reduced harm aspect can help addicted smokers quit smoking while the long term effects of e-cigs are not yet thoroughly understood. Furthermore, based on recent news releases from the CDC, there is an alarming increase of e-cig use by never smokers particularly middle and high school students who might be acquiring nicotine dependence. Twitter has emerged as one of the most popular microblogging platforms since its introduction in 2006 especially among teenagers. A major amount of chatter on e-cigs on Twitter surrounds their marketing by vendors making it generally difficult to analyze regular e-cig tweets (from the general public) that are not dominated by marketing noise. In this effort, we build a text classifier that identifies non-marketing tweets on e-cigs and employ topic modeling techniques to extract popular themes in non-marketing tweets from a corpus of over 500,000 e-cig tweets. Our main objective is to accurately separate marketing and non-marketing tweets and explore topics in the latter group.

Methods: A total of 540,579 tweets were collected during a seventh month period (4/15 – 10/15) using Twitter’s streaming API with a set of e-cig related keywords: electronic-cigarette, e-cig, e-cigarette, e-juice, and e-liquid including variants where hyphens are replaced with either spaces or empty strings. From this dataset, both the authors independently hand-labeled a random collection of 1000 e-cig tweets as marketing or non-marketing. The labels matched for 87.3% of the tweets with an inter-annotator agreement of \( \kappa = 0.726 \) indicating substantial agreement. The disagreements for the 127 instances where labels didn’t match were resolved in a face to face discussion to obtain a consolidated dataset of 1000 tweets. We observed that 48.6% (95% confidence interval of [45.51%, 51.70%]) are marketing tweets; that is, close to half of the tweets were marketing related. We pre-processed tweets by removing stop words and replacing user mentions and URLs with two separate special tokens. We built a logistic regression classifier with n-grams, tweet vector representations [1] with dimensionality of 100, and numbers of hashtags and URLs as features. We computed average performance measures based on 100 distinct 80%-20% train-test splits of the dataset. Our model achieved a mean F-score of 88.7% (95% confidence interval [88.37%–89.04%]) for the non-marketing class. We applied our model to all the tweets in the dataset and conducted topic modeling based [2] and key phrase based analyses on tweets identified as non-marketing by our model.

Results: Our method resulted in a total of 269,538 (51% of the full dataset) non-marketing tweets. We manually analyzed the top 20 topics (note that topics are usually represented as ranked sequences of tokens) resulting from our topic modeling experiments. As expected, none of the topics were related to marketing e-cigs although there was one topic about e-cig reviews, the closest to a marketing theme. We found one topic on safety issues in using e-cigs specifically about exploding cartridges. There were three topics related to health policy and regulation of e-cigs, one each on epidemiological and business/financial aspects of ecigs, and five topics on health effects of e-cig usage including scientific research conducted in the field. We were not able to clearly ascertain themes for five topics. A similar analysis for marketing tweets revealed topics mostly on deals, promo codes, free shipping, and particular e-smoking devices. Given the concern that adolescents might be at risk of getting addicted to nicotine, we searched both marketing and non-marketing tweets with words such as teens, teenagers, kids, youth, child, and children. We observed that 3% of non-marketing tweets contain these keywords while only 0.15% of marketing tweets have them. This is not surprising since most of the marketing is done implicitly to appeal to adolescents (flavors, packaging) but the seriousness of the issue has deservedly gained traction in the general populace.

HIE Expansion Improves Identification of Frequent Hospital Visitors

Xiao Han, MD1, Tina Y. Lowry, MS1, George T. Loo, DPH1, Elaine J. Rabin, MD1, Zachary M. Grinspan, MD2, Lisa M. Kern, MD, MPH2, Gilad J. Kuperman, MD, PhD3, Jason S. Shapiro, MD1.

1Icahn School of Medicine at Mount Sinai, New York, NY; 2Weill Cornell Medical College, New York, NY; 3New York-Presbyterian Hospital, New York, NY

Introduction

Health information exchange (HIE) provides benefits through primary clinical use at the bedside and increasingly through various forms of secondary use of HIE data. The importance of HIE is increasingly recognized, but we are still far from achieving a nationwide HIE. Our objective was to show that increasing the size of an HIE network allowed increased identification of frequent ED users, demonstrating that data from increased HIE size has a secondary use in quality measurement that more accurately reflects the way that many patients access healthcare across multiple, otherwise unaffiliated provider organizations within a region.

Methods

Healthix is a regional HIE that comprised 31 hospitals in the New York metropolitan area and Long Island at the time of this study. NYCLIX, a precursor HIE and subset of Healthix, comprised 10 hospitals. Using de-identified Healthix data from 03/01/2009 to 02/28/2014, we compared the detection rate of frequent ED users from three sets of data: hospital-specific data (treating each hospital as an independent dataset), NYCLIX-wide data, and Healthix-wide data. All ED visitors were divided into three mutually exclusive cohorts: 1) high frequency (HF) ED users, who had more than 4 visits in any given 30-day period, 2) medium frequency (MF) ED users, who had more than 4 visits in any given year, 3) infrequency (IF) ED users, who had less than 4 visits in any given year. The results were compared for statistical significant using Chi square and Kruskal-Wallis.

Results:

Healthix (31-site HIE) had 3,627,490 unique ED patients and 8,078,624 ED visits; NYCLIX (10-site HIE) had 1,686,904 unique ED patients and 3,855,747 ED visits. Of the Healthix patients, 1.45% (52,544 patients) were HF users and 6.20% (224,848 patients) were MF users. Of NYCLIX patients, 2.00% (33,672 patients) were HF users and 6.47% (109,124 patients) were MF users. We identified 10.1% more frequent ED users (142,796 versus 129,637) using NYCLIX, and 18.6% more frequent ED users (277,392 versus 233,888) using Healthix, compared to hospital-specific data. During the study period, using Healthix, we were able to identify 409 patients with more than 100 ED visits, and 44 patients with more than 300 ED visit. However, there were no patients with more than 300 ED visits identified with hospital-specific data. The median numbers of total visits from the Healthix dataset were as follows: IF 1-2 (median[IQR]), MF 7-9, and HF 9-16 (p<0.001 with Kruskal-Wallis test). The percentage of patients who visited more than 1 ED were as follows: IF 9.4%, MF 40.5%, and HF 44.8% (p<0.001 with Chi square test).

Conclusion:

Expanding HIEs improves identification of frequent ED users, especially very frequent users with hundreds of visits. We suspect that similar results would be found when other measures that may be affected by patient crossover visits are applied to HIE datasets. Analyses such as these, and more advanced services like notifications, that use HIE as a new, community-wide, real-time clinical dataset may allow provider organizations and the healthcare system to allocate resources such as care management more effectively. The goal of this study was to provide evidence to support expanding HIE to larger nodes including more patients and hospitals. Improving detection rate of frequent ED users is an example of how larger HIEs can identify problems that can otherwise be missed by hospital-specific data or smaller HIEs.
Overcoming interoperability challenges of community-based health interventions

Saira N. Haque, PhD, MHSA, Shellery Ebron, MSPH, Westleigh A. Quattrone, MA, Robert Bailey, BA, Barry Blumenfeld, MD, MS

1RTI International, Research Triangle Park, NC, U.S.A

Abstract

This reports on analysis of three Health Care Innovation Award (HCIA) grantees to determine the factors influencing health information exchange (HIE). Findings indicate that these community-based health interventions could facilitate HIE by understanding and anticipating the impact of technical implementation, organizational support, and governance. Organizations leveraging HIE should familiarize themselves with how federal investment in HIE infrastructure, and local pilot activities, have supported using information across establishments to support care coordination.

Introduction

Community-based health interventions use information exchange to support population health. However, disparate systems make aggregating and using data from multiple sources challenging. The purpose of this study was to learn how three community-based health innovations overcame data interoperability challenges to facilitate HIE. The Health Care Innovation Awards (HCIA) were granted by the Centers of Medicare and Medicaid Services (CMS) to organizations with innovations designed to enhance the quality of healthcare, improve health outcomes, and reduce the cost of care through the use of care coordination/patient navigation, health information technology (HIT), and the delivery of preventive or health promotion services.

Methods

We used information gathered during the course of a larger program evaluation including grantee-prepared progress reports, site visits, and telephone interviews, which were then coded and thematically analyzed in NVivo, a qualitative analysis program. We analyzed data from 3 HCIA awardees whose interventions focused on health information exchange.

Results

We found that HIE was influenced by technical factors, organizational support, and governance. Technical factors included file size, fields not being used in the same way, errors in exchange and infrastructure. Interoperability challenges included stakeholders at different organizations interpreting standards differently, populating data fields differently across systems, and varying familiarity with information exchange across organizations exchanging data. Organizations can facilitate health information exchange by sharing with a central coordinating organization, having regular inter-organizational meetings and regular review of error reports. In addition, community-based resources such as implementation guides and coordinated training may facilitate HIE.

Conclusion

Our findings suggest ways in which healthcare organizations can facilitate health information exchange within their communities to facilitate community-based health interventions. Organizations are increasingly leveraging information exchange for population health interventions. Federal investment in HIE infrastructure, EHR uptake through the Meaningful Use Incentive Program and local pilot activities have supported using information across organizations to support care coordination. This work can aid policymakers and providers in developing and using technical and operational infrastructure needed to implement information exchange innovations. Progress toward interoperability and successful population health projects that leverage it have the potential to improve care, improve health outcomes, and lower the cost of health care.

Visual Optimization of a Provider Dashboard for Patient Reported Outcomes in Surgical Spine Patients

Mary Beth Hasselquist MD1, Elizabeth Austin MPH1, Brett Fey1, Liz Kellogg MPH1, Cynthia LeRouge, PhD1, Andrea Hartzler PhD 2, David R Flum MD,MPH 1, Danielle C. Lavallee PharmD, PhD1
1University of Washington, Seattle, WA   2 Group Health Research Institute, Seattle WA

Introduction
With the rising use of patient-reported outcomes (PROs) in clinical practice, there is an increasing need to understand the data visualization needs of clinical teams to support their use of PRO data for both individual patient decision-making and broader population health applications. Previous research has indicated that end users of PRO data have different needs with regards to data visualization based on how the data will inform decisions and the PRO workflow implemented within their clinical settings. The CERTAIN Hub is a patient-reported outcomes web-based platform developed by investigators at the University of Washington designed to collect and report PRO data (e.g., pain, function) and risk factors (e.g., smoking, age) for patients undergoing cervical and lumbar spine fusion surgery. One feature of the system is a prototype dashboard that displays aggregate, de-identified PRO data for use by clinicians and staff. Heuristic evaluation where usability experts review user interfaces against accepted usability principles is one form of usability assessment. This study showcases improvements resulting from heuristic evaluation to be considered in PRO design guidelines.

Methods
We conducted a heuristic evaluation (as part of a human-centered design approach to dashboard development) of the CERTAIN Hub dashboard to identify opportunities to optimize the visual display of PRO data. This evaluation was led by a visual design expert utilizing heuristic principles based on visual science, graphical perception and cognitive theory. Recommendations from the heuristic review were then contextualized with feedback obtained from users during their initial implementation period of the dashboard. Users were exposed to both before and after visualizations (see Figure 1).

Results
The heuristic evaluation led to several recommendations to improve the visual display of the dashboard and the accessibility and interpretability of the dashboard’s data. Two graphs were displayed in new graphical formats (i.e. a line graph was replaced by a column graph) to more appropriately display the PRO data in the way that complemented how clinicians were applying the data in clinical practice. Additional revisions were made to several graphs to improve readability and facilitate interpretation of the data by clinical teams, including changes to the color scheme of the graphs and the addition of a Minimal Clinically Important Difference (MCID) reference line. Users expressed preference for the revised visualizations.

Conclusions
Usability principles from other visualization contexts hold in the PRO context. Integrating heuristic evaluation usability principles contextualized for PRO into the design of PRO systems yields better dashboard design.
Business Process Modeling: Capturing the Workflow of Medicine

Peter J. Haug, MD1,2; Herman Post, BS1; Joseph Bledsoe, MD1,2
1Intermountain Healthcare, Salt Lake City, Utah; 2University of Utah, Salt Lake City

Introduction
Modern businesses face a constant challenge due to continuing changes in the business environment and the increasingly complex efforts necessary to plan, document, and manage the workflows associated with these processes. Business Analysts are continually developing models for new workflow processes. These workflows involve participation from a variety of individuals, departments, and external partners. The challenge of managing these processes has led to a number of tools that can be used to design and implement optimum workflows.

The delivery of medical care in many ways parallels the variety and complexity of processes in the business world. Many diagnostic and therapeutic activities are defined by complex, multistep processes involving a variety of caregivers across a multitude of care settings. A core challenge for any medical enterprise is to understand and manage the workflows necessary to deliver care.

In this poster presentation we will present and describe an application in which we have taken a tool originally designed to support business process modeling and adapted it to the medical setting. We have implemented a system based on an OMG standard, Business Process Modeling Notation, version 2.0 (BPMN 2.0), in four local emergency departments. The goal of the system is to assist in the diagnostic workup of Pulmonary Embolism.

The software environment described provides an infrastructure in which to both author and deliver medical protocols. During the course of any protocol, BPMN 2.0 provides a number of ways to execute decision logic including “gateways” which implement various types of flow-control logic, “script tasks” which allow insertion of small pieces of code into the workflow, and “business rule tasks” with which a workflow author can invoke the services of a rules engine to implement more complex clinical logic. If additional inferencing tools are required, they can be configured as “custom service tasks”, added to the palette, and made available to the workflow author.

Experience
An automated workflow for diagnosing Pulmonary Embolism (PE) is available on computer desktops in four emergency departments within Intermountain Healthcare’s Urban Central Region. A reminder to use this tool is triggered upon receipt of an order for a test associated with PE (D- Dimer, CT Pulmonary Angiogram, Ventilation-Perfusion scan). The workflow begins by guiding the user through a series of algorithms designed to estimate the likelihood of PE (based on the Pulmonary Embolism Rule-Out Criteria2 and the Revised Geneva Score3). It combines BPMN Gateways, Service Tasks (for data access), Script Tasks and User Tasks with some custom services to navigate the logic necessary to choose the most appropriate sequence of diagnostic tests. It concludes when sufficient information is collected to confirm or deny the presence of PE.

The pulmonary embolism protocol was implemented in four emergency departments within Intermountain Healthcare. Between June 2014 and February 2016, the prototype system underwent testing. The protocol was completed for 1084 patients; it was exited before completion in 620 cases. In many of the latter, the clinician reviewed suggestions before exiting. Of 2471 total suggestions displayed to the user (suggest D-dimer lab test, suggest imaging examination in general, and a suggestion for a specific imaging examination), 2353 were accepted and 118 were not accepted.

Discussion
Available technologies developed to design and implement workflow processes for the business community can be used to build a powerful environment in which to develop complex, stateful, clinical protocols. We are engaged in an effort to adapt these technologies for use in the medical environment. Initial experience has been gained through the development of a Pulmonary Embolism diagnostic workflow. Our experience suggests that these tools will ease the design, implementation, and long-term maintenance of electronic protocol that are capable of providing robust decision support as a part of an interactive computerized workflow.

Roadmap for Integrating an EMG Machine with the EMR

David Haustein, MD\textsuperscript{1,2} and Brenton Bohlig, MD\textsuperscript{2}
\textsuperscript{1}Robley Rex VA Medical Center, Louisville, KY; \textsuperscript{2}University of Louisville, Louisville, KY

Abstract

Electrodiagnostic testing, also known as a nerve conduction study or electromyogram (EMG), is a medical procedure that can help diagnose nerve or muscle diseases by using a stand-alone laptop or desktop computer equipped with EMG software, a preamplifier and a stimulator. Integrating this device with the electronic medical record (EMR) can be an expensive and daunting task for physicians; this poster will explain the cost and steps to upload the report directly into the VA’s EMR.

Project

Electrodiagnostic testing (EDX) or an electromyogram (EMG) is a medical diagnostic test that can document abnormalities after a nerve or muscle injury and is frequently used to confirm common conditions such as carpal tunnel syndrome, a pinched nerve in the neck or back or nerve damage in the hands or feet. EMG machines are stand-alone laptops or desktops with a preamplifier and stimulator and are infrequently connected to the electronic medical record (EMR). EMG machines that integrate with an EMR are reported to improve workflow efficiency, reduce clerical errors and provide faster communication of reports to referring providers. However, this integration requires extra software and hardware expenses and requires significant coordination with health information technology professionals. When the manufacturer no longer supported the older EMG machines at the Louisville VA, we began to research systems and the process for integrating EMG machines with the VA’s EMR, VistA. We first needed to choose an EMG machine that was an approved device through VA Clinical Procedures and also needed confirmation of interoperability with the local VistA Coordinator. For a fully integrated system with both importing of patient demographic data into the EMG machine and exporting of reports to VistA, Health Level 7 (HL7) software was required at an additional cost of $5,000 to $10,000. Finally, it was necessary to work with IT and biomedical engineering to obtain a server on-site to host the software and data. Many EMG manufacturers offer reader software which allows a provider to manipulate the EMG document from a remote workstation for about $1000 per workstation; this was important for our facility where we have multiple attendings and residents working in the EMG lab daily. Going live with this new process first required several weeks to get comfortable with the new EMG machines and then many administrative/health IT meetings to coordinate the vendor’s remote access to our on-site server for set up and maintenance. Our experience with this transition will serve as an informative roadmap for other clinicians of the prices and personnel involved in integrating EMG machines and their EMR.
Design Considerations for Patient Portals: Needs and Preferences from Elderly Adopters

Yuqi He, MLIS
University of Wisconsin-Madison, Madison, WI

Abstract
Patient portals adoption creates great opportunities and challenges for the growing aging population; focus group interviews with people age over 65 were conducted to understand their needs and preferences for patient portals and design considerations were presented based on the initial findings.

Introduction
In response to Stage 2 of the Meaningful Use under the HITECH Act, health care providers across the U.S. are required to implement patient portals and demonstrate a certain amount of portal usage to qualify for financial incentives. In addition to the law, patient portals are considered a promising tool to manage personal health information and improve patient engagement. A systematic review reported that portal use is associated with improvements in disease awareness, medication adherence, patient-doctor communication, and self-management of disease. Patient portals are believed to be beneficial for older adults because the increased occurrence of chronic conditions demands disease self-management and health information management. However, these portal benefits will only be realized if the portals are well designed and are used effectively by older patients.

We lack knowledge on how to make patient portals accessible for older adults and how to design them taking into account the needs, preferences, and capabilities of older adults (e.g., cognitive, perceptual, and motor abilities). To help design better information technologies that promote personal health information management and patient engagement, this study, now in progress, explores the range of older adults’ needs and preferences for patient portals regardless of their current adoption status. Health institutions that implement patient portals and IT designers may benefit from design considerations.

Methods
Focus group interviews are employed as the main data collection methods because ideas tend to emerge from groups and this method elicits a wealth of descriptive data. Groups are separated into elderly portal users and non-users to allow for more detailed discussion. Participants are primarily recruited from senior centers and public libraries. In current phases, two focus groups of portal users have been conducted. Eleven subjects (3 males, 8 females) aged 65 or older participated. Each focus group session lasted an average of 90 minutes. Participants’ demographics, computer proficiency, and portal use were assessed by three questionnaires. The interviews were recorded and transcribed verbatim. Notes were also taken at the time of the focus group to capture verbal content and nonverbal behaviors. Transcribed interviews and the interview notes were analyzed using Nvivo 10. The basic principles of constructivist grounded theory guided the data analysis.

Early Results
This presentation reports preliminary results on elderly portal adopters’ needs and preferences. Almost all participants felt positive towards the portal they were using, which were primarily versions of Epic MyChart. They mainly used the patient portals to send messages to the doctor’s office, make and verify doctor’s appointments, check lab results, and gain proxy access to a family member’s portal. Four themes emerged: (1) older adults would like various formats of training on how to use the portal, (2) they would like push notifications when new information comes to the portal, (3) additional resources are needed for understanding unfamiliar medical terminology, (4) managing multiple portal accounts from different providers makes portal experience frustrating.

Implications
The findings point to design considerations for older adults: (1) provide various formats of training (e.g., small group training workshops, video training, and written manual) to cater to older adults’ diverse computer experience and learning preferences; (2) provide options for notification methods and what kind of information should be pushed; (3) provide helpful and relevant information resources. Older patients desire an integrated health information system that provides a comprehensive approach to care. This forces us to think ahead in terms of not only meet the short-term meaningful use goal but also create long-term strategic plans to enable integrated IT to span the entire care continuum.

Assessing the Impact of Mobile-based Intervention on Health Literacy among Pregnant Women in Urban India

Aparna Hegde, MD1, Riddhi P. Doshi, MBBS, MPH2
1ARMMAN, Mumbai, Maharashtra, India; 2University of Connecticut Health Center, Farmington, CT, USA

Introduction

Every year, more than a fifth of the half million global maternal deaths occur in India.1 In 2012-13, almost half of the pregnant women in Mumbai received complete antenatal care (ANC) including three ANC visits, one tetanus toxoid injection and 100 iron folic acid supplements.2 Over 2/3rd of the pregnant women (15-49 years old) in Mumbai suffer from anemia. Only 69.2% of the children under 2 years of age received complete immunizations as recommended by the World Health Organization.3

Methods

This quasi-experimental study involved a single group, pre-post evaluation design. Of the 400 women recruited at Lokmanya Tilak Municipal General Hospital, 247 responded to the follow-up survey at 9 months. The intervention through Project mMitra was a free mobile voice call service that sends timed and targeted preventive care information messages directly to the mobile phones of enrolled women throughout pregnancy and infancy in their preferred language and time. The messages were developed by expert group of physicians from FOGSI (Federation of Obstetrics and Gynaecological societies in India), IAP (Indian Association of Pediatrics), and NNF (National Neonatology Forum) and modified based on focus groups studies. For this study, the voice messages included information regarding anemia and nutrition during pregnancy, breastfeedi ng, and immunization. The baseline and follow-up surveys were conducted by research staff to assess women’s awareness and understanding of health care during pregnancy and infancy. Chi square tests were performed to compare the changes in health literacy.

Results

At baseline, only half of the women had their own mobile phones, whereas over a third used a family member’s phone. A majority of women were skilled in receiving calls but only 56% knew how to send a text message. The proportion of women aware that iron folic acid supplementation is to be taken for ideally 100 days (p<0.01) and minimum 90 days (<0.01) improved significantly after the intervention. Awareness regarding ideal duration for exclusive breastfeeding (p<0.01) and importance of colostrum (p<0.01) also improved drastically. Almost 97% of women were aware about the importance of immunization during pregnancy upon follow-up compared to the 61% at baseline. About 93% respondents were aware about immunization schedule during infancy during the follow-up compared to 71% at baseline. Over 95% of the respondents were satisfied with the frequency, timeliness and relevance of the voice messages.

Discussion and Conclusion

This study demonstrates the feasibility and value of delivering mhealth messages to pregnant women in order to improve health literacy regarding preventive care during pregnancy and early childhood in urban India. One of the major limitations for this study is the potential for respondent bias. We have attempted to overcome this shortcoming by adopting the randomized controlled trial design in future studies.

Efficacy and types of health information technology used in diabetes education for medically underserved adults: A systematic review and meta-analysis

Elizabeth M. Heitkemper, MSN, RN¹, Lena Mamykina, PhD², Jasmine Travers, MSN, RN¹, Arlene Smaldone, PhD, RN¹

¹Columbia University School of Nursing, New York, NY; ²Columbia University School of Biomedical Informatics, New York, NY

Abstract

A systematic review (SR) and meta-analysis (MA) to examine the effect of diabetes education health information technology (HIT) interventions on health-related outcomes in the medically underserved was completed. Five databases were searched and 13 studies met criteria for SR inclusion and 11 for the MA. Results show that HIT is effective in improving blood sugar at 6 months with dissipating but significant effects in 12 months in underserved adults with type 2 diabetes.

Introduction

Diabetes impacts 29 million individuals in the United States and is the 7th leading cause of death. Health disparities illustrated by higher disease prevalence, poorer glycemic control and more diabetes-related complications are seen in racial and ethnic minorities, low-income and rural populations, known together as the medically underserved (MU). Successful management of diabetes entails lifestyle modifications and long-term behavior change, which are taught via individual or group-based diabetes self-management education (DSME). However, for MU populations, many do not receive DSME due to the considerable barriers that exist such as language and literacy, health beliefs and cultural considerations, and access. One timely solution to this problem is the use of health information technologies (HIT) since studies show increased adoption of technologies by groups that previously had little to no access makes HIT an increasingly viable option for the MU to receive DSME.

Methods

Following an a priori protocol and the Preferred Reporting Items for Systematic Review and Meta-Analysis guidelines, five databases were searched. Any duplicate publications using the same sample, opinion pieces, literature reviews, other systematic reviews and meta-analyses, or articles published in non-peer reviewed journals were excluded. Studies reporting either A1c pre and post intervention or its change at ≥6 months were eligible for inclusion in the MA using random effects models.

Results

Of 318 articles identified, 13 randomized trials met criteria for SR and 11 for the MA and represent data from 3,257 adults (mean age 55 years; 66% female; 74% racial/ethnic minorities) with diabetes. Interventions varied by HIT type: computer software with no Internet (n=2), cellular and/or automated telephone technology (n=4), Internet based (n=4), and telehealth/telemedicine (n=3). Most studies (n=10) reflected an unclear risk of bias overall. Pooled decreases in A1c were found at 6 months (-0.38 [95% CI: -0.50 and -0.26]; I²=35.1%, Q=5.0) with diminishing effect at 12 months (-0.24 [95% CI: -0.39 and -0.09]; I²=42.4%, Q=10.4). Heterogeneity was not greater than expected by chance alone.

Conclusion

The results from our study show that HIT DSME is effective in improving glycemic control at 6 months with dissipating but significant effects in 12 in underserved adults with type 2 diabetes. It will be important for developers to find novel ways to improve the technologies that this population has access to, such as smartphone applications, since our findings show that cellular or automated telephone technologies were not as successful as other technology types.
TransformDB: A Data Management System for Multimodal Imaging Data

Karl G. Helmer, Ph.D.\textsuperscript{1,2}, Qi Wang, M.D.\textsuperscript{1}, Graham C. Warner, B.S.\textsuperscript{1}

\textsuperscript{1}Massachusetts General Hospital, Boston, MA; \textsuperscript{2}Harvard Medical School, Boston, MA,

TransformDB was created to serve the Transdiagnostic Repair of Affective Networks by Systematic, Function-Oriented, Real-time Modeling and Deep Brain Stimulation (TRANSFORM-DBS) project (https://transformdbs.partners.org), which will generate a large, heterogeneous set of high-value neuroscience data. These data include brain electrophysiology recordings from humans and animals performing a variety of cognitive tasks and brain imaging (MRI and MEG) scans during similar tasks. These goals is to not just make the data available to the public, but to provide a semantically aware dataset that will enable discovery and meaningful reuse.

TransformDB is a registration-based system; both subject demographic as well as experimental data sets are registered into the system, either automatically or by users. The subject’s demographic data is entered upon initial contact and the subject is given a universal user ID (UUID). Data is registered at the level of a “run”, which is defined as an acquisition period of a single type (though this can involve multiple data files). Data with personal health information (PHI) is de-identified before transfer or storage and no PHI is stored in the system at any time. A compressed archive file of the data from each run is created and is transferred from a public-facing Globus (http://www.globus.org) shared endpoint to the file system where the metadata is extracted. The archive is then stored in the file system with a schema that reflects the experimental organization (project, subject, acquisition modality type, session, run). Currently, this process is performed automatically for MRI and MEG data, but manually for electrophysiology data due to the paucity of identifying metadata in those data formats. A comprehensive data and database integrity code library has been created to check for data and database integrity.

TransformDB is run on a CentOS (ver. 6.4) server that consists of a website front end and a CouchDB database (http://couchdb.apache.org/) and Flask server in the back end. The website is based on a Drupal framework. The Flask server is used to run Python scripts to perform data anonymization upon registration, data movement within the infrastructure, and the extraction and storage of metadata. The file metadata is both extracted from the file header, as well as entered by the user at the data registration step in the case of important information not in the file header, such as electrode type and manufacturer. The metadata records are fully query-able in both basic (e.g., subject demographic information and acquisition modality) as well as advanced (specific fields in the file header). Unregistered users are able to search the data collection; however, limited fields are returned. With registration, a comprehensive view of the data is available through the advanced search capability.

The data sharing infrastructure supporting the TRANSFORM-DBS project is based on a modern design meant to fully support the discovery and sharing of heterogeneous raw and processed data. At its core is the NoSQL document store, CouchDB\textsuperscript{2} that stores Javascript Object Notation (JSON) documents. These documents are ideal to handle the evolving nature of the data and the variety of file metadata in this project. JSON documents that can be easily updated and queried allowing for maximum flexibility as new data types are added, while minimizing query time.

Reporting tools are available for both internal and external use. At-a-Glance pages are available to projects noticing global views of subject data, displaying which scans have been completed as well as the tasks performed. Comprehensive reporting pages are also available so that users can determine the number of subjects with a given criteria set that exist within the data. Users can search for data, and create Shared Searches, named collections of data that can be stored for personal reuse or for transmission to others. By using a Shared Search, users do not have to physically transfer the data to others, with the Shared Search name, recipients can download the data themselves. These collections can also be used to create fixed collections of data that are independent of the state of the database and the addition of new data.

The terms used to describe the data are chosen based on our ongoing work with the INCF Program on Standards for Data Sharing’s Neuroimaging Data Model (NIDM) that build on previous ontological work in neuroimaging. The goal is to use standardized terms so that this data collection can be more easily queried with other collections using the NIDM data model thereby enhancing the data’s visibility. Each term is also defined to ensure comprehension of the data and to promote its reuse.
Evaluation of Clinical Score Calculator Programmability within the Electronic Health Record

Vitaly Herasevich, MD, PhD, Mikhail A. Dziadzko, MD, PhD, Christopher A. Aakre, MD
Mayo Clinic, Rochester, MN

Abstract
Clinical scores are frequently used in clinical practice, however many are cumbersome and require manual entry of multiple variables into web-based score calculators. We performed a preliminary programmability assessment of 171 commonly used, evidence-based clinical score calculators to guide score automation efforts within the electronic health record.

Introduction
Although a few clinical scores have been integrated into electronic health record (EHR) platforms, most score calculation is still performed manually by clinicians - assisted by smartphone or web-based applications. These other scores are used frequently in clinical practice for decision support, risk prediction, and disease severity assessment. Automation of these clinical score calculators within the EHR has the potential to save clinician time and to improve the quality of clinical care. However, the ability to automate each score depends on its programmability; programmability has not been assessed for most clinical scores. Filling this knowledge gap would help to focus research on future EHR-based score calculator automation.

Methods
Variables from 171 clinical score calculators identified from the medical literature in a prior study(1) were tabulated. Each variable was classified as either “subjective” or “objective”. Objective variables included laboratory values, demographic values, test results, vital signs, and regularly charted standardized data. Subjective variables included elements of clinical history, diagnoses, examination findings, and clinical judgments. Subjective variables with established advanced retrieval techniques, such as natural language processing, were also identified. Programmability was defined as the proportion of objective variables.

Results
1343 variables (618 unique) were tabulated from 171 clinical score calculators. 270/618 (43.7%) unique variables represented objective data present in the EHR. An additional 114/618 (18.4%) of variables are potentially extractable with advanced retrieval techniques. 23/171 (13.5%) clinical scores were completely programmable and 73/171 (42.7%) of clinical scores are composed of 75% objective variables or greater. 31/171 (18.1%) contained fewer than 25% objective variables. When advanced retrieval techniques are applied, 50/171 (29.2%) could be completely programmable and the number of scores with 75% or greater programmability increased to 108/171 (63.2%). A summary of the programmability of the 171 scores can be seen in Figure 1.

Conclusion
More than 60% of commonly used clinical score calculators are highly programmable (> 75%) for automation in the EHR using objective data and advanced variable extraction techniques. Further research into automation of complex, highly used, highly programmable scores within the EHR could save significant clinician time.

Inconsistency and Variation in Concordance of Social History Documentation between Nursing and Provider Clinical Notes

Jamie S. Hirsch, MD,1,2 Kevin Bock, MD,1,2 John Chelico, MD,1
Petros Karamanlakis, MD,1 Deborah Mensch, MD,1,2 Michael Oppenheim, MD1,2
1Northwell Health, Lake Success, New York;
2Hofstra Northwell School of Medicine, Hempstead, New York

Introduction
Electronic health records (EHRs) with clinical documentation are widely implemented across many health systems. As a primary and major source of rich information, clinical notes provide knowledge of a patient’s social history and context, with implications for patient care as well as quality improvement and regulatory reporting. To aid in documentation consistency and generation of reusable data, notes often contain structured, discrete data entry forms, with many elements identical in documents entered by several members of a patient’s health care delivery team. To what degree this information is reliable and concordant across this care team, however, is unknown.

Methods
In order to improve documentation of crucial variables the EHR at Northwell Health affords the ability to document similar observations among members of a health care team. An additional option allows charted observations to carry over from previous notes. We examined the social history portion of provider and nursing admission notes across 8 hospitals at Northwell Health for adult admissions in 2015. Focusing directly on elements with discrete data entry, we examined the proportion of observations completed by providers and nurses in their respective admission documents, and when both completed a similar observation, the degree of concordance in the valued observation.

Results
In 2015, there were 95597 non-elective, adult admissions with a provider and nursing admission note, with at least one containing documentation of social history. The median number of social history observations documented was 5 for providers and 4 for nurses (IQR, 4 and 5, and max 46 and 45, respectively). While some observations are unique to only one document type, most (78%) are available within both. Despite overlapping availability, most observations were primarily documented in only one of the two notes for each patient, with the exception of “Substance Use” and “Tobacco Usage” that were typically documented in both. For instances of dual documentation, there was a wide range of concordance in the value of the observation, ranging from about 20% to 100%, with the most commonly documented observations (e.g., marital status, living situation, substance use, and tobacco use) having concordance only about 75% of the time.

Conclusions
EHRs, including electronic clinical documentation, have been touted as a way to improve the quality of clinical care, including the ability to leverage data elements for quality and consistency. We have found that documented observations such as a patient’s social history is frequently inconsistently recorded by members of a patient’s health care team. Moreover, wide variation in the degree of concordance exists between notes authored during a single patient hospitalization. Future work should try to uncover reasons for differing documentation patterns, with the aim of streamlining and cross-verifying valued observations to promote quality, consistency, and accuracy of data. Current efforts must also be undertaken to align incongruous data in EHRs.

INTRODUCTION
Motivational Interviewing (MI) is a widely studied and effective method of psychotherapy for substance abuse treatment. However, the quality of psychotherapy in clinical practice remains largely unknown. In training contexts and clinical trials, the evaluation of psychotherapy providers relies on a human who listens to a recording of a session and makes decisions regarding whether certain therapist behaviors have occurred. Feedback can be provided informally (e.g., a supervisor listens to the session and offers their perspective and input) or in the form of standardized, numeric ratings from a theory-derived rating system – a process that has remained fundamentally unchanged for decades. Given the labor intensiveness of human ratings of psychotherapy, and the scale of demand in clinical practice, it is not surprising that most real-world psychotherapy is never evaluated. Thus, providers rarely receive feedback on the quality of their care. There is a strong need for an evaluation technology that makes feedback that is proximal to the clinical encounter feasible, which led to the development of the Counselor Observer Ratings Expert for MI (CORE-MI).

CORE-MI
CORE-MI combines speech and language processing with automated coding and interactive visualization to help therapists and trainers identify strengths and areas for improvement. CORE-MI utilizes foundational speech signal processing methods to translate an audio-recording of an MI session into a numeric representation of semantic and vocal acoustic data, which are in turn used as features in machine learning predictive models. Paralinguistic information such as prosody, pitch, speech rate, and intensity are also computed.

Figure 1. Core-MI user interface.

CORE-MI provides feedback on standard MI quality measures described in the Motivational Interviewing Treatment Integrity Scale. Two measures are considered “Global Ratings” and meant to capture the overall quality or “gestalt” of the session. The system also tracks three “Behavior Count” measures that characterize the quantity and quality of questions and reflections in the discourse. CORE-MI provides a report card-like, visual summary of counseling sessions (Figure 1). The report prominently features an “Overall MI Fidelity” score that aggregates all measures to give an impressionistic view of the participant’s general level of adherence to MI principles. Bar charts indicate global and behavior count measures, highlighting the counselor’s level of proficiency in MI techniques. The visualization also offers a “Session View” that enables users to examine detailed session transcripts and talk turn level annotations for therapist and client behaviors.

EVALUATION
Evaluation of the CORE-MI’s speech and language processing and automated coding achieved a correlation of 0.643 between expert annotated empathy codes and machine-derived estimations, and an accuracy of 81% in classifying high vs. low empathy [1]. A study is currently underway with therapists and therapists-in-training to evaluate utility, usability and desirability of the visualization system for clinical and training use. Results of this study are expected in late 2016.

CONCLUSION
The CORE-MI offers the first scalable technology for evaluating the quality of client-therapist interactions. The CORE-MI offers an additional contribution wherein feedback not only occurs rapidly, but is presented in a way that may facilitate therapist understanding and engagement with the raw material of the session. We are hopeful technological augmentations of psychotherapies similar to CORE-MI may lead to improvements in the quality of treatment available in the community and contribute to a reduction in the disease burden of substance abuse disorders.

Ranking PubMed Hits by Projection on an Axis of Words Having Varied Relevance to Search Intention

Teruyoshi Hishiki, MD, PhD¹, Takuro Tamura²
¹Toho University, Funabashi, Japan; ²LINE Co., Ltd, Tokyo, Japan

Problem Addressed

In existing information retrieval models, bag-of-words queries represent the user’s search intention where the relevance of a document to the query is defined as the cosine of the angle between a word content vector made from the document and one from the query. We can consider the query vector as the axis onto which document vectors are projected. The scalar product of the query and document vectors gives the document a coordinate on the axis; the coordinate is proportional to the cosine value if the document length has been normalized. At this point, suppose that we introduce into the query another bag of words that have different meanings to those of the search intention and are assigned negative values. The coordinates of the document would then produce a spectrum ranging from the search intention to the different topic, and a cut-off for relevance could then be set easily and objectively.

Specific Purpose of the Project

The aim is to reduce the number of PubMed hits for a broad query to be scanned over by the user before gathering articles about the factors of decision errors in diagnosis. We chose aortic dissection (AD) as the search term because the symptoms associated with this condition overlap with those of other conditions, and some of the treatments for the other conditions are contraindicated for AD. We developed a browser-based interactive program that calculates the score for article titles as the sum of the word values in the title. The word values are defined by the user.

Interim Results of the Project

We obtained 5340 titles from a PubMed search for AD in titles. Four groups of words were indexed: symptom (24 words; value, 4), diagnostic modality (10 words; value, 2), causal or temporal (15 words; value, 1), and treatment or outcome (42 words; value, −3). The distribution of scores for all titles (Figure 1) shows large peaks for scores 14, 15 and 6, 7 (10 is the neutral score given to all titles) and smaller peaks for scores 18, 19 and 0, 1. We sampled the titles for them and found that most of the articles relevant to our search occurred within the intervals of scores higher than 13, with few less than eight. We estimated that ~10% of the titles needed further screening.

Conclusion

The addition of words with a negative value (i.e., with an “opposite” concept to the search intentions) into the query bag-of-words could facilitate making sense of information retrieval results. A limitation of this method is the effort required to find the opposite words. Prior knowledge as well as word frequency and co-occurrence information could be used to find these words.
Workflow-guided development of a clinical decision support tool for patients with advanced liver disease.

Samuel B. Ho, MD1,2, Julie E. Ducom, PhD3, Anne Miller, PhD3, Jennifer H. Garvin, MPH4,5, Jejo D. Koola, MD3,6, Russ Beebe, BS3, Jason M. Slagle, PhD3, Dax M. Westerman, MS5,6, Carrie Reale, MSN, RN3, Matthew B. Weinger, MD3,6, Erik J. Groessl, PhD1,2, and Michael E. Matheny, MD3,6

1 VA San Diego Healthcare System, San Diego, CA, 2 University of California, San Diego, CA 3 Vanderbilt University, Nashville, TN, 4 VA Salt Lake City Healthcare System, 5 University of Utah, Salt Lake City, UT 6 VA Tennessee Valley Healthcare System, Nashville, TN

Objectives: Patients with chronic liver disease and cirrhosis represent high-risk, high-cost patients, and optimizing the quality of care they receive is of high priority. We previously employed a Human Factors Engineering (HFE) approach to identify key design goals for clinical interventions aimed at improving the care of patients with cirrhosis1. Here, we describe the process of developing a clinical decision support (CDS) tool based on those design goals, with a focus on optimizing its integration into standard clinical workflow. Methods: A multi-site interdisciplinary collaborative Design Workshop consisting of 14 clinicians, graphic designers, informatics specialists, and health service researchers convened into two workgroups to develop a CDS tool prototype. Using participatory design, the two groups created user interface concepts in response to 8 structured scenarios of actual patients with chronic liver diseases in outpatient and inpatient settings. The groups’ designs were discussed and reconciled in a combined meeting. The resulting design concept included: 1) evidence-based order sets most relevant to patients at increased risk for liver disease; 2) an interactive web-based medium-fidelity prototype of the user interface (UI) design, consistent with the current electronic medical record (EMR) infrastructure; and 3) contextually relevant patient scenarios for multi-site usability evaluations of the UI prototype by front-line clinicians. These products were then iteratively refined based on structured interviews with primary care clinicians using web-based prototypes at three hospital sites. Results: The interactive UI prototype identifies patients at high risk for cirrhosis based on laboratory and radiology findings. Users are alerted to the patient’s condition via an automated alert on the existing EMR patient cover page. Selecting the alert leads to a web-based CDS split screen tool that provides the clinician with a consolidated view of risk factors and relevant test results on the left side. The right side pane gives users direct access to appropriate order sets, organized by clinical category. Actionable, recommended order sets are provided, with informational icons describing current evidence-based guidelines. Key elements refined by iterative development include different clinical categories, number and types of lab tests used, types of order buttons, and informational icons. Usability testing is underway. Conclusions: Following a HFE approach, we developed an interactive CDS tool to improve the risk stratification and care of patients with advanced liver disease, both in the acute care setting (e.g., decompensated cirrhosis) and for routine health maintenance. Following further refinement and full integration with the EMR, we plan to evaluate the impact of CDS use at two hospitals on provider acceptance, usability, and compliance with quality of care indicators for patients with cirrhosis.

Development of an Electronic Trigger Tool for Identifying Inpatient Diagnostic Error

Katherine A. Homann, M.D., M.A.S. and Robert El-Kareh, M.D., M.S., M.P.H.

1University of California, San Diego, La Jolla, CA, USA

Introduction

Diagnostic errors—defined as incorrect or delayed diagnoses—are common and often preventable. Trigger tools have been proposed to improve the identification and study of diagnostic error; however, established criteria did not yet exist. We sought to create a trigger tool for diagnostic error in hospitalized patients through literature review and prioritization via established methods for expert review.

Methodology

Applying established methodology, the 29 diagnostic error trigger criteria identified by our comprehensive literature review underwent additional refinement. These criteria were reviewed and prioritized by two multi-disciplinary focus groups, a clinical advisory panel, and three Delphi rounds with experts in diagnostic error (Figure 1).

Results

The diagnostic trigger tool criteria were narrowed to 10 high yield triggers and 4 secondary tier triggers (Table 1).

Table 1. Final diagnostic error trigger tool criteria.

<table>
<thead>
<tr>
<th>Primary Diagnostic Error Trigger Criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>Incident report for case that was classified as diagnostic error</td>
</tr>
<tr>
<td>Case referred to quality assurance or quality improvement committee</td>

<td>Discrepancy between admission diagnosis and discharge diagnosis</td>
</tr>
<tr>
<td>Discrepancy between preliminary and final radiology diagnoses</td>
</tr>
</tbody>
</table>

Figure 1. Methods for trigger tool creation

Conclusions

Diagnostic error is a significant source of preventable healthcare harm. Our study established a preliminary trigger tool for diagnostic error in hospitalized patients. These criteria should be prospectively validated in different settings to verify their utility in identifying important diagnostic errors.

Perceived Effectiveness of Clinical Decision Support to Improve VTE Prophylaxis: A Comparison of Physicians, Pharmacists and Nurses

Peter Hoonakker1, PhD, Shimeng Du1,2, BSc, Ann S. Hundt1, PhD, Jason Stamm3, MD, Brian Patterson, MD4, Pascale Carayon1,2, PhD
1 Center for Quality and Productivity Improvement, University of Wisconsin-Madison
2 Department of Industrial and Systems Engineering, University of Wisconsin-Madison
3 Department of Medicine, Geisinger Health System, Danville, PA
4 Department of Emergency Medicine, University of Wisconsin-Madison

Venous thromboembolism (VTE) is a frequent, but preventable complication for hospitalized patients that can lead to significant morbidity and mortality [1-3]. It has been estimated that more than 900,000 VTE cases occur in the US every year [4]. In our study, we use a sociotechnical systems approach to determine design requirements for clinical decision support (CDS) to prevent VTE and address some of the cognitive and team work issues that have limited the adoption, acceptance and effectiveness of CDS for VTE. To better understand the socio-technical context of the VTE prophylaxis process we asked the principal clinicians in the process (physicians, pharmacists and nurses) about their perceptions of VTE prophylaxis and the perceived effectiveness of different CDS interventions to improve the process, including computer, human and organizational decision support.

We conducted a survey on perceptions of clinicians with regard to importance, effectiveness, safety and utilization of VTE prophylaxis and on possible effectiveness of interventions to address VTE prophylaxis among more than 700 clinicians (physicians (n=189), pharmacists (n=56) and nurses (n=456) in two hospitals (response 92%).

Results show that, overall, the three clinician groups think that VTE prophylaxis is important, safe, effective and appropriately utilized. With regard to possible interventions to improve VTE prophylaxis, results show that all respondents have a strong preference for computer CDS. Out of the 16 possible interventions, the 4 top-rated interventions for all clinician groups are technological interventions: 1. computerized alerts to inform that prophylaxis has been interrupted and needs to be resumed, 2. order sets, 3. a hard stop in the order set, and 4. an alert that contra-indications have changed. Note that some of these interventions involve smart alerts. The first human intervention (pharmacist reminders) ranks 5th in preference by physicians and 8th by pharmacists and nurses. Organizational interventions such as educational meetings, periodic audits, feedback, posters on the units and laminated pocket cards as reminders were preferred least. Unlike pharmacists and nurses, physicians have a strong preference for an alert that informs them that prophylaxis has been interrupted and needs to be resumed. Otherwise differences in preferences between clinicians are relatively small.

VTE prophylaxis is not limited to a single task (e.g. placing an order for prophylaxis) but is a complex process that continues to be addressed throughout the patient stay (e.g. resuming VTE prophylaxis after a procedure), in which multiple actors are involved. The literature [4] shows that a single intervention (e.g. education and training) will not improve VTE prophylaxis significantly. What is needed is CDS that supports all clinicians throughout the hospital stay that is not limited to health IT, and takes teamwork into account. A socio-technical approach can help to identify the factors that can improve VTE prophylaxis in this context.

Implementing Semantics-Based Cross-domain Collaboration Recommendation in Biomedicine with a Graph Database

Dimitar Hristovski, PhD¹, Andrej Kastrin², Thomas C. Rindflesch, PhD³
¹Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia; ²Faculty of Information Studies, Novo mesto, Slovenia; ³National Library of Medicine, Bethesda, MD, USA

Introduction
Research collaboration is an important condition for conducting high quality science. Current systems provide a list of potential collaborators but do not further motivate the basis for the recommendation. We address this deficiency and propose a novel approach for semantics-based recommendation of research collaboration that exploits an extended literature-based discovery (LBD) methodology. The system provides a list of potential collaborators and topics for collaboration, and also explains why the collaboration is compelling⁴. Here we describe the implementation of this methodology with the Neo4j graph database and its query language Cypher².

Methods and Results
We first constructed a large network and loaded it into the Neo4j graph database. The network consists of two major types of nodes: authors and biomedical concepts. We extracted authors from the full MEDLINE bibliographic database. We used SemRep³ to identify biomedical concepts from the set of arguments (subjects or objects) of semantic relations extracted from all MEDLINE titles and abstracts. Our network contains several types of arcs and edges. co_author edges link any two authors who have been co-authors on at least one paper. writes_about arcs link authors to biomedical concepts. These arcs are derived from the semantic relations extracted from articles written by the authors. The writes_about arcs are used to represent the expertise of the authors. Finally, we have 30 types of semantic relations extracted with SemRep that link the nodes representing biomedical concepts. These relations represent current biomedical knowledge. The network consists of: 9,516,106 author nodes, 269,047 biomedical concept nodes, 181,664,746 co_author edges, 189,294,999 writes_about arcs, and 69,333,420 arcs that represent semantic relations between biomedical concepts.

We implemented the algorithm for recommending research collaboration with the Cypher query language and it operates as follows. For a given input author, we first compile the author’s topic (concept) profile, which represents both the authors interests and expertise; this is done by following the writes_about arcs as described above. For each input concept we perform an open LBD discovery. LBD proposes target concepts as novel collaboration (research) topics that are not yet published in the literature. For all target concepts found by LBD, we find authors who have these concepts in their profiles and eliminate those authors who are already coauthors with the starting author. The output is a list of the remaining authors as potential collaborators along with topic(s) for collaboration. Shown below is a generic implementation with a Cypher query, which can be made more specific as needed:

MATCH (author1:author) -[:WRITES_ABOUT]-> (X:Concept) -[Rel_XY]-> (Y:Concept) -[Rel_YZ]-> (Z:Concept) <-[:WRITES_ABOUT]- (author2:author)
WHERE NOT (X)-[RelXZ]->(Z) AND NOT (author1)-[CO_AUTHOR]-(author2)
RETURN author1, X, Rel_XY, Y, Rel_YZ, Z, author2;

Conclusion
Using a graph database such as Neo4j for storing the large network data structure needed for semantics-based cross-domain collaboration recommendation is more natural and efficient than using a relational database. Implementing collaboration recommendation algorithms is conceptually easier and more simple when using a graph query language such as Cypher when compared to standard SQL.

Machine Learning Methods for the Early Identification of Diabetes

Kang Lin Hsieh, MS¹, Susan.H.Fenton,Ph.D¹
¹University of Texas Health Science Center School of Biomedical Informatics

Introduction: Identifying pre-diabetes and undiagnosed diabetes are needed for the prevention of diabetes. Two major tests, the hemoglobinA1c (HbA1c) and fasting plasma glucose (FPG), are used to diagnose pre-diabetes and diabetes. However, persons with diabetes or this predisposition do not always have consistent results between these 2 tests. Further study of the patients with discordant and concordant test results may assist in identifying new relevant risk factors leading to pre-diabetes and undiagnosed diabetes. [1]

Material and Methods: The National Health and Nutrition Examination Survey is a biannual survey that enrolled 78,518 people from 1999-2011. Variables included in the predictive model for the development of diabetes included daily eating habits, interview of diabetic risk factors, demographic data, and lab tests relevant to diabetes. The demographic data included age group, not age for anonymity purpose. 7,915 records were selected for this research. In this population, 5,377 people had concordant results between their HbA1c and FPG test and 2,538 people had discordant results. A prediction model for the development of diabetes was created using the concordant data and tested using the discordant group data to determine the impact of the lab tests on predictive accuracy.

Results: The prediction results between the 2 groups were not significantly different for any factors except age. In Figure 1., the total population predictive accuracy was 61.4% for the HbA1c and 31.4% for the FPG. When examined by age group, the over 65 accuracy was 39% for the HbA1c and 57% for the FPG, age 40-65 was 57% for the HbA1C and 34% for the FPG, age 18-40 was 77% HbA1C and 20% FPG, while age less than 18 was 79% HbA1C and 20% FPG respectively.

Figure 1. RandomForest Analysis Results

<table>
<thead>
<tr>
<th>Accuracy</th>
<th>HbA1c, 79%</th>
<th>FPG, 20%</th>
</tr>
</thead>
<tbody>
<tr>
<td>61.90%</td>
<td>57%</td>
<td>77%</td>
</tr>
<tr>
<td>31.40%</td>
<td>39%</td>
<td>20%</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>over 65</th>
<th>40-65</th>
<th>18-40</th>
<th>below18</th>
</tr>
</thead>
<tbody>
<tr>
<td>All population</td>
<td>HbA1c</td>
<td>FPG</td>
<td>HbA1c</td>
<td>FPG</td>
</tr>
</tbody>
</table>

Figure 2. Material of research

Discussion: The model based on the concordant group did not achieve high predictive accuracy in the overall population. In further analysis, the accuracy of HbA1c is usually higher than FPG except in the group aged 65 and over. These results suggest the value of the HbA1c in predicting diabetes is more dominant than the value of the FPG except for those aged 65 and over. This is a very interesting phenomenon. Confounding factors or unknown relationships may also impact this analysis.

Conclusion: The conclusion is that the two populations are very different especially above age 40 which is when the risks of being diagnosed with diabetes increases dramatically. Continued study is needed to identify the factors resulting in the discordance between the HbA1c and FPG. This can provide a new perspective on identifying pre-diabetes and undiagnosed diabetes.

A mockup interface for searching similar patients using temporal patterns

Henry Huang¹, Xiaoqian Jiang, PhD¹

¹Health System Department of Biomedical Informatics, UC San Diego, La Jolla, CA 92093

Abstract
We build a mockup interface for a patient to query statistics of similar patients based on his or her symptoms and medical event history. This interface is a part of an ongoing deep learning project of developing predictive models for early prognosis. Treating patient reported data as a timeline, we can generate the statistics of similar patients. Available online: http://dquery.ucsd-dbmi.org:8800/formssets/

Introduction
Patients have benefited from online knowledge bases like WebMD [1] or online patient networks such as PatientsLikeMe [2]. But it is not easy to find the right information for an individual given the complexity of medical conditions. It would be more useful to have a web service that aligns temporal patterns of symptoms and medical events of patients in order to provide users with useful information (e.g., statistics of diagnosis and medication of similar patients) that is most beneficial to their own personal health.

Methods
Our predictive model uses a vector space model to represent each medical event in a continuous vector space. Construction of the vector space with training data take into account each medical event’s neighbors in the timeline with a 2-layer neural network. We were able to achieve AUC of average of 78% in predicting over 30 diseases. This predictive model paper is currently under review. Using this model in the backend, users can enter their symptoms, diagnosis, treatment, conditions, and/or symptoms into our interface in a chronological order. Given such sequence of events, the backend predictive model will project the user onto the vector space in order to find most similar patients in the same vector space and return the next most likely diagnoses and treatments, as well as corresponding statistics (as illustrated in the figure below).

Evaluating Patients’ Perceptions of Infobuttons

Nathan C. Hulse, PhD1,2, Jie Long, PhD1
1Intermountain Healthcare, Salt Lake City, UT; 2Department of Biomedical Informatics, University of Utah, Salt Lake City, UT;

Abstract

Infobuttons have been used in electronic health records for some time, and their value in providing context-aware information for clinicians has been demonstrated by previous research. However, their utility in providing answers for patients directly via the personal health record has not been well characterized. In this poster we will present results of an experiment in which patients are presented with infobuttons related to problem list, medication list, and lab value entries, and asked to evaluate the relevance of the results returned. We will present descriptive data and agreement statistics that describe the perceived relevance of the returned results for a number of information providers. We will also present survey data related to patients’ perceptions of infobutton usefulness and ease of use.

Introduction

One of the important challenges of the information age is that of quickly providing access to relevant, well-sourced material that can answer questions well at the time and place that they arise. In medical informatics, infobuttons have been shown to be an effective tool in meeting this challenge for clinicians, yet, the same types of resources targeted directly for patients have not been well-characterized.

Background

In 2014, we implemented a local instance of the OpenInfobutton project and made it available for patients to use from our patient portal, myHealth. We enabled seven different electronic resource providers from five different domains in the patient portal, including problems, medications, lab results, allergies, and microbiology. In order to study patients’ impressions of the relevance and usefulness of the results returned by the infobutton, we conducted a pilot study to quantify patients’ perceptions of the tool.

Methods

We sampled a set of concepts from a commonly used panel of data derived from recent EHR usage metrics; identifying 15 each (10 common, 5 less so) from labs, medications, and problems and created infobuttons for patients to test. We asked 5 patients to review and score each results for relevance, and usefulness, as well as complete a survey of their perceptions of the tool’s ease of use and usability. Relevance and usefulness scores ranged from 0-3, per a qualitative scale, while the remaining survey questions were based on the TAM model.

Results

Statistical analysis showed clear differences across information providers as to overall relevance and utility of results returned. Patient-facing infobuttons performed better in medication list than in lab value entries and problem list. Providers who offer infobutton content through standardized HL7 APIs consistently scored higher for relevance and utility. Overall, survey data showed patients’ perceptions of infobuttons as highly useful and easy to use.

Conclusion

We have evaluated seven different resources linked from patient-facing infobuttons to test patients’ perspectives about their relevance, usability, and usefulness. In doing so, we identified several resources which perform better than their counterparts in providing relevant results; the data showed significant differences across content providers within domains. The value of HL7-based access to content for providing relevant content was evident in the results. TAM-based survey data suggests that patients find infobuttons both usable and useful. We feel that our focus on understanding patients’ information needs will empower them as they use consumer-facing informatics tools.

Triggers for VTE Prophylaxis: Sociotechnical System Considerations

Ann S. Hundt, PhD1, Peter Hoonakker, PhD1, Jason Stamm, MD2, Vaibhav Agrawal, MD2, Brian Patterson, MD3, Pascale Carayon, PhD1,4

1Center for Quality & Productivity Improvement, University of Wisconsin-Madison
2Dept of Medicine, Geisinger Health System, Danville, PA
3Dept of Emergency Medicine, University of Wisconsin School of Medicine & Public Health
4Dept of Industrial & Systems Engineering, University of Wisconsin-Madison

It is estimated that more than 900,000 venous thromboembolism (VTE) cases occur in the US every year1 and about sixty-percent of the people with VTE developed it during, or within 30 days of, their hospitalization.1,2 In addition to health consequences, VTE represents a major economic burden attributed to the costs of the initial hospitalization and readmissions due to VTE (5-14%).3 Prophylaxis is known to decrease the incidence of VTE. Therefore VTE prophylaxis has received significant attention from physician professional societies (e.g., American College of Chest Physicians) and the Joint Commission. In the study described here, we gained a greater understanding of triggers, in light of the sociotechnical system, that affect VTE prophylaxis ordering decisions throughout patient hospitalizations.

In this study we observed 8 morning rounds on 3 services for a total of 13 1/2 hours, focusing on clinical practice and discussion related to VTE prophylaxis orders. We also conducted 18 interviews of attending physicians and residents lasting a total of 12 hours and 13 minutes. In the interviews we addressed VTE prophylaxis ordering practices and communication at six stages: on patient admission, during daily rounds, when prophylaxis is interrupted, when prophylaxis warrants re-initiation, cases when prophylaxis is not ordered on admission due to a contraindication that later stabilizes or is resolved, and on patient transfer from a different clinical service. We analyzed the observations in which VTE prophylaxis communication occurred and conducted qualitative content analysis of the interviews and identified 1) the initiator and others participating in VTE prophylaxis-related communication, 2) the technology and/or tools used to facilitate the communication, 3) whether the communication occurred within or outside of team rounds and 4) clinical practice (idiosyncratic and not) that influenced ordering. We then identified the triggers that prompt such communication and changes to existing VTE prophylaxis orders.

Aside from clinical information in the electronic health record (EHR) that influences prophylaxis ordering (e.g., lab values denoting heparin-induced thrombocytopenia, renal insufficiency, patients scheduled for procedures such as pain control with an epidural anesthetic), other aspects of the sociotechnical system provided triggers that influenced the decision to continue, stop or (re)initiate prophylaxis. In many instances, verbal communication outside rounds prompted timely changes in prophylaxis orders. This was especially true of nurses who, though they generally participate in rounds, are more influential outside of rounds when they identify the need to stop or re-initiate prophylaxis. Preferences by proceduralists and their willingness to perform procedures on patients recently (or currently) receiving anticoagulants also influenced orders to hold, stop or continue VTE prophylaxis. These findings point to the need to understand the sociotechnical system in which clinical teams function and communicate, and to determine the role of the EHR in providing meaningful, timely clinical decision support for VTE prophylaxis.

Predicting ordered diagnostic tests from patient triage data

Haley Hunter-Zinck, PhD1, Stephan Gaehde, MD, MPH1
1 VA Boston Healthcare System, Boston, MA

Introduction

Emergency departments (EDs) are continuously working to increase patient satisfaction and reduce length of stay. Laboratory testing or imaging procedures are often ordered only after evaluation of the patient by a provider. There is an opportunity to improve ED efficiency by shortening the interval of time between triage and diagnostic testing. Accurate prediction of appropriate complaint specific diagnostic testing has the potential to allow ordering to be initiated immediately after patient triage rather than later in the visit when the provider conducts an initial patient assessment. With predicted, triage-time ordering, diagnostic test results could potentially be available to providers during this initial patient assessment, allowing them to initiate patient treatment immediately. To pursue this aim, we investigated whether we could predict a patient’s ordered tests from data collected at triage.

Methods

Using the National Hospital Ambulatory Medical Care Survey, a publicly available dataset from the Centers for Disease Control and Prevention, we extracted information on patient visits that would be available upon triage or from previous medical history as well as procedures ordered during the visit. Using a multi-label machine learning framework, we compared performance of binary relevance and label powerset methods, the Random k-labelsets method, and a modified multi-label neural network classifier. We assessed prediction performance in aggregate and for each order individually as well as calculating the relative importance of each data feature.

Results

Prediction performance varied greatly depending on the test but mostly due to its frequency of administration in the dataset. Performance, as measured by the F1-score, as well as the frequency with which each test was ordered, is shown in Figure 1. For example, we predicted the order of a complete blood count, administered in 44% of sampled visits, with a F1-score of 0.74 while we predicted blood alcohol assessments, administered in less than 4% of sampled visits, with a F1-score of 0.43. Several variables were important for prediction across all procedures, including arrival by ambulance, acuity score, age, and injury.

Conclusion

Overall, we have adequate information in triage data alone to predict relatively common test orders. Variables important for prediction are standard data collected at triage or readily available in the electronic health record.

Figure 1. (left) Frequency of diagnostic blood test orders over all sampled visits. (right) Classification performance using a multi-label neural network approach as measured by the F1-score for diagnostic blood test orders.
Evaluating Differences Between MIMIC II and III Critical Care Databases

Matias I. Hurtado, Undergraduate1, Jette Henderson, Phd Student2, Joydeep Ghosh, Phd2
1Pontificia Universidad Católica de Chile, Santiago, Chile; 2The University of Texas at Austin, Austin, Texas, USA

Introduction The Medical Information Mart for Intensive Care (MIMIC) is an Electronic Health Record (EHR) database containing information about patient visits to the Beth Israel Deaconess Medical Center Intensive Care Unit (ICU). MIMIC has had three versions to date. MIMIC II contains ICU patient information from 2001 to 2008, and MIMIC III, which was released in 2015, extends MIMIC II with data from 2008 to 2012.

In this poster, we begin to explore the differences between MIMIC II and III using the following approaches: 1) compare MIMIC II to III using descriptive statistics; 2) perform topic modeling (LDA) on MIMIC II and III to examine whether latent topics change significantly between the two datasets; and 3) create a mortality prediction modeling using structured and unstructured (mostly nurses notes) data. The third approach closely follows the methodology of Ghassemi et al.,2,3 which was successfully applied to MIMIC II. Our results provide several indications regarding the value of the newer dataset and changes in the population that the data represents and will be valuable specially to the large research community that has previously worked on MIMIC II.

Methods Observations and descriptive statistics were extracted from PostgreSQL databases housing MIMIC IIv1.2 and IIIv1.3 respectively. We followed Ghassemi et al. and first filtered patients using the following criteria: patients must be older than 18 years old and patients must have more than 100 non-stopwords in their notes. This filtering led to 19,792 patients with 25,026 ICU stays in MIMIC III and 14,656 patients with 17,079 ICU stays in MIMIC II. We explored the differences by applying Latent Dirichlet Allocation (LDA) to clinical notes of eligible patients in MIMIC II and III. A vocabulary for the LDA models consisted of the 500 most informative words of each patient based on a tf-idf model.

For the mortality prediction models, we used several distinct feature sets, but for the sake of brevity, we only discuss the Admission Baseline Model here, which contains basic features such as gender, age, and SAPS-II admission score. These features serve as the input for SVM models that use the radial basis function as a kernel function to cater to non-linear effects.

Results We discuss a subset of results here, and will show a more complete set in the poster. Using the Admission Baseline Model on MIMIC III we obtained an AUC of 0.93, in contrast to the earlier2 MIMIC II study, which obtained an AUC of 0.77. Examining the features individually reveals that this high score is due to the SAPS-II score feature.

The plot shows the median proportion of topics by survival outcome for MIMIC III. As Ghassemi et al. found, some topics seem to be correlated with the likelihood of long-term survival.

Conclusions One important step to harnessing the power of MIMIC III is exploring the differences between MIMIC II and III. In this poster, we begin that process by replicating a MIMIC II study performed by Ghassemi et al. using MIMIC III as well as explore the latent features of MIMIC III.

Exploring the Use of ClinicalTrials.gov Trial Results Data for Pharmacovigilance

Vojtech Huser, Olivier Bodenreider
Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction
Pharmacovigilance aims to monitor drug safety using sources such as spontaneous reporting systems, biomedical literature or electronic health record data. Clinical trials represent a source of drug-event pairs data complementary to these sources for signal detection in pharmacovigilance platforms. The advantage of ClinicalTrials.gov (CTG) over other pharmacovigilance sources is the large number of negative drug-event pairs (explicit evidence that a given drug is not causing a particular adverse event; count of 0 is reported in the deposited results). With 208,959 trials registered and 20,025 trial results, CTG is the largest repository of trial summary results (with more than 3700 new trial results deposited per year). CTG trial registration data provide information about trial type, sponsor, arms and interventions. CTG results data further provide trial participant counts, baseline characteristics, outcome measures and, most importantly for our study, significant adverse events. Adverse events (AE) are recorded separately by trial arm (or trial group). Although some data submitted to CTG are structured, such as number of arms or intervention type (e.g., drug vs. procedure), many elements are collected as free text (e.g., the drug(s) used in the trial). This preliminary investigation explores the selection of clinical trials of interest for pharmacovigilance and the feasibility of extracting drug concepts from CTG trial registration data.

Methods
To investigate the proportion of drug trials that can be directly used for pharmacovigilance (without additional manual curation), we analyzed results of interventional trials with drug interventions. We used CTG’s tabular data format and the structured element intervention_type. To identify drug names in the CTG intervention_name field, we mapped them to RxNorm using increasingly aggressive techniques, namely using the findRxcuiById (exact/normalized match) and getApproximateMatch functions of the RxNorm API.

Preliminary Results
Feasibility counts: As of February 22, 2016, the tabular CTG data included a total of 14,007 results of interventional trials that had at least one drug intervention (dataset S1; supplemental data are available at github.com/vojtechhuser/CTG). We found that 5,192 trials (37% of our sample) have exactly one trial arm and drugs from such trials can be unambiguously associated with AEs reported in the deposited trial summary results. Additionally, in 2,049 two-arm-trials (14.6% of our sample) we converted their free-text specified placebo arms into formally modelled placebo arms which may allow us to use additional pharmacovigilance methods. Overall, a total of 7241 trials would be amenable to processing for pharmacovigilance purposes.

Drug term detection: We processed 63,817 unique interventions strings (extracted from all CTG interventions of type ‘drug’). For 10.4% of those strings, the RxNorm API exact or normalized match function identified RxNorm concepts of type ingredient, clinical drug or branded drug (dataset S2). When no exact or normalized match was found, we proceeded with approximate match and were able to map additional 0.6% of input strings without the need for human review (single RxCUI detected with 100% detection certainty score; dataset S3). For the remaining input strings, approximate match provided multiple inputs (6.1 RxNorm terms on average) with a wide range of scores.

Conclusions
These results indicate that intervention names are usually not simple drug names and would require parsing for extraction of drug names (e.g., with MedEx, a medication text processing tool). Overall, our work indicates that a significant portion of the CTG result database can generate some drug-adverse event pairs that can be used for pharmacovigilance purposes. In our experience, the main obstacle to leveraging CTG for pharmacovigilance is the difficulty in unambiguously associating information from registration (intervention drug + trial arms) with information from result summaries (AEs), because of the absence of an explicit link between trial arms in these two resources.

Secondary Data Analysis on Ventilator-associated Pneumonia and Pressure Ulcer with Regards to Head of Bed Elevation

Sookyung Hyun, RN, PhD1, Cheryl Newton, RN, 2
Susan Moffatt-Bruce, MD, PhD3

1Pusan National University College of Nursing, Busan, Korea, Wexner Medical Center at The Ohio State University 2Department of Critical Care Nursing, and 3Chief Quality and Patient Safety Officer, Department of Surgery, Columbus, OH, USA

Introduction

Typical process measures to prevent ventilator-associated pneumonia (VAP) are elevation of the head of the bed (HOB) as lower HOB is associated with incidence of VAP. Conversely, pressure ulcer (PU) prevention guidelines recommend that HOB positioning should be lower to reduce risk for PU development which contradicts VAP prevention guidelines for the HOB between 30 and 45 degrees for intensive care unit (ICU) patients. This presents a care dilemma and tension. The purpose of this study was to perform a secondary data analysis using cumulative electronic health record data in order to determine the association of HOB elevation with VAP and pressure ulcer development in ICU patients.

Methods and Results

Data were retrieved from an information warehouse from an academic medical center. The dataset was from adult ICU patients who were admitted to adult ICUs between January 1st, 2007 and December 31st, 2010 and they were on ventilator during their ICU stay. Pressure ulcer and VAP data were recorded in physicians discharge documentation and HOB data were recorded in nursing documentation, respectively, in the electronic health record systems. Descriptive statistics and chi-square test were used to analyze the data. Table 1 summarizes characteristics of patients and the association was illustrated in Table 2.

<tr>
<td>&lt; 30°</td>
<td>8</td>
<td>332</td>
<td>10</td>
<td>330</td>
</tr>
</tbody>
</table>

Note. VAP=ventilator-associated pneumonia; HOB=head of bed

The association between HOB elevation and pressure ulcer occurrence was significant, $\chi^2(1, N=7739)=10.8$, p=.001 while the association between HOB elevation and VAP was not significant, $\chi^2(1, N=7739)=3.28$, p=.07.

Discussion

In our ICU care setting, patients regularly had their HOB greater than 30 degrees with pressure ulcer prevention measures. Nurses documented HOB every 2 hours or more frequently. Our data showed that HOB elevation was not likely to be associated with VAP whereas it was likely to be related to pressure ulcer occurrence. The findings of this study have limited generalizability and additional research is needed to better understand risks and benefits of process measures, including HOB elevation, to prevent ICU associated safety events.

Assessing the Feasibility of Developing an Inpatient Telehealth Referral System for Veterans with Poorly Controlled Diabetes

Umar Iqbal, MD¹, Khaleel S. Hussaini, PhD², J Edward Maddela, MD³, Hamed Abbazadehgan, MD, MBA⁴
¹,²,³University of Arizona College of Medicine, Phoenix, Arizona; ⁴Phoenix VA Healthcare System, Phoenix, Arizona

Introduction
The Phoenix VA Healthcare System presently has various home telehealth programs that are offered to veterans if they meet eligibility criteria. Presently, veterans are enrolled into these programs from physician referrals in the ambulatory clinics. There are no referrals being placed from the inpatient setting. “Telemedicine-based care diabetes management improves outcomes versus clinic care but is seldom implemented by healthcare systems”¹. In a recent study by Crowley et al., baseline HbA1c was at 10.5%, and by 6 months, estimated HbA1c had improved by 1.3% for intervention participants with telehealth visits and 0.3% for usual care¹.

Objective/Aim
To assess the feasibility of implementing an inpatient telehealth referral system prior to scaling up, we retrospectively examined baseline HbA1c values for veterans who are currently enrolled in the diabetes telehealth program from the ambulatory setting at the Phoenix VA Healthcare System.

Methods
This single-group pretest posttest study utilized baseline and current HbA1c data from enrolled veterans in the diabetes telehealth program from an ambulatory setting during August 2015 to December 2015. Inclusion criteria for the diabetes telehealth program requires a documented HbA1c ≥ 8.0, veteran’s to be on insulin, and are willing and able to perform finger sticks as instructed. A total of 169 veteran’s baseline HbA1c and most current HbA1c’s were extracted from the CPRS system who were enrolled in the telehealth program. Univariate, bivariate, and multivariate statistical procedures were conducted using SAS v9.2 (SAS Institute, Cary, NC). Univariate analyses included examining the distribution of the HbA1c and appropriate transformations were performed to reduce skewness and normalize the data. We assessed differences in baseline HbA1c by key demographic variables and used chi-square test for nominal variables and t-tests for continuous variables. We performed a paired t-test to assess differences in baseline and current HbA1c and estimated the effect size as small, moderate, and/or large based on Cohen’s criteria.

Results
The average age of the currently enrolled veterans was 64.63 years (SD = 8.80) and approximately 95 percent of the veterans were males (n = 160), and slightly over 50 percent of them were married and the majority of them resided in an urban county (~95%). The current HbA1C values (M =8.42; SD = 1.50) were lower as compared to baseline values (M = 9.15; SD = 1.20) t(168) = -7.60, p < .0001, d = -0.53 with a moderate effect.

Discussion and Conclusion
Preliminary evidence suggests that the veteran’s currently enrolled in the diabetes home telehealth program had a lower Hb1Ac value after being enrolled into the program. While the impetus to scale up the new inpatient telehealth program is promising, the study is limited due to lack of randomization, availability of a proper control group and perhaps subject to selection bias. In addition, the study did not account for factors influencing utilization of the current telehealth program from the ambulatory setting. This new pilot inpatient telehealth referral program, that is currently underway, bolsters some of these limitations by assessing factors that influence utilization of the telehealth program and developing clinical decision support to alert inpatient program coordinators to enhance utilization.

Information and Communication Needs of Hispanic Dementia Caregivers
Informing Design of a Family Health Information Management System

Sarah J. Iribarren, RN, PhD1, Samantha Stonbraker, MPH, RN1, Niurka Suero-Tejeda, MS, MA, CHES,1 Robert Lucero, RN, MPH, PhD, FAAN2,3, Suzanne Bakken, RN, PhD1
1Columbia University, New York, US; 2University of Florida, Gainesville, FL, US; 3VA HSR&D Center of Innovation on Disability and Rehabilitation Research

Abstract
This study used a multimethod qualitative design to elucidate information and communication needs of Hispanic caregivers for those with dementia and required functionalities for an online information management system.

Introduction
Dementia is an increasing problem and is more prevalent in Hispanics.1 Caregivers for patients with dementia are at high risk for poor mental and physical health outcomes.2 Little is known about the information and communication needs of Hispanic caregivers for individuals with dementia or the manner in which online tools may meet their needs.

Methods
We conducted 11 participatory design sessions with 10 English- and 14 Spanish-speaking Hispanic caregivers to understand their information and communication needs and potential tools to meet these needs. Audio/video recordings of sessions were transcribed verbatim and analyzed using a theory-based framework3 with three-level coding in Nvivo 10. Rigor and replicability were supported through member checks during sessions, peer debriefing following sessions, coding by multiple coders, documenting an audit trail, and meetings to resolve differences.

Results
Participants were 60 years old (±7.7), caregivers for an average 6.5 years (±4.2), and spent an average of 68.7 hours caregiving per week (±56.6). The majority were female (80%), spoke Spanish as the primary language at home (67%), and were caregiving for a parent with dementia (67%). Communication and Information needs or tasks were reported by the majority of participants (21 and 22, 87.5% and 91.7% respectively) while fewer reported online tools (19, 79.2%). Not knowing how to care for their ‘loved one’ effectively and needing reassurance as to what to do were common themes. Results included:

- Communication needs: communicate with healthcare team/provider for questions as they arise, ability to notify others when the person with dementia is lost (alerts), and communicate with other family caregivers.
- Information needs: information on dementia type and progression, “how to” information (e.g., lifting techniques, better take care of themselves), about medications (e.g., effects, side effects and drug-drug interactions), community services, and health status of individual (e.g., lab results, medical records).
- Online tool needs for: care coordination (e.g., appointment tracking, find/communicate with healthcare providers), important information (e.g., phone numbers, resources, medications, immunization records), support groups, missing person alert, and schedule or to-do list that can be marked off as completed.

Conclusion
Family caregivers have a range of needs related to self-managing their role that inform the FHIMS design.

Understanding Delays In Abnormal Test Result Follow-Up Using Electronic Health Records In Outpatient Primary Care Settings

Roosan Islam\textsuperscript{1,2}, PharmD, PhD Viraj Bhise, MBBS, MPH\textsuperscript{2,3}, Janet Schwartz-Micheaux\textsuperscript{1,2}, Elise Russo, MPH\textsuperscript{1,2}, Daniel R. Murphy, MD, MBA\textsuperscript{1,2}, Dean F. Sittig\textsuperscript{1,3}, PhD, Hardeep Singh\textsuperscript{1,2}, MD, MPH

\textsuperscript{1}Department of Medicine, Baylor College of Medicine, Houston, TX
\textsuperscript{2}Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX
\textsuperscript{3}The University of Texas Health Science Center, Houston, TX

Background:
Delays in follow-up of abnormal test results are a significant safety concern in outpatient settings. Although, electronic health records (EHRs) can help ensure reliable delivery of important clinical information, they do not guarantee appropriate follow-up actions are taken. In order to improve test results follow-up, it is important to understand how clinicians’ follow-up abnormal test results within the complex “socio-technical” context of EHR-enabled healthcare systems. In this study, we sought to explore reasons for delays in abnormal test results follow-up.

Methods:
We recruited primary care physicians from multiple family medicine outpatient clinics site in Houston, TX. We queried the site’s clinical data repository from January 1\textsuperscript{st}, 2015 to September 30\textsuperscript{th}, 2015 to identify potential delays in abnormal results follow-up for ten common imaging, laboratory and pathology tests (e.g. Hemoglobin, Thyroid-Stimulating Hormones, Chest X-Ray, PAP Smears) within patient charts. A physician reviewed these selected charts to evaluate if appropriate follow-up took place within 14 days of the patient visit. We defined a delay in follow-up if there was no documentation of patient notification, repeat or follow-up testing, referral or change in medications within 2 weeks of the test result. In this ongoing study, we have thus far interviewed 5 physicians in which a delay was identified. We interviewed participants using the critical decision method (CDM), a semi-structured interview technique that enabled us to elicit specific rationale for delays in follow-up actions. The interviews were audio-recorded and transcribed. Using an 8-dimensional socio-technical framework, a team of three multidisciplinary researchers with backgrounds in medicine, pharmacy and psychology coded the transcripts using qualitative content analysis. The researchers met multiple times to seek group consensus and codes were refined based on discussions. We used a deductive approach to reduce the data to substantively relevant categories.

Results:
We found 7 dimensions of the socio-technical framework (all except “systems measurement and monitoring) to be relevant for ensuring follow-up of abnormal test results. The technology-related dimensions (hardware and software, clinical content and user interface) included specific factors that could contribute to lack of timely follow-up, such as inability to share information across the systems, inability for patients to access electronic results, lack of prioritization of alerts by the EHRs, lack of multiple patient views in the display, lack of functionalities for task coordination among team members and lack of user-centered design in the EHR. The dimensions related to internal and external environment (internal organizational policies, procedures and culture and external environment) included factors such as inflexible internal organizational policies for test results follow-up, difficulties in delegating responsibilities within the organization and difficulty in external care coordination with outside providers. Clinical staff shortage (“personnel” dimension) was also seen to be a contributing factor. Moreover, we found that overall the rationale for delays in follow-up was more significantly related to the “clinician’s workflow” dimension. Factors such as excessive ordering of unnecessary tests, time constraints to deal with delayed results, difficulty in notifying patients, unique patient’s conditions requiring different prioritizations (such as very sick patients requiring more attention) and lack of standardized workflow processes (such as personalized work arounds to deal with follow-up) contributed to missed abnormal test results follow-up due to variations in clinician’s workflow.

Conclusion:
A broad range of socio-technical factors may lead to delays in abnormal test result follow-up. Enhancing the design of current EHRs and focusing on a host of sociotechnical factors that we identified may improve follow-up of abnormal test results in outpatient settings. In order to improve patient safety, more research is needed to understand the underlying causes for delays in abnormal test results follow-up.
Informing the Requirements for IT-Based Fall Risk Management Solutions in Home Health Care

Onimi Jademi, MS, Uchenna Uchidiuno, MS, Dari Alhuwail, MSc, and G"unes ¸ Koru, PhD
University of Maryland, Baltimore County, Baltimore, Maryland, USA

Significance: Emergency care for injuries caused by a fall is the most frequently encountered potentially avoidable event in home care. Falls can easily lead to major health problems or death. Therefore, managing fall risks becomes an integral component of quality care delivered by home health agencies (HHAs). Currently, most agencies do not adopt or customize IT solutions to specifically address fall-risk management. Among those which do, a thorough understanding of how performance can be improved in fall-risk management is not clearly understood before IT adoption.

Objective: This study aimed at informing the requirements for IT-based fall-risk management solutions by uncovering the challenges and opportunities of achieving better fall-risk management in home care.

Methods: A secondary document analysis of fall and near-fall incidents was performed by examining the incident reports provided by a Medicare-certified not-for-profit HHA located in the mid-Atlantic region of the United States. The reports contained rich and contextual data such as severity of fall, availability of caregivers, patient’s mobility status, and attempted actions prior to fall. The reports were analyzed by two of the researchers using the Framework method. The analysis was guided by the previously established key performance improvement domains to identify the challenges and opportunities to achieve better fall-risk management. A high inter-rater reliability was achieved between the raters: 83% percent agreement and a Cohen’s Kappa of 0.76. The Institutional Review Board approval was obtained before carrying out this study.

Results: The results show that engaging patients and their caregivers, as well as adequately managing their expectations is essential for improved outcomes. Patients had limited understanding of their physical limitations caused by their conditions, and therefore did not comply with the recommendations of using durable medical equipment (DME). Some patients refused to seek help when they needed it. In most cases, caregivers were unavailable; in instances where caregivers were available, they insufficiently monitored patients or were inattentive to their needs. Often, patients and caregivers lacked knowledge of fall-risk management and environmental risks. Some caregivers were unaware of which activities patients were able to perform safely. Some caregivers had their own physical limitations and health problems; therefore they were unable to provide adequate support for the patients. Additionally, poor coordination of interventions, such as delays in the delivery of DME and scheduling lapses, contributed to fall incidents. Other challenges included untimely delivery of care services and incomplete care delivery activities e.g. not following up on medication changes or DME orders.

Conclusion: The results inform the requirements for IT-based fall-risk management solutions, by providing insights into the challenges and opportunities for improving fall-risk management in home care. The HHA could better integrate the EHR and the incident reporting system to facilitate better coordination of care. It was evident from the results that poor engagement was a contributing factor in many fall and near-fall incidents. Leveraging patient portals to deliver relevant information to the patients and their caregivers, can improve their health literacy and increase their levels of engagement in the care plan. Health IT vendors can use this evidence to better understand the needs, and challenges of home care patients and clinicians to develop more effective solutions for fall-risk management.

Big-Data Method to Advance Public Health Informatics: Smarter Public Health Prevention System (SPHPS)

Arash Jalali, MPH/PHI, MSHI¹, Douglas Rahden¹, Joerg Heintz¹, Greg Filla², Jason DiNovi², Edward K Mensah, PhD¹, ¹University of Illinois at Chicago School of Public Health, Chicago, IL, United States, ²DePaul University, Chicago, IL, United States

Abstract

The Smarter Public Health Prevention System (SPHPS) provides smarter predictive analytics through big data and cloud computing for reducing health disparities among the working poor and enables smarter workforce health protection or occupational health.

Introduction

This poster presentation will demonstrate public health big-data analytics and integration of health-related information from CMS Virtual Research Data Center (VRDC), Occupational Safety and Health Administration (OSHA), National Emergency Medical Services Information System (NEMSIS), Center for Employee Health Studies Workers’ Compensation (CEHS-W.C.) and external search engine data including Google Health Trends.

Figure 1. Infographics representation of Smarter Public Health Prevention System (SPHPS).

SPHPS¹ is based on the theory that the gravitational force between two objects, which are population health and patient-centered care, is workforce health protection or occupational health. SPHPS integrates CMS VRDC, OSHA, NEMSIS, CEHS-W.C., Google Health Trends and IBM Watson Analytics to improve the health status of low wage workers and health of the general population.

Does Health Status Affect Patient Preferences for Sharing Clinical Data for Research?

Imho Jang¹, Diana Guijarro², Jimmy Quach¹, Jihoon Kim, MS², Hyoeun Kim, RN, PhD², Elizabeth Bell, MPH², Robert El-Kareh, MD, MS, MPH², Lucila Ohno-Machado, MD, MBA, PhD²

¹Division of Biological Sciences, UC San Diego, La Jolla, CA, ²Health System Department of Biomedical Informatics, UC San Diego, La Jolla, CA, ³Department of Bioengineering, UC San Diego, La Jolla, CA

Introduction and Background

To improve current practice of obtaining informed consent from patients, we implemented iCONCUR (informed CONsent for Clinical data and biosample Use for Research), a prototype of web-based tiered informed consent system, and surveyed 126 patients recruited from two outpatient clinics – an HIV clinic and Internal Medicine (IM) Clinic – at UC San Diego Medical Center to determine their data sharing preferences. This survey showed that the patients from HIV clinic were more inclined to share their medical data than those from IM clinic. Also, the patients who reported their perceived health status as poor or excellent tended to be more willing to share their medical data for research than those with perceived health status of fair, good, or very good. To better understand the impact of health status on patient’s data sharing decision, we investigated whether there is an association between health status objectively measured with Charlson Comorbidity Index (CCI)¹ and data sharing preference.

Methods

We calculated CCI scores of 126 patients who indicated data sharing preferences in iCONCUR based on their visit diagnoses and medical histories. We also explored the association between data sharing decision and Health Impact Index (HII) scores, which was claimed to be more sensitive to self-reported health status². In both indexes, higher scores indicate worse health status. The data sharing preferences were represented with data sharing scores that range from 0 to 3, where 0 means no intent to share data at all, 1 means sharing only with researchers from UCSD affiliated medical centers, 2 means sharing with researchers from UCSD affiliated medical centers and from non-profit institutions, and 3 means sharing all data with researchers from any institution (including for-profit). We performed correlation analyses between the data sharing scores and each type of health status scores.

Results and Discussion

We observed a weak but statistically significant correlation between data sharing scores and CCI scores (corr=0.24, p=0.007). No significant correlation was observed between data sharing scores and HII scores (corr=0.05, p=0.61). These results indicate that patients with more comorbidities may be more inclined to share their medical data for research. This is consistent with the high level of willingness for data sharing observed among the groups of patients with perceived poor health status. However, it does not explain the high level of willingness for data sharing observed among those with perceived excellent health status. Of note, neither of the health status indexes showed a statistically significant correlation with self-reported health status. This study was done in small scale thus findings are not conclusive. Nonetheless, the results of this study suggest that data sharing decision is a rather complex process influenced by one’s health status, but also by other factors. We have recently launched a larger scale of iCONCUR Phase II study, which will include a larger number of subjects with varying health conditions and sophisticated measures of perceived health status and CCI scores.

Using Familiar Concepts to Elicit Technology Design Insights

Alvin D. Jeffery, PhD(c), RN, Lorraine C. Mion, PhD, RN, Laurie L. Novak, PhD

1TN Valley Healthcare System, U.S. Department of Veterans Affairs, Nashville, TN, USA
2School of Nursing, Vanderbilt University, Nashville, TN, USA
3Department of Biomedical Informatics, Vanderbilt University, Nashville, TN, USA

Introduction

Predictive analytics are gaining popularity in clinical settings and are being used to identify factors related to high-cost patients, readmissions, triage, acute decompensation, adverse events, and treatment optimization. Although statistical outputs of these predictive analytic models can be highly accurate, nurses’ perceptions and information display preferences of prediction/probability-based information are relatively unknown. Our aim was to explore nurses’ perceptions of predicting outcomes (within a larger study on clinical deterioration) by investigating how nurses respond to probability-based information in more familiar scenarios, i.e., using precipitation probabilities from weather predictions.

Method

We conducted 15 semi structured individual interviews and 1 focus group with direct care provider nurses (n=10) and charge nurses (n=8). Each interview lasted 60 minutes and was conducted by 1-2 interviewers. The focus group lasted 2 hours and was conducted by 2 moderators. Explored themes included: (a) perceptions of risk, uncertainty, and probability of adverse events and (b) participant interpretations of weather prediction scenarios. One of the philosophical foundations of qualitative research is that participants, in order to provide valid results, have previously experienced the phenomenon of interest. Because participants had prior exposure to probability-based weather information, we used this as a surrogate to understand how they might use and interpret probability-based decision support tools in the future. Thus, in addition to asking for participant definitions and understandings of risk, uncertainty, and probability, we asked them to interpret 4 different weather scenarios that were consistent across respondents.

Scenarios and accompanying images (see Figure for example) were created to elicit responses from participants that we expected nurses might use when inferring a patient’s likelihood of experiencing clinical deterioration from a predictive tool. An example question was: “Given the following weather scenario, what are your thoughts on planning a major outdoor event?”

Results

Responses to weather scenarios revealed: (a) the desire to review trends rather than absolute values in isolation, (b) an interest in knowing the source of information and type of variables used to develop predictions, and (c) a preference for thresholds to recommend action. When asked about the use of clinical prediction models developed from real-time analysis of electronic health record (EHR) data, almost all participants expressed interest in having access to the predictive information. Participants expressed heterogeneous responses with respect to expression of risk, uncertainty, and probability with some unable to discriminate between the three terms and others providing clear definitions and examples. We hypothesize that interpretation and use of these words are largely acquired from the words their professional peers use rather than a concept about which an individual cognitively processes.

Discussion and Conclusion

By better understanding nurses’ current workflows and perceptions of risk, we hope to achieve greater success in developing novel, probability-based clinical decision support tools. Understanding how nurses cognitively process risk data can contribute to improved design and deployment of predictive tools in the clinical setting and informs important expansions of nursing educational curricula. Given respondents’ positive attitudes toward the proposed availability of clinical prediction models, we plan to examine nurses’ use of prediction models in simulated and real-world settings in the near future.
Utility of the Fast Healthcare Interoperability Resources (FHIR) Standard for Representation of Non-Query Data Mappings in the Arden Syntax

Robert A. Jenders, MD, MS, FACP, FACMI
Charles Drew University & University of California, Los Angeles, CA

Abstract

Context: Arden Syntax encodes knowledge as Medical Logic Modules (MLMs) but lacks a standard data model. Objective: Assess the Fast Healthcare Interoperability Resources (FHIR) standard, previously shown to represent MLM query data elements, for representing non-query data mappings. Methods: 325 MLMs containing 1457 non-query mappings were examined. Result: FHIR can be used to represent all of these data mappings. Conclusion: FHIR adequately represents non-query data mappings in a robust corpus of Arden Syntax MLMs.

Introduction

Arden Syntax is an American National Standards Institute (ANSI) formalism supervised by Health Level Seven International (HL7) for representation of procedural medical knowledge with the goal of facilitating sharing units of knowledge known as MLMs. Some site-specific changes must occur in order for a knowledge base to be transferred from one site to another. Key to minimizing site-specific changes is the standardization of mappings to local clinical data. While these mappings are primarily queries to retrieve data for processing in an MLM, they also include non-query data mappings such as event statements that are used to define MLM triggers and destination statements that route MLM output. HL7 FHIR is a new framework that allows references to data to be defined, represented in XML and bound to terminologies in modular components known as “resources.” For example, concepts such as “patient,” “medication” and “observation” are key FHIR resources, each with structured attributes that may be other resources. Prior work has demonstrated that FHIR is adequate to represent query data elements in a sample of MLMs.

Methods

A robust convenience sample of MLMs was examined. The non-query data mappings were extracted from these MLMs, and the data elements therein were identified. Each then was assessed whether it could be represented—that is, whether the mapping data element could be assigned to a FHIR resource attribute—using FHIR version 1.0.2.

Results

A total of 325 MLMs were pooled from 5 source decision support systems. MLMs concerned mainly with lab tests were the most common (137/325 = 42%), followed by clinical assessment or classification (67/325 = 21%) and medication (41/325 = 13%). The remainder addressed administrative and miscellaneous topics. A total of 1457 explicit non-query data mappings were identified – 430 event statements (30% of all mappings) and 1027 destination statements (70%). The data elements therein were compared to current FHIR resources to assess whether they could be represented. The most common event mappings were hospital admission (representable by the Encounter resource), laboratory test result (DiagnosticReport resource) and ordering of a medication (MedicationOrder resource). While many MLMs had an unmapped, implicit output destination (usually the patient’s electronic chart), the plurality (429/1027 = 42%) of the explicit destination statements were email (telecom attribute of the Person resource), while most of the rest were special project logs, system queues and database tables. The latter could be represented by the Location resource if the extensible value set for Location.type were extended.

Conclusions

FHIR is adequate to represent the data elements found in a large set of non-query data mappings in a robust corpus of Arden Syntax MLMs, although it could be improved to represent specialized system storage locations better. Consideration should be given for use of FHIR to represent data elements in a standard way in the Arden Syntax in order to facilitate procedural knowledge sharing for clinical decision support.

An NLP Extension to the Quality Data Model for EHR-Driven Phenotype Algorithm Authoring and Execution

Guoqian Jiang¹, MD, PhD, William K. Thompson², PhD, Luke V. Rasmussen², Richard C. Kiefer¹, Jennifer A. Pacheco², Huan Mo³, MD, Peter Speltz³, Joshua C. Denny³, MD, MS, Jyotishman Pathak⁴, PhD
¹Mayo Clinic College of Medicine, Rochester, MN; ²Northwestern University, Chicago, IL; ³Vanderbilt University, Nashville, TN; ⁴Cornell University, New York City, NY

Introduction
Unstructured data in electronic health records (EHR) has been increasingly recognized as an important source for enabling accurate phenotyping [1-2]. Natural language processing (NLP) tools have been widely used for the purpose of phenotype identification and extraction from clinical narratives. Previous studies [1-2] have demonstrated that many phenotype algorithms include text queries (e.g., keywords, concepts, or regular expressions) to facilitate pattern matching of clinical narratives to be used in conjunction with NLP engines. The Quality Data Model (QDM) [3] has been adopted by the PhEMA project [4] as an information model to support standard representation of phenotype algorithms. However, QDM lacks features in support of representing the NLP components of phenotype algorithms. The objective of this study is to develop and implement an NLP extension to QDM to better support EHR-driven phenotype algorithm authoring and execution.

Methods and Results
We followed the QDM design principles with the notions of category, datatype, attribute and value set, and defined a QDM extension based on collaborative feedback from phenotyping researchers and a literature review [5]. As an initial version, the extension specifies one single category “NLP Extension”, one datatype “Unstructured Data, Document” and 7 attributes (see Table 1). It is expected that most attributes may be associated with a value set with enumerated values or using standard vocabularies. For example, the permissible values in the value set associated with the attribute Document Section can be defined using the HL7 Clinical Document Architecture (CDA)/SNOMED CT/LOINC section type or the section type used in any local EHR system. The data elements of the NLP extension have been loaded in our data element repository and implemented in the PhEMA authoring and execution applications. We tested the utility of the NLP extension by successfully creating a QDM representation of a NLP component in a real-word Benign Prostatic Hyperplasia (BPH) phenotype algorithm developed within the eMERGE consortium, i.e., NOT: “Unstructured Data, Document: Keywords for cancer patients” (Document Section: Problem List). This is an exclusion criterion that describes the exclusion of cancer patients using keywords of “prostate cancer, malignant tumor of prostate, bladder CA, and bladder cancer” in Problem List. In summary, we designed an NLP extension of QDM and implemented it in our PhEMA applications. We plan to collaborate with clinical research informatics and standards communities to rigorously examine the utility of this proposed extension to QDM.

An Evaluation of Activity Trackers for Monitoring Parkinson’s Disease Patient Outcomes
Josette F. Jones, PhD¹, Hwanmei Wu, PhD¹, Jay Patel, BDS,MS¹², Suranga N. Kasthurirathne, BEng¹, Nicole Thai, BS¹, Sunanda Mukherjee, Btch¹
¹Indiana University-Purdue University School of Informatics and Computing, Indianapolis, IN
²Indiana University School of Dentistry, Indianapolis, IN

Problem: Parkinson's disease (PD) is the second most common neurodegenerative disease in the United States. PD results in adverse outcomes including motor impairments as well as non-motor impairments affecting cognition and sleep. Since PD is a neurological disorder, medication has a limited impact on treating PD. Previous research showed that exercise could be beneficial to decrease disease progression and reverse the onset of PD symptoms. However, there has been a little systematic effort to identify the impact of different exercise methods, intensity, frequency, and duration in enabling better PD patient outcomes.

Purpose: The long-term goal of this study is to demonstrate the impact of the vigorous and intensive activity on the progression or recuperation of PD. For this purpose, we propose a pilot study to discover the activity tracker (a) most suitable for use by PD patients and (b) can accurately recognize patterns for different types of activities.

Methods: Activity tracker devices widely available in the market were used to monitor PD patient exercise behavior. We performed literature searches to identify information such as cost, longevity and major functionality of existing activity trackers and used these to compare them against one another. The top devices will be selected and applied to track PD patient exercises. The PD patients will be divided into two groups: the control group with no PD and the intervention PD patient group. The devices will be used to track their activities they engage in, as well as the progression of their PD symptoms.

Results: We present the results of our initial investigation. We evaluated a number of devices including Fitbit, Jawbone, and MotionWatch on criteria including HIPAA compliance, PC software compatibility, the activities/tasks they could measure and many others. Based on this analysis, we identified five devices most suitable for further evaluation. These devices will be tested on patients recruited from RockSteady Boxing (RSB), and used to evaluate how exercise could improve PD outcomes.

Discussion: We found that many activity trackers available in the market were unsuitable for use due to wearability issues/restrictions for PD patients. Additionally, many trackers did not provide direct method to access sensor data that would be used to identify patient activities. However, off the shelf trackers were capable of being used for tracking patient activities, and could be used to monitor patient health. We anticipate that our findings could inform the future design of activity trackers more suitable for use in healthcare management.

Assessment of radiation oncology clinician information needs in radiotherapy treatment planning

Alan M. Kalet, PhD, Rebecca J. Hazen, Mark H. Phillips, PhD
University of Washington, Seattle, WA

Purpose and Introduction
The purpose of this study was to characterize the needs of radiation oncology physicians and medical physicists. Radiation oncology is a complex, innovative, and technology driven medical domain utilizing several interconnected software and hardware systems to deliver high energy radiation beams to cure and/or palliate cancer patients. In this study, we sought to glean insights and development directions for informatics tools to improve clinician access and understanding through presentation of historical data and other critical sources of information.

Methodology
45 physicists and physicians working in the Department of Radiation Oncology at the University of Washington Medical Center were solicited to complete a 21 question web survey, providing both structured and unstructured feedback. We asked about the types and sources of information necessary, and clinicians’ perceived ability to obtain that relevant treatment information in planning and decision making activities.

Results
We found that all clinicians (17 total responding – 37.7% response rate) make use of historical patient data when making decisions on current patient treatment plans. Moreover, we found that physicists report better access to data than physicians, and that, among physicians, there was a desire for multiple types of treatment plan data conglomerated from varied sources. A comparison of clinical information types desired/used by the two groups studied is shown in Figure 1. Here, we see that physicians prefer information such as Histology and Karnofsky Score (biological factors) more so than physicists, who report utilizing Orientation/Setup Device (technical factors) more.

Conclusions
The results point to distinct information needs among practitioners, and suggests two possible directions for informatics tool development: one application focusing more on technical planning components, and the other focusing on biological components, with both allowing for comparison of a current case in question to sets of historical cases available to the practice. Our results encourage further development of informatics tools in these two areas to meet the needs of radiation oncology clinicians seeking decision-making information.
Socioeconomic and Clinical Correlates of Computer Use in Cancer Patients
Youjeong Kang¹, PhD, Salimah H. Meghani², PhD,
¹School of Nursing, University of Washington, Seattle, WA
²School of Nursing, University of Pennsylvania, Philadelphia, PA

Abstract: Computer web-based interventions have been increasingly employed. However, they have not been fully effective. Little is known which underlying barriers may affect successful utilization of technology in research setting. This study is a secondary data analysis to describe clinical and sociodemographic correlates of difficulty with computer use in patients with cancer. The findings of this study show that those who are comfortable using computers are wealthier, more educated (i.e. have college degree), are frequent internet users, and have least pain of 3 or less in past week. Future study is warranted to assess whether pain least score is a predictor of comfort even among those who were wealthy and educated.

Introduction: Computer web-based intervention studies across different disciplinary has been increasing. Also, online surveys have become a common method to evaluate the effectiveness of interventions. In particular, as smartphone users are increasing, there are numerous health apps available to monitor health-related information such as diet, physical activity, and to recognize any symptoms. Importantly, despite a continuously rapid increase in health apps use, they have not been fully effective. Little is known about socioeconomic (SES) and clinical barriers to of successful utilization of computer web-based intervention for research purposes in patients with cancer.

Objective: To describe clinical and sociodemographic correlates of difficulty with computer use in cancer patients.

Methods: This study is a secondary analysis of a 3-month observational study (N=241) that used a computer-assisted Choice-based-Conjoint experiment to assess disparities in the outcome of cancer-related pain treatment. Although having internet access was not one of the exclusion criteria, there was also a question about asking internet access at home (N=195). There were four computer use-related questions; difficulty levels of completing the survey using a computer, comfort levels of using a computer, frequency of internet or e-mail use, and preferred method of completing survey (computer vs paper and pencil). Descriptive statistics and bivariate analyses (Fisher Exact/Chi-squared) were conducted in SAS 9.4.

Results: The mean age of the sample was 53 ±11. More participants aged 60 and younger (younger adults) had internet access than those aged older than 60 (older adults). Female participants were 54% of the sample. More White participants had internet access than African Americans (34%). Nearly half of participants had a college degree, and 32% had less than a high school degree. Nearly half of the participants with internet access reported greater than $50,000 of income, and they were the most frequent internet users (p<0.00). Most younger adults (81%) reported that they were comfortable using a computer (p<0.00), and tended to use internet more frequently than older adults (p=0.03). Also, participants with “pain least” scores of 3 or less out of 10 in the last week (lower scores indicate greater pain relief) reported that they were comfortable using a computer (p=0.03). In terms of preference for completing the survey, participants who preferred using a computer (rather than a paper pencil) reported that it was not difficult for them to complete the survey with a computer (p=0.03); they were comfortable using a computer (p<0.00); they used internet more frequently than others (p<0.00).

Conclusions: The findings of this study suggests that those who are comfortable using computers are wealthier, more educated (i.e. have college degree), are frequent internet users, and have least pain of 3 or less in past week. These may inform future computer web-based research about screening profiles (e.g., SES and pain levels in past week) to determine which subgroups of cancer patients who would be more likely to use computer and those needing assistance with research participation in studies that leverage technology. Future study is warranted to assess whether pain least score is a predictor of comfort even among those who were wealthy and educated.

Self-management apps for breast cancer survivors: Applying clinical terminology standards for personal decision support

Akshat Kapoor, Ph.D.$^{1}$, Priya Nambisan, Ph.D.$^{2}$

$^{1}$East Carolina University, Greenville, NC, USA
$^{2}$University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Introduction

Most modern electronic medical record (EMR) systems today utilize advanced terminology or coding standards, such as SNOMED-CT, ICD, etc. These standards allow data sharing, accurate coding and billing and overall efficiency in various e-Health functions. By implementing a standard terminology (SNOMED-CT) in a web app for breast cancer survivors, we demonstrate how it may be utilized to provide personal decision support.

Purpose

The system aims to integrate disparate breast cancer survivorship care plans for use in an online web app, by utilizing standardized terminology (SNOMED-CT), in order to provide personalized alerts and reminders for breast cancer survivors.

Problem addressed

Upon completing treatment, a patient is usually provided with a breast cancer survivorship care plan by their provider, to aid in self-management and follow-up care. However, various providers may utilize different terms to describe the same procedure, treatment or symptom in their respective care plans. There is a need to integrate the diverse vocabularies in survivorship care plans, by mapping them to a single concept in a standardized terminology, to allow for the implementation of rules for decision support.

Method

We developed a web app for breast cancer survivors, called ACESO (After Cancer Education and Support Operations) to aid patients in self-management of treatment related symptoms. Rules for alerts [1] were created based on clinical guidelines issued by the ASCO. We utilized a sample of six breast cancer survivorship care plans available online and manually identified each term that described a procedure, test, treatment or symptom. Each term was then mapped to a single concept unique identifier (CUI) in SNOMED-CT (Figure 1). System’s performance in generating the alerts was tested using a randomly generated set of 100 patient scenarios.

Results

From preliminary testing, we were able to identify 52 terms in a set of six different survivorship care plans, which were mapped to 37 unique concepts in SNOMED-CT. The system’s accuracy, recall and precision rates were 90%, 84% and 47% respectively.

Conclusion

This system demonstrates the current variations how incorporating a standardized terminology paves the way for further value-added features, such as personal decision support in the domain of consumer health apps. Further research is required on how these systems can be made more accurate, accessible and efficient for wider use.

Abstract
Mild traumatic brain injury is a prevalent and sometimes chronic condition in military service members. Currently, there is a gap in our understanding of the short-term patterns of health care utilization following traumatic brain injury. We focus on injury-related health care encounters recorded in the military electronic health record. Analysis of utilization clusters against patient demographics provides a comprehensive summary of short-term changes in health care utilization following a first mild traumatic brain injury, which may inform us of variation in health outcomes and provide an estimate of resource consumption.

Introduction: A mild traumatic brain injury (mTBI) or a concussion is a poorly understood injury that can alter the way the brain functions. During the last decade a significant amount of attention has been given to the acquisition of clinical data from patients that have suffered mTBI and psychological health (PH) problems after a concussion. Despite widespread prevalence of mTBI in deployed and non-deployed military service members, little is known about health care utilization post-injury and how the frequency and characteristics of the utilization can be used as a measure of outcomes. Through analysis of existing electronic health record medical encounters, we determine relationships between demographic characteristics and patterns of health care utilization by military service members.

Background: Approximately 327,000 military service members sustained a traumatic brain injury (mTBI) between 2000-2015, an estimated 15-20% of who will experience chronic sequelae, resulting in increased health care utilization. The modern active duty military is younger, has a higher percentage of females, and deploys with greater frequency than service members from previous wars. Few studies of the relationship between mTBI symptomatology and health care utilization in the active duty population exist, and the impact of chronic mTBI symptomatology on health care utilization within the Military Health System is unknown.

Methods: A combination of rule-based filters and data-driven models was used to clean more than 14 million EHR encounters from service members diagnosed with traumatic brain injury, resulting in a final population of 109,107 active duty patients with more than 4 million TBI-related clinical encounters.

Results: Preliminary results indicate substantial increases in utilization of outpatient services within 3, 12, and 24 months of injury, with high levels of utilization related to somatic, affective, and cognitive symptomatology. Ongoing analysis is focused on utilization and comorbidity variation by population clusters, as well as potential relationships between short-term utilization intensity and long-term clinical outcomes.
Data Mapping in Development and Implementation of Clinical Data Management Technology for Clinical Research

Shogo Kato, Ph.D.¹, Yoshihiko Morikawa, Bachelor², Seiji Mitsui, Bachelor¹, Takeshi Kuriyama, Bachelor¹, Takahisa Ogasawara¹, Kazuyuki Saito, Bachelor¹, and Naohisa Yahagi, Ph.D.¹

¹National Center for Clinical Research and Development, Tokyo, Japan; ²Tokyo Metropolitan Children's Medical Center, Tokyo, Japan

Introduction

Advances in information management technology create opportunities for researchers to more easily share information in clinical research. Such technology allows clinical research and patient care to become more integrated and interactive. Data sharing is necessary to improve the quality of healthcare and to accelerate the progress in clinical research from bedside to community.

As the Electric Medical Record (EMR) in Japan has been evolved from ordering system, items in EMR are not standardized, because it has not been designed to share data among multiple sources. In the previous trial, the average number of items with standard code of prescription, injection, laboratory and disease, among nine institutes, was 1796 ± 447(mean ± SD), 782 ± 220, 3801 ± 1738 and 23580 ± 7887, respectively. The percentage of mapped items was 12.0 ± 14.0%, 1.7 ± 2.0%, 2.8 ± 1.4% and 93.4 ± 5.0%, respectively. Therefore, collecting, integrating and reconstructing the high quality data into a centralized system from many institutes is challenging.

This study aims to evaluate the importance and effectiveness of code mapping to assemble data for clinical research from different formats and multiple data sources into a centralized system.

Method

The Division of Data Science for Clinical Research at National Center for Child Health and Development, Tokyo, Japan, implemented clinical data management system (CDMS), which is a user-friendly, versatile, and secure network system for clinical data. The data was actually collected from 35 clinics and 11 hospitals geographically dispersed whole Japan. There was no such report before, at least in Japan.

The CDMS used a metadata-driven model that contained built-in knowledgebase to control medical terminology. It was well-constructed knowledgebase consisted of multi-indexed data such as physical examination, laboratory, diagnosis and treatment. The data dealt in HL-7 standard, however, the code for items from EMR such as drug, ICD and laboratory was various in each institute or vendor.

The items in the central database were mapped into the standard code from local codes, by one engineer in systematic method using a supporting software. In addition, items were mapped in manual processing by the engineer, through communicating with each institute and vendor, to improve and ensure the quality of clinical data. The improvement in the percentage of mapped items among actual registered data in each classification was evaluated.

Results

By the operation, the proportion improved to 94.0 ± 3.0%, 94.5 ± 4.2%, 62.9 ± 21.9% and 93.6 ± 4.9%, respectively. In the actual running data, the percentage was 92.2 ± 6.8%, 93.9 ± 9.1%, 65.8 ± 12.6 and 82.1 ± 38.3%, respectively.

Conclusion

The mapping rate before operation was extremely low and it was dramatically improved by the operation both in systematic and manual processing. Development and implementation of clinical science technologies demand a close interaction between clinical research and clinical practice. The global standardized master code, which is independent from vendors or institute, should be developed to share information more easily.
Design, Implementation, and Maintenance of Relevant ASAP Data Report Tools for Patients Presenting to the Emergency Department

Chris Katsura, MD, Frank C. Day, MD MPH, Lynnell McCullough, MD
David Geffen School of Medicine at UCLA, Los Angeles, CA

Abstract

Few clinical decision support tools exist to extract in real-time the pertinent portions of a patient’s voluminous medical record. This is problematic in the Emergency Department (ED), where clinicians face time constraints reviewing extensive records when evaluating a patient. We have created a modular tool that automatically gathers and displays relevant data in a concise format to improve the quality of patient care in the ED, with the ability to expand into ambulatory settings.

Introduction

Healthcare providers today are often inundated with massive amounts of stored electronic data. This can be particularly problematic in the Emergency Department (ED), where clinicians constantly face constraints on the amount of time that can be allocated to combing through the electronic health record (EHR) comprised of terabytes of data, potentially missing crucial information. At our institution, relevant data is often generically entered as progress notes or stored under various categories, depending on the generating service. Chest pain and fever are frequent reasons for ED visits; fever comprises twenty percent of all ED visits, while chest pain comprises five percent. These patients will typically present with multiple comorbidities and extensive medical records. The likelihood that these complaints represent an acutely life-threatening process may be informed by the results of a wide variety of imaging, procedural, and specialist assessment resources. We hypothesize that inserting a relevant data report into physicians’ standard EHR workflow will result in increased awareness of relevant data sources, and that patients may receive more appropriate antibiotics, workups, and dispositions. For practical purposes, we decided to focus our efforts on patients presenting to the Emergency Department complaining of chest pain or fever, with the ultimate goal of expanding this concept to other medical complaints. The report toolbar was initially trialed in the ED and has since been implemented in various ambulatory clinics and infectious disease clinics.

Methods

A multidisciplinary task force comprised of physicians, EHR vendor technical support, and EHR system builders was formed to develop and evaluate a new clinical decision support tool, in the form of an expandable side bar that automatically gathers relevant patient data from multiple sources and displays it all in one convenient location as a single report. For patients presenting to the ED primarily for chest pain, the most recent cardiac tests (stress, echo, cardiac catheterization, troponin) are readily available with the click of a button. For patients presenting with a fever, the most recent WBC, ANC, microbiology culture and sensitivity, medical history, and filtered outpatient immunosuppressant medications are compiled and displayed in an easily viewable tabular format. Print groups are modified to recall and display desired information in an HTML report. The patient’s medical record is filtered by the following categories: date, exam type, pharmaceutical subclass, and laboratory type. The toolbar has been integrated into the ED trackboard, inpatient patient list, and clinic tabs as an informational report. The toolbar will be shared with other departments to allow further integration into ambulatory clinics and other settings. To determine the effect of the relevant data report tool, physicians will be surveyed on their use of the toolbar in their workflow and the effect on their efficiency.

Conclusion

As a result, the clinician will have a powerful tool to extrapolate relevant information quickly to more accurately treat and risk stratify a patient complaining of chest pain or fever. Furthermore, this tool will streamline overall workflow, boost efficiency, improve the coordination of patient care, improve antibiotic selection in sepsis, and minimize unnecessary cardiac testing. In the future, this model will be implemented across other medical complaints and other medical specialties as an invaluable clinical decision support tool.
Grammar frequency and simplification: when intuition fails

David Kauchak, PhD¹, Gondy Leroy, PhD² and Melissa Just, EdD³
¹Pomona College, CA; ²University of Arizona, AZ; ³Rutgers, NJ

Abstract

We investigate whether a medical writer can simplify text by only changing the grammatical structure. Based on a user study, we find that while the sentences look simpler after simplification, they are not easier to understand. For grammatical simplification, better tools are needed to provide more concrete guidance and feedback.

Introduction

Providing text to patients and health information consumers that facilitates comprehension helps create a health-literate patient group. Over the last decades, readability formulas have been touted as writing support tools, but evidence shows they are inefficient and ineffective [1]. We are systematically examining different text features for their potential for simplifying text. We measure the prevalence of each feature, their relationship to text difficulty and how they can be used to simplify text. In previous work, we demonstrated strong results with term frequency, noun phrase complexity, and grammar frequency. In this paper, we examine grammatical simplification.

Methods

To evaluate sentence difficulty based on grammatical structure, we parsed all sentences in English Wikipedia and counted the frequency of the 3rd level in the parse tree (which we denote the grammar frequency). In earlier work, we found that grammar frequency is indicative of sentence difficulty, even when controlling for other variables. We randomly selected 220 sentences from 11 grammar frequency bins (10 per bin) representing increasingly difficult grammatical structures. The writer was told to simplify each sentence by changing only the grammatical structure, i.e. not changing words to simpler variants. We evaluated the simplicity of the sentences before and after simplification with a user study measuring two metrics: perceived difficulty, measured on a 5-point Likert scale, and actual difficulty, measured using a multiple choice Cloze test over four blanked nouns in the sentences. Each sentence was evaluated by 30 participants on Amazon’s Mechanical Turk.

Results

Over half (52.7%) change to a more frequent frequency bin after simplification and 22.3% stayed the same. The expert writer was able to transform sentences into more frequent structures. The simplified sentences also appeared easier; perceived difficulty increased from 2.13 to 2.35. However, the sentences were not any easier to understand and the Cloze score did not change. Figure 1 shows the scores aggregated by bin. We conclude that writers need more direction to simplify text and are testing similarity functions to guide writers towards simpler structures.

Figure 1. Actual difficulty scores (left, multiple choice Cloze test) and perceived difficulty (right, 5-point Likert) for the original sentences, “Original”, and medical writer simplified, “Simplified”.

Introduction

Phenome-wide association scans, or PheWAS, entail scanning a set of phenotypes to determine whether any are significantly associated with a genotype of interest\(^1\). PheWAS inverts the methodology of genome wide association studies, which find genotypes associated with a specified phenotype\(^2\). This type of study holds tremendous potential in the current era of personalized medicine – the ability to tell from a patient’s genetic makeup what diseases they are most at risk for will be an integral part of healthcare going forward. As part of a set of teaching modules intended to help clinicians learn to use analytics applications, we created a module that allows the user to interact with a simplified version of an existing R package and accomplish some basic PheWAS tasks.

Methodology

We publish an R package and a teaching module. The R package builds upon an existing R package called PheWAS produced by a team at Vanderbilt University\(^3\). The PheWAS package has complexity that makes it difficult for novice R users; for example, there are multiple functions with over 10 input parameters, which can be daunting for an inexperienced coder. We created an R package, simplePheWAS, that serves as an abstraction layer on top of the PheWAS package. We applied several software design principles laid out in *Clean Code*\(^4\) such as input parameter reduction, descriptive parameter naming, and data abstraction. These principles motivate an R package that simplifies usage and has the capability to explain its output to a less experienced user.

The teaching module uses the simplePheWAS package to teach novices about PheWAS analysis. We built the learning module in an interactive Jupyter (formerly IPython) Notebook\(^5\). This application allows the user to write, run, and see the results of their code within a web browser. We provide several types of functionality: (1) The module begins with an explanation of PheWAS analysis and its uses, then moves to (2) a walkthrough of basic PheWAS tasks – loading existing data or generating an artificial dataset with signal from one or more phenotypes selected by the user, to the actual PheWAS, to visualization and analysis of results – borrowing some workflow from the example code in the original PheWAS package. (3) We also allow them to do a backwards analysis not included in the original package – now that we have found a phenotype associated with the SNP of interest, how often does this SNP imply the phenotype, and can we infer possible causality? (4) Then, we take the user through a series of exercises – they run the full PheWAS pipeline from scratch and attempt to find which of an enclosed set of datasets carries a signal. Through this interactive teaching module, users should become comfortable using PheWAS to find associations in their own datasets.

Conclusion

We have created simplePheWAS, an R package and learning module that will teach a novice user how to run a PheWAS study. Our code is available at https://github.com/ekawaler/simplePheWAS.

The Impact of a Portal for Parents of Hospitalized Children on Healthcare Team Workflow

Michelle M. Kelly, MD1,2, Peter Hoonakker, PhD2, Brad D. Ehlenfeldt, B. Robert Steingass3, Crystal M. Curry, RN, MSN, CPN2, Shannon M. Dean, MD1,3
1 Department of Pediatrics, University of Wisconsin School of Medicine and Public Health, Madison, WI; 2 Center for Quality and Productivity Improvement, University of Wisconsin-Madison, Madison, WI; 3 University of Wisconsin Health, Madison, WI

Introduction

Patient portals are intended to engage patients in care by providing access to healthcare information and facilitating communication with the healthcare team (HCT)1. Although patient portals have been used primarily in the outpatient setting, recent literature suggests they may be beneficial to engage hospitalized patients and their families in care2. Before endorsing widespread adoption, research is needed to understand how inpatient patient portals are used and integrated into the workflow of inpatient HCTs. This study aimed to evaluate HCT perspectives pre- and post-implementation of a portal application (Figure 1) on a tablet computer given to parents of hospitalized children.

Figure 1. Inpatient portal home screen (MyChart Bedside, ©2016 Epic Systems Corporation. Used with permission.)

Methods

In this cross-sectional pre-post study, HCT members (nurses, physicians and ancillary staff) completed surveys on their portal perceptions before and 6-months after portal implementation at a tertiary children’s hospital. The portal shows real-time vitals, medications, lab results, schedule, education, and HCT information and provides a way to send staff messages/requests. Variables were described and compared using percentages and chi-square tests.

Results

Surveys were completed by 94 HCT members pre- and 70 post-implementation (response rate 94 and 88%). Pre-implementation, many respondents thought parent use of the inpatient portal would increase HCT workload (52%), parent portal users would know lab results before the HCT (65%) and have too many questions (68%), and the HCT would be too busy to incorporate the portal into their workflow (71%). Compared to pre-implementation, significantly fewer HCT respondents thought portal use increased their workload (10%, p<0.001) post-implementation and even less reported parents knew lab results before the HCT (4%, p<0.001). Only 3% reported spending more time responding to parent portal user questions, concerns or requests.

Conclusion

HCT respondents anticipated a negative impact of portal use on their workflow; however, these concerns were not realized 6-months after portal implementation.

**Patient Accessible Electronic Health Records Portal**

Shreya Chakrabarti, Christopher Kemper, Huanmei Wu  
IUPUI, Indianapolis, IN

**Problem:** It is difficult for a doctor to keep track of the medical history of each of his patients. Similarly, it is also challenging for a patient to remember all the details of each doctor office visits and previous medical conditions. With the paperless electronic medical records and fast-paced technology advances, it is crucial and feasible for the medical world to stay up to date with the newer advent of these technologies. The adoption of these technologies makes lives easier for physicians as well as their patients.

**Purpose:** This project is to create a secure portal for real-time access to patient health information, which helps to improve clinical outcomes by allowing patients to take ownership of their health records. In addition, this project will perform additional medical information analytics with timely alerts and reminders to help patient better utilizing their health information.

**Methods:** An integrated medical information management system is built for patient to access and manage their health records. The system combined the traditional relational database SQL databases (Also includes MongoDB and QGIS (a geographical database system)). Friendly user interfaces using Ruby on Rails are designed to have patient looking at his/her own records. The Apache middleware will connect the backend database and front end patient portal. Once a patient understands the information available, they can update their health conditions, monitor health change patterns and take appropriate actions in a timely manner. System generated alerts for abnormal or out of range results can further a patient's knowledge and better healthcare.

**Results:** A prototype of the patient portal and the integrated medical information management system have been developed. De-identified patient records are input as the test bed. The patient portal accesses the Patient Database and keeps a track of each patient medical information like the current and past medications prescribed to the patient, the various diagnosis of the physicians during different visits by the patient. It also records the Vitals of the patient updated by the doctor during the patient’s last visit. In addition, it gives the patient a way to update his/her own vitals, these vitals will also have restrictions on them with respect to values. Different dashboards are designed for patient viewing, updating and managing their records. The figure below lists two sample dashboards: one is for the general information about the patient upon logging in and the other is a visualization for the patient to check on the historical changes of the patient vital records. Database security is enforced for patient privacy.

**Conclusion:**
Patient portals help a patient keep track of his/her health over a period of time and be motivated to maintain their vital chart in a healthy range. The patient portal would also help a physician with patient history in case the patient moves to a different state or country.

Secondary Use of Health Information Exchange: Bivariate Analysis of Return Visits After Emergency Care

Eugene Kim, MD12, Tina Lowry, MS2, George T Loo, MPA, DrPH2, Bradley D Shy, MD2, Ula Hwang, MD2, Nicholas Genes, MD, PhD2, Lynne D Richardson, MD2, Cindy F Clesca, MA2, Jason S Shapiro, MD2

1Division of Clinical Informatics, Beth Israel Deaconess Medical Center, Boston, MA
2The Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, New York, NY

Introduction:
Health information exchange (HIE) provides a window into patient behavior across medical systems. Early (within 72 hours) emergency department (ED) returns have been used as a quality metric and other types of revisits (e.g. 30-day readmissions) may currently incur penalties for reimbursement. However, motivations for these early revisits and patients’ choice of location are poorly understood. We hypothesize that this novel secondary use of HIE data may determine differences in specific attributes of: 1) patients without early return visits, 2) patients returning to the same initial “index” ED, and 3) those returning to a different ED. Elucidating these qualities may give insight into health care utilization and ways to improve outcomes.

Methods:
De-identified data from 3/1/09 to 2/28/14 were used from Healthix Inc., an HIE with data from 31 hospitals in the New York metropolitan area. Early ED returns were defined as having the first index visit to one ED and a second visit within 72 hours to the same or another hospital’s ED or inpatient service. As per the Association of Academic Health Centers, an academic program was defined as having an affiliation with a medical school having at least one health professions program and an affiliated teaching hospital. A bivariate analysis of the encounters was performed, analyzing the sex and age of the patients, time of the visit, hospital county in relation to the patients’ home county, and the academic status of the hospital.

Results:
The analysis included 12,621,159 total visits. There were 948,972 (7.5%, p<0.001) early returns made by 563,687 unique patients; of these return visits, 11.35% occurred at a site other than the initial hospital.

ED encounters with a return visit to the same or different hospital were 16% more likely to be by males and 48% less likely to be by patients under 18 years of age when compared to encounters that did not result in a return visit. The return visits after an initial ED encounter were 23% more likely to be in the patients’ county of residence and 3% more likely to occur during the day than encounters without return visits.

Visits with early returns to an institution different from the initial index visit were 32% more likely to be by male patients and 64% more likely to be by those under 18 years of age compared to encounters with early returns to the initial index hospital. The initial visits were 24% more likely to occur during the day, while the return visits were 30% less likely to be during the day in comparison to returns with both visits at the same site. An initial visit to a site housing an emergency medicine residency or being located in the same county as the patient was 63% or 9% less likely to result in a different site return visit when compared to initial visits having returns to the same site, respectively.

Conclusion:
HIE data may be secondarily used to characterize patients after visits to the ED. Patients returning within 72 hours to a different hospital were more likely to be male and younger, with the initial hospital less likely to have an emergency medicine residency program. Patients seeking more definitive care, the local incidence of disease, and the existence of fewer pediatric centers could play a role in these findings. Thus, factors associated with the patient, visit, and hospital itself may have influence on early returns and may not necessarily reflect quality of care. Moreover, early return rate calculations without the use of HIE may be misleading since these may miss more than 11% of early returns. Further study using HIE or similar technologies may suggest motivations behind return visits and potential areas for improvement in care delivery.
Developing A Mobile Application to Improve Diabetic Patients’ Self-Care Behaviors: A Functionality Analysis

Min Soon Kim, PhD1,2, Qing Ye, MS1, Uzma Khan, MD3, Suzanne A. Boren, MHA, PhD1,2
1Informatics Institute; 2Department of Health Management and Informatics; 3Department of Medicine, University of Missouri, Columbia, MO

Abstract
We analyzed functions and sub-functions of 168 diabetes mobile apps from iTunes and Google Play according to the validated American Association of Diabetes Educators (AADE7) Self-Care Behaviors™. A majority of the apps were designed to support Monitoring, Healthy Eating, Taking Medication, and Being Active. Fewer apps focused on Problem Solving, Reducing Risks, and Healthy Coping, which should be incorporated to enhance diabetic patients’ self-care behaviors.

Introduction
Changing patients’ self-care behavior improves control and decreases the risk of long-term disability and complications of diabetes. Mobile apps have the potential to improve patients’ self-care behaviors. However, current literature lacks discussion about the design and ability of diabetes apps to change self-care behaviors of diabetic patients. The purpose of this study was to examine the functionality on self-care behavior of current diabetes apps.

Methods
Usability experts, a diabetes educator, and a clinician utilized a multi-step review process. In an online search of two stores with major market share (iTunes and Google Play), three distinct and broad search terms were used to capture a wide range of diabetes apps: diabetes, blood sugar, and glucose. Apps were excluded if they (1) were not designed for diabetic patients, (2) were not written in English, or (3) only provided access to reference material. The functionality of each app was analyzed and classified according to the validated AADE7 Self-Care Behaviors™ by the American Association of Diabetes Educators. The seven behaviors are Healthy Eating, Being Active, Monitoring, Taking Medication, Problem Solving, Reducing Risks, and Healthy Coping. The functions that support the seven healthcare behaviors were then divided into sub-functions. We conducted a descriptive analysis of the functions and sub-functions.

Results
Out of 1,050 apps retrieved, 168 apps were identified as eligible. The majority of the apps were designed to support behaviors of Monitoring (72%), Healthy Eating (71%), Taking Medication (52%), and Being Active (37%), all of which require tracking patient-entered information. On the other hand, few apps explored behaviors of Problem Solving (20%), Healthy Coping (8%) and Reducing Risks (5%), all of which provide management guidance based on patient-entered data. The functions that support seven behaviors were categorized as 70 sub-functions (Table 1).

Table 1. The three most frequent sub-functions according to the AADE7 Self-Care Behaviors™.

<table>
<thead>
<tr>
<th>AADE7 Self-Care Behaviors</th>
<th>Three Most Frequent Sub-functions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Healthy Eating (71%)</td>
<td>count carbohydrates, read food labels, measure each serving</td>
</tr>
<tr>
<td>Being Active (37%)</td>
<td>keep track of activity, check blood sugar levels, knowledge of exercise</td>
</tr>
<tr>
<td>Monitoring (72%)</td>
<td>record blood sugar results, log height, weight, or BMI, log blood pressure or pulse</td>
</tr>
<tr>
<td>Taking Medication (52%)</td>
<td>manage medication list, calculator, reminder</td>
</tr>
<tr>
<td>Problem Solving (20%)</td>
<td>alert or reminder for abnormal data, sharing others, analyze daily issues</td>
</tr>
<tr>
<td>Reducing Risks (5%)</td>
<td>foot care, monitor signs and symptoms, knowledge of reducing risks</td>
</tr>
<tr>
<td>Healthy Coping (8%)</td>
<td>record mood, attend support groups, knowledge of healthy coping</td>
</tr>
</tbody>
</table>

Conclusion
Discussion with an experienced endocrinologist and literature review revealed that Healthy Eating, Problem Solving and Healthy Coping are critical principles for improving self-care behaviors. However, Problem Solving and Healthy Coping principles may be more difficult to address in app design than the other five principles. This may attribute to the skewed app development trend. Future diabetes apps should incorporate functionalities of Healthy Eating, Problem Solving, and Healthy Coping, to better support changing diabetic patients’ self-care behaviors.
Data Topography of a Large Multi-Site Research Network
Jeffrey G. Klann, PhD1,2,3, Vijay Raghavan, MS, MBA1, Doug MacFadden, MS1, Sarah Weiler, PhD1, Kenneth Mandl, MD, MPH1,4, Shawn N. Murphy, MD, PhD1,2,3
1Harvard Medical School, Boston, MA; 2Partners Healthcare, Boston, MA; 3Massachusetts General Hospital, Boston, MA; 4Computational Health Informatics Program, Boston Children’s Hospital Boston, MA

Background
The Scalable Collaborative Infrastructure for a Learning Health System (SCILHS, pronounced “skills”) is a growing network of health centers across the United States, presently covering over 10 million patients at eleven sites. SCILHS is a Clinical Data Research Network (CDRN) in the Patient-Centered Outcomes Research Institute’s PCORnet, a national effort to instantiate a ‘network of networks’ that supports large-scale comparative effectiveness research.

The dizzying variety of data representations and terminologies in clinical systems makes developing an interoperable network difficult. To support interoperability in a distributed network, SCILHS has uniformly adopted the PCORnet Common Data model (CDM). However, the network sites do not tend to have their source data in the terminologies required by the CDM. To that end, SCILHS developed a methodology to allow mapping from source terminologies to the CDM ontology, which has been implemented at eight network sites. The implementation gave us insight into the challenges and potential pitfalls of data interoperability in a real-world scenario. Here, we report the data topography of the network and some lessons learned.

Methods
SCILHS uses Informatics for Integrating Biology and the Bedside (i2b2) as its technical backbone. i2b2 is an open-source clinical data warehousing and analytics platform funded by the National Institutes of Health. It is used at over 100 sites nationwide, including several CDRNs and the National Center for Advancing Translational Sciences (NCATS) Accrual to Clinical Trials (ACT) network. i2b2 supports live distributed queries through the Shared Health Research Informatics Network (SHRINE) platform.

i2b2’s data model is highly adaptable to ingest data from various source systems, and local implementations develop concept hierarchies (called “ontologies”) that provide a window into the imported data. For SCILHS, the data are exposed as a single CDM ontology, and each site used our methodology to map from their local terminologies’ codes to the CDM ontology. We assisted the sites with this process and worked to resolve challenges. At completion, we received a report from each site on which CDM ontology terms are available at each site.

Results
The CDM ontology is divided into many clinical domains, each of which has its own coding system requirements. Major terminologies used are listed below, along with a summary of challenges encountered.

- **ICD-9:** All sites had at least some of their diagnoses and procedures in ICD-9 format (due to billing requirements). However, the problem list sometimes used non-standard codes that required manual mapping.
- **CPT:** Most sites had some procedure codes in CPT format. However, several sites discovered some procedure codes were stored in separate billing systems for professional staff, which were not available to researchers. Also, retired CPT codes were not initially placed in our CDM ontology, making some procedure categories appear empty when an old code was being used in historical data.
- **RxNorm:** Sites did not tend to store their data in RxNorm, but often a crosswalk to RxNorm was available. However, these were frequently incomplete and resulted in some data loss. At some sites, only NDC was available, and even with a variety of terminology resources for mapping NDC to RxNorm, the sheer number of NDC codes make maintaining these resources difficult, leaving NDC to RxNorm mappings incomplete.
- **LOINC:** Many sites involved in research had invested in mapping their laboratory codes to LOINC already. However, frequently the LOINC codes used were inconsistent between sites and did not match the expected codes specified in the CDM. This problem was not caught for some time, because the availability of LOINC codes created a false sense of security surrounding data completeness.

Discussion and Conclusion
A wide variety of subtle terminological and data mapping issues hamper interoperability. SCILHS has gathered significant experience with these issues, and we lay out some highlights above. The largest problems encountered were *historical (retired) codes, inconsistent mappings, non-standard local codes, and data availability.*
Incorporating Televisions into Older Adults’ Health Routines: A Case Study

Laura Kneale¹, MS, Hilaire J. Thompson², PhD, RN, CNRN, ACNP-BC, FAAN, George Demiris¹,², PhD, FACMI
¹Biomedical and Health Informatics, ²Biobehavioral Nursing & Health Systems
University of Washington Seattle, WA 98195

Introduction
Older adults spend three times as many hours watching television than younger adults¹. Digital Interactive Televisions (DITVs) are televisions that use an Internet connection to incorporate non-traditional functions. DITV’s for health and social care have been previously studied but no trials have been conducted with older adults in the United States². The purpose of this study was to evaluate the feasibility of using a DITV with health and wellness functions and a companion caregiver portal with community-dwelling older adults and their informal caregivers.

Materials and Methods
We tested a commercially available DITV that was designed for older adult users. Our team was not involved in the design of this device. The DITV allows users to: a) alert caregivers that help is needed, b) place video-calls, c) view pictures and messages, d) view a calendar, and e) respond to health alerts. The system had a caregiver portal to manage the DITV functions. This study recruited Seattle-area community-dwelling older adults and their informal caregivers for a 30-day trial. The DITV was installed in the older adults’ home. Participants were trained on the system, and asked to complete an in-person, audiotaped interview at the beginning and end of the trial. We thematically coded the interview transcripts to identify benefits and challenges with using the DITV.

Results
Participant Recruitment and Retention: Despite varying recruiting techniques, it was difficult to identify older adults that were both eligible and interested in the study. Potential participants aged 60-70 years old, were interested in the study but were not willing to identify a caregiver, and potential participants over age 70 often refused to participate because installing the new television may disrupt their current viewing routines. We also had difficulty installing the DITV because of space constraints and Internet availability. We completed one trial during the 12-month study.

Case Study Results: One 28-day trial was completed in May 2015 with a 61-year-old Caucasian female and her adult daughter. The interviews with these participants highlight several benefits of using the DITV’s functions. The participants found the reminders helpful in supporting the desired health routines, and the caregiver felt that the system improved the daughter’s understanding of the older adult’s health behaviors. The participants also reported challenges with the system. The older adult discussed challenges with the alerts firing during family viewing times. In addition, the older adult would be unaware that she missed the DITV-based alerts when the TV was off, as missed alerts were only communicated through the caregiver portal. The participants discussed how a DITV could fit in a household with other technologies, and discussed the information that should be shared between different technologies (e.g. alerts), and the features that should be kept separate (e.g. entertainment and email). The caregiver described her use of the portal, and provided recommendations including allowing the older adult to update the DITV content through the television interface.

Discussion
While ubiquitous objects may end up playing a role in health and disease prevention, the practical implementation of this concept carries some challenges. Replacing older adults’ television, even with another television, may be difficult for some older adults. Our findings suggest disrupting an individual’s television routine may make some older adults unwilling to adopt DITVs. Perhaps a standalone set-top device that can be connected to an existing TV, similar to an Apple TV, would have better acceptance among these older adults. In order to identify these challenges, more testing needs to be completed with older adult end users to assess their acceptance of new devices, even if the devices appear to be similar to items already in their homes.

Conclusion
Our case study suggests that there are many potential benefits of using a television to incorporate health routines into older adults’ homes. Future research is needed to better understand the DITV features that older adults’ desire, how these technologies will best fit into existing technology in the home, and how to encourage older adults to adopt these types of technologies.

MagnoMath: Mobile Application for identifying Dyscalculia Symptoms related to Magnocellular Reasoning

Greger S. Knudsen, M.Sc⁠¹, Ankica Babic, PhD⁠¹²
¹ Department of Information Science and Media Studies, University of Bergen, Norway
² Department of Biomedical Engineering, Linköping University, Sweden

Abstract

This poster presents a study that measured correlations between learning disabilities in mathematics and magnocellular reasoning using MagnoMath, a software application for smartphones. Unlike most software aids used in diagnosing symptoms of learning disabilities, which rely exclusively on scoring users’ performance, MagnoMath additionally measures the correlation between these symptoms and magnocellular reasoning. To achieve this, a k-Nearest Neighbor classification algorithm was applied. Field expert evaluation has found the application to be appropriate and productive for its intended purpose. Initial user testing has been positive and provided suggestions for further improvements.

Introduction

The majority of software tools for assisting students with learning difficulties focus on teaching mathematical principles. Often there is no further insight given regarding the causes. This study explored the relationship between neurons believed to be responsible for developing learning disabilities, called magnocellular cells, and underperformance in mathematics [1]. By measuring these correlations, one could improve diagnosing and obtain a greater insight into the condition.

Method

The software applies two parameter groups for identifying and measuring correlation. Selected tasks activating reasoning in magnocellular cells are contrast sensitivity and spatial ability. The latter is the process of mentally manipulating three-dimensional figures. Selected tasks for evaluating dyscalculia symptoms are counting, subitizing and arithmetic. Subitizing is the process of recognizing patterns of objects and immediately determining the quantity without counting them one by one. The parameter groups were classified separately by two k-Nearest Neighbor classifiers using data gathered by given evaluation tasks. The key evaluation result is the correlation computation between dyscalculia symptoms and magnocellular reasoning. This computation applies mathematical reduction crucial to identifying possible reasoning dependencies. The evaluation of MagnoMath was two-folded. Ten software and mathematics field experts from the Department of Biomedical Engineering, Linköping University assessed the application’s usability and behavior. In addition, two learning disability field experts coming from the Department of Behavioral Sciences and Learning, Linköping University, and Dyslexia Norway, Oslo, evaluated the application for its validity and accuracy.

Results and discussion

The classification algorithm applied shown accurate and efficient performance allowing users to run several evaluations while getting updated feedback. Using MagnoMath regularly could benefit learning and understanding. Feedback from field experts stated that the application was easy to use, had suitable features and performed well, stably and efficiently during use, thus proving it to be suitable for its intended audience.

Selecting Health Insurance Coverage: Can Complexity and Context Be Used to Manipulate Choices?
Malgorzata Kolotylo MScBA and Monica Chiarini Tremblay PhD, Florida International University, Miami, FL

Abstract. Despite its low trust score, the internet remains to be one of the main sources of information for health insurance seekers (Furtado et al. 2016). Many of the uninsured who constitute the primary target market for private health insurance companies are unemployed or low-income social groups who, although may not use PC to shop for insurance, tend to use smartphones or at least cell phones, thus a substantial portion of advertising and reaching the customer occurs via not only websites but also mobile applications and texting. Under the Affordable Care Act, health insurance is mandatory and those uninsured must apply for a minimum level of coverage or face a tax penalty. However, choice of health insurance coverage is difficult, as the consumer may have to judge costs vs. their medical and financial risks: evaluate his/her future use of healthcare services, assess, compare out-of-pocket costs and premiums provided by different plans while still taking into consideration provider features (such as network, drug coverage of potential exclusions), way of working with a doctor and coverage level (bronze, silver, gold and platinum) (Rice, Jacobson, Cubanski and Neumann, 2014). In order to facilitate the choice of an insurance plan Americans were provided with federal- and state-based Health Marketplaces, which constitute online-based platforms that enable comparison and purchase of health plans. Additionally, there are also private non-governmental websites that facilitate health insurance search, such as healthcare.com. Some of those websites may not provide full information (they usually contain a disclaimer). Healthcare.gov is not open for use outside of the open enrollment period unless under Special Enrollment, Medicaid or CHIP. Thus, under certain circumstances, the consumer has no choice but utilize intermediaries. Privately-owned websites utilize well known marketing techniques to influence choice (Xiao and Benbasat, 2011). Many privately-owned websites receive compensation from third-party providers (advertisers), which in turn may influence the way offers concerning insurance companies are presented to the user. We propose a multi-method study concerning how manipulated information influences consumers’ purchase decision. We seek to understand how consumers can be manipulated in their choice in order to warn and educate the public. Future research may build upon our findings to scrutinize the contextual dynamics that enable online vendors deceive consumers.

Methodology: This research will undertake a multi-method approach: Field interviews and observations will be carried out in order to gain deep insights which include: 1) an examination of private health insurance broker websites 2) interviews with health consumers in order to obtain their perspective and their experiences with insurance purchase decisions. Next, we will conduct a controlled experiment. The dependent variable is constituted by purchase intention, the independent variable is manipulation of information (manipulation of content and presentation) and its impact is mediated by affective and cognitive responses of the buyer (based on Xiao and Benbasat, 2011). The relationships are hypothesized to be moderated by: a) task complexity (high vs low) and purchase situation (impulse vs planned) b) measured variables of health status, prior knowledge of insurance and uncertainty avoidance. During the experiment a random sample of consumers will be asked to purchase insurance online. Sample size will be calculated with a power analysis. A survey will be distributed before and after the task to measure the difference in affective and cognitive mechanisms of the respondents. A website resembling online insurance broker will be designed with information manipulations as specified in research design.

Early Research Findings. The poster will explain the design of the experiments and early findings from interview and pilot study.

An Electronic Health Record Phenotyping Algorithm for Identifying Patients with Hepatorenal Syndrome

Jejo Koola1,2, Samuel B. Ho3,4, Michael E. Matheny1,2

1Tennessee Valley Healthcare System VA, Nashville, TN; 2Vanderbilt University, Nashville, TN; 3University of California at San Diego Medical Center; 4Dept. of Veterans Affairs, San Diego, CA

BACKGROUND: Patient phenotype identification serves as an essential step for outcome prediction, survival analysis, and other retrospective and prospective research studies. The Hepatorenal Syndrome (HRS), one of several cirrhosis associated kidney disorders, stands as an archetype of multi-organ failure; the median survival for Type 1 HRS is two weeks. An International Classification of Diseases version 9 (ICD9) code exists for HRS; however, its accuracy is unknown. ICD 9 codes are well known for being poor markers of patient phenotype. Hepatorenal Syndrome is an especially complex phenotype as it requires ruling out other causes of renal failure in patients with cirrhosis, of which there are many.

OBJECTIVE: We sought to identify the accuracy of the ICD 9 code for Hepatorenal Syndrome and develop a phenotyping algorithm based on electronic health record (EHR) data.

METHODS: We analyzed a retrospective cohort of patients hospitalized nationwide in the Department of Veterans Affairs between 2005 and 2013. We selected 504 hospitalized patients with a prevalent or incident ICD 9 diagnosis of cirrhosis and laboratory evidence of acute kidney injury stratified by renal (AKIN Stage I, II, or III) and cirrhosis (MELD score < 20 versus >= 20) severity. We performed manual chart review of the entire inpatient admission including medical notes, labs, and radiology procedures to categorize patients into one of five phenotypes: HRS Type 1, HRS Type 2, HRS Type Indeterminate, Maybe HRS, and Not HRS. For probabilistic phenotyping, we constructed a data matrix with 704 candidate predictor variables consisting of demographic variables, laboratory values, pre-existing and inpatient conditions and procedures based on administrative codes, and outpatient and inpatient medications. We performed penalized logistic regression using a Least Absolute Shrinkage and Selection Operator (LASSO) to select a subset of the candidate predictor variables. The outcome variable of interest was HRS phenotype by chart review (HRS Type 1, Type 2, and Indeterminate Type were lumped into a single category of Yes HRS). We constructed three models based on the “Maybe HRS” outcome: in the first, observations that were annotated as Maybe HRS were given an observation weight of 0.5 in the LASSO outcome prediction, survival analysis, and other retrospective and prospective research studies. The Hepatorenal Syndrome (HRS), one of several cirrhosis associated kidney disorders, stands as an archetype of multi-organ failure; the median survival for Type 1 HRS is two weeks. An International Classification of Diseases version 9 (ICD9) code exists for HRS; however, its accuracy is unknown. ICD 9 codes are well known for being poor markers of patient phenotype. Hepatorenal Syndrome is an especially complex phenotype as it requires ruling out other causes of renal failure in patients with cirrhosis, of which there are many.

RESULTS: Of the 504 patient cohort, 115 and 28 had HRS Type 1 and Type 2 respectively, 21 had HRS Type Indeterminate, 58 were annotated as Maybe HRS, and 282 did not have HRS. Treating the patients with a “Maybe HRS” annotation as positive for HRS, the discharge ICD 9 code had a sensitivity, specificity, positive predictive value, and negative predictive value of 0.58, 0.91, 0.83, and 0.73 respectively. Conversely, treating “Maybe HRS” annotations as negative for HRS, the ICD 9 code had operational parameters of 0.63, 0.85, 0.68, and 0.83 respectively. Of the 704 candidate predictor variables, the LASSO regression model identified 20 that were predictive of a HRS diagnosis. The model had an AUC of 0.92 (95% CI: 0.91 – 0.94). Table 1 lists the variables along with their odds ratios from the unpenalized logistic regression model. Using Youden’s point to define the optimal threshold, the sensitivity, specificity, positive predictive value, and negative predictive value of the EHR phenotyping algorithm were 0.88, 0.83, 0.80, and 0.90. Sensitivity analysis of the “Maybe HRS” annotation showed no significant difference from the “original model” with AUCs for the two additional models of 0.93 (95% CI: 0.91 – 0.95) and 0.91 (95% CI: 0.89 – 0.94) respectively.

DISCUSSION: Hepatorenal Syndrome is a complication of cirrhosis with high morbidity and mortality. As all studies with HRS have been limited to few patients (between 15 and 100), retrospective analyses of large EHR cohorts may prove useful. However, no published literature exists on the accuracy of the ICD 9 code for Hepatorenal Syndrome. In this study, we show that the ICD 9 code has very poor sensitivity most likely because patients with Hepatorenal Syndrome are coded (if at all) with the more general “Acute Kidney Failure.” We further develop a probabilistic EHR phenotyping algorithm with significantly improved sensitivity while maintaining comparable specificity.

Table 1: Odds ratios and confidence intervals for the variables identified by the lasso model. Odds ratios are derived from rerunning the model in an unpenalized general linear model.

Challenges and Triumphs: Developing an NLP Pipeline for Thyroid Ultrasound Reporting

Rajesh Koralkar, MSHI, Eric LaRose, BS, Yiqiang Song, M.S, David F. Schneider, MD, Peggy L. Peissig, PhD

1Marshfield Clinic Research Foundation, Marshfield, WI; 2University of Wisconsin, Dept. of Surgery, Madison, WI

Introduction
Thyroid nodules are extraordinarily common. Approximately 66% of adults will have a thyroid nodule. Thyroid ultrasonography (USG) remains the best method of imaging thyroid nodules and prioritizing them for biopsy, observation, or surgery. Unlike the reporting for other imaging techniques, USG reporting is largely unstructured and variable in pattern. This makes extraction of critical nodule features challenging. We report on the development of a natural language processing (NLP) pipeline to extract thyroid nodule characteristics from thyroid USG reports present in the electronic health record (EHR).

Methods & Results
This study was approved by the Marshfield Clinic Institutional Review Board. The study includes patients who had thyroid USG and Fine needle aspiration cytology (FNAC) within the Marshfield Clinic Health System from January 2007 –September 2015. Patients with indeterminate cytology results were selected for this study. Radiology documents including thyroid USGs, are stored in a structured XML format within the EHR. Descriptive nodule information is embedded within text strings that required NLP. We used NLP to identify terms in radiology reports and to decide their status such as certainty and negation. Study terms were identified in the Unified Medical Language System and extracted using clinical Text Analysis and Knowledge Extraction System (CTAKES), from the processed documents. Similarly, measurements of nodules were identified using customized regular expression operations. The relation between terms and values were then evaluated by their presence in the same sentences to construct logical groupings. (refer to Figure 1: Workflow Overview). Post processor items included thyroid lobe and nodule for extraction of characteristics. We identified 4593 patients who had USG and FNACs done on a thyroid nodule. Of these, 1400 patients had indeterminate cytology results. We manually validated data from 100 documents calculating the percentage of correct extractions for the characteristics for each of study items: measurements (height, width, diameter) 90%; unit of measure 92%; location 83%; calcification 75% and echogenicity 92%. One of the challenges we had is in determining location of the item as most sentences had mention of both Left and Right in context to different items. The missing measurements were attributed to where no study item was associated to measurement in same sentence. CTAKES output for most part Negated terms appropriately.

Discussion
This is an example of a novel NLP application for extracting critical thyroid nodule features from USGs. The unstructured and variable pattern of thyroid USG reporting makes determining calcification status the most challenging. This preliminary work will be extended by improving post-processing of multiple sentence logical groupings and then to another institution to test the generalizability of the NLP pipeline.

Analysis and Redesign of Alerts and Reminders in a Commercial Electronic Health Record System to Reduce Alert Fatigue

Polina Kukhareva, MS, MPH, Damian Borbolla, MD, MS, Kensaku Kawamoto, MD, PhD, MHS
Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah, USA

Abstract
“Alert fatigue” is an important barrier to clinical quality improvement through the use of information technology. At the University of Utah Health Care, the Clinical Decision Support (CDS) committee is employing a pragmatic approach to monitoring and managing CDS interventions in the context of a commercial electronic health record (EHR) system. Through the analysis of the top volume CDS alerts and reminders and their associated process and outcomes measures, we are aiming to reduce alert and reminder volume and associated fatigue. Here, we describe our approach to alert management in a commercial EHR system and discuss planned next steps.

Introduction
Many CDS alerts and reminders are inaccurate or contextually irrelevant, causing “alert fatigue” that can lead to ignoring appropriate CDS interventions, threatening patient safety.[1] While recognized as an important problem, many healthcare IT departments are unable to dedicate significant resources to address this issue, due to competing demands for meeting regulatory requirements or simply meeting new end-user requests. Therefore, there is a need for a pragmatic approach to address alert fatigue problems. Here, we share our experiences in identifying and modifying low accuracy and high volume alerts and reminders. To improve the specificity of our alerts and reminders and to reduce alert fatigue, we (1) analyzed success level of the alerts and reminders and (2) proposed pragmatic methods to improve specificity.

Methods
University of Utah is currently using a commercial EHR system (Epic). Medication alerts are supported by the Medi-Span drug database. Information about alerts history is recorded in the EHR and transformed into the data warehouse. We performed a descriptive analysis of all medication alerts and other custom alerts and reminders (known as best practice advisories or BPAs) which fired during 2015. For medication alerts, we focused on high volume alerts with acceptance rate below 10%, defined as the number of medication orders that were cancelled, removed or discontinued within one hour after the alert fired. For BPAs, we focused on high volume alerts and reminders with cancellation rate above 95%. We performed a data-driven impact assessment and made changes through deliberation in the institutional CDS committee.

Results
The overall number of medication alerts shown was 3,563,354, with 27% seen by clinicians, with an average of 483 alerts per clinician per year. Number of alerts in groups determined by the volume and acceptance level is shown at the top of each bar (Figure 1). For example, 11 alerts with 5-10% acceptance accounted for 13% of alert volume. By switching off inactive allergy ingredient alerts, we reduced their volume by 24%.

The overall number of BPAs was 5,833,045, of which 36% were seen by clinicians, with an average of 980 BPAs shown per person per year. As an alert fatigue mitigation strategy we decided to turn off BPAs for "uninsured mammograms" and “Hepatitis C screening”, which entailed 2 of our top 5 BPAs by volume in the system.

Conclusion
Assessing the level of acceptance and appropriateness of alerts and reminders is an important task but it is often not performed due to insufficient resources and prioritization. We show here how a pragmatic and targeted approach focused on the highest volume alerts and reminders can be implemented with relatively limited resource allocation. Reducing alert fatigue remains a critical area of need for effectively supporting clinical decision making and improving patient care.

Towards the creation of a novel career-based Health Informatics (HI) curriculum assessment instrument: Mapping HI job competencies to HI curriculum competencies

Anand Kulanthaivel, MIS\textsuperscript{1}, Enming Zhang, MS\textsuperscript{1}, Shilpa Katta\textsuperscript{1}, Josette F. Jones, RN, PhD\textsuperscript{1}

\textsuperscript{1}Indiana University, Indianapolis, IN, USA

Introduction

In order to best determine what competencies and skills are required for various careers in Health Informatics (HI) and create appropriately matched academic curricula accreditation recommendations, it is important to inventory current HI industry job requirements and posted curricula outcomes with respect to existing curriculum assessment frameworks. For this study, a Clinical Informatics-related career competency list as published by the American Nursing Association (ANA)\textsuperscript{1} is used as a guiding framework to establish the competencies required in HI-related careers.

The Commission on Accreditation for Health Informatics and Information Management Education (CAHIIM), in conjunction with the American Medical Informatics Association (AMIA), furthermore, have created a list of seven knowledge domains and skills relevant to HI curricula; three of these domains (behavioral/social sciences, health sciences, and information technology) form the core while the other four domains are conceptual overlaps of the three basic competency domains.\textsuperscript{2} Anderson & Krathwohl\textsuperscript{3} performed a review and revision of Bloom's classical taxonomy\textsuperscript{4} of learning; it is thus possible to utilize the taxonomy's revision in tandem with the CAHIIM-AMIA knowledge domain classification in order to assess the ANA’s instrument with respect to how its competencies match the competencies set forth in general pedagogy as well as those seen in existing HI curricula.

Methodology & Initial Results

Prior to coding, several changes to the provided terminologies were required as per consensus between the three producing authors (AK, EZ, SK). As needed, the titles and descriptions of the CAHIIM-AMIA competency domains were modified and definitions expounded upon in order to make them less ambiguous and more inclusive. Many competencies in the ANA instrument were re-worded by the authors in for similar reasons.

Two co-authors (EZ, SK) have determined which CAHIIM-AMIA competency maps best to each ANA job competency; furthermore completed is making the CAHIIM-AMIA domains more specific by mapping to the two dimensions of Anderson's revision of Bloom's taxonomy. Initial analysis of interrater reliability of this mapping shows that there is a raw concordance of over 60% between the two raters.

Conclusion & Future Work

We conclude at this point the fact that current assessment instruments require more explicit detail and other modifications in order to be useful. For validation reasons, a statistically sound method will be used to compare inter-rater reliability beyond raw percentage of concordance. Broader future goals include the creation of novel curriculum assessments that are based upon appropriate intelligence from both the academic world as well as that of the professional one.

Participants’ View on Picture Taking in a Behavior Change Intervention

Pei-Yi Kuo, MA , Michael S. Horn, PhD
Northwestern University, Evanston, IL

Introduction

In diary studies and behavior intervention research, asking participants to take photographs of their actions is a common approach to elicit reflection1. Pictures can hold participants accountable2 and serve as source of learning and motivation3. Yet, we do not fully understand how users feel about responding to daily prompts by recording both words and pictures1. This paper presents qualitative findings from a 20-day behavior intervention on sustainable lifestyle choices and examines how people feel about capturing themselves using words and pictures.

Method

A total of 62 adult participants (83.6% female) were recruited for a 20-day intervention. The study involved asking participants to complete one sustainable lifestyle challenge per day (e.g., challenges related to exercise, diet, and transportation). Challenges were delivered to participants through a smartphone app called PACO4. Participants were required to describe what they had done for each challenge and submit an accompanying photograph. At the end of the intervention, participants filled out a post-study survey. We then selectively interviewed 15 participants who had disagreed with the survey questions: “I liked that I could capture my behavior with a picture.” and/or “The option to capture my behavior with the camera made me more aware of my behavior.” These participants were asked to reflect on how they felt about capturing their behaviors with words and photographs.

Findings

In the survey, the majority of participants indicated that they liked capturing their behavior with a picture (48.4%) and that this made them more aware of their behavior (46.8%). 67.7% of the total participants indicated they liked describing their behavior in the app. We found the male participants in our study had a positive attitude toward capturing their behavior with a picture, unlike earlier findings on the relationship between gender and photo sharing1. Similarly unexpected, only two out of 13 participants above 35 years old disliked the idea of capturing their behavior with a picture. On the one hand, when participants indicated that they disliked photographing their behaviors, their reasons included difficulty remembering to take pictures and difficulty capturing actions with photos (e.g., do 20 push-ups). Few participants said that taking pictures made the challenges more difficult and few did not like to be held accountable with pictures. On the other hand, some preferred describing what they had done with words only, saying that it seemed more helpful and logical, and that writing helped them think more.

Conclusion

To better understand the value of participant photographs in behavior change intervention, we examine what participants liked and disliked about capturing their behaviors with pictures. Though participants who liked capturing their behavior with a picture did not necessarily complete more challenges or describe their behaviors with more words, they mentioned that it was fun and they felt motivated. By talking to those who disliked capturing themselves, we identify several areas of improvement to make photographing behaviors a smoother process. These included: allow participants for more time to record pictures than words, enable separate recordings of words and pictures, and offer examples on capturing actions upfront. Our next steps will also involve developing a framework to determine the amount of user efforts spent in challenge completions from participants’ photos.

Integrating Usability Engineering into System Testing and Implementation: A Multi-Phased Approach to Ensure System Usability and Safety

Andre W. Kushniruk, MSc, PhD, FACMI1, Elizabeth M. Borycki, RN, PhD1
1University of Victoria, Victoria, British Columbia, Canada

Abstract
Usability has become recognized as being a major issue in the successful design and implementation of health information systems. We describe a multi-phased approach to integrating usability engineering into system testing to ensure both usability and safety of healthcare IT upon widespread deployment. The approach integrates laboratory testing with clinical simulations (conducted in-situ prior to widespread system deployment) and near-live recordings of user interactions with systems. At key stages in this sequence usability problems are rectified.

Introduction
Ensuring the usability and safety of healthcare IT is essential in order to lead to successful adoption of healthcare IT. Many different approaches have been proposed and applied for testing the usability of systems and for evaluating their impact on patient safety 1. While each method has its advantages, there are also limitations associated with each. For example, usability inspection methods can be easily and cost-effectively applied to make predictions about problems users may face. However, these methods are not a replacement for live testing of users involving application of usability testing methods and clinical simulations conducted in-situ 1. In this poster we argue for a multi-phased and mixed methods approach to ensuring system usability and safety. It is argued that in order to detect majority of errors, the methods should be applied in a phased approach, beginning with laboratory testing, followed by clinical simulations and near-live testing of systems.

Methods
An approach to the testing of healthcare IT was developed that involves several sequential phases. In the first phase classic usability inspection methods (including cognitive walkthrough and heuristic evaluation) are applied to predict usability problems. This is followed by laboratory-style usability testing under artificially controlled conditions, where video recording is used to collect data on typical user interactions. Problems arising from these phases are rectified and then a phase of testing under simulated conditions (i.e. by applying clinical simulation methods) is conducted. After rectifying any serious problems, the testing moves to the phase of near-live testing, where user interactions are observed under close to or real conditions and settings.

Results
The multi-method, phased approach described above has now been applied in a number of studies of EHRs and DSSs. The type of errors and usability problems detected at each phase were found to differ. For example, early phase usability inspection and usability testing typically uncovered surface level usability problems, but testing involving clinical simulations was needed to detect issues related to impact on clinical workflow. Near-live testing typically revealed a range of contextual issues that would otherwise have not been predicted by the previous phases.

Conclusion and Discussion
In our work we have attempted to integrate a number of different methods for ensuring system usability and safety. It was found that each method detected different types of problems, starting with surface level usability problems and leading to issues related to workflow and patient safety. It is argues that such a multi-method phased approach is needed to create a “safety net” to detect and rectify a range of errors and problems prior to widespread system release. The approach described in this poster has begun to be applied more widely in organizations where usability and safety have been deemed of utmost importance in system implementations and deployments.

Development and Validation of an Electronic Health Record (EHR)-Based Risk Stratification Rule for Inpatient Delirium

Joanne LaFleur, PharmD, MSPH,1,2 Jacob Crook, MStat,2,1 Scott Nelson, PharmD, MS,2 Lacey J Lewis,2,1 Kristin Knippenberg, MS,2,1 Grace Gardner, RN,2 Charlene R. Weir, RN, PhD, FACMI2,1

1University of Utah, Salt Lake City, UT; 2Department of Veterans Affairs, Salt Lake City, UT;

Introduction
Delirium during a hospital stay can have profound implications for elderly inpatients, increasing the risk of death at discharge and 12 months by 20% and 100%, respectively.1,3 Though reported rates vary from 14-56%,4,5 it is thought the true incidence is unknown because of low awareness and poor documentation.6 Though delirium-prevention strategies are effective,7 inpatient delirium remains largely unaddressed. We developed and validated a risk algorithm for identifying patients at high risk of delirium, with the goal of increasing clinician awareness of delirium risk in appropriate patients.

Methods
Our algorithm used structured data collected as a routine part of healthcare operations for a national cohort of hospitalized Veterans ages 40+ in 2011-2013. We developed the model using Cox Proportional Hazards Regression to predict delirium associated with an order for sitters or restraints. Candidate risk factors were clinical and demographic traits known or theoretically associated with inpatient delirium. We randomly sampled 8 x 50,000 patients from the full cohort and fit a model in each sample using backward selection. Risk factors that were significant at alpha=0.05 in at least 7/8 models were fit in the full cohort to estimate coefficients, which were multiplied by 10 to create “scores” for each risk factor. Scores generated for each patient based on the presence of risk factors. Test characteristics were calculated in the full cohort and in an external sample of prospectively assessed Veterans from one hospital. In the external sample, delirium was assessed using the Short Confusion Assessment Method (Short CAM).

Results
In 700,180 Veterans, 15,656 (2.2%) had orders for sitters or restraints. In the national cohort, accuracy for predicting sitter/restraint orders was maximized at a score threshold of 33 (C=73.1%). Test characteristics for the tool at that threshold are summarized in the Table. These results suggest that every 2.5 patients scoring as “positive” would include one case of true delirium. Higher thresholds (i.e., scores ≥175) are needed to obtain similar positive predictive values for predicting sitter/restraint orders.

Conclusion
Patients at highest risk for delirium can be identified using data collected as a routine part of healthcare operations. Future work should focus on developing and evaluating a clinical alert for delirium.

Integration of a Healthcare Data Dictionary Front-end Tool with Data Visualization: Architectural Features and Early Implementation in the Laboratory Domain

Jaehoon Lee, PhD1, Nathan C. Hulse, PhD2, Michael G. Newman, MS2, Douglas Mitchell1
Gyan Sharma, MS1, Naveen Maram, MD, MPH, MSHI1

1Intermountain Healthcare, Salt Lake City, UT; 2University of Utah, Salt Lake City, UT

Abstract

In this manuscript we integrated interactive data visualization with a web-based healthcare data dictionary (HDD) front-end tool. We used a commercial visualization tool: Tableau 1) to pipeline data extraction, aggregation, and visualization generation and 2) to use Tableau server as a visualization service provider. We implemented data visualization using the laboratory domain and the early usage in production demonstrated that the proposed approach is plausible in terms of computational efficiency and productivity of visualization pipelining.

Introduction

Athena is a locally developed web-based tool at Intermountain Healthcare used to support knowledge engineers to navigate HDD concepts and relationships. What the tool has not yet provided is information of clinical instance data to inform how HDD concepts have been practically utilized in Intermountain’s clinical data repository (CDR). The goal of the Athena visualization project is to enhance the tool with visual representations and interactive navigation of clinical data in conjunction with HDD concepts and terminologies.

Method

We used Tableau as a toolkit for whole data visualization pipelining, which includes 1) data retrieval and abstraction, 2) visualization transformation, and 3) visualization service. The visualizations were created in an authoring environment (Tableau Desktop) using data and knowledge extracted from HDD and CDR. Once the visualizations were created and deployed upon a Tableau server, the server provided remote retrieval as a service based on Tableau Javascript APIs, such that Athena could embed the visualizations in its web pages. Access control and user privileges in the two applications were synchronized so that patient health information could be managed in a secured way. The visualizations on the Tableau server side constantly refreshes their data to maintain an up-to-date status in an automated manner separately from Athena.

Conclusion

The implementation in production was successful and its early usage pattern demonstrated that 1) the integration of the two applications are feasible in terms of architecture such as interfaces, security control, and performance; 2) data pipelining was separated from the Athena application and fully managed on Tableau side to ensure productivity and maintainability of the visualizations, and 3) visualization response time was acceptable (average elapsed time to view: 0.55 seconds / request). Our future plan is to add diverse use cases and domains based on the framework such as problems and medications.
Clinical Decision Support for High Risk Medications in the Elderly at the Point of Prescribing

Joseph R. LeGrand, PharmD1, Erin B. Neal, PharmD2, Bryan E. Shepherd, PhD3, Scott D. Nelson, PharmD, MS1,3, Shane P. Stenner, MD, MS1,3

1Vanderbilt University Medical Center, Nashville, TN, 2Vanderbilt Health Affiliated Network, Nashville, TN, 3Vanderbilt University, Nashville, TN

Introduction
High risk medications (HRMs), such as those with high anticholinergic and antihistaminergic activity are associated with increased morbidity and mortality in the elderly.1 The American Geriatrics Society (AGS) recommends avoiding HRMs in older adults to improve safety and quality of care in this population.2 Further, performance on HRM metrics now impact reimbursement of health systems, payers, and pharmacies as national quality organizations have adopted these recommendations. Several interventions have targeted HRM prescribing in the elderly with inconsistent results, and only a few have incorporated clinical decision support (CDS) at the point of prescribing.3,4

Methods
The most common HRMs prescribed using Vanderbilt’s e-prescribing system were evaluated in order to target the CDS rules for the most frequently used medications. Targeted CDS was limited to those HRMs that had at least one evidence-based potentially safer medication (PSM).5 A PSM alert is triggered within the e-prescribing workflow when a HRM prescription is initiated for a patient 65 years or older. The alert displays a list of PSMs, as well as an option for the user to continue with the current HRM. If a PSM is selected, the user is provided available doses and dosage forms and can continue with the order. Descriptive statistics were collected for the target population, and post-implementation rates were compared to baseline rates using a quasi-Poisson regression model in R to detect a change in prescribing habits.

Results
Following the implementation of a HRM CDS alert, a 10.6% decrease (95% CI 6.5% to 14.5%, p < 0.0001) in the risk of prescribing HRMs in the target population was observed.

Table 1. Average weekly percent and quantity HRM in target population pre- and post-intervention.

<tr>
<td>Avg # HRM / Week</td>
<td>265.3</td>
<td>255.6</td>
<td>265.1</td>
<td>235.5</td>
</tr>
</tbody>
</table>

Conclusion
CDS at the point of prescribing is effective at reducing the incidence of HRM prescribing in the elderly. It is unknown if the reduced prescribing of HRMs results in decreased adverse drug events or improved patient outcomes. One limitation of the study is that a control group was not established, which could have helped identify any potential confounding factors.

Designing Avatars to Assist with Self-Management for Overweight and Obese Adolescents

Cynthia LeRouge, PhD¹, Savitha Sangameswaran, MS¹, Toree Malasanos M.D.²
¹University of Washington, Seattle, WA, ²Kiwee Health, LLC, Gainesville, FL

Introduction
Adolescent overweight and obesity is a major public health concern. Evidence has accumulated about the efficacy and user acceptance of computer-based interventions (CBI) to modify behaviors. Given the interest that youths have in avatars from their experience with avatars in computer games, consumer health applications designed with virtual agents (a.k.a. avatar characters representing the user in virtual environments or artificial health assistant characters) may be an effective way to engage them in behavioral lifestyle support tools. The objective of this study is to examine adolescent preferences regarding avatar design and functionality (i.e., the collective features and functions adolescents will find most useful, usable, empathetic, and sociable) for potential use in a healthy lifestyle/weight loss assisting application.

Methods
Using one-on-one user-centered design methods, 77 adolescents (ages 12 to 17) enrolled an intensive lifestyle modification summer camp program served as study participants. The adolescent participants: 1) responded to general questions of computer use (i.e., technology access questions, level of avatar, or virtual agent experience) 2) reviewed mid-fidelity mock-ups of seven types of graphical embodiments of virtual agents and provided design recommendations regarding specific attributes of the character(s), such as voice (options presented from professional recordings), accessories available to the character, and a facial expressions chart review and 3) provided data on the interactive functions the avatars could serve. Thematic analysis of the transcripts was conducted by a team of three researchers.

Results
Adolescents indicated a great level of interest in avatars assisting self-management efforts – “…Yeah I think it would be really cool to like be able to make a creatable Avatar, and see like maybe have progress shown in the Avatar.” Some of the adolescent preferences for avatar design are outlined in the Table below.

<td>“Virtual Me” avatar exemplifies goal progress through both external avatar appearance &amp; internal changes of the body (e.g., a beating heart that reflect the effects of progress &amp; choices)</td>
</tr>
<tr>
<td>Interaction</td>
<td>Ranged from initial greeter to exercise pal to always present empathic support</td>
</tr>
</tbody>
</table>

Conclusion
Our results call for a mass customization (with options such as hair and eye color) approach to the design of avatars that can facilitate self-management of overweight/obese adolescents and augment efforts in the continuum of care. Designing avatars based on adolescent preferences may increase the probability of engagement and long-term retention of participants with behavioral lifestyle support tools.
Reviewing Asthma-related Grey Literature and Personal Opinions on Twitter using LDA and CTM Clustering

Gondy Leroy, PhD, Joe Koolippurackal, Shikha Swami, and Philip Harber, MD MPH
University of Arizona, Tucson, Arizona, USA

Abstract
Twitter is a big data source useful for sampling opinions and information in the community. In this exploratory study, we compared the usefulness of information shared about asthma. We collected tweets using asthma and #asthma and compared tweets with and without URLs. To automatically create topic overviews that can be efficiently reviewed, we used LDA and CTM clustering. We evaluated using 2, 5 or 10 clusters.

Introduction
Social media play an increasingly important role in medicine. We focused on asthma, which affects 8% of the US adult population(1), and analyzed Tweets to assess: (a) what proportion is unique; (b) differences between tweets from individuals vs grey literature (i.e., those referring to professional information); (c) whether searching for tweets with or without a hashtag matters.

Methods and Results
In fall 2016, we collected 178,796 tweets for asthma and #asthma using the Twitter Search API. Based on prior work(2), we made the broad assumption that tweets with a URL refer mostly to grey literature tweets (by professionals), while tweets without URL are more often comments by individuals. We removed duplicate tweets and stopwords, then stemmed the terms. To review tweet content, we compared Latent Dirichlet Allocation (LDA) and Correlated Topics Model (CTM) clustering for 2, 5 and 10 cluster.

Overall, 70% of the tweets were unique (Table 1). Tweets with a URL are 64-77% unique. Tweets without URLs were more unique and almost completely unique for asthma. This is not unexpected since this query is broad (appearance of word asthma) and personal comments can be expected to be unique. To evaluate the content of the entire set in an efficient manner, we clustered the tweets and evaluated the clusters. All cluster sets were shown in random order and evaluated (blind) by a domain expert, who scored each term on a 4-point scale of relevance to asthma (an asymmetric scale was used to penalize nonsense terms). Figure 1 and 2 show the average normalized scores. Scores for all terms were combined per condition. LDA clustering resulted in more relevant clusters and more consistent quality. Tweets for #asthma (with hashtag) by individuals contained the most relevant terms. Terms were least relevant for the asthma query without URL (personal comments, broad query). Implication: For estimating community members’ opinions & information, relevance is improved by use of LDA clustering of tweets without URL references.

Drug-drug Interaction Detection with A Topic-modeling Based Framework Augmented with Distant-supervision

*Dingcheng Li1, *Sijia Liu2, Majid Rastegar-Mojarad1, Yanshan Wang1, Xiaodi Li3

Introduction Potential drug-drug interactions, defined as the co-prescription of two or more drugs that are known to interact, are one of primary causes of medical error. A report in Australia mentioned that 75% of hospital admissions related to medication errors are preventable. Indeed, health care providers often have inadequate knowledge of what drug interactions can occur of how to properly manage an interaction when patient exposure cannot be avoided. One of the primary reasons for this knowledge gap is the lack of complete and authoritative source of DDI knowledge. The dynamic nature of drug knowledge, combined with the enormity of the biomedical literature, makes the task of collecting and maintaining up-to-date information on drug-drug interactions extremely challenging and time-consuming. Therefore, there is a strong need to approach this task with automated methods, supplemented with human effort. Natural language processing (NLP) and information extraction methods for identifying and extracting DDIs have been receiving increased attention in the last few years, and several attempts have already been made to develop methods for this task, showing good potential for success.

Methods In light of this, we propose to design, implement and evaluate a Bayesian model complemented with knowledge-driven distant supervision called relation topic modeling (RelTM for short). It is a semi-supervised probabilistic generative model for inducing clusters of DDI types and recognizing drug entities as well. The set of relation types is not pre-specified but induced from observed unlabeled data. The relation induction is augmented with distant supervision by incorporating resources-based similarity functions. Our observed data consists of a corpus of sentences and each sentence is represented by a bag of relation pairs. Each pair represents an observed drug-drug interaction between two drugs and consists of three components: the relation features, the source drug and the destination drug. The relation pair is the primary observed random variable in our model and we construct our models so that clusters consist of textual expressions representing the same underlying relation type. Since unlike classical LDA where observed words are independent and shared by the whole collection of documents, it will be reasonable to assume that each word may be generated by some specific topic. In our framework, a set of drug mention features supports one drug and relation features and mention features jointly support one relation. Therefore, the generative process is somewhat different. Namely, all of its features are only sampled under one specific relation and all of mention features are only sampled under one specific drug entity as well.

Experimental Results As a gold standard for all experiments in this work, we used DDIExtraction-2013 corpus provided by the challenge organizer, for development. It contains 142 Medline abstracts on the subject of drug-drug interactions, and 572 documents describing drug-drug interactions from the DrugBank database. The corpus includes 6976 sentences that were annotated with four types of pharmacological entities and four types of DDIs. To demonstrate the effectiveness of our proposed model, we conducted a series of experiments on DDI Drugbank dataset. There are two models evaluated in this section: RelTM model and the combined model with RelTM and similarity measure coefficient (SMC) model. The performance metrics is computed by the code in Java and it is provided by DDIExtraction 2013 Challenge organizers. The performance of the two models mentioned above is shown in Table 1. Comparing these results, we can draw the conclusion that the combination of RelTM and distant supervision together improve the overall performance, which is indicated in the micro-average F1 score, from 0.362 increasing to 0.480.

Conclusion and Future Work In this work, we propose a topic modeling based distant supervised approach for the task of drug-drug interaction from biomedical text. The proposed approach does not require human efforts such as annotation and labeling in data preparation stage, which is its advantage in trending big data applications. Meanwhile, the distant supervision combination allows us to incorporate rich existing knowledge resources provided by domain experts. In future, we will extend similarity function by incorporating updating rules and correlation between latent relations. One direction of exploration includes the release of symmetric Dirichlet prior to non-symmetric considering the unbalanced numbers of relation categories.

Introduction. Along with the widespread use of advanced information technology in the healthcare system the availability of a huge and heterogeneous amount of electronic medical data has proportionally increased. It has provided a novel opportunity to accelerate progress on the quality of patient care (1). Meanwhile, it also makes patient care more complex (2). There is no common clarity on how much data is being generated by electronic medical records (EMR), particularly in a highly data intensive setting environment like an intensive care unit (ICU) and how to manage the huge data amount for quality and research purpose. Mayo Clinic Rochester ICUs have an average of 15,000 admissions each year and generate considerably large amounts of clinical and administrative data stored and distributed in heterogeneous EMR systems.

The ICU DataMart at the Mayo Clinic is a near-real time database storing and integrating ICU patients’ clinical and administrative data which has served as a central data warehouse for decision support, quality control reporting, and data mining.

Objective. The aim of the current project is to quantify and understand the amount of data generated by ICU patients.

Methods. The Mayo ICU DataMart is a MS SQL based relational database integrating ICU patient clinical and administrative data extracted from various EMR systems and populated through extract transfer load (ETL) processes to DataMart in nearly-real time. We calculated the amount of one year of data which were generated during the year 2014.

Results. A total number of 13,355 patients with 19,409 ICU admissions were stored in Mayo Clinic Rochester ICUs in 2014 (summarized below).

<table>
<thead>

Ontology-Based Analysis of Adverse Drug Reactions Associated with Anti-infection Drugs in China

Mei Li, MD1, Yuying Cao, MD1, Liwei Wang, MD, PhD1,2, Hongfang Liu, PhD2, Yongqun He, PhD3

1School of Public Health, Jilin University, Changchun, Jilin, China; 2Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA; 3 Center for Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, MI, USA

Abstract

To understand the characteristics of adverse drug reactions (ADRs) associated with anti-infection drugs in China, based on the Ontology of Adverse Events (OAE), we analyzed 2,355 ADR case reports from the literature including the patients’ age and gender distribution, the administration routes, the drug classes, the most and severe ADRs, and the characteristics of ADRs caused by drugs of different pharmacological effects.

Introduction

In China, the number of adverse drug reactions (ADRs) reports associated with anti-infection drugs (AIDs) has continuously ranked top according to the Annual Report on Adverse Drug Events Surveillance (2014)1. In order to avoid severe ADRs, it is important to understand characteristics of ADRs associated with AIDs. However, there is no existing way to systematically analyze the ADRs due to the lack of standards in Chinese for ADR terms. Recent research shows that the Ontology of Adverse Events (OAE)2, with complete logical reasoning and classification structure, describes concepts and the concept relationship in the field of ADRs. And it gives a clue for our study. This study aims to analyze the ADR reports from the literatures based on the OAE, in terms of the patients’ age and gender distribution, the administration routes, the drug classes, the top and severe ADRs, and the characteristics of ADRs caused by drugs with different pharmacological effects.

Methods

The method contains four steps: data collection, data cleaning, data standardization and statistical analysis. In the first step, we collected ADR reports associated with AIDs from “National Scientific Data Sharing Platform for Population and Health” (from the literature in China during 1996-2014). In the cleaning up step, we removed the data irrelevant to anti-infections drugs, and extracted ADR terms from reports. During data standardization, the drugs were classified according to the Chinese textbook New Pharmacology (17th version), and then ADR terms were mapped to OAE terms from Chinese to English. In the last step, we used the Excel and CIMMiner to retrospectively analyze ADRs in the case reports.

Initial Results and Discussion

In all ADR reports, ADRs of AIDs in male and female were basically similar. Most reports of ADRs were found among the patients aged 30 to 40 (18.76%). The most reports involving Traditional Chinese Drugs were for children under 10 years of age (23.81%). Intravenous drip is the administration route that caused the most ADRs. The drug category that caused the most ADRs was quinolone class. And the chest discomfort was the primary ADR in all reports. In total 31 drugs, corresponding to 9 drug classes, and 2 Traditional Chinese Medicines caused serious ADRs. The drug Fosfomycin Sodium for Injection has caused severe ADR of death.

In this study we used OAE to systematically and effectively analyze the characteristics of ADRs in Chinese, and discover the correlation between the drug category and ADR category. Building a bilingual Chinese-English OAE ontology is significant for analyzing ADRs based on existing ontology.

An Exploratory Study of Continued Use of HIE

Huigang Liang, PhD1, Yajiong Xue, PhD1, Anne Marie Robertson2, Yvonne Hughes, MPA2, P. Allen Gray, PhD2, Patty Lewis2

1East Carolina University, Greenville, NC, USA; 2CoastalConnect Health Information Exchange, Wilmington, NC, USA

Introduction

Health Information Exchange (HIE) can potentially improve the quality, efficiency, and safety of health care delivery and be useful in engaging patients and improving care coordination and public health surveillance. Although the number of HIEs in the U.S. is growing rapidly in recent years, many struggle to sustain a healthy business. According to a report from eHealth Initiative, many new HIEs are starting up and existing ones are seeking ways to overcome various hurdles. The use of HIE is low. A review study based on 85 HIE evaluation articles finds that most studies reported HIE use in only 2-10% of the patient encounters (Rudin et al. 2014). The actual impact of HIEs on healthcare industry is still unclear. Only 57% of published analyses reported HIE benefits (Rahurkar et al. 2015). The number of HIEs that have been evaluated is low. Only 7-10 out of more than 100 HIEs were evaluated (Rudin et al. 2014). Given the huge federal investments on HIT and HIE, it is important to understand what lead to physicians’ positive perceptions and continued use of HIE. The logic is that if physicians perceive that HIE is valuable and are satisfied with HIE, they will be more likely to continue using HIE, thus reducing the sustainability problem of HIE.

In this research, we develop a theoretical model based on the IS success model (DeLone & McLean, 1992; 2003) to explain what factors influence continued use of HIE. We propose that the benefits of HIE are mainly derived from three key characteristics: data quality (accuracy, reliability, completeness, and timeliness of HIE data), data accessibility (the degree to which external health data can be accessed via HIE), and system compatibility (the degree to which HIE is compatible with the users’ current system and work context). These three factors can improve operational efficiency by reducing work time, costs, and test redundancy. Improved operational efficiency and data quality will help to create a heightened value of HIE. Further, if HIE is perceived to increase efficiency and bring value into the practice, a greater level of user satisfaction will be achieved. Finally, we propose that perceived value, operational efficiency, and user satisfaction will jointly enhance the continued use of HIE.

Method

Coastal Connect Health Information Exchange (CCHIE) is a nonprofit regional health information organization dedicated to enabling the secure and reliable exchange of health information in Eastern North Carolina. Supported by a Duke Endowment Grant, CCHIE engaged in a three-year project to connect Community Care of North Carolina (CCNC) providers, safety-net organizations, and some specialists identified by CCNC through a HIE network. By electronically sharing patient data, CCHIE intended to increase the efficiency of patient care and improve care coordination. This study is part of a large project to evaluate the outcome of the HIE implementations in participating physician practices from 2012 to 2014. For this study, we surveyed 626 managers of physician practices that joined the CCHIE network. A total of 126 completed surveys were returned. We used linear regression to estimate the relationships among variables.

Results

As hypothesized, operational efficiency is increased by data quality (b=.33, p<.01), data accessibility (b=.31, p<.01), and compatibility (b=.23, p<.01). Perceived value is influenced by data quality (b=.24, p<.05) and operational efficiency (b=.48, p<.01). User satisfaction is enhanced by perceived value (b=.45, p<.01) and operational efficiency (b=.42, p<.01). Finally, Continued use is increased by satisfaction (b=.28, p<.05) and operational efficiency (b=.18, p<.05), but not perceived value (b=.15, p>.05). Further analysis shows that the effect of perceived value on continued use is fully mediated by satisfaction. The explained variance (R²) for efficiency, value, satisfaction, and continued use are .45, .63, .62, and .31, respectively. Common method bias was addressed by the Harmon’s one factor test.

Conclusion

Continued HIE use can be directly promoted by user satisfaction and operational efficiency, and indirectly promoted by perceived value, data quality, data accessibility, and system compatibility.

Three-Dimension (3D) Blood Vessel Reconstruction and Spatial Analytics with Whole-Slide Histological Images

Yanhui Liang, MS1, Jun Kong, PhD2, Fusheng Wang, PhD1
1Department of Biomedical Informatics, Stony Brook University, Stony Brook, NY; 2Department of Biomedical Informatics, Emory University, Atlanta, GA

Abstract

Digital pathology images present to researchers and clinicians rich information on tissue morphological and pathological signatures at the cellular level. In this study, we report a complete framework for 3D histological structure reconstruction of blood vessels with serial whole-slide microscopy images, and a high performance spatial query system to characterize the spatial relationships across reconstructed 3D histological objects. We vision our work as a new avenue to facilitate biomedical research with histopathological imaging data.

Introduction

Thanks to advances of large-throughput scanning technologies, digital pathology images are increasingly adopted in clinics for disease diagnosis and treatment evaluation. By studying whole-slide histological images, researchers and clinicians can better understand the underlying mechanisms of disease onsets and pathological evolutions. Therefore quantitative imaging and spatial analysis of histological entities with microscopy images are in great demand, especially for those studies involving 3D histological structure characterization and 3D spatial analytics (such as blood vessels and nuclei). We present such a framework for 3D primary vessel reconstruction with a set of serial histological images, and a high performance data warehousing system for large-scale spatial analytics with 3D medical data.

Methods

The Framework for 3D Blood Vessel Reconstruction (Figure 1): Our 3D vessel reconstruction framework consists of multiple processing components: image registration, vessel segmentation, vessel cross-section association, intermediate slide interpolation and 3D volumetric rendering. Given a set of histological whole-slide images, we register all slides to a reference image to align all slides into the same space. We next segment vessels by an improved level set method with prior information on vessel wall probability in the energy minimization paradigm. We achieve the optimal vessel cross-section associations by local bi-slide mapping and global vessel structure association within a Bayesian Maximum A Posteriori (MAP) framework. We generate intermediate slides by B-spline interpolation for smooth transition, and finally visualize the reconstructed 3D primary vessels by volumetric rendering with mesh model.

The High Performance System for 3D Spatial Queries (Figure 2): As changes of 3D histological structures and their spatial relationships are essential to study various diseases, we build a high performance 3D data warehousing system to store, manage and analyze 3D histological objects. The system supports multiple spatial query cases, such as 3D spatial cross-matching and 3D spatial proximity query. Spatial cross-matching of reconstructed 3D histological objects (vessels or nuclei) from different methods can be used to evaluate algorithm performance, and spatial proximity query such as nearest neighbor can inform pathologists of such answers as “for each 3D stem cell, return the nearest 3D blood vessel and its distance”. Our system includes 3D data partitioning, a real-time 3D spatial query engine and MapReduce based query processing. It is scalable and effective for querying massive 3D spatial data.

Conclusion

We evaluate our 3D reconstruction framework with a set of 54 whole-slide images from liver tissue sections stained by Immunohistochemistry (IHC), and apply our 3D spatial query system to the reconstructed 3D histological objects. Experiments present satisfactory results and quantitative evaluations demonstrate the efficacy of our methods. Our work is generic and applicable to other 3D biological entities with 3D pathology image datasets of diverse diseases.

Abstract

Team Based Learning (TBL) consists of several well established components: individual readiness assurance test (iRAT), team readiness assurance test (tRAT), team applications (tAPP), and peer evaluation. We have developed integrated web-based modules that deliver the TBL components to learners via the web. Facilitators are able to monitor on going and cumulative results.

Introduction

Team Based Learning (TBL), which is student centric & accountable and which is used in many medical schools, consists of several well established components: individual readiness assurance test (iRAT), team readiness assurance test (tRAT), team applications (tAPP), and peer evaluation. In order to streamline the delivery of TBL components to learners in a paperless fashion and to simplify facilitator administration of TBL these components were made into web deliverable modules.

Technology

A web services solution stack consisting of Apache web server, MySQL database and PHP (hereinafter, web stack) was used to develop the TBL delivery system. Initially Uniform Server and later Bitnami web stacks were employed. The Uniform Server, a Microsoft Windows operating system web stack, can run from a thumb drive or any USB storage device and requires no installation. Thus the system can simply be used on any computer with Windows operating system and a static IP address. The Bitnami web stack can run in Windows, Mac OS X or Linux environments as well as VMware or VirtualBox virtualized environments, and popular cloud platforms such as Amazon Web Services (AWS), Microsoft Azure, and Google Cloud Platform.

Design

The tRAT & tAPP components have the full functionality of expensive self-scoring scratch off multiple answer sheets. Real time monitoring show facilitators each team’s correct & wrong answers, duration time and completeness as well as team test scores for each tRAT & tAPP and cumulative scores and rankings. The iRAT module allow only one answer attempt and provide facilitators with the same metrics as the tRATs and tAPPs. The Peer review modules allow each team member to rate their peers using either radio buttons, sliding bars, or divide the points as well adding text comments. The peer evaluations are available anonymously to team members & non-anonymously to facilitators from their respective home pages. Midterm and final grades are automatically calculated using any percent weighting for iRAT, tRAT, tAPP, and peer evaluation.

Conclusion

This integrated web based system delivers all of the necessary TBL components in an efficient and paper & printer saving manner that is functionally consistent with the paper format. When asked anonymously their preference, 8 students preferred web based delivery, 5 students preferred paper based, and 3 had no preference. Modules monitor, in real time component results and progress. Database storage of learner data makes for rapid summative assessments.
A Comparison of ESpell and GSpell Spell-Checker Tools

Fang Liu, MS; Paul Fontelo, MD, MPH
National Library of Medicine, Bethesda, MD

Abstract
Accurate spelling is crucial for obtaining optimal results with PubMed search tools. With increased usage of mobile devices and smartphones, we have noticed higher spelling errors. Auto spell-checkers, like, ESpell and GSpell, provide spelling suggestions and improve data retrieval. Using actual 500 search terms, we compared the use of these two utilities in ‘PubMed for Handhelds’. Both utilities are useful but we found that ESpell has higher precision and recall.

Introduction
ESpell and GSpell spell-checkers, both developed at National Library of Medicine (NLM), provide spelling suggestions to improve retrieval of PubMed data. ESpell, a recent addition (2015), is part of NCBI’s E-Utilities suite and is implemented through an API in existing search tools to provide spelling suggestions for misspelled terms within a single text query. GSpell uses several word similarity algorithms and can provide multiple suggestions even with compound words. Its Java software requires software installation on a server and migration when servers are updated or replaced. GSpell development and support ceased in 2006, so it is made available under "as is" condition. GSpell was used in “PubMed for Handhelds” for many years, but a recent hardware upgrade made migration challenging. Our goal for this project is to compare the ESpell and GSpell auto-suggestion functions.

Methods
From askMEDLINE’s query database, 500 search queries which retrieved no citations were randomly selected. The set of queries were fed to a script which simulated the automatic spelling correction function for both ESpell and GSpell. GSpell was configured to return the closest suggestion only. A manual normalization process removed queries that were Non-English, numbers (PubMed IDs) or people names, since spell-checkers are unable to autocorrect these terms. One of the authors (PF) evaluated the spelling suggestions to determine the accuracy of suggestions.

Result
Of the 500 queries, 45 (9.0%) were non-English queries, 66 (13.2%) were person names, and 11 (2.2%) were numbers. There were 378 queries in the normalized set. Among the 378 queries remaining, 175 were misspelled terms, and 203 queries were correct terms. ESpell gave suggestions for 124 misspelled queries (109 correct) and on 1 correct query. GSpell had autosuggestions on 127 misspelled queries (71 correct) and on 1 correct input query (“Dimexidum”). The precision for ESpell and GSpell are 87.2% (109/125) and 55.5% (71/128), respectively and their recall rates are 62.3% (109/175) and 40.6% (71/175), respectively.

<table>

Table 1. Left panel, normalized data; middle panel, autosuggestion comparison; right panel, precision and recall.

Conclusion
We found both spell-checkers useful but from these results, ESpell seems to show better precision and recall. A recent hardware upgrade also provided challenges in GSpell installation. ESpell is now integrated in all “PubMed for Handhelds” servers.
Implementing Precision Predictive Analytics for Unplanned 30-Day Readmissions for Real-Time Use at the Point of Care

David F. Lobach, MD, PhD, MS1; Deb McGowan, BSN2; Nish Hartman, BA3; Michael Dulin, MD, PhD4; Marcy Neale, MS4; Jacqueline Mikuleza, BSN4; and Jean Wright, MD, MBA4

1Klesis Healthcare, Durham, NC; 2COPD Foundation, Washington, DC; 3Predixion Software, Aliso Viejo, CA; and 4Carolinas HealthCare System, Charlotte, NC

Introduction
Risk prediction models are increasingly used to identify patients who are likely to experience high cost health events, especially hospital readmissions.1 While these models have variable predictive capacity, the results have had only limited impact on readmission rates.2 One issue that may limit the impact of these predictive models on care outcomes is the lack of tools to enable the predicted insights to effect care delivery.3 In this project we solved this “last mile” problem by creating tools that integrated the results from a predictive readmission risk model into the workflow in order to use these insights to directly impact the delivery of care around the time of discharge. Identification of patient-specific modifiable factors allows personalized customization of the readmission prevention program though interventions that address specific patient care needs.

Methods
The model to predict the risk of unplanned 30-day readmissions was created using data extracted from electronic health records and billing data at Carolinas HealthCare System in Charlotte, NC. The data fields included: social-demographic characteristics, comorbidities, index admission and history of health care utilization, vital signs and other physical parameters, lab data, medications, and treatments/procedures. The target outcome for the model was defined as 30-day unplanned all-cause readmission that was aligned with the methodology used by CMS. We extracted 155,907 hospital discharges spanning two years and over 200 variables. The original data were randomly divided into a 70% training set and a 30% testing set. These data were analyzed using logistic regression for evaluating individual continuous covariates and chi-squared tests for categorical covariates. The modeling was conducted using the PredixionInsight tool (Predixion Software, Aliso Viejo, California), which allowed for multiple modeling techniques to be assessed (Naïve Bayes, Neural Network, Decision Tree, and Logistic Regression) and compared to one another for predictive accuracy.

Results
The readmission risk prediction model with the best performance used neural networks and retained 71 variables. It generated a C-Statistic of 0.78, sensitivity of 64.5%, specificity of 78.9%, positive predictive value (PPV) of 27.0% and negative predictive value (NPV) of 94.6%. Patient-specific predicted risk results were generated for all admitted patients and were refreshed hourly throughout the duration of a patient’s hospitalization. This information was communiccated to the care managers, physicians and other providers through a window inserted into the EHR that presented the readmission risk score within an individual patient’s record and through a dashboard that displayed risk scores for all patients on a hospital floor. This display included: 1) a list of patients with room number tagged with a colored flag indicating level of risk (low, medium, high, very high); 2) a percentage of patients within each category; and 3) a list of specific risk indicators that will increase or decrease the risk of readmission for a selected patient. The tool also provided specific evidenced-based recommendations to address the most significant risk factors. Over 200 care managers have use these insights in real-time to select and implement personalized care interventions (e.g., home health, remote monitoring, pharmacist consult, etc.) to mitigate a patient’s specific risks on more than 300,000 discharges over 3 years.

Conclusions
Insights from predictive models for readmission risk can be used in real-time at the point of care to potentially reduce readmission rates by customizing the discharge interventions to the risk elements that are germane to a specific patient.

Integration of Genomic, Specimen, and Cancer Registry Data in an i2b2 Data Analytics Platform for Oncology Research

Jack W. London, PhD¹, John Reber¹, Chirayu Goswami, MS¹, Robert Stapp, DO¹, Stephen Peiper, MD¹
¹Thomas Jefferson University, Philadelphia, PA,

Introduction

Precision Medicine research requires access to comprehensive data describing a patient’s clinical attributes, including their diagnoses, treatment and outcomes. Of particular value are any molecular diagnostic test results noting genomic mutation expressions, or lack thereof. For oncology research, the basic patient diagnostic and treatment information found in the EMR must be supplemented by more comprehensive information, such as disease stage, recurrence, treatment details, and patient outcomes. These data can be obtained from the institution’s cancer (or tumor) registry. Additionally, investigators often need information on available well annotated, properly acquired and banked biospecimens for their research, as well as ready access to slide images. The Sidney Kimmel Cancer Center at Thomas Jefferson University has developed a central comprehensive data resource to provide investigators with these data.

Methods

The i2b2 platform was used to model patient data concepts for data obtained from Jefferson hospital’s EMR, cancer registry, biobanks, and pathology clinical systems. Unique ontologies (taxonomies) were developed to describe the concepts relating to cancer registry, biospecimen, and molecular diagnostic genomic test results, and integrated with the diagnostic, procedure, medication, and laboratory concepts for patient data obtained from Jefferson’s EMR. The data in the resulting i2b2 data mart are refreshed on a weekly basis.

Results

An i2b2 research data mart describing over 1 million patients with ~100 million observations, including molecular diagnostic results on over 300 genes and 3,000 associated mutations is available to researchers. Detailed oncology data including disease stage, histology, treatment, recurrence, and survival data on over 100,000 patients from Jefferson’s cancer registry are incorporated. The i2b2 data is de-identified, but may be re-identified when necessary and with IRB approval. An honest broker system is used to perform tasks such as biospecimen acquisition. The i2b2 query tool is used for cohort identification, and a data visualization tool from TriNetX Corporation (Cambridge, MA) is used to explore cohort characteristics for clinical design and hypothesis generation. Links from the specimen banking system, OpenSpecimen, provide direct access from the i2b2 query tool to a web-based pathology image viewing application.

Conclusion

Identification of patient cohorts for precision medicine clinical trial research is facilitated by this comprehensive data resource. This is not only for patient recruitment, but also for clinical trial design. By determining the size of recent patient populations corresponding to proposed clinical trial eligibility criteria, the number of trials failing to accrue sufficient patients can be reduced. These comprehensive integrated clinical, genomic, cancer, and specimen data resources also facilitate hypothesis generation by defining associated characteristics of patient populations.

Multiword Frequency Analysis Based on the MEDLINE N-gram Set

Chris J. Lu, Ph.D.¹, ², Destinee Tormey¹, Lynn McCreedy, Ph.D.¹ and Allen C. Browne¹
¹National Library of Medicine, Bethesda, MD ²Medical Science & Computing, LLC, Rockville, MD

Abstract

Multiwords are vital to better precision and recall in NLP applications. The Lexical Systems Group (LSG) developed an effective approach to add multiwords to the SPECIALIST Lexicon from the MEDLINE n-gram set. This paper describes a frequency analysis on LexMultiwords (LMWs) and acronym expansions (e.g. blood pressure for BP) based on the word count (WC) in MEDLINE. Results show most LMWs locate in the low WC range with better precision and F1 score.

Introduction

LMWs are terms in Lexical records containing space(s). To be in the Lexicon, these terms must: 1) have a single part-of-speech (POS), 2) have inflections, and 3) be a special unit of lexical meaning by themselves. A set of filters and matchers based on empirical models has been developed to retrieve LMW candidates from the MEDLINE n-gram set¹. This process generates high precision LMW candidates for efficient LMW building. An analysis of WC allows us to use the frequency filter effectively for better LMW acquisition.

Approach

First, all unique single words (464,781) and multiwords (431,432) in Lexicon.2015 are retrieved. Second, the acronym expansions are retrieved by applying the Acronym Expansion Pattern (AEP) matcher to the MEDLINE n-gram set. This AEP set includes 14,440 LMW candidates. They are tagged by LSG linguists and are added to the Lexicon if they are valid LMWs. The WC from the MEDLINE n-gram set is added to these three data sets to derive the frequency spectrum of WC class vs term number. Term number (TN) is the total terms in a WC class with a range of 100 incremental (Figure 1). The frequency spectrum of WC class vs local precision (valid tags/total tags), recall (valid tags/total valid tags), and F1 measurement (PRF) are derived for AEP (Figure 2). The recall is normalized between 0 and 1.

Conclusion

Figure 1 shows that most LMWs are located in the low WC range for both the Lexicon and the AEP. This result coincides with the distribution of single words in the Lexicon and “Alice in Wonderland”². It seems both single words and multiwords share the common characteristic of distributing in the low frequency range. Figure 2 shows that low frequency n-grams in the AEP have higher normalized recall and F1 score, with precision above 0.8. Very few LMWs exist in the high WC range with a variation in precision of either 0 or 1. Accordingly, the frequency of LMW acquisition should be set on the lower WC range (100-10k) while the frequency of single word acquisition is set on the high WC range (because most unigrams are valid single words). This frequency strategy is applied with filters and matchers to generate LMW candidates from the MEDLINE n-gram set to enrich the coverage of LexMultiwords. Ultimately, this enhanced coverage provides better NLP results for projects that use the SPECIALIST Lexicon, and our WC results may guide MW acquisition efforts in others’ datasets.

How Strong is the Evidence for the Effectiveness of Dementia Family Caregiver Information and Communication Technology Interventions?

Robert J. Lucero PhD, MPH, RN, FAAN1,2, Aditi G. M. Patel, MPH, BS3, Elizabeth Fehlberg, BSN, BA, RN1, Michelle Santoni-Miranda, BA1, Karis Lee1, Renessa Williams1

1College of Nursing and 3Medicine, University of Florida and VA HSR&D Center of Innovation on Disability and Rehabilitation Research, Gainesville, FL, USA

Introduction

Information and communication technology (ICT) enabled interventions can improve decision confidence and self-efficacy, decrease spousal relationship conflict and activity restriction, and reduce emotional strain and burden in caregivers of persons living with dementia1,2. The Internet has been used to make available disease-specific information, private email, question-and-answer forums, monitoring and counseling, in-home support groups, and telephone access to information about caregiver issues3,4. The purpose of our study was to evaluate the current state of empirical research about the effects of ICT interventions on the health of dementia family caregivers (DFC).

Study Design

We conducted a systematic review. We searched PubMed, CINAHL, PsycINFO, and the Web of Science for literature referencing ICT, dementia, and caregiving concepts without date limits. We included randomized controlled trials (RCT) conducted in the United States in English or Spanish with non-professional caregivers. Non-RCTs, studies not in English or Spanish, and studies of professional caregivers were excluded. We used the Effective Public Health Practice Project (EPHPP) Quality Assessment Tool for Quantitative Studies in our review.

Population Studied

Family caregivers of non-institutionalized family members diagnosed with dementia.

Principal Findings

We found 523 articles and removed 21 duplicates. An additional 13 articles were identified from the reference lists of 2 systematic reviews. Two primary reviewers screened the abstracts, which resulted in removing 203 articles. A full-text screening by two secondary reviewers resulted in taking out 300 articles. The secondary reviewers conducted the quality assessment of 12 articles. Their independent ratings across six assessment components (i.e., selection bias, study design, confounders, blinding, data collection method, and withdrawals and dropouts) yielded an interrater agreement of 83.33%. Selection bias was rated as weak in a majority of the studies (i.e., 58%). However, 75% to 100% of the studies received moderate to strong ratings for all other quality assessment components. The secondary reviewers met with the principal investigator to clarify differences in ratings. Based on the EPHPP guidelines, this review found 4 strong studies, 5 moderate studies, and 3 weak studies.

Conclusions

These early findings provide a glimpse at the current state of the science on the effectiveness of ICT interventions with DFCs. These studies provide a viable foundation for ongoing discovery of effective ICT solutions. As consumers of health care adopt ICTs, it is important that ICT-enabled interventions improve health, including decreasing activity restriction and reducing emotional strain and burden in family caregivers.

A Research Capability Framework

Airong Luo, PhD1, Marcelline R. Harris, PhD, RN2, Frank J. Manion, MS3, Barbara Mirel, D.Arts4

1Research IT Med School, 2School of Nursing, 3Cancer Center Informatics, 4School of Education, University of Michigan, Ann Arbor MI

Research capability is the competency to leverage resources and services for purposes defined by the goals of the research project. The rapid maturing of research informatics as a sub-discipline within biomedical informatics reflects, in part, a growing awareness of the need for new types of sustainable research environments that support multi-scalar and multi-disciplinary collaborative science. While a growing literature addresses capability models (e.g., software capability maturity1, scientific data management capability maturity2), and features of consortia and collaboratories3,4, no framework systematically assesses researchers’ needs for informatics support, and assists in institutions’ strategic planning. In addition, research capability framework is needed to provide a bridge between the scientific community and solution-focused research supporting units and organizational leaders.

Methods We interviewed 40 biomedical researchers in different fields at an institution characterized as “very high research activity”. We complemented the interviews with an in-depth case study of a highly productive research group that exhibited collaborations at various scales5. Next, 130 researchers within a comprehensive cancer center responded to a survey to identify needs and gaps in research informatics. We also reviewed the literature to identify factors leading to successful research performance in consortia and collaboratories. Interview data were analyzed using standard qualitative data analyses techniques (AL & FM), the case study was analyzed using visualization techniques (BM), and the literature was analyzed using integrative synthesis techniques (MH). We jointly iterated across these analyses to identify factors that enable research capability across a range of research requirements and collaborations. Based on our data analyses, we developed RCF, which consists of six modules of questionnaire.

Results One RCF module gathers profile information; the other five modules focus on components of scientists’ research processes empirically derived from our data. They include: “collecting, storing and transferring data,” “discovering, accessing and retrieving data,” “defining data to facilitate sharing, linking and discoverability,” “interpreting data through statistics and bioinformatics,” and “addressing governance, legal and commercial issues.” Each research process module consists of three “layers” of capacities and capabilities that were identified from our data as essential to achieving the goals of the research teams: people and organizational layer, information layer, and a technology layer. For each set of questions scientists specify how well supported or sustained they and their collaborators are in conducting research activities on a scale of 1-5. They also rate whether they are satisfied or not, and – if dissatisfied - identify the support that would satisfy them more. Given the user-centeredness of the survey, responses reveal the extent to which sub-processes in the research workflow are systematically supported, that is, maturity levels of the various technological and organizational support. Responses reveal patterns/groupings in practice across different profiles of biomedical researchers, which, in turn, can show successes and gaps in the support these groups respectively need. Validation suggests that RCF captures key resource and service requirements across a range of types of research and collaborations.

Discussion We are ready to administer RCF to a large group of diverse biomedical researchers. RCF has great potential to help researchers specify their needs, requirements, and priorities for centralized support, resources, and for funding proposals, thus enabling the specialists responsible for providing support to identify users’ needs and requirements in the context of research workflows, leading to appropriate solutions.

Using Results of Statistical Text Mining in Big Data Analysis

Stephen L. Luther, PhD, James McCart, PhD, Dezon K. Finch, PhD, Lina Bouayad, PhD, William Lapcevic MS, MPH, Michael Matheny, MD, MS
HSR&D Center of Innovation on Disability and Rehabilitation Research.
James A, Haley Veterans Hospital, Tampa, FL

Introduction
The Veterans Health Administration (VHA) has one of the largest electronic health record (EHR) systems in the world including more than 3 billion text records. The VHA has invested significant resources to develop infrastructure to extract and analyze text-based data. An ongoing study aims to improved risk models for pressure ulcers in Veterans with spinal cord injuries (SCI). While ICD-9-CM codes are available for documentation of pressure ulcers, under-coding is suspected which would impact the validity of the dependent variable for the analysis. Here we discuss efforts to use statistical text mining (STM) to find the occurrence of pressure ulcers.

Methods
All available data from FY 2009-2013 were obtained from a cohort of 11,884 Veterans with SCI seen in VHA SCI Centers during FY 2009 who had no recorded pressure ulcers in the previous year. This resulted in approximately 13 million text documents and several million inpatient and outpatient administrative records. A sample of 2,500 documents were chosen from across VHA facilities and independently reviewed by two clinical annotators and adjudicated by a clinical expert. The data were split into a training (n = 1,750, 70%) and test set (n = 750, 30%). STM models employing support vector machines were built and compared via 5x10 fold stratified cross validation on the training set to select model parameter values. Using the best performing parameters, a final model was built from the training set and achieved sensitivity = .85, specificity = .91, positive predictive value = .87 and an F measure = 0.86 on the test set. This model was then applied to all 13 million documents in the cohort. In parallel, inpatient and outpatient records for the cohort were searched to identify outpatient visits and inpatient admissions in which at least one ICD-9-CM in the range of 707.00 to 707.9 was included.

Results
There were 3,336 patients (33%) classified as having a pressure ulcer based on ICD-9-CM codes. There were 10,218 patients (86%) classified as having a pressure ulcer based on the STM results (at least one document with a confidence of .50 or higher). One strategy to reduce the likelihood of false positives in this analysis would be to interpret higher cut points. Table 1 describes results of setting higher cut points in our test sample (n = 750). As expected, there is a sensitivity/specificity trade off, with little room for improvement in specificity and PPV beyond a cut point of .70. Another strategy to reduce false positive reduce would be to summarize positive documents over time. Analysis of the thirty day window after the first positive pressure ulcer document found that many Veterans had multiple positive documents. A combination of higher cut points and patterns of positive documents across time will be used to explore statistical methods to maximize information from text in this study.

Table 1. Effect of Varying Cut Point on Results from Test Sample

</table>

Conclusion
The cut point of .50 for confidence for a single document is commonly used to interpret results of STM models at the patient level. In this study the simple interpretation of this convention would suggest that nearly 90% of the cohort had a pressure ulcer. While this important clinical outcome is likely under coded in administrative data, this three fold increase over results using ICD-9-CM alone seems unlikely. However, when using STM to summarize multiple documents across time to classify patient level attributes more sophisticated techniques might be preferred. Here we describe a strategy to combine of cut points of predicted probabilities and patterns of positive documents to interpret data from a large observational cohort study in the VHA.
Use of SNOMED CT Relationships for Optimizing Automatically Extracted Problem List Entities from Clinical Narratives

Sina Madani, MD PhD1, Jerry Henderson, MD2
1Department of Institutional Analytics & Informatics; 2Department of Emergency Medicine, The University of Texas MD Anderson Cancer Center, Houston, TX

Introduction
Natural Language Processing (NLP) solutions, such as MetaMap, can be used for extraction of medical concepts from clinical narratives. MetaMap uses an open architecture to perform lexical and syntactic analysis of the input text and generate structured data such as problem list. The patient problem list in a structured format with backend mappings to standard terminologies like SNOMED CT is an essential component of the electronic medical record (EMR) systems. However, problem list entities extracted with NLP methods may contain similar concepts with various levels of granularities. These concepts that are often related to each other may seem duplicate from physician’s perspective. During the transition period from our legacy system to Epic, we investigated whether we can eliminate such duplicate concepts in the problem list by using SNOMED CT ontological relationships.

Methods
MD Anderson Cancer Center’s EMR repository contains more than 15 million transcribed notes. For our study, we selected the last ten instances of the clinical notes for all patients. We defined a patient “Problem” as something that requires a plan for diagnosis and/or management. Based on this definition, we only analyzed part of the clinical notes that pertained to “Assessment & Plan” section headers. We limited MetaMap output to the Disorder semantic group and an extended version of the UMLS Clinical Observations Recording and Encoding (CORE) Problem List subset of SNOMED CT (v2015). Two reference tables were generated from a Web Ontology Language version of SNOMED with pairs of concepts that have “is-a” or “attribute” relationship. These relationships in SNOMED CT connect concepts in the same or different hierarchies. We eliminated the most general concept in such relationships and kept the most granular one only if all concepts seen together in the same problem list. Subsequently, we analyzed the effect of such reduction in the number of the reported problem list entities for all patients.

Results
We identified 2,966,344 clinical notes from 496,901 patients who had two or more clinical problems. The broader concepts like “Renal Mass” in an is-a relationship pair (Renal Mass - Angiomyolipoma of Kidney) or “Small Cell Carcinoma” in an attribute relationship pair (Small Cell Carcinoma - Small Cell Lung Cancer) were eliminated from patient problem lists during NLP post processing step. More than 80% of the problem lists had a reduction between 5% to 25% in the number of the reported problem entities (Figure 1). The average number of the dropped concepts from the problem list was 1.65 in which the largest drop (7 concepts) was observed in the 55% reduction bin.

Discussion
This study shows that similar clinical problems with various degrees of granularities can be detected from patient charts and adjusted by using SNOMED CT relationships. Use of the most detailed format of a clinical concept in the patient problem list may result in a more accurate documentation and better mappings to billing codes with higher granularities. Further analysis is still needed for identification of other sources of concept duplications caused by NLP output. Such analysis is particularly important in NLP methods that are often dependent on external contexts for disambiguation purposes, while a pre-coordinated context, such as “history of - “ or “other –“, has already been embedded internally in the clinical concept itself.
Reducing Clinician EHR Screen Time and Increasing Patient Face Time

J Edward Maddela, MD1, Khaleel Hussaini, PhD2, Umar Iqbal, MD3
1,2,3University of Arizona College of Medicine, Phoenix, Arizona

Introduction

EHR optimization entails reducing clinician EHR “screen time” and increasing patient-provider “face time.” Though early adopters have already begun this work1, few studies in peer-reviewed journals provide evidence-based guidance2,3,4,5. Consequently, enhancing EHR use post-implementation remains a daunting challenge for applied informaticians. Should optimization efforts begin with improving clinicians’ documentation time, computerized provider order entry (CPOE), or chart review time? This study aims to answer this question through a quantitative, data-driven method to optimize EHR efficiency for ambulatory providers across three medical specialties within a large hospital system.

Methods

We obtained three months of de-identified, aggregated, timestamped EHR data for providers (physicians, nurse practitioners, and physician assistants) employed by a large health care system within the medical specialties of Family Medicine, Internal Medicine, and Pediatrics. A total 138 providers were included in the final analytic sample for whom complete data were available. All providers used the same EHR. We utilized timestamped activity log data captured in the EHR using a response time measurement system. The primary outcome variable of interest to measure efficiency was Actual Time per Patient, defined as “the active time a provider spends within the EHR for each patient.” Univariate, bivariate, and multivariable statistical procedures were conducted using SAS v9.4 (SAS Institute, Cary, NC). Where appropriate variables were log transformed to meet Gaussian distributional assumptions of linearity, independence, and homoscedasticity. We tested the assumption of equality of variances after transforming of our primary outcome variable of interest using Levene’s test for homogeneity of variances and then performed one-way Bonferroni corrected ANOVA to test means between the three specialties to adjust for multiple comparisons.

Results

Internal Medicine providers spend more time in the EHR (27.1 minutes) than Family Medicine (22.9 min) and Pediatrics (10.4 min). Summary page chart review, documentation time, and flowsheet time explained over 90 percent of the variance in actual time per patient in the EHR. Irrespective of specialty, providers who spent more than five minutes on the summary page were 70 times more likely to spend over 22 minutes on Actual Time per Patient in the EHR.

Conclusion

The main goal of this study is to show how EHR usage data can be leveraged to optimize provider efficiency. Based on the data, CPOE does not influence the Actual Time Spent per Patient as strongly as chart review (summary page and flowsheet) and documentation. Thus, helping providers optimize these specific areas may produce a greater impact on their EHR efficiency. Despite its limitations, similar statistical modeling can be applied to other medical specialties, but more research is needed. Ultimately, reducing provider “EHR screen time” can potentially enhance clinical efficiency, improve provider satisfaction, and increase much needed quality “face time” with patients.

In Patient Usability Testing Results of a Patient-Centered Postoperative Wound Surveillance Smart Phone App Utilizing Digital Photographs
Andrea N. Mahnke, MS1; Rebecca Gunther, MD2; Sara Fernandes-Taylor, PhD2; Kate L. Baker, MA1; Jason T. Wiseman, MD2; K. Craig Kent, MD2
1Marshfield Clinic Research Foundation Biomedical Informatics Research Center, Marshfield, WI
2Department of Surgery, University of Wisconsin-Madison, Madison, WI

Background
Surgical site infection (SSI) is the most common nosocomial infection in surgical patients and accounts for 38% of post-operative complications1. Patients rarely recognize early stage wound infections and often require intensive treatment and rehospitalization2. It also produces increased health care costs and is the leading cause of unplanned, potentially preventable hospital readmissions for surgical patients1. The fact that SSI develops or progresses in the outpatient setting makes transitional care coordination an important focus in the effective management of SSI. Patient-centered technological interventions to improve transitional care for surgical patients are necessary to stem the burden of SSI and readmissions.

Objective
We designed and tested a patient-centered, outpatient wound surveillance program using smartphone digital photography to promote early recognition of SSI following discharge with the goals of (1) empowering patients to partner with their surgeons in monitoring their SSI symptoms and overall postoperative recovery, (2) diagnosing SSI at an early stage, enabling outpatient management, and (3) preventing hospital readmission and the serious morbidity and mortality associated with wound complications.

Methods
We designed a patient-centered smartphone app that enables patients to transmit wound photos and symptom information to the vascular service. In collaboration with geriatricians and community/patient research advisors, we designed a patient-centered training process to teach patients or caregivers to take and transmit photos of their wound using smartphones. We undertook formal usability testing of the app on inpatient surgery patients to evaluate (1) patient experience, (2) picture and information quality, and (3) successful information transmission and assimilation into PACScan. Screen and audio recordings were captured during the inpatient usability testing for analysis and identification of usability issues. Improvements were recommended and implemented iteratively.

Results & Conclusions
Two rounds of testing were conducted with a mix of vascular and oncology surgery patients. Round 1 (n=4) on Nov. 4, 2015 and Round 2 (n=5) on Dec. 11, 2015. Testing was done with a mix of race, sex, age and smart phone familiarity. Caregivers assisted with three of the nine participants. Smart phone training was given to patients who were not already confident working with a smart phone, but all participants received a brief training on the app. Only two Round 1 participants required guided app training and practice, the rest were confident to try the app on their own after the initial brief training. Significant usability issues were found after Round 1 testing and improvements were implemented for Round 2. All participants were able to successfully complete stepping through the app with their wound with no or some assistance, but none failed to complete. The average System Usability Scale (SUS) score for Round 1 was 85 and 82 for Round 2. Broadly interpreted, scores under 60 represent systems with poor usability; scores over 80 would be considered above average.

Proactive Patient Management Worksheets: an opportunity to support clinical care while addressing increasingly complex reporting requirements

Julie Maitland, PhD¹, Natalia Largaespada Beer, MD², John N. Rutter, BSc Eng¹, Jeff Beairsto BSc Eng¹, Iain MacNeil BSc¹, Colin Kilburn BSc¹, Ian Smith, BSc²
¹Populus Global Solutions Inc., Fredericton, Canada; ²Ministry of Health, Belmopan, Belize

Introduction

When considering the reporting burden of developing countries, Belize is at an advantage over many countries thanks to the Belizean Health Information System (BHIS), an integrated HIS that captures structured data from clinical encounters within the public health care system. In addition to the clinical and operational reports embedded within the BHIS, the Belizean Ministry of Health (MOH) has a skilled IT team who work with the Epidemiology Unit and various Ministry Technical Advisors (TAs) to extract and report on custom queries. Despite this, the burden of timely reporting is not an insignificant one; one which is only going to increase with the advent of the United Nations’ Sustainable Development Goals¹.

Approach

In 2015 we embarked on a project with the Belizean Maternal and Child Health (MCH) Program. The original goal of the project was to increase the reporting capacity and autonomy of the MCH team. Over the course of the project, the focus shifted from after the fact reporting to the design of proactive patient management through BHIS-integrated worksheets; creating a secondary goal of providing access to reportable data in a format that could facilitate proactive patient management, helping to identify and manage the cases that are at risk of slipping through the net and becoming an undesirable statistic identified in after-the-fact reports. With a focus on Antenatal Care and Child Immunization, we carried out User-Centered Design activities with Ministry of Health Personnel, Regional Managers, and Clinicians “on the ground” to ensure that the worksheets were configured to reflect existing protocols and designed to provide value to as many MCH stakeholders as possible.

Worksheets

The worksheets, that are automatically populated by data already being collected in the BHIS during clinical encounters, list the details of a specific cohort of patients that a clinician or administrator can work from. Each worksheet provides an overview of how well each patient’s care adheres to the appropriate clinical protocol. Each entry links to the patient’s e-health record where data can be reviewed in more detail and new encounters can be documented. The Antenatal Care Worksheet provides an overview of women who are currently or were recently pregnant, listing all clinical encounters, last recorded measures, diagnostic screening status, and pregnancy outcomes. The Child Immunization Worksheet provides an overview of children and their immunization status and child growth measures. It is hoped that the worksheets will enable health professionals to identify and manage high risk patient cases in real-time, e.g.: by enabling a Community Health Nurse to generate a list of infants who are currently due/overdue vaccines in a particular district, or by enabling a Nurse Manager to generate a list of women who have not yet received a postnatal visit.

Conclusion

We suggest that protocol-based patient management worksheets can inform and enhance clinical practice while increasing the accessibility of the data required by international reporting and funding obligations. Both worksheets are in the process of being deployed at the time of poster submission. The success of the project will be measured in terms of the MCH team’s reporting capacity and autonomy, their use of the worksheets to inform clinical practice, and the identification, management, and health outcomes of high-risk mothers, newborns, and children.

Incorporation of Case Setup Complexities into the Analysis of Operating Room Turnover Times

John D. Manning, MD¹, Manmeet Singh, DO¹, Pavithra I. Dissanayake, DO¹, Elizabeth Day¹, MPH, Richard J. Banchs, MD¹

¹The University of Illinois at Chicago, College of Medicine, Chicago, IL

Introduction
The operating room (OR) achieves optimal efficiency when it provides the highest quality of care with the lowest use of time, money, and space [1]. Parameters such as case duration, OR workload, and case turnover times (TOTs) may be automatically generated for analysis [2], though factors such as TOTs are subject to wide variation [3]. Since the setup for a hernia repair differs vastly from that of a spinal fusion, we sought to examine if separating cases by complexity would impact their average TOTs.

Methods
This was a retrospective study at a single academic tertiary hospital. Case setup complexity levels were determined a priori using a panel of physicians and surgical nursing staff. All OR cases for a single month (December 2015) were placed into one of three category tiers. TOT calculations were then made using Compass Portal (The Advisory Board Company), with customizations to view each OR case individually. Data was analyzed using Minitab Statistical Software.

Results
A total of 1,177 cases were observed, of which 768 were eligible for TOT calculations in Compass Portal. To avoid outliers (also called delays), cases with TOT of more than 90 minutes were excluded (n=98). Of the remaining 670 cases, 173 were labeled Type 1 (simple, 25.8%), 348 were labeled Type 2 (intermediate, 51.9%), and 149 were labeled Type 3 (complex, 22.2%). Mean TOTs and standard deviations for each case are listed above [Figure].

Conclusions
We demonstrate significant variation in TOT at a single institution when separating cases by setup complexity. This may provide added benefit in TOT workflow assessments, such as focusing on TOTs for less complex cases. Improved accuracy of case complexity TOTs may also improve the accuracy and efficiency of OR scheduling. The potential also exists to identify surrogate markers of setup complexity, such as the number of trays opened per case. Lack of objectivity in determining setup complexity is a possible limitation of our study. Nevertheless, we believe that our classification system offers utility for optimizing OR TOT and can be readily adapted to other institutions.

Identifying Treatment Refusal Through Natural Language Processing
Joel J. Martin, MS, Nathaniel S. Ring, MA, Andrea A. Kelley, MPH, Jon D. Duke, MD
Regenstrief Institute, Indianapolis, IN

Introduction
Patient refusal of treatment (including medications and procedures) is a valuable data point for research and clinical quality initiatives but is poorly captured in traditional structured data sources. Natural language processing (NLP) has the potential for increased yield of information related to treatment refusal but has not been well studied for this purpose. Previous research in this area has been limited to colonoscopy refusal. No studies have addressed identification of general treatment refusal events. In the current project, we sought to examine NLP performance in identifying treatment refusal.

Methods
Our source data was the Indiana Network for Patient Care, a health information exchange with clinical data on thirteen million patients. Specifically, we looked at a subset of 2.8 million patients with unstructured documents available in the Regenstrief natural language processing platform. We developed the treatment refusal algorithm through an iterative process comprising the following steps: 1) heuristic token selection (e.g., refused); 2) generating synonyms and lexical variants; 3) term discovery from documents with structured refusal data (e.g., vaccination); 4) manual annotation; and 5) evaluation and iterative review.

We then ran the final refusal algorithm across a dataset of 95 million clinical documents and found 908,992 matches. A convenience sample of 400 of these documents was reviewed by four reviewers for the presence or absence of treatment refusal. To perform a comparison between capture of refusal information in structured and unstructured data, we paired our refusal algorithm with a set of vaccination terms (e.g., pneumovax, MMR) and identified 4,603 matching reports. Again, we selected 400 random documents from this set for manual review. In this case, reviewers recorded whether the patient refused an offered vaccine.

Results
Our general refusal algorithm achieved a 83% PPV, with false positives primarily due to the use of the term ‘decline’ in the setting of laboratory values or failing health. Our algorithm looking specifically at vaccination refusal yielded a 78% PPV. When comparing of NLP-based vaccine refusal detection compared with structured vaccine refusal data in the same population show, 3440 unique patients were identified with vaccine refusal via NLP compared with 977 documented in structured data, and 85 patients that were identified in both.

Conclusion
Treatment refusal can be identified with good accuracy using unstructured data. For vaccination refusal, a 350% increase was observed using NLP compared with structured data. While this approach requires additional refinement, NLP holds promise for improving the capture of ‘non-events’ such as refusal in electronic medical records.

Comparison of Electronic Health Record Data Sources to a Gold Standard Patient Data Set in Correctly Identifying Chronic Conditions

Shelby J. Martin, MS, RD\(^1\), Nicole Weiskopf, PhD\(^1\), David A. Dorr, MD, MS\(^1,2\)
\(^1\)Oregon Health & Science University, Portland, OR, United States; \(^2\)General Internal Medicine & Geriatrics, OHSU, Portland, OR, United States

Introduction. Electronic Health Records (EHRs) may store data about a patient’s diagnosis in one or more areas depending on how the user interacts with the EHR, the workflow required for billing or documentation, and the perceived relevance of the diagnosis. Diagnoses may vary in accuracy and reliability based on the location of the diagnosis,\(^1\) potentially affecting key tasks related to prognosis, treatment planning, and prediction of adverse outcomes from disease burden. We sought to visually characterize the trade-offs between different EHR data sources of diagnoses.

Methods. We queried data about adult patients seen in primary care from the EHR for any evidence of 13 conditions. Diagnoses that were determined to be “positive” from a structured gold standard chart review were compared with frequency of positive diagnoses in four EHR data sources (problem list, outpatient encounters, medical history, a phenotype-based rule, or combined - the presence of the condition in any one of the four sources). Diagnostic characteristics of each source versus the gold standard were calculated, and EulerAPE version 3 software was used to create diagrams to visually represent the trade-offs from each source.

Results. 2,152 patient diagnoses in the gold standard data set were reviewed. Specificity was highest for the problem list (0.82), while sensitivity was highest for the combined data sources (0.95), followed by medical history (0.55). Figure 1 shows the trade-offs between sources. Green represents true positives, yellow missed diagnoses from the data source, and blue false positive diagnoses from the source. The Problem List shows a large number of missed diagnoses (42%), while the Combined had the largest true positives (67.4%) and false positives (23.7%).

Discussion. Choosing different EHR data sources for diagnosis definition altered the accuracy and completeness of the cohorts; visual representations of the data may help users understand the trade-offs between these diagnoses.

Figure 1. Diagnoses identified as positive as a proportion of all gold standard diagnoses

Review of Existing Mobile Apps to Support Symptom Management for Adults with Heart Failure Using the Mobile Application Rating Scale

Ruth M Masterson Creber, PhD, MSc, RN, Grenny Hiraldo, Meghan Reading, BSN, MPH, RN, Sarah J Iribarren, PhD, RN; Columbia University, New York, NY

Introduction
Heart failure is the fastest growing cardiovascular condition in the United States affecting 5.7 million Americans (1). Smartphone apps have the potential to support heart failure symptom monitoring and self-management. The purpose of this review was to identify and assess the functionalities of apps targeting patients with heart failure to support symptom monitoring and self-management.

Objective: The purpose of this review was to identify and assess the functionalities of patient-facing mobile apps targeted towards supporting patients with heart failure with symptom monitoring and self-management.

Methods
We searched 3 online mobile app stores using multiple terms and combinations (e.g., “heart failure”, “cardiology”, “heart failure and self-management”). Apps meeting inclusion criteria were evaluated using the Mobile Application Rating Scale (MARS) (2), IMS Institute for Healthcare Informatics functionality scores (3), and Heart Failure Society of America (HFSA) guidelines for non-pharmacologic management (4). Apps were downloaded and assessed independently by 2 reviewers, interclass correlations were calculated and consensus was met by discussion.

Results
Of 3,636 potentially relevant apps returned, 35 met inclusion criteria. Most apps were excluded because they were unrelated to heart failure, not in English or Spanish or were games. Interrater reliability was high (two-way mixed CA-ICC=0.93, 95% CI: 0.68-0.99). AskMD app had the highest average MARS total (4.9/5) and subscale scores followed by WebMD (4.4/5), which also had the highest functionality score (11/11). More than half of the apps (66%) had acceptable MARS scores (>3.0). Factoring both the MARS and IMS functionality scores (Figure 1), the highest performing apps included: AskMD, webMD, Heart Failure Health Storylines, Continuous Care Health App and Symple. Only one, Heart Failure Health Storylines, met all of the HFSA guidelines for non-pharmacologic management. Peer reviewed publications were identified for only three of the included apps.

Conclusions
Few apps had both a high MARS and functionality scores. No apps had high scores and met all of the HFSA guidelines. Therefore, involving patients in the design for further development of a heart failure tailored app and meeting criteria proposed in the guidelines by the HFSA is recommended.

Implementing Computerized Provider Order Entry Increased Rates of Duplicate Laboratory Testing in Inpatient and Outpatient Settings

Patrick C. Mathias, MD, PhD, Noah G. Hoffman, MD, PhD
University of Washington, Seattle, WA, USA

Introduction

While many studies of computerized provider order entry (CPOE) demonstrate decreases in overall medication prescribing error rates, CPOE implementation has been associated with increased duplicate medication errors1,2. This increase in errors has been attributed to many factors, including inadequate clinical decision support for reconciling duplicates, added effort required in cancelling or modifying orders, and the ability of multiple users to enter orders nearly simultaneously3. To date, medication orders have been a large focus of work examining CPOE’s effect on duplicates because of patient safety issues, but there are significant impacts from duplication of diagnostic testing as well. Duplicate laboratory testing can contribute to iatrogenic blood loss from repeated unnecessary draws and has downstream impacts in increasing costs from additional testing as well as labor in cancelling recognized duplicates. The aim of this study was to determine the impact of CPOE implementation on cancellation rates for duplicate laboratory tests within one health system.

Methods

Test cancellations and volumes over more than 4 years (May 2011-September 2015) were queried from a single laboratory information system (LIS, Sunquest, Tuscon, AZ) used throughout the duration of the study. Two laboratories share the LIS and serve a tertiary care academic medical center (Site 1) and a county hospital (Site 2). Site 1 implemented CPOE in PowerChart (Cerner, Kansas City, MO) in May 2012, followed by implementation with the same EHR at Site 2 in September 2012. In May 2014, all of the health system’s outpatient clinics (which send testing to both sites) were transitioned to Epic (Verona, WI) with CPOE. Data included the dates of collection, ordering location, and a code signifying the reason for cancellation. Only cancellations for duplicate orders associated with an accession generated in the LIS were included (excluding automated cancellations). Monthly duplicate cancellation rates were calculated over 1 year periods before and after each CPOE implementation, and stratified by hospital and location type (inpatient or outpatient). Statistical comparisons of proportions of cancellations before and after each go-live were performed using a two-sided test for equality of proportions.

Results

Rates of cancellations for duplicate orders increased significantly after each CPOE implementation. The inpatient implementations were associated with increases in cancellation rate from 1.3 to 30 cancellations per 1000 accessions at Site 1 (p < 0.001) and from 1.9 to 18 cancellations per 1000 accessions at the Site 2 (p < 0.001). The system-wide transition in the outpatient EHR also increased cancellation rates at both sites, from 5.5 to 17 cancellations per 1000 accessions at Site 1 and from 11 to 29 cancellations per 1000 accessions at Site 2 (p < 0.001 for both sites).

Conclusions

Implementation of CPOE increased the proportion of duplicate laboratory orders requiring cancellation by ten-fold or more in the inpatient setting and by three-fold in the outpatient setting. These findings suggest that configuring CPOE to prevent the creation of duplicate laboratory orders should be considered during implementation to prevent the effort required to reconcile duplicate orders in downstream systems.

Ensuring Data Integrity from Anesthesia Information Management Systems: An Approach by the Multicenter Perioperative Outcomes Group

Michael R. Mathis, M.D.1, Sachin Kheterpal, M.D., M.B.A.1
1University of Michigan, Ann Arbor, Michigan

Introduction

Within the era of big data analytics, healthcare provider access to anesthesia information management systems (AIMS) has become increasingly available. However, with continued expansion, maintaining complete and accurate AIMS-derived data has emerged as a new challenge. Traditional AIMS data sources have included administrative data, a preoperative history & physical, and an intraoperative record. New sources of AIMS data have included nursing flowsheets, as well as blood bank, pharmacy, radiology, and pathology data. National and global registries have additionally allowed for linking patient comorbidities and outcomes to AIMS data. With this explosion of information accessible for guiding clinical assessment and decision-making, maintaining data quality has become paramount, and calls to ensure data integrity derived from AIMS have been made.1,2

Quality of Reporting Driving Quality of Care

Challenges to maintaining data integrity are numerous, and must be addressed if AIMS-derived databases are to be sustained as tools for outcomes research and quality improvement. Within the field of anesthesiology, adverse events are rare; to characterize such adverse events, AIMS data must necessarily be complete and accurate. If methods to ensure data integrity are not followed, patient, provider, and process measures associated with specific outcomes are likely to be inaccurate, and unable to drive quality improvement. Limitations of each data source used must be considered, such as the training of data entry personnel, method of entry, and data structure itself. Within our Multicenter Perioperative Outcomes Group (MPOG), we synthesize AIMS data and systematically address these pitfalls.

The MPOG Approach to Data Integrity

Within the MPOG research consortium, participating centers identify key personnel within their institution to maintain departmental and technical support. Interfaces are built to enable data transfer from each site to a central database. Next, a database “mapping” utility is used at each site to transform the structure of local AIMS data elements to a uniform centralized structure. Variable mapping, overseen by a clinician at each site, is performed across multiple data types, including patient, provider, and surgical characteristics.

Next, a “data diagnostics” process is used to ensure data validity. Across all mapped data, percentages of meaningful and complete data entry are noted and tracked chronologically. Accuracy of data mapped are recorded, and thresholds for success (with a mandatory minimum requirement) are publicly reported to all participating institutions. A “case-by-case validation” tool is next employed to determine if case times and caregiver management are feasible; feedback for re-mapping database elements can be given to each site. A “case viewer” enables caregivers to view centrally-uploaded AIMS data as it would appear in an intraoperative record, to provide further instruction on quality improvement.

With AIMS data mapped, validated, and uploaded to a central database, outcomes research and quality improvement projects are proposed and discussed at weekly MPOG conferences, using standardized manuscript and data query templates with instruction through an online curriculum. Accepted projects are subjected to research “data cleaning”, in which data queried are audited by investigators and further mapped to discrete concepts for research purposes. Numerical data are cleaned through establishing valid ranges, and employing monitoring artifact reduction algorithms.

Conclusions

Through the use of systematic measures to ensure data integrity, our MPOG consortium makes strides to improve data quality that have been previously greatly outpaced by data quantity. In developing rigorous data validation measures, high-integrity AIMS-derived data can be maintained, correlated to outcomes, and used to drive quality improvement.

MedicineMaps: A Tool for Mapping and Linking Evidence from Experimental and Clinical Trial Literature

Nicholas J. Matiasz, MS1,2, Wei-Ting Chen1,3, Alcino J. Silva, PhD2, William Hsu, PhD1
1Medical Imaging Informatics, Departments of Radiological Sciences and Bioengineering, University of California, Los Angeles, CA; 2Integrative Center for Learning and Memory, Departments of Neurobiology, Psychiatry, and Psychology, Brain Research Institute, University of California, Los Angeles, CA; 3Department of Computer Science, University of California, Los Angeles, CA

Introduction. A significant barrier in the translation of clinical research has been the inability to effectively explore the large information space of published experiments to catalyze hypothesis generation and validation studies. Researchers need to become familiar with a body of research of increasing size and complexity: in 2013 alone, over 700 papers related to neurofibromatosis type 1 (NF1) were indexed on PubMed. Achieving an integrated understanding of a disease requires a shareable, machine-readable representation that not only captures high-level (causal) relationships but also incorporates relevant supporting evidence about the studies. Having a formal way to represent causal connections using semi-automated graphical and interactive tools would provide the research community with a map of what is known, unknown, and disputed, thus facilitating experiment planning.

We present an open-source web application called MedicineMaps that facilitates clinical translational research by systematically and collaboratively capturing results of experimental studies and clinical trials reported in literature in a shareable, machine-readable way. We build upon the concept of research maps4-3 to formalize causal relations based on a taxonomy of clinical experiments and rules for integrating evidence from multiple studies.

Materials and methods. At its highest level of abstraction, our representation includes three main entities: INTERVENTION (a treatment administered to a patient suffering from a condition), OUTCOME (an operationalized measure to assess a patient’s response to the intervention), and RELATION (a directed relationship between an intervention and an outcome that describes how the outcome is expected to change in response to the intervention). Details of each experiment are captured as properties of each relation, and a SCORE provides a heuristic measure to convey the amount of evidence represented. Each score is based on the convergence and consistency of the relevant experiments.

Results. MedicineMaps is implemented as a web application that assists target users (i.e., clinicians and researchers) with extracting and mapping information from papers to generate medicine maps. Functionality of this interface includes: (i) structured forms for entering details about the study; and (ii) visualization of semantic predications as a collection of nodes and edges. During the annotation of individual papers, experiments with specific intervention–outcome pairs can be inputted using a structured form that includes a variety of relevant fields to capture each study’s context. MedicineMaps is developed with Node.js, a JavaScript-based runtime environment for creating web applications. Given that the information is encoded as graphs, we use Neo4j 2.2.1, a NoSQL graph database. The database is queried using the Cypher Query Language (CQL) of Neo4j. Medicine maps are visualized using Cytoscape.js.

Introduction

Well-structured controlled vocabularies such as MeSH are designed to address language problems encountered in information retrieval including polysemy (multiple meanings for the same term). In an analysis of the visibility of Game Theory in the biomedical literature, McCain reported an apparent case of inadequate polysemy control, based on a contextual co-descriptor mapping of the MeSH term GAMES, EXPERIMENTAL (Games designed to provide information on hypotheses, policies, procedure or strategies). GAMES, EXPERIMENTAL is subordinate (NT, Narrower Term) to GAME THEORY (a subject within MATHEMATICS--essentially the mathematical analysis of interactive decision-making involving players who anticipate other players’ decisions in making their own). By extension, GAMES, EXPERIMENTAL would refer to the decision scenarios (games) adopted by the players in an experimental setting. However, the contextual descriptor linkage map for GAMES, EXPERIMENTAL showed a frequent co-assignment of MeSH terms relating to nursing education and neuro-imaging as well as human behavior, cognition, and decision making. Here I report an analysis of the MeSH term assignment (indexing) patterns for terms co-assigned with GAMES, EXPERIMENTAL and the content of articles retrieved with this MeSH term. The goal is to demonstrate the effect of introduced polysemy—multiple meanings of “games” in experimental settings.

Methods

Contextual co-descriptor analysis of the top substantive MeSH terms co-occurring with each other and with GAMES, EXPERIMENTAL was used to map descriptor co-assignment patterns over two time periods separated for contrast: 1974-1999 and 2005-2015. A full-text content analysis of primary research reports indexed with GAMES, EXPERIMENTAL identified the “games” and game-related research goals reported in this literature.

Results

In the earlier dataset (1974-1999), TEACHING was one of two MeSH terms with the highest degree centrality in the co-descriptor network, linked to more specific terms in nursing education (the other was GAME THEORY, the immediate parent term of GAMES, EXPERIMENTAL). The retrieved literature focused primarily on the use of “games” in education of nursing students and hospital staff—the top “games” were Q&A quiz show/board game formats and simulation/role-playing activities. In 2005-2012, the MeSH term DECISION MAKING dominated the co-descriptor network. Removal of this term and remapping of the remainder highlighted two different aspects of decision-making. One dealt with interactive social behavior using game-theoretic scenarios (e.g., The Ultimatum Game) while the other focused on individual risky decision-making activities (e.g., the Iowa Gambling Game). fMRI was used to map brain activity during both individual and interactive decision-making. Primary research using “games” in biomedical education was still visible but a minor part of the literature retrieved.

Conclusion

If GAMES, EXPERIMENTAL is only and directly NT to GAME THEORY in MeSH, it should retrieve only articles reporting experimental work in game theory/economics. Here, however, two other definitions emerge: (1) everyday games/skills assessment involving two or more people and (2) single person solitaire games and gambling/risk-taking activities. This indexer-introduced polysemy will result in a high proportion of non-relevant documents, no matter which of the notions of a “game” in an experimental setting is relevant to someone searching on the term. Vocabulary designers, indexers, and searchers should be aware of the potential for indexer-introduced polysemy when term definitions are incomplete or overly broad in the context of their hierarchical relationships.

Extending the PCORnet Common Data Model to Encompass Emergency Department Clinical Research.

James C. McClay, MD, MS, Bret Gardner, BS
Department of Emergency Medicine, University of Nebraska Medical Center, Omaha, Nebraska

Background: In 2013 the Patient Centered Outcome Research Institute (PCORI) established the Patient Centered Outcomes Research Network (PCORnet.org). PCORnet contains 13 Clinical Data Research Networks (CDRN) based on hospitals and integrated delivery networks with full implementation of electronic health record systems (EHR). PCORnet established a robust organizational structure for sharing EHR derived data in support of comparative effectiveness research (CER) trials. One major initiative is development of the PCORnet Common Data Model, currently in its third version (CDM V3). Each participating institution in the member CDRNs maintains a standardized data mart based on the CDM V3. PCORnet participants have also entered into reciprocal IRB agreements and sharing of data. Fundamental to this data sharing is the ability to generate de-identified data sets based on CDM V3. The current CDM V3 was developed based on lessons learned developing prior research networks such as Mini-sentinel and does not generalize easily to other types of clinical research. Specifically, in its current iteration CDM V3 does not support many of the data elements relevant to Emergency Department (ED) based research as reflected in the recently released HL7 Data Elements for Emergency Departments (DEEDS) specification. We developed a set of pragmatic extensions to CDM V3 enabling data marts maintained by PCORnet CDRNs to participate in multicenter ED based research studies.

Methods: CDM V3 consists of 15 tables organized around a patient record ID. A patient may have multiple episodes of care. DEEDS consists of a set of data elements organized into process oriented categories organized around an episode of care in the emergency department. DEEDS contains a comprehensive set of data elements mapped to standardized codes such as LOINC and SNOMED. We mapped data elements categories from the DEEDS specification to the PCORnet CDM. Elements from both data specifications were removed from analysis if they were not directly related to patient care, were not relevant for the ED setting, or too detailed to be reliably found in institutional data marts. We determined missing concepts and attributes to extend the CDM tables in order to enable ED research. The ED based extensions to the CDM were modeled in a data mart.

Results: A subset of CDM V3 tables are relevant to clinical care (Figure 1). A reduced set of research oriented data element categories from DEEDS were then mapped onto the CDM. Changes to accommodate ED research include the following: addition of missing data elements to tables such as add other vital signs to VITAL; Adding further table information such as PROVIDER in order to capture other roles in the ED; adding values such as “once” to RX_FREQUENCY field in the PRESCRIBING table and adding “Admitted” to DISCHARGEDisposition in ENCOUNTER table.

Discussion: The PCORnet national research network represents a significant investment in infrastructure and organization in support of clinical research. We propose a set of extensions to the PCORnet CDM that could be implemented at any CDRN site to support ED base based research for CER, outcomes studies and clinical trials. These extensions include additions to value sets, new fields in tables and new tables. With the near universal implementation of ED specific data systems at all participating PCORnet CDRN sites the represents an unprecedented opportunity to advance emergency care based research with a minimal incremental investment.

An Analysis of the Utility of Coded Override Reasons for Drug-Drug Interaction Alerts at Eleven Sites

Dustin S. McEvoy, BS1, The DDI Team, Dean F. Sittig, PhD2, Adam Wright, PhD1,3,4
1Partners Healthcare, Information Systems, Wellesley, MA; 2University of Texas Health Science Center, Houston, TX; 3Brigham & Women’s Hospital, Boston, MA; 4Harvard Medical School, Boston, MA, USA

Introduction

Although potentially harmful drug-drug interactions (DDIs) have long represented a serious threat to patient safety, preventing them remains an unsolved problem in healthcare. Point of care alerts within computerized provider order entry systems have the potential to lessen this threat, but are often overridden which may limit their effectiveness. A previous study analyzing prescriber reasoning for overriding DDI alerts suggested that coded override reasons (ORRs) should be required on more DDI alerts to facilitate communication of override rationale to the pharmacy, thereby preventing delays in the prescribing process.1 Many institutions now offer coded ORR choices for their interruptive DDI alerts, but the utility of these ORRs has not been analyzed. We analyzed coded ORRs for DDI alerts in various electronic health record (EHR) systems to assess their coverage of potential reasons, clinical utility (in terms of the assessment of potential patient harm), and whether they might be used to improve alert specificity.

Methods

Coded ORRs for interruptive DDI alerts were collected from 7 different EHR systems used at 11 health care organizations across the United States. These ORRs were classified to determine the percentage of ORRs useful in the assessment of potential patient harm and in improving alert specificity. ORRs were classified as useful or not using the criteria established by Grizzle et al., which classified an ORR as useful to verification pharmacists if it documented that the prescriber was 1) aware of the drug interaction, and 2) had indicated measures to mitigate potential harm to the patient.1 To assess whether ORRs might be used to improve the specificity of DDI alerts, we added a third criteria, assessing whether ORRs contained information pertaining to when the alert should or should not fire. Results were analyzed to assess the usefulness of current ORRs offered for DDI alerts in EHRs.

Results

We collected 60 coded ORRs for DDI alerts from 11 health care organizations using 7 different EHRs. Of the 60 ORRs, 48 (80%) documented prescriber awareness of the potential drug interaction. However, only 28 (47%) of these ORRs also indicated that steps had been taken to mitigate patient risk. Example ORRs that did not document physician awareness of the DDI included “Not true allergy” (which is irrelevant to DDIs), and “Unverified”. These were found in systems where there was a single set of ORRs in use across multiple alert types. Examples of ORRs which failed to document steps to mitigate patient harm included “Physician approved” and “Benefit outweighs risk”. The utility of ORRs varied by institution, but only one institution had ORRs which were all considered to be useful by these two criteria. More than half (32) of ORRs contained information pertaining to alert specificity. Examples included “Patient tolerated before” (i.e., the alert should not have fired due to medication history), and “This alert is NOT useful" (i.e., the alert should not have fired because the interaction is not clinically significant).

Conclusion

Of the observed ORRs for DDI alerts, 20% failed to document prescriber awareness of the drug interaction. In systems using a single set of ORRs for all alert types, some ORRs were irrelevant to DDIs. While use of a single set of ORRs across alert types is more consistent, it creates situations where a provider could inadvertently choose an ORR unrelated to the alert. Less than half of the ORRs documented both prescriber awareness and steps to mitigate potential patient harm. As a result, institutions should consider reviewing the coded ORRs that they offer for DDI alerts to ensure that they clearly communicate prescriber reasoning, or removing them all-together to reduce strain on prescriber attention. Over half of DDI ORRs contained information that was potentially relevant to the alert logic, suggesting that ORRs may be a useful tool to collect information to improve upon DDI alert logic. However, they may be best used for a short period of time given that they do not appear to add significant clinical value.

RexDB & GSM Provide Iterative Cohort Selection for GWAS: A Case Study of Gains through Interoperability of Two Open-Source Technologies

Owen McGettrick1, Ezekiel Maier, PhD2, Natasha Sefcovic, PhD2, Leon Rozenblit, PhD, JD1, Paul Hodor, PhD2,3
1Prometheus Research, New Haven, CT, 2Booz Allen Hamilton, Rockville, MD, 3Seattle Children’s Research Institute, Seattle, WA

Introduction: The increasing availability of human whole genome sequences makes it possible to build large data resources for precision medicine (Stephens et al. 2015), allowing analyses such as genome-wide association studies (GWAS) on an unprecedented scale (Welter et al. 2014). We describe a computational infrastructure that solves two fundamental challenges in building such a resource: (1) the backend that stores and manages the data has to be scalable from thousands to millions and more of complete human genomes, without loss of performance; (2) the system should have an intuitive and configurable user interface for cohort selection, based on (potentially changing) metadata about subjects represented in the database.

Methods: The backend consisted of the previously developed Genomic Sequence Manager (GSM, http://tinyurl.com/BAH-AMIA2015), a novel system based on a Hadoop prototyping environment (Hodor et al. 2016), HBase, and Amazon Web Services (AWS). We created a user interface using RexDB, an open source platform for supporting research data management workflows. A novel RexDB component called RexGuide was used to configure linked filter screens to support incremental cohort selection. The demo application maintains a database of anonymous subjects initially populated from the 1000 Genomes Project (http://www.1000genomes.org) (1000 Genomes Project Consortium 2015), which includes basic demographic characteristics such as gender and population of origin. The data has been further enriched for demo purposes by several synthetic phenotypic groupings and genetic variant presence. RexGuide allows user to easily configure independent filter controls simply by specifying the data elements or expressions of interest. Once configured, RexGuide generates a user interface for incrementally narrowing the population set down to the specific cohort of interest. Interoperability between RexGuide and the GSM is through a simple HTTP protocol using an XML job configuration file and CSVs of the cohorts. A job, consisting of an experimental cohort and a control cohort, can be submitted for GWAS analysis on the GSM. RexGuide monitors the progress of the job and when GWAS results are returned users can view the raw results or an interactive Manhattan plot of the results set. Data or the Manhattan Plot can be exported for external use.

Results: The interface supports: population filtering through configured filter screens; cohort selection; cohort management (saving, searching, editing, etc.); GWAS job submission and monitoring; GWAS results listing, searching, sorting, and graphing; linking GWAS results automatically to SNP_DB. The panel below shows four screenshots for (1) selecting individuals, (2) filtering by phenotype, (3) graphing results, and (4) configuring auto-generated filter screens.

Conclusions: By integrating RexDB with GSM we have created a powerful and intuitive tool for GWAS analysis from large-scale data repositories. Encouraging is how easy it was to configure and modify the cohort selection interface through RexGuide, which provided a flexible mechanism for managing a variety of metadata. Use of AWS cloud services involved zero upfront infrastructure investment and has the potential of organic expansion of the system with future data growth.

Introduction: Nanomedicines can demonstrate improved targeting efficiency and reduced side effects over conventional formulations. Hence, there is a critical need to automatically synthesize knowledge and trends in nanotechnology research from an exponentially increasing body of literature. In nanomedicine, new engineered nanostructures and formulations are continuously being created, and Natural Language Processing approaches can semi-automate the cataloguing and tracking of the different nanomedicines being developed. The goal of this project is to automatically identify nanomedicines characteristics from the literature using name entity recognition. In this work, we present (1) the initial development the Engineered Nanomaterial Database [1] (END) to support the evaluation of nano-entity extraction; (2) the evaluation of current entity extraction systems developed for general English; and (3) the initial development of our own nano-entity extraction system (NanoB2B Entity Extractor).

Methods: The END nano-entity test data was developed using the Drugs@FDA Database which contains product inserts of a wide variety of FDA approved drugs. The data was manually annotated for entity mentions consisting of nanomedicine physico-chemical characterizations, exposure information, and biological response information of 42 FDA-approved nanomedicines. We evaluated the performance of two state-of-the-art named entity recognition systems developed for general English (StanfordNER [2] and OpenNLP NameFinder [3]). We compare the results of those systems to the initial development of our NanoB2B entity extraction system which uses lexical information about the entity as features into a supervised learning algorithm using the WEKA datamining package [4].

Results: We evaluated the StanfordNER, OpenNLP NameFinder and our NanoB2B Entity Extraction system using leave-one-out cross validation on the END nano-entity dataset. The results show that the state-of-the-art entity recognition systems developed for general English are not sufficient to extract the nanomedicine mentions with F-measures ranging from 0.1 to 0.7. However, our specialized NanoB2B entity extraction system produced initial results that show great promise; demonstrating an increase in F-measure for almost all entities with results ranging from 0.5 to 0.8.

Conclusion: Our results demonstrate that there is sufficient reason and promising proof to the validity of developing an entity extraction system specifically for nanomedicines. Our initial NanoB2B Entity Extractor which incorporating lexical information increases accuracy of the results for some nanomedicine entities. In the future, we will explore utilizing additional syntactic and semantic information as identified by MetaMap into our system.

Homeless patients driving innovation: Establishing a community innovation panel to create patient-facing technology in a large urban health clinic

D Keith McInnes, ScD1,2, Salem Johnston, BA2,3, Robert Hass, BA, BSE4
1Center for Healthcare Organization and Implementation Research, Edith Nourse Rogers Memorial VA Medical Center, Bedford, MA; 2Department of Health Law Policy and Management, Boston University School of Public Health, Boston, MA; 3Finance Office, Boston Health Care for the Homeless Program; 4Information Systems, Boston Health Care for the Homeless Program

Abstract
Homeless populations have complex medical needs and a diminished ability to address them. Information technologies such as cell phones and the internet allow ubiquitous communication and broad access to information, but are beneficial in a health setting insofar as they mesh with patients' needs and abilities. At Boston Health Care for the Homeless Program, we established a patient Community Innovation Panel to address the gap between homeless patients' low use of technology and the promise that technology holds.

Introduction
Homeless populations simultaneously exhibit complex medical needs and a diminished ability to address them. Cell phones and the internet allow ubiquitous communication and broad access to information, but are beneficial in a health setting only insofar as they mesh with patients' needs and abilities.

Description of the Patient Community Innovation Panel (CIP)
At Boston Health Care for the Homeless Program, we established a Community Innovation Panel to address the gap between homeless patients' low use of technology and the promise that technology holds. This panel, comprised largely of homeless patients, 1) Identifies problems facing our patient population and proposes technological systems to meet these needs; 2) Supervises a tech training program tailored to the priorities and abilities of Boston's homeless population; and 3) Recommends improvements to current technological systems from the perspective of homeless consumers of health services. The seed of this idea was planted last year when we created a Patient Portal to let patients request appointments and prescription refills – interest was high, but adoption was low. Patients helped us identify obstacles such as unfamiliarity with technology, fear of doing something wrong with a device, and shame at admitting one’s ignorance. Our initial response was to start a computer training program for patients, but this approach had limited capacity and was only partially meeting patients’ technology needs. To tackle the underlying problems more directly, we joined forces with a public health technologist to form a Community Innovation Panel of patients, researchers, and health workers. This panel includes 8 patients, with a variety of cultural backgrounds and a wide range of comfort with technology. The Panel has begun developing a multi-year technology strategy for the clinic, including use of text messaging to increase patient-clinic interaction; and addressing technology training needs with an innovative and scalable “train-the-trainer” approach that is creating a cadre of homeless peer technology tutors. This session will describe how elements of community based participatory research (CBPR) guided the concept and formation of the Community Innovation Panel, how homeless patients created and instituted the technology training curriculum and its peer tutoring model (including findings from training evaluations), and the functions that will be included in the automated text message system (ideas proposed by the panel include appointment reminders, adherence reminders for chronic conditions, weather alerts, and health-promoting advice).

Conclusions
The Community Innovation Panel shows great promise in making health information technologies more patient-centered at health care for the homeless programs and other safety net systems. This panel is developing a multi-year technology strategy for the homeless clinic, and addressing technology training needs with a “train-the-trainer” approach that will rely on homeless peers as technology tutors and trainers. This contributes to important goals of more patient-centered health care and increased patient engagement in their health.
Qualitative Assessment of Women’s Attitudes Towards a Tracking App for Phenotyping Endometriosis

Mollie M. McIlllop, MPH, MA¹, Tamer Seckin², MD, Noémie Elhadad, PhD¹
¹Columbia University, New York, NY; ²Endometriosis Foundation of America, New York, NY

Introduction

Endometriosis—a chronic disease of the female reproductive system in which the uterine lining grows outside the uterus—is associated with significant morbidity, a reduced quality of life (0.809 quality-adjusted life years/woman) and substantial health care costs and productivity loss [1]. It is estimated to affect 1 in 10 women [2]. Despite its impact and prevalence, little is known about the disease, and diagnosis is often delayed by several years because of the lack of phenotypic knowledge about it. Our long-term goal is to phenotype endometriosis—a particularly challenging task for such an enigmatic condition [3]. A first step is to elucidate the catalogue of signs and symptoms of the disease and their manifestations throughout a patient’s menstrual cycles. Creating such a catalogue is important for identifying clusters of symptoms and their interactions throughout a cycle that could in turn indicate potential disease subtypes. While there exist research surveys to collect patients’ experiences, they assume a static set of symptoms. In contrast, we aim to engage patients in becoming active participants in disease phenotyping through a mobile app called Phendo. Phendo will allow patients to track their endometriosis symptoms as they occur throughout their menstrual cycle, and allow its users to contribute tracking custom/individualized symptoms. To assess the need and elucidate functionalities for Phendo, we conducted a series of focus groups to explore patients’ attitudes towards a tracking mobile application for the sake of disease phenotyping.

Methods

A series of 5 focus groups were conducted with a total of 27 women from the New York metropolitan area over a period of three weeks. Women were recruited through emails to endometriosis patient advocacy groups and flyers posted on the Columbia University campus and through Twitter. Eligibility included official endometriosis diagnosis through laparoscopic surgery. Each focus group lasted approximately 90 minutes and a semi-structured focus group guide was used to direct the conversation. Each focus group was audio recorded and transcribed verbatim. Thematic analysis was carried out to identify major themes related to tracking and endometriosis.

Results and Discussion

Overall, focus group participants felt positive towards tracking, although some women worried that tracking would lead to being reminded that “nothing helps”. Most participants used some sort of tracking for one or more aspects of their endometriosis (e.g., pain, diet and GI issues, exercise, emotions), but they felt that existing tracking apps (e.g., period trackers, fitness, diet trackers) were not appropriate for the range of symptoms and granularity of symptoms they wanted to track. Several participants reported having created their own customized tracking system.

Women expressed a range of motivations to track: to better understand their own experience of the disease (i.e., discover and reflect on potential patterns of symptoms throughout their cycle); to explore strategies for symptom management (“what works and what doesn’t”); to help manage their work and personal schedule based on their past tracked data and forecasted flares; and to communicate better with their doctors. Participants expressed a strong altruistic will to contribute their data for the sake of research.

Our findings indicate that patients would welcome an app for phenotyping endometriosis that captures the wide range of endometriosis symptoms. The discovered themes also help elucidate different strategies to engage patients in tracking, which we are currently exploring in the design of Phendo. Contrary to the few existing apps that track menstruation and even endometriosis, Phendo will enable the research community to gather and analyze unprecedented phenotypic descriptions of the disease.

Qualitative Analysis of Proxy Utilization of Patient Portal for Older Adult Patients

Brittany L. Melton, PhD, PharmD¹, Crystal Burkhardt, PharmD, MBA, BCPS²
¹University of Kansas School of Pharmacy, Lawrence, KS; ²University of Kansas Medical Center, Kansas City, KS

Introduction
Meaningful Use (MU) is part of the effort to increase utilization of healthcare technology, and requires interfaces, such as patient portals, which allow patients to view health records and interact with providers online. In 2014, over 90% of hospitals reported having the capacity for patients to view their health record online, but only 22% of patients reported viewing medical tests online.¹,² Older patients are less likely to enroll with a patient portal and even fewer actively use one.³ Requirements for patient portal use can be met if patients designate a proxy who regularly uses the portal on their behalf. The objective of this study was to evaluate how proxies for older adult patients use a patient portal and how that use impacted their relationship with the patient.

Methodology
The study was conducted at a large teaching medical center which implemented a patient portal in 2011. A list of older adult patients who had enrolled in the patient portal was evaluated for those patients who had designated a proxy for possible inclusion in the study. Patients and their proxies were contacted by phone and asked if they would like to participate in a survey, and verbal consent was obtained. Basic demographic information and relationship with the patient was obtained. The proxy was then asked about how they became involved in the management of the patient’s healthcare information, how often they access the patient portal and what patient information/portal features they use regularly, and which they use least. Participants were also asked how becoming involved in the patient’s healthcare affected their personal relationship. The interviews were transcribed and analyzed for emerging themes. This study was approved by the Institutional Review Board.

Results
Approximately 150,000 patients over 65 years old were seen at the study site between 2011 and 2015. Almost 20,000 older adult patients had accessed the patient portal, and only 39 had designated a proxy in that timeframe. Patients contacted did not know the portal existed and had never used it, therefore they were excluded from the study. Most proxies were female (80%), and Caucasian (80%), with an average age of 60 years. Proxies stated they use the patient portal because their older adult patient was not computer literate or had other limitations. Proxies reported most frequently using laboratory test review, communication with providers, and prescription refill requests. They felt portal use reduced the number of questions they had to ask provider and made healthcare information easier to understand. Proxies reported accessing the portal when they received an e-mail indicating new information was available. Generally proxies felt patient portal use improved their relationship with the patient.

Conclusion
Proxies believe having access to the personal health information for an older adult patient was beneficial for providing care and improved their relationship with the patient. Older adult patients often have cognitive or physical limitations which make patient portal use difficult or impossible, but proxies can serve as a link between the providers and the patient through patient portal access.

A Framework for Robust Information Extraction from Free Text Documents

Frank Meng PhD\textsuperscript{1,2}, Craig Morioka PhD\textsuperscript{1,3}, James Sayre PhD\textsuperscript{1,4}

Clinical NLP has a rich history with many examples of systems that have performed well within laboratory settings [1]. However, most of these systems have not successfully transitioned into operational workflows due to several factors: they are designed mainly for use by informatics experts, they must be re-trained for new extraction problems, and they require relatively large amounts of expert-annotated data for training [2]. In this work, we describe an information extraction (IE) system that attempts to provide an end-to-end solution to address these issues centered around the following goals: 1) generate manually annotated data as a by-product of existing operational tasks using user-centered tools that streamline clinical workflows in order to increase the likelihood of adoption; 2) minimize the amount of annotated data needed to train IE systems to perform at acceptable levels; 3) maximize knowledge re-use to minimize re-training for new extraction tasks; and 4) perform periodic and regular validation on the extracted data to determine the goodness of the data as well as to ensure the continued performance of the system as time progresses.

The overall system architecture is depicted in the figure below and consists of three main elements: the user interface facilitates chart reviews for abstracting data elements from patient records as well as validating automatically extracted data; the IE system automatically extracts data elements from clinical documents using extraction patterns generated from annotated training examples; and the validation and quality assurance process consisting of evaluating extracted data as well as the deployment of alerts to detect performance deviations from expected behavior. The pattern-based IE system was implemented and validated for extracting data from radiology reports of lung cancer patients and was shown to perform better than baseline methods [3]. Because of its reliance on lexical patterns, preliminary results indicate that reasonable extraction performance can be achieved with smaller numbers of training examples. In addition, patterns can be abstracted to represent higher level concepts that potentially make them immediately reusable for other extraction tasks. We designed the user interface as a form-based web application that enables users to efficiently pull specific data elements from patient documents into structured forms without the need for keyboard data entry. The user interface will also enable experts to quickly validate randomly sampled data that was automatically extracted by the IE system. The quality assurance process can be tailored to the amount of resources available as well as the specific goodness level required of the data.

Automated Dynamic Problem and Allergy Lists for Efficient Electronic Health Record Management

Stéphane M. Meystre, MD, PhD\textsuperscript{1,3}, Jianyin Shao, PhD, MS\textsuperscript{1}, Greg Jones, PhD\textsuperscript{2,3}

\textsuperscript{1}Department of Biomedical Informatics, \textsuperscript{2}Scientific Computing and Imaging Institute, University of Utah, Salt Lake City, Utah, \textsuperscript{3}Clinacuity, Inc., Salt Lake City, Utah.

Abstract: To automatically improve the quality of medical problem and allergy lists, and enable more efficient clinical decision support to reduce medication prescription errors, we developed a new prototype to automatically extract structured and coded medical problems and allergies from clinical narrative text in the electronic health record. When evaluated with a focus in cancer outpatient care and a manually annotated corpus of 770 clinical notes, the prototype identified approximately 95% of medical problems, and 90% of allergens.

Introduction: Medical errors are recognized as the cause of numerous deaths, and even if some are difficult to avoid, many are preventable. Computerized physician order-entry systems with decision support have been proposed to reduce these errors, but these systems rely on structured and coded information in the electronic health record (EHR). Unfortunately, a substantial proportion of the information available in the EHR is only mentioned in narrative clinical documents. Electronic lists of problems and allergies are available in most EHRs, but they require manual management by their users, to add new problems, modify existing ones, and the removal of the ones that are irrelevant. Consequently, these electronic lists are often incomplete, inaccurate, and out of date. Our hypothesis is that a system based on natural language processing (NLP) using stepwise hybrid methods can continually extract relevant information from the EHR with high accuracy, to then improve the completeness, correctness, and timeliness of electronic lists of medical problems and allergies. This new system will help ensure the majority of medical problems and allergies of a patient are known by their healthcare providers, and are available for decision support and quality improvement.

Methods: To establish the feasibility of a high accuracy stepwise hybrid NLP system to automatically extract medical problems and allergies from clinical narrative text, we 1) created a reference standard for training and testing, 2) developed the prototype to automatically extract medical problems and allergies, and 3) tested the prototype with the aforementioned reference standard. A web-based problem and allergy lists mock-up resembling the commercial EHR was also developed to prepare the EHR integration. A cohort of 154 patients with breast, lung, or gastrointestinal cancer was randomly selected, and 5 most recent clinical notes of select types (chosen by domain experts) were extracted and de-identified. A new text annotation tool was installed (Brat(1)), tested and then used by 9 experts. Their agreement when annotating was good (F\textsubscript{1}-measure 0.70, or even 0.90 if not considering detailed modifiers), allowing for a good quality reference standard.

The application prototype was developed within the Apache UIMA framework, with text pre-processing analysis engines adapted from Textractor(2) or OpenNLP with trained models from cTAKES. The high-sensitivity component includes a dictionary lookup module and CRF-based named entity recognition.(3) Candidate medical problem and allergies were then filtered by rule-based and SVM-based filters in the false positive filtering components.

Results: For the final evaluation, the prototype was trained and tested using a 10-fold cross-validation approach, and performance reached an average recall of 0.922, precision of 0.960, and F1-measure of 0.940. High-precision filtering in the stepwise hybrid approach allowed eliminating 69\% of the false positive problems identified, increasing precision from 0.673 to 0.921. Precision of allergens identification was already at 1.0, and filtering therefore had no impact (Table 1).

Influenza Vaccine Cancel-Reordering Reveals a Potential Limitation of Immunization Decision Support during Intermittent Vaccine Shortages

Jeremy Michel, MD, MHS;¹ Levon Utidjian, MD, MBI;¹ Jeritt Thayer;¹ Robert Grundmeier, MD;¹
¹The Children’s Hospital of Philadelphia, Philadelphia, PA;

Introduction

Our institution relies on home-grown CDS to support immunization ordering.¹ However, when primary care sites run out of a vaccine, the CDS continues to recommend an out-of-stock product. This is a significant problem for influenza immunization delivery because we use multiple influenza vaccine formulations. Often, clinicians are alerted by nurses that the order must be switched due to a vaccine shortage (creating a cancel-reorder event). As part of an ongoing effort to improve immunization delivery efficiency, we are investigating these cancel-reorder events, their effect on visit duration, and the feasibility integrating real-time vaccine shortage information into the CDS.

Methods

We extracted data on influenza immunization ordering for one clinical care site within our institution from the EHR for the 2015-16 flu season. A cancel-reorder event was recorded whenever a patient had more than one influenza immunization ordered on a given day and at least one of these orders had a status of ‘canceled’. Differences between timestamps were used to calculate reorder-based delay. We are developing a portal to support documentation of out-of-stock events and have modified the immunization CDS to incorporate this data into order recommendations.

Results

A total of 14,572 influenza immunizations were ordered this flu season for 12,934 patients. Of these orders, 19.4% (2,821) were cancelled. Alternate influenza formulations were reordered for 1,496 patients (19.4%) and 58% of patients with a cancelation had reordered immunizations. Reordering occurred 24 minutes on average after the initial order (range 0-200 minutes). Of note, 95 orders were cancelled and reordered within one minute of the initial order.

Discussion

Cancelling and reordering vaccines to change product formulation occurs frequently. More than half of cancelled influenza orders are reordered with an alternate formulation and out-of-stock status is likely the primary cause. Out-of-stock events occur every flu season for formulations, insurances, and care sites. Updating centrally for each event would not be feasible, as the system must be taken offline to update. A web portal (figure 1a) is under development to allow care sites to document local out-of-stock events and share real-time supply data with the CDS (figure 1b).

Figure 1: (a) Prototype portal for nurses to report out-of-stock events. In this example, the practice is out of HPV4 (Gardasil) and Flu Mist. (b) Clinician-facing CDS alters the recommendations to account for vaccine shortages.

Conclusion

Almost 20% of influenza immunization orders are cancelled and 58% of these are reordered with alternate products, likely due to vaccine shortages. Patients wait an average of 24 minutes for reordering to occur, which could affect visit duration. Because central CDS updates in response to vaccine out-of-stock events are not feasible, a portal is being developed and will soon be tested to determine the impact on cancel-reorder events and visit duration.

Expert Interpretations of Prostate Cancer Quality-of-Life Survey Results

Sean P. Mikles, MPH1, Andrea L. Hartzler, PhD2, Ted A. Skolarus, MD3, John L. Gore, MD MS1

1University of Washington, Seattle, WA; 2Group Health Cooperative Research Institute, Seattle, WA; 3University of Michigan, Ann Arbor, MI

Introduction

Collecting patient-reported outcomes (PROs) facilitates the monitoring of prostate cancer patients’ quality of life (QOL) after treatment and is considered an indicator of high quality care. Experts have suggested that graphic visualizations can help in the interpretation of PRO scores.1 However, we lack consensus on how best to represent PRO data to support clinical practice. We aim to identify how experts interpret scores from a standard prostate cancer QOL instrument to address this gap and aid in the design of prostate cancer PRO-based visualizations.

Methods

We sent two rounds of electronic questionnaires using a Delphi method to 9 prostate cancer clinician and research experts involved in an international Movember prostate cancer initiative to understand how they interpret Expanded Prostate Cancer Index Composite (EPIC) scores for three prostate cancer domains: bowel, sexual, and urinary function. Participants were asked to rank the importance of the following concepts in clinical practice: whether a patient’s EPIC score is below a threshold value, below a population average, below a baseline score, whether the patient has improved since treatment, and whether the patient is bothered by their QOL. We presented 6 prototype line charts showing an individual patient’s EPIC scores and average scores from a research cohort over time. Each prototype aimed to aid interpretation by showing one of the following types of visual features: 1) confidence interval (CI) around average cohort scores, 2) CI around individual patient scores, and 3) lines defining severity of illness (examples in Figure 1). We asked whether these visual features were useful for clinical decision-making.

![Figure 1. Prototype line charts of prostate cancer urinary incontinence quality of life scores.](image)

Results

After the second round of surveys, the top three averaged concept rankings in each domain were (from most to least important): whether a patient is bothered by their QOL, scores being below baseline, and whether a patient has improved. When considering the prototypes, all 9 experts thought that charts defining illness severity were useful, 9 thought that CIs around cohort scores were useful, and 6 thought that CIs around individual scores were useful.

Conclusion

Participants thought that charts visually defining illness severity are useful for clinical practice, but that threshold scores were not of prime importance. On average, participants thought that it was most important to consider whether patients are bothered by their QOL. Further research is needed to relate prostate cancer QOL scores to clinical decision-making processes to inform future visualizations. This study is limited by its small sample size.

The Importance of Well-Defined Mapping Heuristics for Mapping Quality

Catherine Hoang, BSN, MS¹, Holly Miller, BSN, MS¹, Nathan Stocks, MS², Tim Williams, BS³, Paloma Hawry³, Mary Ferramosca, RPh²
¹U.S. Department of Veterans Affairs; ²Deloitte Consulting, LLP; ³Deloitte and Touche, LLP

Introduction

The Department of Veterans Affairs (VA) recognizes the need to modernize legacy systems and to work toward semantic interoperability internally, with the Department of Defense (DoD), and external providers. Due to the number of patients that move between VA and DoD health care systems during their service, information sharing is critical to maintain current and accessible health information, patient safety, continuity of care, and the high quality of care.¹

Section 713 of the National Defense Authorization Act for Fiscal Year 2014 (NDAA) indicates that while VA and DoD share significant amounts of read-only data, much of the data is not standardized, limiting interoperability and clinical decision support.² Semantic interoperability can be achieved through the mapping of prioritized clinical domain data to that of standardized clinical reference terminologies.

Discussion

Mapping to standardized clinical reference terminologies allows semantic interoperability between Departments to be realized without overhaul of the entire system. The most important steps for the initiation of any mapping project are to understand the business and use cases and to establish relevant mapping heuristics.³ Clearly defining the rules that will be applied to not only the project, but any future maintenance of the maps is essential to clarify ambiguity, allow for reproducibility, as well as to provide transparency to the methodology used. It is important to define and test these rules against the actual data set that will be mapped. Our poster will highlight examples of weak and strong heuristics, show how to document these for users to understand the maps, and discuss the implications for map quality and use. Ambiguous and untested rules applied while mapping result in higher disagreement rates between the mapper and validator during the quality review process, and increase the level of effort within an already manual and labor intensive process.

The VA Knowledge Based Systems (KBS) Terminology Standards team has performed validation of mappings within 12 domains and 5 subdomains totaling 121,194 individual terms to support VA’s interoperability goals. Reductions in the disagreement rates were found in each domain as the mapping heuristics were refined. The poster will describe the workflow and map quality validation methods used.

Conclusion

Clearly defined mapping heuristics at the start of a project greatly reduces the ambiguity encountered within the mapping process and amount of effort that may be required to refine or maintain maps.

Figure 1: Disagreement Rate
Discovering Community Resources to Support Emerging Models of Care
Mari Millery, PhD & Rita Kukafka, DrPH, MA, FACMI
Columbia University Department of Biomedical Informatics, New York, NY

Background: Emerging healthcare models embrace population outcomes, social determinants, and value-based care. They recognize the role of community resources and supportive services in keeping populations healthy. Engagement of community partners requires accurate information about the complex and dynamic ecosystem of health-related resources. The traditional methods of community asset mapping in public health have not leveraged informatics tools. The goal of this study was to mine multiple available data sources to produce a maximally comprehensive and exhaustive inventory of community health resources in one target community, and to document the steps and data sources required in such effort. The study provides groundwork for partially automating community resource identification in the future.

Methods: The target community of Washington Heights-Inwood (WAHI) in New York City is a densely populated urban area of approximately 280,000 residents; 71% Hispanic and 14% African American. This study is part of a larger GetHealthyHeights.org (GHH) project to implement a community-engaged health informatics (CEHI) platform in WAHI. The resource inventory will be used to populate a publically available resource directory interface on GHH. Use cases to be supported include client referrals, resource access for community members, and a listing of potential collaboration partners. Seven data sources were initially identified through key informants and web searches. Two were excluded due to poor geographic match and outdated information. The remaining five data sources are listed in Table 1, and include online directories, electronic files, and paper-based directories. Table 1 shows resource sectors targeted, geographic coverage, updatability of each data source, and numbers of resource entities found. Key variables were extracted from each source. Non-health entities and duplicates within one source were excluded. Matching of unique entities across sources was conducted manually, using sorting and searching functions. Summary statistics were calculated to examine overlap across sources, unique contributions of sources, and coverage of different resource sectors.

Results: Table 1 shows the numbers of resource entities each data source yielded, after excluding non-health related entities and duplicates within one source (entities kept column). The IRS data was most significantly reduced in this step due to a large number of non-health entities. Before matching for unique entities across sources, the data file had 472 items. After matching, a total of 296 unique entities were found. Among the 296 entities, 58% were found in only one source (single source), 30% in two sources, 7% in three sources, 4% in four sources, and 1% in all five sources. Table 1 shows the number of single source entities per source. All sources yielded single source entities, ranging from 6 to 59. The NYC directory contributed the most single source entities, explained by the fact that it lists many public governmental resources not covered by the other sources. Based on information readily apparent in the sources, it was not possible to code the sector of 38% of entities. The available information suggests robust coverage of the non-profit sector by IRS and HITE, and the public sector by NYC and GHH (Table 1, 3 rightmost columns). The sources included did not provide coverage of the private and informal resource sectors.

Conclusions: The results suggest that it is necessary to utilize a variety of data sources to achieve maximal coverage of resource sectors and entities. The IRS data is available nationally and will provide a source of non-profit entities for any U.S. community. Future steps involve taxonomy-building and semi-automated coding and entity matching.

Applying Machine Learning Methods to Predict Activities of Daily Living for Cancer Patients

Hua Min, Talha Oz, Sava Vukomanovic, Hedyeh Mobahi, Katherine Irvin, Ilirjeta Krasniqi, Janusz Wojtusiak
Department of Health Administration and Policy, George Mason University, Fairfax, VA

Introduction
The ability to predict Activities of Daily Living (ADLs), their changes, and relationships to comorbid conditions are of great importance for clinicians, patients, and caregivers. In recent years, researchers have applied machine learning techniques to create models capable of predicting ADLs for patients. However, unexplored factors remain including the effect of multiple comorbidities and their combinations on ADLs. In this study we applied machine learning methods including AQ21 and WEKA to analyze the SEER-MHOS data. SEER-MHOS links two large population based sources of data. SEER data comes from cancer registries, that collect clinical information, demographics, and cause of death. MHOS provides information about patient physical and mental status obtained in clinical surveys.

Methods
SEER-MHOS data have been used to extract comorbidities and ADLs (self-reported), as well as cancer characteristics (SEER registry). The total number of patients in SEER-MHOS data is 1,849,311 we then extracted only cancer patients 102,269. Furthermore, patients with multiple cancers were excluded resulting in 83,255 patients left. Then we extracted patients who completed both surveys 2-year before and 1-year after the cancer diagnosis. If a patient had multiple surveys, one survey before and one survey after closest to the cancer diagnosis date were used. The final data contain 2,239 cancer patients. This study included six ADLs (walking, dressing, bathing, moving in/out chair, toileting, and eating) measured before and after cancer diagnosis, 12 comorbidities (e.g., Hypertension, Diabetes, etc.) before cancer diagnosis, six cancer characteristics (grade, staging, tumor size, histology, tumor extension, and behavior), radiation and surgery treatment indicators, and three demographics (age, race, and marital status). Models have been developed using AQ21 to predict ADL functionalities after cancer diagnosis. AQ21 is a supervised machine learning system for creating attributional rules for data and background knowledge. The software has been used to discover rules that indicate strong relationships in data, but grouping patient characteristics that are indicative of deficiencies in ADLs. The data have also been analyzed by using WEKA software to create baseline accuracy from methods other than AQ21. Specifically, we tested Logistic Regression, Decision Tree, Random Forrest, Naïve Bayesian, all with 10-fold cross validation.

Results
There are 23 rules generated by the AQ21 for the six ADLs. The following shows one sample rule.
Rule1: [Bathing_disability] ==>[Histology = 2,1: 45, 80, 36%, 45, 80, 36%]
[Staging = 7: 40, 72, 35%, 21, 25, 45%]
[Primary site = Lung and bronchus, Colon, Large intestine: 53, 109, 32%, 20, 14, 58%]
:p = 20, n = 14, q = 0.315, cx = 27
First line in the rule indicates that among the patients with histology type of epithelial neoplasms and squamous cell neoplasms, 45 of them have bathing disability while 80 patients have not. The consistency of the prediction is 36%.

Discussion
The machine learning methods can be used to identify predictors for ADLs for cancer patients. When applying such methods one needs to tradeoff accuracy of the learned models for interpretability and transparency of results. In general, rules are known to be the most transparent representation, directly corresponding to statements in natural language. Since AQ21 cannot calculate AUC for rules it learns, we are currently working on other ways of comparing the results of AQ21 and WEKA.

Visualizing the Effects of Cancers on Relationships Between Comorbidities and Activities of Daily Living

Hua Min, Talha Oz, Sava Vukomanovic, Hedyeh Mobahi, Katherine Irvin, Ilirjeta Krasniqi, Janusz Wojtusiak
Department of Health Administration and Policy, George Mason University, Fairfax, VA

Introduction
Visualization methods are useful in helping researchers discover and explain relationships in data. They can offer new ways to view and present data insights to users faster than traditional analysis methods. In the presented work we use visualization techniques to explore Activities of Daily Living that are important indicators of quality of life. The ability to predict ADLs, their changes, and relationships to comorbid conditions is of great importance for clinicians, patients, and caregivers. In recent years, researchers have applied machine learning techniques to create models capable of predicting ADLs for patients. However, unexplored factors remain including the effect of cancers on comorbidities and ADL relationships. Our hypothesis is that for some patients, the presence of specific cancers may strengthen the impact comorbidities have on ADLs, and for others it may weaken the relationship.

Methods
SEER-MHOS data have been used to extract comorbidities and ADL measurements (self-reported), as well as cancer characteristics (SEER registry). The data consisted of 102,269 cancer and 1,747,042 non-cancer patients. This study included 12 self-reported comorbidities (e.g., Diabetes, Hypertension, etc.) and six ADLs (e.g., walking, bathing, dressing, etc.) from 10 cancers (e.g., Prostate, Breast, Colorectal, etc.). The data have been loaded to PostgreSQL database and pre-processed to extract needed variables. Statistical calculations have been done in Python using SciPy library, and visualization using Gephi. First relationships between comorbidities and ADLs were analyzed and the resulting comorbidity and ADL relationships were paired (comorbidity, ADL). Strength of relationships between pairs was measured as likelihood ratio \( LR_{comorbility,ADL} = \frac{p(comorbility|ADL)}{p(comorbility|no ADL)} \), which was then compared between non-cancer and cancer patients by cancer type. The rationale between the two networks is that figure 1 focuses on direct relationships between ADLs and each comorbidity, while figure 2 examines effects of cancer types on ADLs given a comorbidity. Fisher’s exact test has been used to calculate statistical significance of the effect of the cancers on the paired relationships, and to graph those that were statistically significant (p<0.01). The strength of the connections have been calculated as \( |LR_{comorbility,ADL} - LR_{comorbility,ADL,nc}| \), the difference between likelihood ratios for cancer and non-cancer patients, and edges with strength > 0.51 remain.

Results
Figure 1 shows the relationship between comorbidities (outside nodes) and ADLs (inside nodes). The thicker the connection the more often patients with a comorbidity reported an impact on that ADL. Congestive Heart Failure (CHF), Stroke, and Gastrointestinal disease (GI) comorbidities impact the most ADLs while Hypertension the least, with CHF to walking have the strongest weighted relationship (3.08) and Hypertension to eating the weakest (1.05). Figure 2 pairs the relationships from Figure 1 and presents the effect that cancers have. The smaller circles are cancers and are connected to 68 comorbidities and ADL pairs. Pancreatic cancer not only impacts the most number of pairs but the strength of the relationships are more significant. For example, when you compare Pancreatic and Stomach cancers impacts on the paired node GI disease and dressing ADL, it was found the weighted strength of Pancreatic is 1.37, whereas Stomach is 0.61.

Discussion
The visualization of the SEER-MHOS data discovers not only the complicated relationships among comorbidities, ADLs, and cancers but also the weights of those connections. Findings from the figures are clinically meaningful. For example, Pancreatic cancer which is one of the most aggressive cancers has the strongest impact on ADLs. Our next steps for this study are discovering relationships among cancer characteristics, comorbidities, and ADLs.

Development of a Diagnostic Assistant for Multiple Sclerosis Using Natural Language Processing of the Electronic Medical Record

Lindsey R. Mitrani, BA\(^1\), Gabriel G. Lu\(^1\), Dominick J. Fulgieri\(^1\), Herbert S. Chase, MD, MA\(^1\)

\(^1\)Columbia University Medical Center, New York, NY

Introduction
Missed or delayed diagnoses are a major cause of medical error. Diagnosis could be facilitated by “diagnostic assistants,” algorithms which mine the electronic health records (EHR) for clues of one or more conditions. For diseases characterized by abnormal lab values, such as chronic kidney disease, implementing a diagnostic assistant that surveys the patients’ structured lab data is computationally simple (1). However, for diseases for which there are no routine lab tests and are instead characterized by signs and symptoms such as neurological illnesses, the diagnostic assistant would have to mine unstructured data using natural language processing (NLP).

Objective
The goal of this study was to build a diagnostic assistant for Multiple Sclerosis (MS), using NLP to parse clinical notes, which could identify patients with MS. We chose MS given the importance of prompt intervention in mitigating progression of the disease and the known delay in diagnosis (2, 3).

Materials and Methods
Clinical notes of patients from the adult outpatient clinic were extracted from the Columbia University Medical Center clinical data warehouse. The notes were parsed using MedLEE which maps signs and symptoms to UMLS terms (4). The presence of an ICD9 code for MS was the gold standard for identifying MS patients. Training set data consisted of parsed clinical notes of MS patients who had the illness for at least two years and of controls. We used this data set to identify UMLS terms associated with MS and to build the classification model. Test set data consisted of parsed notes of randomly selected patients from the same adult outpatient clinic, some of whom had a MS. Classification of the training set was performed using the Naive Bayes classifier using 10-fold cross validation and the Weka workbench. Classification of the test set used the training set to generate a model.

Results
Approximately 1000 UMLS terms from the notes of MS patients of the training set occurred more frequently than in controls. Synonymous terms were manually clustered into 67 separate buckets reflecting different characteristic signs and symptoms of MS, such as “paresthesia,” and used as features in classification. If a patient had any one of the bucket terms in a single note they were scored a 1 for that bucket; if not, a 0. Classification using the training set yielded excellent accuracy (Table). When the model was applied to the larger test set, the accuracy of classification was similar. The post-test probability of MS in the test set increased five fold from 1.2% to 6.0%.

Discussion and Conclusion
Our results demonstrate that a classification model that accurately identifies patients with MS can be developed using signs and symptoms of MS extracted from clinical notes using NLP. Although the post-test probability increased 5-fold, the low prevalence of MS and the 87% specificity of classification resulted in false positives. Some of these patients, however, might have MS that was not recognized by their providers. A manual review is underway to explore this possibility. Errors of ICD coding for MS likely reduced classification accuracy, as well.

Predictive Modeling for Appointment No-show in Community Health Centers

Iman Mohammadi, MS1, Ayten Turkcan, PhD2, Tammy Toscos, PhD1,3, Huanmei Wu, PhD1, Brad N. Doebbeling, MD, MSc4

1Indiana University, Indianapolis, IN; 2Northeastern University, Boston, MA; 3Parkview Research Center, Fort Wayne, IN; 4Arizona State University, Phoenix, AZ

Problem. One key measure for improving access to care is reducing the number of “no-shows.” An appointment is considered a no-show when the patient misses the appointment without cancelling. No-show rates from 10% to 50% have been reported in different healthcare settings1,2. Purpose. In our current multiyear and multisite project, we are using simulation modeling to test and find the optimal scheduling processes, staffing and policies for improving access to care2,3. Thus, we estimate patients’ no-show probabilities using statistical methods such as logistic regression. Here, we present a no-show prediction model and report predictors of no-shows by analyzing Electronic Medical Record (EMR) and scheduling data. Methods. We evaluated different factors which we hypothesized may be related to appointment no-show. We collected all appointments and patient encounters during 2014 from an urban Community Health Center (CHC) in Indiana. Data fields included appointment characteristics (date of visit, date the patient had contacted the clinic to arrange an appointment. To test the effect of patient no-show behavior on appointment adherence, we created another variable “prior no-show rate” for each patient. Prior no show rate is the number of no-shows for a given patient prior to the last appointment, divided by the patient’s total number of appointments prior to the last appointment. Appointment adherence (“no-show” or “arrived”), a binary variable, was the outcome variable in this project. We developed the no-show prediction model using logistic regression analysis in SAS 9.4 and also tested variables individually against the appointment compliance. Results. The multivariate logistic regression model considered all variables in the dataset plus lead-time and patient prior no-show rate. Predictors of no-show in our final model included provider specialty, insurance type, age, cellphone availability, lead-time, and patient prior no-show rate. The overall no-show rate was 12%, and the c-statistic for the model was 0.76. Approximations scheduled with pediatricians and gynecologists had higher no-show rates, compared to those with nurse practitioners and internal medicine physicians (p <0.0001). Patients scheduled with pediatricians (OR=4.3, 95%CI=[1.6,6.6]) or with OB-GYN (OR=3.2, 95%CI=[2.2,8.6]) were more likely to no-show than those scheduled with internists. Self-pay and Medicaid patients had higher no-show rates than private insurance or Medicare patients did (p <0.0001). Patients who did not have cell phones had no-show rate of 45% while they had arrival rate of 35% (p=0.005). Patients without cellphone were 1.5 times more likely to no-show than patients who have a cellphone (95%CI=[1.2,1.9]). The univariate tests show that the average lead-time of 22.8 days for “no-show” appointments is larger than the average lead-time of 17 days for “arrived” appointments (p <0.0001). Compared to same-day appointments, appointments made less than 2 weeks in advance, between 2 weeks and 1 month in advance, and more than 1 month in advance are respectively 5.1 (95%CI=[3.3,8]), 4.6 (95%CI=[2.8,7.5]) and 7.5 (95%CI=[4.7,12]) times more likely to become no-show. The mean of prior no-show rates for “no-show” appointments at 11% is larger than the mean of prior no-show rates for “arrived” appointments at 4% (p <0.0001). That means, chronic no-showers are more likely to no-show (OR=5.6, 95%CI=[3.2,6.8]). Other variables, appointments time (AM vs. PM), gender, weekday, ethnicity, race and marital status, did not impact appointment adherence. Discussion. There are three key findings. First, more same-day appointments (greater open access scheduling) can reduce clinics’ no-show rates. It has been suggested that patients might miss their appointments made far in advance because of forgetting the appointment, getting better, or having other priorities1. Second, patients who frequently not shown for appointments in the past are more likely to no-show again. This group might be limited to same-day appointments. Third, higher no-show rates among patients without a cellphone may be a result of reduced appointment reminders. Alternative means for scheduling and appointment reminders may reduce no-show rates and improve access to care. Conclusion. EMR and scheduling data is useful for no-show prediction models, which can inform decisions about system redesign. Patient and provider characteristics and visit features help predict appointment adherence.

Semantic Relatedness and Similarity between Biomedical Concepts

Sungrim Moon, Ph.D., Trevor Cohen, Ph.D., Hua Xu, Ph.D.
School of Biomedical Informatics, University of Texas Health Science Center Houston, Houston, TX, 77030, USA

Introduction: Automatic differentiation of semantic relatedness and similarity among biomedical concepts has been explored by using path-based, Information Content (IC), lexical matching, and semantic vector (or distributional) methods in the biomedical and clinical domains. Nevertheless, automated discovery of grouping semantic relatedness and similarity concepts is still challenging, due to dependence on domain knowledge and limited word-coverage. We used the distributional semantics approach with relevant Named Entity Recognition (NER) to automatically distinguish concepts of relatedness and similarity from a large unlabeled corpus.

Method: This study focused on semantic vector approaches using three different corpora. We used one clinical corpus from the Multiparameter Intelligen Monitoring in Intensive Care (MIMIC) II data (403,871 notes) as well as another set of diverse clinical narratives from the University of Texas Health Science Center Houston Clinical Data Warehouse (911,955 notes). We also used the titles and abstracts (n=1,249,980) from the 2013 edition of MEDLINE. We processed all data to separate sentences and tokens, and extracted UMLS concepts (CUIs) using Clinical Language Annotation Modeling and Processing (CLAMP)\(^1\). CLAMP encoded sentences as sets of problems, treatments, and laboratory test concepts. We trained a distributional semantics model (variants of Random Indexing using the Semantic Vectors software package\(^2\)) with a range of parameter settings for each corpus – e.g. the Random Direction model is a sliding window-based model that takes into account whether a context term occurs before or after a term of interest. We evaluated correlation with human judgments of similarity and relatedness on pairwise terms\(^3\) using Spearman’s rank correlation. We compared our results with those obtained by path-based, IC, lexical matching, and word-based semantic vector methods, which were re-calculated by McInnes and Pedersen (2015)\(^3\).

Results: Table 1 shows the results of the three distributional semantics models compared to other different approaches. The Random Direction model with semantic NER encoding using CLAMP (MEDLINE 2013 corpus) yielded best correlations for similarity (0.5828) and relatedness (0.5336). Additionally, we tested semantic NER encoding using MetaMap. Though MetaMap produced lower correlation (0.5687 for similarity and 0.4874 for relatedness) than CLAMP, results obtained with MetaMap outperformed all other models tested. This strongly suggests that concept extraction and normalization can improve the correlation between semantic vector models and human judgment of similarity and relatedness, as compared with term-based models.

</table>

Conclusion: With NER encoding using CLAMP, distributional semantics models outperformed the state-of-the-art measurements. It suggested that relevant semantic NER encoding is essential to achieve high-correlations to human judgment. Our method could automatically categorize semantic meanings in a practical way.

Resolving Hierarchical Ambiguity in Indexing Recommendations

James G. Mork, MSc, Dina Demner-Fushman, MD, PhD,
Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, National Institutes of Health, DHHS, Bethesda, MD

Introduction
Finding the main points of a given text and mapping them to MeSH® facilitates MEDLINE® indexing, assignment of key terms by authors, cataloguing, etc. One of the problems in assigning terms using the MeSH hierarchies is to decide on the level of specificity that is required for each document. The decision is based on the context of the document, as well as the nature of the indexing task, whether a more general term, a more specific term, or both levels of terms should be assigned. For the task of assisting the MEDLINE indexer, the decision could be based on the indexing rule of assigning the most specific MeSH term appropriate to the article, except in cases where the indexer’s expert judgement is to apply an allowed exception. In this work, we rely on a corpus-based approach to learn how to select an appropriate specificity of the term when our tool, The NLM Medical Text Indexer (MTI) suggests both a general and a specific MeSH term from the same MeSH tree.

Methods
We used 763,227 citations that were indexed in 2015 and also had MTI recommendations (henceforth referred to as Corpus). MTI recommended 6,465,133 MeSH terms and the human indexers assigned 8,454,900 MeSH terms to the Corpus. We focused on citations for which MTI recommended both a more general MeSH term and a more specific MeSH term from the same MeSH tree – for example, Vaccines (D20.215.894) is more general than Anthrax Vaccines (D20.215.894.135.063). When MTI recommends both of these terms for a given citation, we call it Hierarchical Ambiguity. In the Corpus, there are 985,738 (15.25% of MTI total) Hierarchical Ambiguity pairings from MTI and 726,861 (8.60% of human total) from the human indexing, or almost half the rate of occurrence we see from MTI.

Results
The easy solution would have been to just not recommend the more general term per the rule of indexing the most specific term. The problem is that the exceptions noted earlier still constitute 8.60% of the human indexing. In our Corpus, we would lose 314,869 (31.94%) of the correct general term recommendations by always recommending only the most specific terms. Table 1 shows the distribution of indexer assignments where MTI assigned both terms.

Table 1. Human indexing as judgements for MTI recommended Hierarchical Ambiguity.

<table>

<td>43.24%</td>
<td>24.82%</td>
<td>18.92%</td>
<td>13.02%</td>
<td>15.25%</td>
</tr>
</tbody>
</table>

Ignoring MTI recommended pairs in which both the general and specific recommendations were wrong in the Corpus, we identified 6,399 Hierarchical Ambiguity pairs in the remainder of the Corpus where the general term was wrong on average 82.88% of the time accounting for 52.40% (223,361) of the Gen Wrong/Spec Right recommendations in Table 1. A simple rule to always remove the general term recommendation when one of these 6,399 Hierarchical Ambiguity pairs is identified in the MTI results, provided us with an improvement in Precision from 0.6292 to 0.6406 (+1.81%) while only dropping Recall from 0.6463 to 0.6419 (-0.68%) for our Test Collection.

Conclusion
Understanding where the problematic Hierarchical Ambiguities are in the MTI recommendations has provided us with a way of eliminating over 50% of the erroneous general term results with very little loss to Recall.

Apache Spark for the Analysis of High Frequency Neurointensive Care Unit Data: Preliminary Comparison of Scala vs. R.

Laura Moss, PhD, MSc, BSc1, Martin Shaw PhD, BSc2 Ian Piper, PhD, BSc2, Chris Hawthorne, MBChB1, John Kinsella, MD, MB, BS1, Aridha, Philips Healthcare
1Dept. of Anaesthesia, Pain & Critical Care, University of Glasgow, Glasgow, UK; 2Dept. of Clinical Physics & Bioengineering, Institute of Neurological Sciences, NHS Greater Glasgow & Clyde, Glasgow, UK

Introduction

Advances in patient monitoring equipment have led to an increasing amount of complex patient data being stored and collected in Neurointensive Care Units. Additionally, the future use of genomic and proteomic data at the patient’s bedside increases the requirements for technology and tools which can support the bedside analysis of this ‘big data’ to inform clinical practice. In the CHART-ADAPT project we are developing a framework which uses the Apache Spark processing engine to enable physiological models to be applied to high frequency waveform data typically collected in Neurointensive Care Units. Spark is well suited to low latency processing and it is envisaged that it will offer performance advantages required for the analysis of high frequency data in clinically meaningful timescales compared to existing critical care data analysis platforms1.

The CHART-ADAPT Framework

The CHART-ADAPT framework receives HL7 patient data, de-identifies the patient data, then transfers it to cloud computing services for configurable big data analytics, the results from the analyses are re-identified and presented back into the clinical environment. This framework is customized for use by Neurointensive Care Units and a pilot study is being conducted at the Institute of Neurological Sciences, Glasgow. In the pilot study physiological patient data is automatically extracted from Philips ICCA and iXTrend monitoring equipment; sampling rates range from 60Hz to 500Hz. Additionally, waveform data for 6 channels (e.g. intracranial pressure (ICP)) is converted from proprietary file formats into MFER and the entire flow of patient data is automatically transformed into HL7. The data is de-identified and transferred to a cloud based service provision including Spark, Hadoop and Greenplum. A number of Neurointensive Care physiological models will be implemented in Scala; results from continuously running the models will be integrated back into the Philips ICCA system and displayed at the relevant bedside.

Preliminary Comparison of Scala Vs. R.

To evaluate the performance gains of the Spark/Scala implementation on high frequency Neurointensive care data, a preliminary study has been conducted to compare the implementation of two models – the pressure reactivity index (PRx)2 and a hypotension area burden model. 7 different datasets were created from existing patient data, these consisted of: 100,000, 200,000, 300,000, 400,000, 500,000, 600,000 and 750,000 rows of ICP and blood pressure data. Firstly, an algorithm was written in R and Scala to down-sample data from the initial sampling rate of 0.01 seconds to 10 seconds. Secondly, both models were implemented in R and Scala and each experiment was repeated 35 times to assess variance in run time. Performance was then compared using the different sized datasets. For the datasets used, the run time of both the R and Scala algorithms increased approximately linearly with data volume. Scala performed in the range of 50 to 200 times faster than the R code across these experiments for both models. The R run times were seen to increase with both the data volume and the overall duration (for the PRx algorithm) while the Scala run times increased only with data volume (for both models).

Discussion

This preliminary study has indicated that the use of Spark/Scala offers performance enhancements for the Neurointensive care unit data. Future work includes evaluation of the other physiological models. Full evaluation of the CHART-ADAPT framework in-practice is planned.

1University of Utah, Salt Lake City, UT; 2Westminster College, Salt Lake City, UT

Introduction

Health care providers are increasingly concerned with quality in health care delivery, particularly patient satisfaction. Press-Ganey surveys are distributed electronically as a means of gauging patient satisfaction. However, rich, qualitative descriptions of their experiences are locked within the response free-text comments. Sentiment terms within these comments can convey the emotional valence of an experience with degrees of strength and types of polarity suggestive of a patient’s satisfaction or dissatisfaction. For example, in “service was terrific”, the term “terrific” conveys a strength: strongly and polarity: positive suggesting patient satisfaction. Quality improvement abstractors could benefit from visualizations of survey responses based on emotional valence to identify areas of patient satisfaction and dissatisfaction. In this study, we aimed to characterize the types of terms, strength, and polarities observed from Press-Ganey patient satisfaction survey responses.

Methods

In this Institutional Review Board-approved, pilot study, we sampled 60,697 free-text, Press-Ganey patient satisfaction survey responses from the University of Utah Healthcare System from the year 2014. For each response, we encoded observed sentiment terms and their strength/polarity from the Multi-Perspective Question Answering (MPQA) Subjectivity Lexicon1. We report the frequency of sentiment terms for each strength/polarity class and present visualizations of observed terms by frequency for strongly positive, neutral, and strongly negative responses2.

Results

We observed variable frequencies of unique sentiment terms: strongly positive (n=518 terms), weakly positive (n=435 terms), neutral (n=268 terms), weakly negative (n=397 terms), and strongly negative (n=616 terms).

Figure 1. Word clouds of terms associated with strongly positive (left), neutral (middle), and strongly negative responses (right). Larger word size represents more frequent terms; smaller word size represents less frequent terms.

Conclusion

The MPQA subjectivity lexicon can provide a “bird’s-eye” view of emotional valence of patient satisfaction and dissatisfaction. We are leveraging these annotations as features within a supervised machine learning approach that predicts the sentiment and reason for a patient’s satisfaction or dissatisfaction with his/her hospital care experience.

Characterizing the Fever Effect in Autism Spectrum Disorder

Efrat Mullera, BSc, Alal Era nb,c,d, PhD, Denis Agnielb, PhD,
Isaac S Kohaneb,c, MD, PhD, Eitan Bachmatb, PhD

a Department of Computer Science, Ben Gurion University, Beer Sheva, Israel;
b Department of Biomedical Informatics, Harvard Medical School, Boston, MA;
c Computational Health Informatics Program, Boston Children’s Hospital, Boston, MA;
d Department of Life Sciences, Ben Gurion University, Beer Sheva, Israel.

Background

Several anecdotal reports by parents and caregivers suggest that some children with autism spectrum disorder (ASD) demonstrate marked behavioral improvements during febrile episodes. However, the magnitude, scope, and nature of this so-called Fever Effect remain unknown.

Objectives

Improve our understanding of the Fever Effect in ASD by identifying clinical and behavioral characteristics of individuals with ASD reported to improve during febrile episodes, characterizing the domains of improvement, and identifying potential confounding factors.

Methods

We mined medical histories and behavioral data from 2,253 families with ASD from the Simons Simplex Collection. Continuous variables were clustered based on pairwise correlations and categorical variables based on pairwise associations. The relationship of each cluster with fever response was then tested using non-parametric statistics. Multivariate models were constructed based on forward feature selection, using logistic regression.

Results

16.7% [15.2%, 18.3%] of the children included in the analysis were reported to demonstrate behavioral improvements across multiple ASD domains when febrile. They tend to be on the low end of the spectrum, with lower IQ (p < 1x10^{-6}), worse social and communication skills (p < 1x10^{-6}), and increased repetitive and restricted behaviors (p = 1.1x10^{-5}) as compared to children with ASD that showed no behavioral improvements during febrile episodes (Figure 1). Significant associations were detected between fever response and gastrointestinal (GI) dysfunction (OR = 1.45 [1.21, 1.74]), milk, casein and gluten allergies (OR = 2.2 [1.68, 2.91], 3.1 [1.96, 4.96], 2.28 [1.43, 3.52], respectively), and maternal infection in pregnancy (OR = 1.7 [1.42, 2.03]). Maternal cognitive abilities were identified as a confounder, with mothers scoring higher on the Social Responsiveness Scale (SRS) being more likely to observe a fever response in their affected child (p = 3.98x10^{-3}).

Conclusion

An emerging subtype of fever-sensitive ASD may be characterized by GI abnormalities, allergies, and maternal infection in pregnancy. Fever response spans all ASD domains and is more likely to be reported in children on the lower end of the spectrum. Follow-up prospective studies are needed to minimize parental reporting biases.

Figure 1. Cumulative distribution function (CDF) differences in (A) Verbal IQ, (B) Communication skills, (C) Social interaction, and (D) Restricted and repetitive behavior between children with ASD reported to improve when febrile (orange) and those whose behavior reportedly remains unchanged (blue). (B), (C) and (D) are based on the Autism Diagnostic Interview Revised (ADI-R), where higher scores represent severe symptoms.
Validation of an Automated Process for the Comparison of Nutrition Care with Evidence-Based Nutrition Practice Guidelines (EBNPG)
William J Murphy, MS, Academy of Nutrition and Dietetics, Chicago, IL; Martin M Yadrick, MBI, MS, Computrition, Inc., West Hills, CA; Rosa K Hand, MS, Academy of Nutrition and Dietetics, Chicago, IL

Background: This project sought to evaluate a process designed for the Prevention of Diabetes Guidelines Impact Study (PDGIS) to assess the similarity of practiced nutrition care to EBNPG recommendations. PDGIS convened an expert panel to apply a framework that describes nutrition care as 6 connected steps and translate recommendations into expected care plans (ECPs) using the Nutrition Care Process and Terminology (NCPT) standardized language to define expected documentation for each step. PDGIS will compare ECPs with care documented via the Web-based Academy of Nutrition and Dietetics Health Informatics Infrastructure (ANDHII) with an automated process that includes matching based on the use of standardized terminology and natural language processing (NLP) of unstructured text. Our NLP algorithm uses the Princeton University WordNet lexical database to find synonyms of keywords stemmed with Porter's Algorithm and reports a match when at least half of the keywords from the ECP share a synonym with the related documentation. To evaluate this automated process, we compared its results with those of a manual audit.

Methodology: One investigator who was not involved in the development of the ECPs served as the expert reviewer and examined the ANDHII record of encounters from PDGIS for similarity with ECPs, recording a judgment as to whether each step of an ECP was completed. The intra-class correlation coefficient (ICC) was used to evaluate the similarity between the automated and manual processes, and we hypothesized that the two would have good agreement (ICC > .60). A sample size of 23 classifications of success for a step was necessary to differentiate good agreement from very poor agreement (ICC = .1) with 80% power. We sampled 24 initial visit encounters from PDGIS via a block-randomization procedure that sampled 1-2 encounters from each of the 14 participating dietitians. One ECP (n = 13) was randomly assigned for review with each encounter.

Results: For 124 step classifications, the overall ICC was 0.60 and was significantly different from poor agreement (p < 0.001). Figure 1 presents the rates of successful matching to the ECP for each process, the ICC between the two processes by step, and labels for which steps are matched through the use of standardized terms versus NLP keyword matching.

Conclusion: While the overall ICC was at the threshold of our goal of good agreement, large variations appeared between steps. The step of setting goals for treatment outcomes, which relies heavily on NLP for concepts not standardized in terminology, exhibited virtually no agreement despite similar success rates. Our automated process for matching based on standardized terminology is adequate for analysis of practiced care. However, our NLP algorithm for those steps not yet standardized by the NCPT was not sufficiently accurate for use in PDGIS, and we will need to either improve the algorithm, for example through the use of a medical lexicon such as the Unified Medical Language System’s SPECIALIST Lexicon, or manually review these steps.

Electronic Health Record Interventions Improve Patient Centered Medical Home Documentation for Primary Care Practices Seeking National Committee for Quality Assurance Recognition

Sara R. G. Myers, BA¹, Elizabeth R. Silvers, BA¹, Catherine L. Liang, MBA, MPH¹, Lynn A. Volk, MHS¹, Colleen E. Blanchette, BA¹, Amy L. Feeney, MBA¹

¹Partners HealthCare, Wellesley, MA, USA

Introduction: The Patient Centered Medical Home (PCMH) model, originating from a pediatric model of care, seeks to improve care coordination and self-management, particularly for patients with complex, high-risk health conditions. The process for primary care practices seeking National Committee for Quality Assurance (NCQA) PCMH recognition is rigorous, and satisfying chart review documentation requirements was challenging for our 2014 cohort of practices. Based on feedback from these practices, we implemented Electronic Health Record (EHR) interventions and developed new educational materials to support documentation efforts for our 2015 cohort. This study aims to determine whether chart review scores changed from our 2014 cohort to our 2015 cohort.

Methods: We conducted a comparative cohort study to assess changes in chart review scores for primary care practices undergoing PCMH transformation in 2014 and 2015. Because the applicable NCQA standards changed between these two years, we evaluated two factors for which the documentation standards did not change and for which less than 90% of practices passed: documentation of treatment goals and providing information about new medications to patients. In order for a practice to meet these two requirements, at least 75% of charts must have clearly documented treatment goals and at least 80% of charts must have included documentation indicating that information about new medications was given to the patient. We also compared scores of pediatric and adult practices within and between the 2014 and 2015 cohorts.

Results: Table 1. Proportion of adult and pediatric practices meeting PCMH documentation requirements in the 2014 and 2015 cohorts (n=number of practices).

<table>
<thead>
<tr>
<th>Documentation Requirement</th>
<th>Adult</th>
<th>Pediatric</th>

<td>60%</td>
</tr>
<tr>
<td>Information about new medications given to patient</td>
<td>46%</td>
<td>71%</td>
<td>40%</td>
</tr>
</tbody>
</table>

Scores of total practices passing these two documentation requirements improved between the 2014 and 2015 cohorts. Pediatric practices showed greater improvement than adult practices on both of the documentation factors evaluated.

Conclusion: Improved scores for two PCMH documentation requirements may be attributed to EHR interventions and support. Primary care practices in the Partners network use multiple EHR systems, so interventions were specific to EHR functionalities. These interventions included templates in free-text notes and “Patient Educated” checkboxes that primary care providers could check off to indicate that they provided information about new medications to patients. These interventions were easily incorporated into existing workflow, making documentation requirements less taxing for practices. Pediatric practices improved more than adult practices, perhaps due to an emphasis in pediatrics on harnessing support from family and school resources and developing self-management plans that focus on continuity of care. Practices seeking PCMH NCQA recognition could improve their chances of recognition by implementing EHR interventions that support PCMH documentation efforts and are easily incorporated into existing workflow.
Investigation of clinical process visualization using EMR data in clinics

Kodai Nakajima¹, Satoshi Tamura, PhD¹, Prof. Satoru Hayamizu, PhD¹, Takashi Ichinomiya, PhD², Prof. Yasutomi Kinosada, PhD²

¹Graduate School of Engineering, Gifu University, Japan; ²Biomedical Informatics, Gifu University Graduate School of Medicine, Japan

Introduction

Recently, Electronic Medical Record (EMR) systems have been widely introduced not only in hospitals but also clinics. Our goal is to extract a standard medical care pathway from numerous EMRs and compare it with a medical process obtained from EMRs in a clinic, in order to discover any managerial and medical issues in the clinic and finally reduce healthcare costs. This paper investigates a method to extract a clinical process from examination descriptions (unstructured data) in large-size EMRs applying natural language processing, and intuitively visualize the process. We also analyze and discuss the results in engineering and medical standpoints to evaluate usefulness of our proposed method. We believe our proposed process mining technique can be also applied for guiding the care process from a number of EMR data.

EMR data

We collected EMR data recorded in two clinics. There are roughly 7,100 encounters and 2,280 patients in our data. Each record consists of patient information (e.g. ID, date, age and gender), anamnesis, and free description about examination including SOAP notes. The SOAP note is a common format having subjective, objective, assessment, and plan.

Our proposed process mining method

(1) Without using the morphological analysis, all medical terms appeared in anamnesis and examination fields of each record are extracted using drug name and disease name lists. (2) A term vector indicating existence of the terms in the lists is generated. (3) Given a disease name, simple screening is applied to extract related term vectors. (4) Agglomerative hierarchical clustering is conducted to group the vectors into some classes. (5) Transitions between clusters are counted using sequential information (ID and date in records) (6) Finally, visualization is performed to show classes and transitions as a graph.

Experiment and Result

Figure 1 shows clinical processes created by our proposed method from the medical records and the history the patient has received at the clinic. We applied our scheme to two diseases: influenza (incl. common cold) and diabetes. We discussed the results subjectively based on examination fields and several criteria.

Conclusion

In this paper we proposed a method to extract a clinical process from unstructured free-form examination descriptions in EMRs. Experimental results clarified usefulness of our method. Our future work includes developing a standard medical pathway and exploring a data mining scheme to help clinic managements.

An Assessment Tool for Evaluating Shelters during Disasters

Masaharu Nakayama, M.D. Ph.D.¹,², Tadashi Ishii, M.D. Ph.D.²
¹International Research Institute of Disaster Science, Tohoku University, Miyagi, JAPAN; ²Tohoku University Hospital, Sendai, Miyagi, JAPAN

Abstract

After the Great East Japan Earthquake, the assessment of shelters during disasters became seen as helpful for grasping the health status of evacuees and preventing pandemics. To maintain the quality of assessment and to decrease the tedious work in inputting and analyzing enormous amounts of data, we developed a mobile assessment system with a standardized questionnaire to assess shelters during disasters.

Introduction

In March of 2011, the Great East Japan Earthquake destroyed a vast area of the northeastern coast of Japan, and as of March 2015, has resulted in 15,890 dead and 2,589 missing. During the disaster, more than 400,000 people were evacuated to temporary shelters. Continuous surveys of medical and sanitary conditions as well as environmental conditions, including power, gas, and water supplies, were successful in avoiding pandemics in well-managed shelters in the Ishinomaki area, one of the most damaged areas [1]. However, these surveys, which included calculation of the results and analysis, caused high workloads among staff.

Methods and Results

We developed a mobile assessment system using Swift 2; the application was named the Rapid Assessment System of Evacuation Center Conditions (RASSECC). The database was built using MongoDB 2.4.9, and the administrative screen interface was developed using Ruby 2.0.0p451. The application is available on iPads and iPhones with iOS 9 or over. We can store the input data in each device even offline. After the device is reconnected to the Internet, the data are sent to a server. The administrative screen is color-coded to show the severity of conditions in each shelter, and is available on web browsers such as Safari, Internet Explorer, Google Chrome, and FireFox.

Figure 1. Administrative screen

Conclusion

We developed a mobile assessment system; the input application is available on iPads and iPhones. This application may alleviate work burdens for staff teams when evaluating shelters, and the questionnaire on the application is currently being standardized among specialists of disaster medicine. Additionally, the administrative screen is available on any common browser; the table is useful for staff teams when evaluating the status of each shelter, resulting in the prompt development of strategies.

All Alerts are not Created Equal: A Study of Differences in User Perceptions of Drug-Drug and Drug-Allergy Interaction Alerts

Pamela Neri, MS¹, Elisabeth Burdick MS², David W. Bates MD¹, ², ⁴, Shobha Phansalkar RPh, PhD², ⁴, ⁵
¹Partners HealthCare, Wellesley, MA; ²Division of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA; ⁴Harvard Medical School, Boston, MA; ⁵Clinical Effectiveness, Wolters Kluwer Health, Minneapolis, MN.

Introduction Computerized Physician Order Entry systems (CPOE) with Clinical Decision Support (CDS) have the potential to reduce medication errors and improve quality of care. Studies have identified design and implementation issues with medication-related CDS alerts which can lead to provider dissatisfaction and high override rates. To understand the factors that might influence provider dissatisfaction with different types of alerts, we conducted a survey of provider perceptions.

Methods In this international, multi-site study we conducted a survey of CPOE users to assess perceptions related to receiving drug-drug and drug-allergy interaction alerts at the time of prescribing medications. These sites had systems that were both vendor-based and in-house created knowledge base systems. We distributed a previously developed and validated survey by Zheng et al.¹ to 1545 internal medicine physicians at 8 sites in the United States, United Kingdom and the Netherlands. The survey assessed provider’s attitudes about drug interaction alerts on 7 constructs: Performance Expectancy (e.g. useful in helping care for patients, clinically relevant), Effort Expectancy (e.g. reading and responding to alerts takes too much time), Social Influence (e.g. reading and responding because colleagues read and respond), Facilitating Conditions (e.g. received adequate training on how to read and respond to alerts), Perceived Fatigue (e.g. receive too many alerts), Perceived Ease of Use (e.g. find alerts easy to understand), and Perceived Use Behavior (e.g. thoroughly read alerts, provide reasons for override). For each construct of the survey, we pooled the responses to get a mean for DDI and DAI alerts. We set the completion threshold at 50% for a survey and the response rate threshold at 70% to for a construct to be included in the analysis.

Results Of the 1545 surveys distributed, 365 were opened and 48 of these were excluded due to low completion. Our analysis includes 317 surveys that were more than 50% complete. Response rates for all except one construct ranged from 88% to 99%. One construct (Social Influence) did not meet the minimum threshold for inclusion in our analysis. For five of the constructs, the difference in means between DDI and DAI alert perceptions was significant: Performance Expectancy (p<0.0001), Perceived Ease of Use (p=0.0007), Effort Expectancy (p=0.002), Perceived Fatigue (p<0.0001), and Perceived Use Behavior (p<0.0001). The differences in means for the constructs of Social Influence (p=0.42) and Facilitating Conditions (p=0.04) did not attain significance.

Discussion Survey responders answered more favorably to drug-allergy interaction alerts in comparison to drug-drug interaction alerts on all survey constructs, Previous studies on alert fatigue have described override rates overarching all types of medication-related decision support alerts. However, our study found that providers’ perceptions towards different types of alerts vary considerably. By asking providers specifically about two types of alerts, from the same system, we were able to understand these differences in their perceptions.

Conclusion Future studies should evaluate further why differences exist between drug-drug and drug-allergy interaction alerts and whether they are rooted in content, design, or clinical significance considerations specific to the type of alert. This understanding will further inform how we develop systems that change providers’ perceptions resulting in increased acceptance of alerts in EHRs.

Medication Self-Reconciliation Through Automated Telephony

Mark D. Newcomb Jr1,2, Kenneth D. Mandl, MD MPH1,2, Marc D. Natter, MD1,3
1Tufts University School of Medicine, Boston, MA; 2Computational Health Informatics Program, Boston Children’s Hospital, Boston, MA; 3Harvard Medical School, Boston, MA

Introduction. It is well recognized that there are deficiencies in the quality of certain classes of research data derived from electronic health records1. Medication lists, in particular, are often incomplete, inaccurate, or outdated1,2, at least in part because patients often have medications prescribed from multiple healthcare providers and systems. We recognize that patients are often willing to directly share and augment their data for researcher usage using electronic means2, including via interactive voice response (IVR)3 and have developed an IVR application that enables subjects to accomplish patient-reported medication reconciliation using data derived from multiple clinical and research data sources. We therefore enable patients to directly indicate whether they are taking medications not yet documented, whether historically recorded medications are currently being taken, and whether their dosing schedules match the prescribed regimens.

Methods. The architecture for the application comprises 3 software components: (1) a Go application coordinating data transfer capabilities; (2) an IVR application running on an IVR engine (Voxeo CXP and Prophecy, Aspect Software Inc., Chelmsford, MA) that generates and parses VoiceXML files and (3) a Python service handling medication retrieval and mapping between NDC and RxNorm. All application components communicate via RESTful HTTP interfaces. Medication data from multiple sources, encoded in i2b2 using NDC or RxNorm, is de-duplicated by the application and reconciled by the patient utilizing voice or keypad commands over the telephone network. High-quality speech synthesis and automatic speech recognition (Nuance Communications Inc, Burlington, MA) are used for all aspects of user interaction. A mapping of National Drug Codes to RxNorm RxCUIs5 is used to unambiguously identify the medications; RxTerms6 is then used to extract relevant attributes of each medication such as strength, form, and ingredients so that these properties can be presented by the text-to-speech (TTS) engine in a logical fashion. Subjects are given an opportunity to add medications that were not present from data warehouse sources. Finally, the reconciled medication list is uploaded to i2b2 via submission of a FHIR medication list resource to a medication reconciliation cell for i2b2 that we have developed (i2me2. KM, MN, and collaborators)7.

Results. Software applications developed were capable of automatically eliciting information via IVR about current usage of medications, using data aggregated in an i2b2 data warehouse. Pilot testing suggests that our system will be convenient to use, with caller time spent for reconciliation of five medications generally lasting under five minutes. At the end of the call, data gathered during the call is uploaded directly into i2b2 with no intervention on the part of medical or research staff.

Discussion. Our system allows individual research subjects to perform self-reconciliation of medication data via IVR – a convenient mechanism that is accessible from any cellular or landline telephone, and thus available to extremely large and diverse populations, complementing other systems we have developed for web-based self-reconciliation of medications. Such approaches, which can occur without manual intervention by researchers themselves, enable ready scaling to thousands of patients with minimal incremental effort. Further, interoperability using the FHIR messaging protocol will support widespread adoption using a variety of data sources, including the i2b2 platform. Limitations of the current approach include need for tuning of TTS pronunciation of medication names and optimized recognition of drug names entered through the user’s speech. For the former, we have identified a database containing phonemes for every drug in the U.S. market, which can be used to tune our TTS engine’s pronunciations. For the latter, suggesting letter-by-letter spellings or presenting numbered pick lists under certain conditions may help ensure that medication data is entered accurately. A further limitation may lie in the recognition of various accents, but our ability to flexibly use commercial speech-to-text engines allows us to take advantage of the latest developments in the field. A next step in validation of our approach for research use is anticipated to be an exploratory study of medication self-reconciliation using IVR as compared with a web-based medication reconciliation application. This study will also include an evaluation of the absolute accuracy of our speech-to-text-based approach to medication entry.

Conclusion. The state of the art in speech recognition and synthesis software is advancing rapidly, and such systems are suitable for a diverse range of medical applications. Our system has shown that the current state-of-the-art in automated telephony is promising as a mechanism to accomplish patient self-reconciliation of medication data using standardized messaging protocols.

Assessing Patterns of Medication Use across VA and Non-VA Healthcare Systems

Khoa A. Nguyen, PharmD1,2; Alan J. Zillich, PharmD2; Susan Perkins, PhD3; Susan Ofner, MS3; David A. Haggstrom, MD, MAS1,4,5

1Center for Health Information and Communication, Department of Veterans Affairs (VA), Veterans Health Administration, Health Services Research and Development Service (CIN 13-416), Richard L. Roudebush VA Medical Center, Indianapolis, IN; 2College of Pharmacy, Purdue University, West Lafayette, IN; 3Department of Biostatistics, Indiana University School of Medicine, Indianapolis, IN; 4Department of Medicine, Indiana University School of Medicine, Indianapolis, IN; 5Regenstrief Institute, Indianapolis, IN

Introduction: Dual healthcare system use is a common pattern of care for many Veterans. While improving access and choice of healthcare for Veterans, it creates fragmented flows of information that can affect patient care. In an effort to reduce fragmentation, the Department of Veteran Affairs is implementing a nationwide health information exchange (HIE) program called the Virtual Lifetime Electronic Record (VLER), which allows providers to access and share information across healthcare systems. However, what data is available regarding the use of medications in regional HIEs is largely unknown. Therefore, the objective of this study is to describe the prevalence of medication dispensing across VA and non-VA health care systems prior to enrollment in VLER.

Methods: This retrospective cohort study included all Veterans who had two outpatient visits or one inpatient visit during a 1-year period prior to VLER enrollment to a local VA and HIE program. We examined outpatient dispensing during a 2-year time window prior to the VLER enrollment. Data were extracted from the VA Pharmacy Benefits Management system and medication records in a regional HIE. Source of medication data was assessed at the subject level, and categorized as VA, non-VA, or both. We then compared the mean number of prescriptions, as well as overall and pairwise differences in medication dispensing.

Results: Out of 52,444 Veterans, 17.4% of subjects (n=9,123) had medication data available in a regional HIE. On average, 39.8 prescriptions per year were prescribed for Veterans who used both sources compared to 29.3 prescriptions per year from VA only and 24.6 prescriptions per year from non-VA only sources. The annualized prescription rate of Veterans in the dual use group was 36% higher than those who had only VA data available and 61% higher than those who had only non-VA data available (Table 1).

The most common medications prescribed for non-VA source are antibiotics (17.5%), antineoplastics (15.4%), and anticoagulants (11.8%) Table 1: Annualized prescriptions by subject level source*

<table>
<thead>

<td>22 (1, 302)</td>
<td>32 (1, 349)</td>
</tr>
</tbody>
</table>

* Number of prescriptions was annualized by dividing the number of prescriptions in the two year baseline period by 2

Conclusions: Prior to enrollment in VLER, 17.4% of subjects had medication data available outside the VA in a regional HIE, including prescriptions for antibiotics, antineoplastics, and anticoagulants. This large amount of non-VA medication use is not routinely captured within VA electronic health records. Subjects receiving medication from both sources appeared to have more complex medical needs, as reflected by their higher overall mean number of medications. These data support the need for HIE programs to improve coordination of information, with the potential to reduce adverse medication interactions and improve patient safety.
Supporting and engaging Women Veterans through social media:
Informational vs. emotional support for health issues

Lien B. Nguyen, MPH¹, Priya Nambisan, PhD²
¹College of Health Sciences, University of Wisconsin-Milwaukee, Milwaukee, WI;
²Department of Health Informatics and Administration, University of Wisconsin-
Milwaukee, Milwaukee, WI

Introduction: Women veterans are the fastest growing group in the U.S and are projected to increase in the next
decade. There was an estimated 1.5 million women veterans in 2009, which represented 8% of the total veteran
population; this number has increased to 2.2 million in 2013.² Despite this growth, these veterans belong to an
underserved population facing unique and different challenges in a health care system originally designed to serve
mostly men. Numerous health organizations are using social media to actively engage with patients and health
consumers. A national survey reported that 87% of U.S. adults use the Internet and 72% say they have looked online
for health information.¹ People also access health information through social media sites, such as Facebook and
Twitter. However, there is limited research focused on women veterans’ health and use of social media, which is a
popular online web-based technology platform used by millions of people every day.

Objective: The study objective is to investigate what types of information is being communicated to women
veterans by supporting organizations on the social media platform, specifically on Twitter.

Methods: Seven of Twitter’s largest groups were selected for our study analysis. The groups are classified as major
supporting organizations of women veterans, and they represent a total of 51,883 followers and 31,263 posts during
2009 to 2016. Data was collected through an aggregation of tweet messages via the Twitter API (Application
Program Interface). We examined thousands of messages posted by the seven groups and then categorized them into
common themes of the information disseminated over a five-year period. Some of the disseminated information
addresses unique health issues and challenges encountered by women veteran patients today.

Results: This is a current, on-going research study. Preliminary findings show organizational outreach efforts aimed
at women veterans through use of social media to be mostly informational support (rather than emotional support).
Detailed findings will be presented at the conference.

Conclusion / Implications: The study findings will reveal how supporting organizations are using social media as a
tool for communicating key information to women veterans about health. It will provide researchers and health
professionals with a better understanding of what types of actual information are being frequently communicated to
the online community. From this, it can help guide organizational planning to focus on creating online tools for
information-seeking users among women veterans. The findings will hold important implications for future use of
social media by organizations wanting to engage with health consumers, especially underserved populations in
health care.

After participating in this session, the learner should be better able to:

1. Identify the common themes of the online information being disseminated by organizations supporting
   women veterans.

Incidence of Seven ED Visit Diagnoses are a Function of Birth Month

Scott Mankowitz, MD1, Jeffrey A. Nielson, MD, MS2
1Emergency Medicine Associates, Teaneck, NJ; 2Summa Health System, Northeast Ohio Medical University, Rootstown, OH

Introduction
Various studies have shown correlation between birth month and disease incidence. Boland et al related birth month with disease incidence1. Mining existing datasets of primary ED diagnosis and birth date might provide additional clues as to the impact of birth month on the emergency care system. This approach focuses on disease burden as a function of annual cycles. Our principle aim was to explore the relationship between birth month and emergency department visit incidence by ICD9 code.

Methods
We extracted 836,064 consecutive billing records representing 28 emergency departments in the Northeastern United States between 9/1/2014 and 8/31/2015 consisting of date of birth, date of service and primary diagnosis ICD-9-CM billing code. We excluded all visits with diagnoses that were encountered fewer than 144 times. For each diagnosis code, we compared the observed incidence with expected rates based on distribution of birthdates in the sample. The Holm approach for multiple comparisons (with p < 0.05) allowed identification of significant patterns2.

Results
After removing 62,641 records containing rare diagnoses, the sample included 773,393 ED visits representing 614 unique diagnosis codes. Chi-squared analysis using Holm p values resulted in 7 diagnoses of significance. In order, these were: Sickle cell disease NOS, Persistent vomiting, Hb-SS disease with crisis, Gastroparesis, Fetal/neonatal jaundice NOS, Chronic pancreatitis, and Acute bronchiolitis due to respiratory syncytial virus (RSV). Each of these diagnoses was statistically significant (p < 0.00000001).

Discussion
Seven ICD9 codes showed association with birth month. RSV has been shown to have a seasonal incidence3, has not been previously linked to birth month. Neonatal jaundice occurs seasonally in spring and summer. Since it is only encountered in newborns, it is unsurprising that it would be associated with birth month. The two sickle cell anemia codes likely represent the same disease. However, the annual curve of Sickle Disease NOS is sporadic (possibly representing outliers), while the curve for Hb-SS does show a clear annual distribution with a decrease in July through November. Additional studies need to be designed to understand this relationship. Also in our sample, chronic pancreatitis patients were more likely to have been born later in the year (October through December) which has not been previously demonstrated. Stratification of pancreatitis sub-type, would be helpful in a follow-up study since there may be an etiology that is more clearly seasonal.

Conclusion
Normalizing for annual birth variations, and accounting for multiple comparisons, we found that the incidence of seven ED diagnoses are a function of birth month: Sickle cell disease NOS, Persistent vomiting, Hb-SS disease with crisis, Gastroparesis, Fetal/neonatal jaundice NOS, Chronic pancreatitis, Acute bronchiolitis due to respiratory syncytial virus (RSV). Some of these have not been known to have birth date variation and should be further explored.

One Year Usability Results for an Electronic Respiratory Therapy Tool for the Intensive Care Unit

Matthew E. Nolan, MD, Mikhail Dziadzko, MD, PhD, Todd J. Meyer, RRT, James E. Baker, RRT, John Dyke, Ing Tong, MS, Brian W. Pickering, MB, BCh, MSc, Vitaly Herasevich, MD, PhD
Mayo Clinic, Rochester, Minnesota

Introduction

Intensive Care Unit (ICU) Respiratory Therapists (RTs) have unique information needs to best care for patients with respiratory illness, including those needing mechanical ventilation. Current systems at our institution are poorly designed for this task, with relevant information dispersed among multiple systems. AWARE (Ambient Warning and Response Evaluation) is an electronic health record dashboard that synthesizes the data needed by ICU clinicians and reduces information overload\(^1\). In order to address the unique data needs of RTs in the ICU, we developed an electronic Respiratory Therapy tool within AWARE and studied its usability.

Methods

The AWARE RT tool aggregates multiple data sources to generate a standardized report of relevant information used by RTs, including bed location, demographics, code status, ventilator/oxygenation settings, respiratory medications, airway information, invasive lines, and the respiratory problem list/plan of care (Figure 1). It can be viewed, printed or exported in different file formats. One year following open clinical deployment we conducted a web-based usability survey of all medical/surgical ICU RTs via email solicitation. We collected respondent demographic information and used a well-validated System Usability Scale (SUS) to assess overall usability\(^2\).

Figure 1. The AWARE Respiratory Therapy Report.

Results

Out of 155 invitations, 66 surveys (43%) were collected. 33% of responders were affiliated with a surgical ICU. 64% had more than 10 years of professional experience. While 100% of respondents used the tool in daily practice and 92% reported neutral/good ease-of-acquisition, median SUS score was modest at 62.5 (IQR 51-77.5). No statistically significant difference in usability was found across the length of professional experience or affiliation.

Conclusion

Although all Respiratory Therapists used the electronic dashboard tool in daily practice, overall usability was mediocre, indicating the need for revision. Observed and learned results will be used to improve the next version of the AWARE Respiratory Therapy Electronic Tool.

Clinical Decision Support Substantially Improved Appropriate Screening for Vitamin D Deficiency

Ryan W Novince, MD, MS1, David Bar-Shain, MD2,3, David C Kaelber, MD, PhD, MPH1,2,3
Departments of Internal Medicine1, Pediatrics2, and the Center for Clinical Informatics Research and Education3, The MetroHealth System, Case Western Reserve University, Cleveland OH

Introduction: One of the opportunities for electronic health record (EHR) clinical decision support (CDS) is to promote appropriate ordering of tests. Our EHR offers several vitamin D metabolite tests that can be ordered depending on clinical circumstance.1 These include 25-hydroxyvitamin D (calcidiol) & 1,25-dihydroxyvitamin D (calcitriol). We studied whether a point-of-ordering clinical decision support for vitamin D laboratory tests would optimize the delivery of clinical care and limit wasteful healthcare expenditures.

Methods: A point-of-ordering EHR clinical decision support advisory for vitamin D testing was developed utilizing standard clinical decision support functionality in our Epic (Verona WI) EHR. The advisory triggered when the “Vitamin D, 1,25-Dihydroxy” was selected as an independent or order-set order, in an ambulatory or inpatient setting. The modal advisory window notified the end user, “Generally, this test does NOT add value to routine screening of vitamin D deficiency. The preferred test is Vitamin D, 25-Hydroxy.” By default, accepting the advisory performed two actions for the user: (1) removed the 1,25-dihydroxyvitamin D order, and (2) added an order for 25-hydroxyvitamin D. If the user opted to continue placing an order for 1,25-dihydroxyvitamin D, the advisory required a free text comment detailing the indications. The advisory included reference hyperlinks to UpToDate resources for Vitamin D deficiency in adults, adolescents and children.2,3

Results: The vitamin D advisory was implemented system-wide on 7/2/2015. Within 90 days, it had triggered a total of 184 times. In 162 firings, the user accepted the default actions substituting a 25-hydroxyvitamin D order for a 1,25-dihydroxyvitamin D order. In 19 instances, the user proceeded with the 1,25-dihydroxyvitamin D order. In 3 instances, the user canceled placing a vitamin D test order. Overall, the electronic advisory contributed to discontinuation of 90% of 1,25-dihydroxyvitamin D tests. Documented reasons for placing the initial 1,25-dihydroxyvitamin D orders included chronic kidney disease, acute renal failure, workup for hypercalcemia, workup for renal stones, and “per consulting endocrine service.”

Discussion: The Vitamin D advisory led to reduced cost and improved efficiency. Given a $39/cost difference in the tests, the advisory saved the health system over $6,300 in unnecessary healthcare expenditures during the study period. In addition, internal data from the Clinical Core Lab show that, prior to implementation, only 16% of 1,25-dihydroxyvitamin D test orders were clinically indicated. By reducing the frequency of ordering, the advisory decreased the time laboratory personnel spent contacting providers to determine if the test was appropriate. Notably, our EHR advisory for vitamin D laboratory test orders corroborated outcomes recently reported by Krasowski and co-authors within the University of Iowa Health Care System4. Our investigation was novel in that the EHR advisory for vitamin D test orders included point of care interventions for end users.

Conclusion: This research investigation defining the impact of a novel EHR advisory for vitamin D laboratory test orders highlights the opportunity for the development and implementation of other clinically relevant point-of-orders CDS to support appropriate utilization of laboratory tests across healthcare systems.

Exploring the Patient Perspective on Access, Interpretation, and Use of Test Results from Patient Portals

Daniel T. Nystrom, MS AEEP1,2, Traber Davis Giardina, PhD1,2, Jessica Baldwin, BA1,2, Dean F. Sittig, PhD3, Hardeep Singh, MD, MPH1,2

1Houston VA HSR&D Center for Innovations in Quality, Effectiveness and Safety; 2Baylor College of Medicine, Houston, TX; 3School of Biomedical Informatics, University of Texas Health Science Center, Houston, Texas

Introduction

Patient portals provide patients with online access to health information including test results, but it is unclear how patients retrieve and use test result information from patient portals. The current study examines patients’ use of online portals to access and interpret test results and identifies limitations of current patient portal designs that constrain patients’ ability to retrieve and understand their test results.

Method

Ten semi-structured interviews and three observations were conducted with patients who use a patient portal to access test results. Data from interviews and observations were transcribed and used to construct a process map that depicts the patient portal users’ perspective of the test result process. To identify steps in the test result process, comments from interviews that identify different ways patients’ access and use test result information were grouped according to the goal they hoped to accomplish with each piece of information. For example, the task step entitled “Test interpretation” was derived from different methods and sources of information patients used to help comprehend whether their test result was “good” or “bad” and to determine how this result would impact their future health.

After creating the patient-based test result process map, interviews and observations were reanalyzed to determine shortcomings of current patient portal designs that limit patients’ ability to access or understand their test results. Once relevant shortcomings were identified, they were incorporated into the test result process map to identify at which step each shortcoming occurred.

Results

The resulting process map created from interviews and observations with patient portal users portrays: the necessary task steps that need to be fulfilled for patients’ to access and interpret their test results; the methods and sources of information that were analyzed to create each task step; the general location in which each task in the test result process takes place (either in the clinic or at the patient’s home); and at which task steps shortcomings of the design of patient portals limited patients’ ability to access or interpret their test result. In total, six task steps were created and seven limitations were identified from thirty-nine interview comments and observed behaviors. Some particularly interesting shortcomings of patient portals included: 1) the lack of notification to inform the patient a test result is complete; 2) difficulty in determining the relationship between the value reported on the test result and their medical condition; and 3) the lack of ability to trend results across time.

Conclusion

Studying the patients’ perspective to depict the test result process provides a unique look into the way patients use portals to access, interpret, and inform actions regarding their health. Identifying patients’ important task goals for interpreting test results and acknowledging different sources of information used to fulfill those goals will provide direction to developing a more patient friendly design for test result interfaces. For example, one design feature uncovered by this analysis that should be incorporated into future patient portal designs is an explicit representation or description that informs patients of the relationship between the value on their test result and their medical condition (e.g., if the patient receives a low-density lipoprotein (LDL) score of 162 mg/dL, they should be informed of the optimal level for an LDL result (<100) and explained that as the LDL score increases, this is associated with a higher rate of accumulating plaque within the heart’s arteries; resulting in an increased chance of developing cardiovascular disease.) Current and future work will continue to use this diagram to develop a test result interface that enhances patients’ ability to access, comprehend, and follow-up on test results obtained from patient portals.
Purpose: Systemic lupus erythematosus leads to renal disease (lupus nephritis (LN)) in half of patients, many of whom progress to renal failure. The American College of Rheumatology guidelines for the treatment of LN recommend monitoring of all SLE patients for incident LN. If LN occurs, a renal biopsy is recommended to characterize disease. At the time of LN diagnosis, therapy should be started with concurrent laboratory monitoring of therapeutic response. If improvement is not seen in the prescribed timeframe, the provider should switch or add additional therapies. Guideline adherence must be timely, as care delays can lead to renal failure. Guidelines steps are often missed due to patient, provider, and system factors. Novel predictive analytics tools could identify patients at risk for treatment failure so that personalized interventions can be instituted before irreversible renal damage occurs. The goal of this project was to design a LN clinical outcome prediction tool that identifies incident LN cases and reports a treatment failure risk score in the medical record. This implementation would allow limited care coordinator resources to provide sustainable, consistent, and efficient adherence to guidelines in at risk patients.

Informatics Solution: As advocated by the Agency for Healthcare Research and Quality, our intervention is based on a conceptual framework. The conceptual model includes LN antecedents such as: an individual’s personal characteristics (including race/ethnicity, age, gender, body mass index, and smoking; patient characteristics e.g. co-morbid conditions such as diabetes, hypertension, and depression) and LN characteristics (such as duration of disease and severity of disease by measuring baseline estimated glomerular filtration rate (eGFR), urine protein/creatinine (UPrCr), C3, C4, anti-double stranded DNA (anti-dsDNA) antibodies, blood pressure, and classification of renal lesions by biopsy). The outcome risk score predicts treatment response probability using ACR Guideline outcomes (eGFR, UPrCr). Our group developed a random forest model based on a patient’s baseline LN characteristic labs to predict complete response to therapy at one year. This model’s receiver operating characteristics area under the curve for outcome was 0.74. During Phase 1 of the project, this lab-based model will calculate the risk score for LN patients. During Phase 2, model refinement using the personal, patient, and disease derived antecedents and longitudinal LN characteristics described above will be captured and utilized using over 20 years of data from the Enterprise Data Warehouse (EDW). This includes data such as pathology reports (annotated by NLP), billing diagnosis codes, and laboratory values. NLP annotation of text progress notes will be used to populate vital sign data from a legacy medical record. Random forest modeling will be used to refine the model, and the risk score from the refined model will be reported as on Phase 1. The data flow scheme for both phases will occur as in Figure 1. InfoSphere® BigInsights from IBM® is utilized for storing and analyzing large volumes of both structured data (from the EDW, which stores discrete laboratory and diagnosis code data), and unstructured data (annotated by Natural Language Processing (NLP), first using the Linguamatics®’ algorithms, followed by BigInsights processing). BigInsights will interface with SPSS for random forest model calculation of a risk score to populate an Epic smart data element. A registry of LN patients (defined by ACR guidelines) with a complete response risk score as a reporting metric will be created and used to populate a care coordinator dashboard with high, medium, and low risk patients (based on the risk score) to prioritize patient and provider contact to optimize care.

Conclusion: Novel predictive modeling risk scores for LN outcome can be presented in the medical record so that valuable care coordination efforts can be triaged to patients most at risk for treatment failure.
Carelign®: Early Reactions to a Mobile Care Management and Handoff Tool

Jillian Olsen, MD1, Jacqueline Soegaard, SB1, Geoffrey Bass, MD, MBA2, Ryan Leone3, Glenn Falai2, Rich Urbani2, William Hanson III, MD1,2, Subha Airan-Javia, MD1,2
1Perelman School of Medicine, Philadelphia, PA; 2University if Pennsylvania Health System, Philadelphia, PA; 3University of Pennsylvania, Philadelphia, PA

Introduction

Failures in transitions of care are a well-established risk to patient safety. Written handoffs can reduce that risk by ensuring the constant availability of accurate information. Our legacy handoff tool, used at our institution through 2015, consists of an array of text boxes that were used in diverse ways and updated irregularly, limiting readers’ ability to trust the information. Carelign® is an internally-developed responsive web application that imports real-time patient data into a handoff platform accessible and editable from all electronic devices, where all providers manage a common care plan. We hypothesized that this interactive handoff with up-to-date clinical data, a shared care plan, and mobile access would improve (1) inter-provider communication, (2) efficiency, and (3) satisfaction.

Methods and Results

In early 2016, we compared provider perceptions of our new handoff tool (Carelign®) and the previous handoff tool (PHT). The general medicine services at the Hospital of the University of Pennsylvania are naturally divided into 2 groups with identical structures and nearly equal numbers of patients; 1 group continued to use the PHT while the other transitioned to Carelign®. After 1 to 8 weeks, 51 physicians responded to 16 Likert-type scale statements (Figure 1). The percent responding positively (“Agree/Strongly Agree”) and negatively (“Disagree/“Strongly Disagree”) were compared via a Chi-squared test, with statistical significance in favor of Carelign® found for 3 statements: “The current written handoff system is safe for patients” (p = 0.022), “I am satisfied with the current handoff system” (p = 0.012), and “I would recommend the current handoff system to colleagues” (p = 0.011). Responses among early Carelign® users (weeks 1-4) and late Carelign® users (weeks 5-8) were compared to each other in the same fashion, with no statistically significant differences found between the 2 groups.

Figure 1. Percent of providers using each system who responded positively (“Agree”/“Strongly Agree”).

To assess Carelign’s® effect on written communication, patients’ “summary statements” were evaluated for whether they had been updated daily. A total of 730 statements were examined, revealing that 24.7% of Carelign® and 21.7% PHT statements were newly edited and thus presumably more current. Additionally, 152 patients cared for by these teams were asked in person to respond to Likert-type scale statements about provider communication and perspectives on healthcare IT. Notably, 72% replied positively to, “My care providers should use mobile devices to access and manage my health information,” thereby negating one anticipated concern about a mobile platform.

Conclusion

These early data suggest that changing the handoff tool to one with an intuitive user interface with real time patient information, mobile accessibility, minimal training requirements, and standardized data entry can improve perceptions of communication, efficiency, satisfaction, and patient safety. Objective measures of the reliability of written handoffs suggest a positive trend, and patients view clinicians’ use of mobile devices favorably. Studies of Carelign’s® impact are ongoing and will have broad implications for future improvements in transitions of care.

Application of Ontobedia on Cell Line Ontology Development

Edison Ong¹, Yongqun He, DVM, PhD¹
¹ University of Michigan Medical School, Ann Arbor, MI, USA

Introduction
Ontology has played an important role in representing biomedical knowledge and data. The community-based Cell Line Ontology (CLO) records and annotates over 35,000 cell lines¹. It is difficult to edit and annotate so many cell lines without community involvement. Ontobedia, a Wikipedia-like knowledgebase with ontology editing features, is applied to support the collaborative editing and distribution of CLO². This report presents the usage of Ontobedia and its enhancement on the community-based development of CLO.

Ontobedia Usage for Community-based CLO Development
Ontobedia is developed based on MediaWiki software platform with Ontokiwi extension support². MediaWiki is the software that runs Wikipedia server. Ontokiwi is an extension to MediaWiki that supports ontology query, storage and modification. The MySQL relational database and Virtuoso triple store database are used for both Wikipage and ontological data access, storage, and processing. The latest version of CLO is loaded to Ontobedia using Ontokiwi importing function. The process of community-based development of CLO through Ontobedia web server is illustrated (See example, Hela cell: http://ontobedia.hegroup.org/index.php/CLO:CLO_0003684).

1) WikiText Editor: Ontobedia provides convenient access for users to edit existing cell line information via Wikitext source editor. The extended Wikitext supports ontology editing with some specifically designed formats on top of the original syntax. For example, we use the text “label =”, “subclassof =” and “equivalent =” to represent the type of information and the text following “=” sign is automatically validated and re-formatted appropriately. A cell line can also contain text descriptions that are not linked to the ontology annotations and axiom definitions. Users can edit this information using the original MediaWiki Wikitext format similar to Wikipedia.

2) Ontology Form Editor: A cell line can also be annotated via the form-based editing system, which contains four major ontology editing sections: (i) General information includes the label IRI and type of the cell line. Note that IRI and type are restricted to the administrative user because improper modification may introduce ontological conflicts. (ii) The hierarchical definition of each cell line can be easily entered with the help of cell line searching function. (iii) Annotation information can be modified with pre-defined annotation properties such as “editor”, “comment” and “version”. (iv) Axiom definition of the individual cell line can be defined via W3C Manchester format.

3) Version Control and Discussion: Wiki page version control and discussion page are two important features in MediaWiki and such features are naturally inherited in Ontobedia. As a result, Ontobedia supports history checking, version control and social discussion. After we make text changes, the history of the changes is recorded and the information can be displayed in the future. A user can compare the text differences at two selected time points. Users can also raise their concerns or questions on the discussion page of the individual cell line.

A more comprehensive tutorial is located at http://ontobedia.hegroup.org/index.php/Ontobedia_tutorial.

Conclusion
Ontobedia has many unique features to support community ontology development compared to other existing tools such as WebProtégé (http://webprotege.stanford.edu/) and Semantic MediaWiki (SMW; https://www.semantic-mediawiki.org). WebProtégé does not support the Wikipedia style non-ontology text editing, and its usage requires professional ontology training. While SMW extends Wikipedia features, SMW treats normal pages as instances instead of ontology classes, and therefore it is not designed to support ontology development.

Informatics in the International Medical School Curriculum: A Pilot Survey

Amy Opalek, M.S.¹,², Sarah W. Leng, M.A.¹, Danette W. McKinley, Ph.D.¹
¹ Foundation for Advancement of International Medical Education and Research (FAIMER), Philadelphia, PA; ² PhD Student, Information Studies, Drexel University College of Computing and Informatics, Philadelphia, PA

Background
A recent meta-analysis has shown the importance of IT competencies and experience among clinical leaders. As clinical leaders often come from the medical profession, the extent to which informatics is addressed in the medical curriculum is a matter for concern. Unfortunately, another recent study has shown that, despite their interest in clinical informatics, medical students are often unaware of available training opportunities in the field. Further, data and research describing the clinical informatics workforce outside developed, English-speaking countries is limited. This pilot study aims to describe the extent to which international medical schools report having biomedical informatics (BI) in their curricula, and any variations that may occur by region or school type.

Methods
A questionnaire was distributed to 227 medical schools outside the United States and Canada that participate in an ongoing data exchange program with the Educational Commission for Foreign Medical Graduates and its foundation, FAIMER. The questionnaire included items about the schools' programs, including details about required and elective BI courses within the medical program and independent BI degree programs offered. Medical school demographic data from the World Directory of Medical Schools, including school type (public/private) and location, was merged with the questionnaire response data. A chi-square test of statistical significance (SPSS v. 22) was used to assess the relationship between school funding type and BI offerings.

Results
117 (51.5%) questionnaire responses were received from schools in all world regions, with more than five surveys each from the United Kingdom (8), Australia (7), and Japan (7), and Poland (7). Over half (n=66; 57.9%) of responding schools were private medical schools. Of the 113 who answered the question, only 21 (18.6%) reported offering a BI program at their school. Only one of the private schools offered such a program; the relationship between school type and offering a BI program was statistically significant (p<.01). Within the medical curriculum, 40 of 112 respondents (35.7%) reported having a BI course, with 28 (25.0%) schools indicating this was a required course rather than an elective. An additional 32 respondents indicated that the topic was covered across other courses in the curriculum. Among responding Australian schools, 6 (85.7%) offered BI within the medical curriculum, while only 2 (25%) in the United Kingdom did so.

Conclusion
There is wide variation in the extent to which BI education is available in medical schools around the world. Full BI programs appear more likely to be available at public rather than private medical schools. However, a minority of medical schools surveyed offer full programs in BI, and, worryingly, over a third indicated no BI exposure in their medical curriculum. There appears to be much room for improvement internationally in the education of future clinical leaders in informatics issues. Further studies should sample schools more broadly and longitudinally to attempt to ascertain whether there are regional differences in the coverage of BI issues and whether a greater number of schools choose to include BI in their curricula over time.

Pediatric Inpatient Medication Reconciliation using EMR in a Community Hospital

Haifa Jaedi, MD1, Chionye Ossai, MD1, Fernanda Kupferman, MD1, Diana Aschettino, MD1

1Brookdale University Hospital and Medical Center, Brooklyn, New York

Introduction

According to the Joint Commission, medication reconciliation is the process of comparing a patient’s medication orders to all the medications that the patient is currently taking. Reconciliation is done to avoid medication errors and EMRs provide a good medium for the reconciliation process. This study was a quality improvement project aimed at increasing the medication reconciliation rates among patients admitted to the pediatric inpatient/ICU departments of Brookdale University Hospital and Medical Center.

Methods

A retrospective chart review of all patients admitted to the pediatric department in June and July 2015 was done and baseline medication reconciliation rates were noted.

In the first phase of intervention, computer generated prompts and alerts were designed to remind residents about reconciling patient medications upon admission. Alerts were generated every time the patient’s chart was reviewed without a complete reconciliation process. Residents and faculty were formally trained on the importance and process of medication reconciliation using the electronic medical record.

The second phase of intervention required senior residents to manually perform spot checks for adherence to the medication reconciliation process by reviewing H&P notes and reconciling patient-reported medications with medications actually entered into the electronic medical record.

Results

![Fig 1: Medication Reconciliation Rates](image)

Discussion

We were able to accomplish our goal of 90% or more reconciliation rates with our interventions. The graph above reports the rates following our second intervention. The rates were much higher (up to 98% in January 2016) without the manual reconciliation by senior residents because some patient-reported medications in the H&P notes were not entered into the EMR. EMRs therefore might have some limitations in the medication reconciliation process. Further studies need to be carried out to assess the quality of the reconciliation process using EMR generated prompts and alerts.
Using Tablet Computer Journals to Capture Patients’ Chronic Disease Management in Daily-living Settings

Mustafa Ozkaynak, PhD¹, Katia Hannah, MPH¹, Gina Woodhouse, BS², Rupa Valdez, PhD³, Patrick Klem, PhD²

¹University of Colorado Anschutz Medical Campus, Aurora, CO; ²University of Colorado Hospital, Aurora, CO; ³University of Virginia, Charlottesville, VA

Abstract

We tested a tablet computer journal designed to capture both health activities and relevant challenges and facilitators in daily-living settings. Our feasibility study showed that tablet computer journals could capture health-related routines and incidents affecting anticoagulation management. Our approach informs consumer informatics interventions by revealing individual needs and social/organizational contexts. This approach also informs collaborative informatics interventions by revealing information related to chronic disease management in daily-living settings that should be discussed with clinicians.

Introduction

Individuals with chronic conditions are often required to perform various health-related activities in daily-living (home and public) settings. Examining these activities, including the challenges and facilitators patients face while performing these activities, can inform consumer informatics interventions. Traditional workflow methods such as observations have been used effectively to capture activities, including relevant challenges and facilitators, within well-structured clinical settings. However, these methods may be more difficult to apply in the unstructured daily-living settings of patients’ homes and communities. Informatics researchers and designers need new methodologies to understand chronic health management in this context. The purpose of this study is to test a tablet computer journal designed to capture health activities as well as relevant challenges and facilitators in daily-living settings.

Methods

From October 2015 to March 2016, thirteen patients receiving anticoagulation pharmacologic therapy were recruited from the anticoagulation clinic at a Western academic hospital. Patients were given a tablet computer with a customized 11-question survey to journal about daily-living health activities pertaining to anticoagulation therapy management for one month. The tablet computers included voice entry software. Eleven patients (undergoing anticoagulation therapy between 1.5 months and 25 years) participated in the study until completion. Patients were predominantly female, aged from 26 to 71 years. After journaling, participants were interviewed about tablet usability and journal-entry content. The Colorado Multiple Institutional Review Board approved this study.

Results

One hundred twenty-nine tablet entries were made during this five-month timeframe. Early analysis of the journals revealed patient frustration with bruising and bleeding, impact of social environment on treatment, difficulties with food restrictions, details of medication use (e.g., time of day, use of tools), and situations where they failed to take medications. Feedback pertaining to tablet computer usability in tracking daily-living health activities indicated that tablets were of appropriate size and application formatting was ideal. Patients also found voice entry helpful. Technical issues encountered were mainly a result of poor Internet connection.

Conclusion

Our preliminary study showed the feasibility of tablet computer journals in capturing health-related routines and incidents that affect anticoagulation management. Our approach also demonstrated feasibility in capturing some challenges patients faced at home. One strength of journaling is that data are collected in near-real-time, when the memory of the participant is fresh. Journal information also facilitated obtaining rich information during follow-up interviews. Important limitations of this method could be cost and the need for administrative support. The approach we tested can inform consumer informatics interventions by revealing individual needs and social and organizational contexts. This approach can also inform collaborative informatics interventions by revealing important information related to chronic disease management in daily-living settings that should be discussed with clinicians. This study was supported by AHRQ under award number R03HS024092 (PI: Ozkaynak).
Visualizing Clinical Event Sequences to Support EHR Data Retrieval

Brian M. Paciotti, Ph.D., M.S.¹, Fan Du, M.S.², Shang Wei, M.S.¹, Samuel Morley, M.S.¹
¹University of California, Davis Health System, Sacramento, CA; ²Human-Computer Interaction Lab, University of Maryland, College Park, MD

Abstract

EventFlow is an application that helps analysts visualize complex temporal patterns—often an important task when retrieving and processing clinical data for retrospective observational studies. EventFlow illuminates how event types and sequences impact particular research questions. The visualization process improves the efficiency of data retrieval by revealing more specific requirements before analysts have to create complex query logic. The application also highlights data quality issues such as duplicate records or 100 year old babies.

Visualizing Temporal Sequences with EventFlow

The Human-Computer Interaction lab at the University of Maryland developed EventFlow to help analysts visualize categorical temporal event data. It has been applied to domains such as cybersecurity, sports analytics, and healthcare management. The application creators believe that user interfaces are evolving toward larger, information-abundant interactive visual displays that will help analysts assess data quality, compare populations, and spot actionable anomalies. Figure 1 illustrates the three panels on the EventFlow interface: the left panel has controls and a legend, the middle panel summarizes all sequence patterns in the dataset, and the right panel has a scrollable timeline browser showing all of the individual records. The top sequence in the overview is selected (drug A, followed by stroke, followed by drug B). The distance between events corresponds to the average time between events. The height of the bar corresponds to the proportion of records with that sequence.

Figure 1. EventFlow with a small sample dataset.

Using EventFlow to Improve EHR Data Retrieval Requests

Researchers are increasingly asking for EHR data extractions for observational research and many of these studies focus on the timing and sequence of clinical events. Analysts have been using EventFlow to communicate complex event sequences with researchers and facilitate a more efficient way to gather requirements and implement SQL query logic. EventFlow has improved the data retrieval process by reducing the time required to solidify requirements and separate data that are true signal to the analysis (e.g., specific types of events) from the noise (e.g., duplicates, too many rows of redundant clinical events, data errors).

Sociotechnical Interventions to Optimize Research-Focused EHR Data Retrieval Requests

Brian M. Paciotti, Ph.D., M.S., Shang Wei, M.S., Samuel Morley M.S.
University of California, Davis Health System, Sacramento, CA

Abstract
An increasing number of researchers are requiring high-quality and pre-processed clinical EHR data for observational research and cohort discovery. To meet these challenges, a grant-sponsored data retrieval unit is implementing social and technical interventions to improve the quality and speed in which processed datasets are delivered to researchers. Technical interventions include more advanced datamarts and social interventions involve additional training and more strategic communication with clinicians.

Summary of Current Data Retrieval
The University of California Davis Health System (UCDHS) implemented an EHR supported by Epic in 2003. Since about 2006, various units at UCDHS have been responsible to create reports and extract data from the EHR. An informatics team supported by a Clinical and Translational Science Award (CTSA) has been responsible to retrieve data for research projects (e.g., cohort discovery for patient recruitment, retrospective observational studies). This small team is tasked with processing requests, defining requirements through in-depth meetings, and retrieving data from the EHR. When time allows, the team has worked hard to format the data into readily analyzable files. Recently the team implemented a requirements screening questionnaire to better assess early on what particular data specific researchers require. A new era has arrived. Organizational leaders have changed their driving questions from, “Can informatics teams extract clinical data?” to “How can informatics professionals create more efficient sociotechnical systems to provide a larger number of researchers with high-quality data?”

Process Improvement
The UCDHS informatics team is pursuing a number of technical and social interventions to improve the data retrieval process. From a technical perspective, the team is improving the effectiveness of the I2B2 “Cohort Discovery” tool to better allow researchers to query and visualize de-identified output. For example, researchers are better able to refine their requirements when they have the ability to create their own complex queries and visualize important traits of the cohort such as age, gender, and race. In addition, analytical datamarts supported by a standards-based informatics platform are being created so that analysts can more efficiently extract data. The team has investigated a number of social interventions: clinical champions/gatekeepers to bridge communication between clinicians and analysts, documentation of the retrieval process, and training sessions. A specific social intervention is to better inform clinical researchers about five EHR data quality dimensions—completeness, correctness, concordance, plausibility and currency.²

Conclusion
The growth of clinical data within EHRs combined with a increasing interest in observational research will continue to pressure informatics teams to improve their data retrieval processes. The UCDHS informatics team is facing these challenges by simultaneously improving both technical and social aspects of the data retrieval process.

Text Processing of Clinical Research Protocols and Informed Consents to Facilitate Tracking of Research Procedures

Alok Sagar Panny BDS¹, ², Vojtech Huser MD PhD²
¹Department of Health Administration and Policy, George Mason University, Fairfax, VA
²Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction: Clinical Research Informatics (CRI) aims to improve the conduct of clinical research studies. Research decision support (RDS) alerts and reminders can monitor whether study protocol is being followed. This support is similar to clinical decision support (CDS) systems that monitor compliance to clinical guidelines. A necessary pre-requisite for provision of research decision support is a computable representation of a study protocol.

Background: National Institutes of Health Clinical Center (NIH CC) conducts a large number of clinical trials (in 2014, it has 1611 active research protocols, of which 48% were interventional (phase 1-4), 46% natural history and 6% other). NIH CC maintains a research data warehouse and numerous clinical research informatics systems, including a system to manage study protocols and informed consents. From an informatics perspective, computable representation of study milestones and study procedures for every research protocol could be beneficial to numerous research system, including electronic data capture (EDC) systems, electronic health record (EHR) system or research cost accounting. However, with a large number of protocols and different needs of various CRI systems, the current CRI software relies mostly on traditional formats (such as semi-structured text or PDF) to store and manage clinical study metadata and study documents (specifically the study protocol and study informed consent [IC]). Computable representation of research studies is an ongoing CRI challenge with only limited support by existing CRI standards.

Rather than requiring researchers to use additional protocol modelling software, our study pilots an approach where we use natural language processing (NLP) methods on study documents (protocol or IC) to detect study procedures. Extracted study milestone events (or procedures) can be subsequently used to track progress of individual study participants through the protocol by observing the events recorded in the research data warehouse.

Methods: We created a pipeline of multiple text processing and NLP tools that starts with protocol or informed consent as input. For PDF documents, we first extract the text and remove repeating header and footer text. The current pipeline uses MetaMap as the main NLP tool but we are evaluating several other tools (e.g., Noble Coder, Apache cTAKES). To assess the quality of the procedure terms NLP extraction, we created an evaluation reference standard (for a random subset of protocol documents). Examples of protocol procedures targeted in our pilot are: ‘whole blood count test’, ‘liver biopsy’ or ‘questionnaire administration’. We mark by special flag procedures that are traceable via the NIH CC data warehouse.

Preliminary Results and Discussion: From NIH CC, we obtained 2,013 ICs (all PDF files) originating from 764 active research studies (some studies had multiple versions of ICs). In addition to ICs, we also obtained 3 full protocols and 21 protocol synopsis from inttrialshare.org data sharing platform. The evaluation gold standard data are available at https://dx.doi.org/10.6084/m9.figshare.3100765.v2 (the link also contains additional results). We wrote scripts (in R language) that invoke MetaMap remote API, parse MetaMap text (or XML) output and filter only procedural detected concepts. Our comparison of multiple MetaMap configurations (restricting by semantic type [e.g., only procedures] or restricting by UMLS terminology [e.g., only SNOMEDCT_US] indicate best results with the least restrictive NLP configuration and more intensive post-processing of MetaMap outputs. Our results indicate the need for better representation of protocol documents (PDF format disadvantages are loss of formal document sections (heading and subheadings), rich text formatting and tables formatting). We have created a proposed extension to the CDISC Operational Data Model (ODM) and plan to collaborate closely with CDISC XML technology team to advance existing standards towards a computable representation.

Annotating Patient’s Smoking Status From Electronic Dental Record Histories

Jay Patel, BDS, MS¹, Zasim Siddiqui, BDS, MS¹, Danielle Mowery, PhD², Thankam Paul Thyvalikakath, DMD, MDS, PhD¹,³
¹Indiana University School of Dentistry, Indianapolis, IN; ²Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; ³Center for Biomedical Informatics, Regenstrief Institute, Indianapolis, IN

Introduction
Smoking is a major risk factor for periodontal disease and can be leveraged to assess a patient’s dental health status over time. However, a patient’s smoking status is typically documented in free-text histories within the electronic dental record (EDR); therefore, manually abstracted for use within periodontal risk prediction models. Natural language processing (NLP) can automatically abstract patient smoking status from these histories eliminating human effort. The long-term objective of this study is to develop an NLP system to extract patients’ smoking status from the free-text EDR histories for study within a periodontal risk prediction model. In this study, we report our smoking schema and our reliability applying the schema to EDR patient histories.

Methodology
In this pilot study, we randomly sampled 100 patients and their smoking histories (December 31, 2011-January 1, 2012). First, we developed a schema representing the types of patient smoking statuses described within patients’ medical histories by conducting a literature review of smoking status definitions (top-down modeling). Simultaneously, we manually reviewed 100 patients’ (5 batches of 20 patient medical histories) to refine our smoking status subtypes (bottom-up modeling). Two trained annotators independently annotated each batch of patient histories. Any disagreements between the annotators were discussed and agreement was reached using consensus. We report our inter-annotator agreement (IAA) (F1-measure) between annotators for each batch both overall and across smoking status subtypes.

Results
We observed an overall IAA of equal or greater than 85% across batches. Intermittent, heavy, and past smoker descriptions were not always observed (NOF) in each batch.

Table 1. Smoking status schema subtypes with IAA between two annotators over 5 batches.

Conclusions
We achieved high reliability annotating patient smoking status from dental medical histories. In future work, we will leverage this dataset to develop and evaluate an NLP tool that provides a patient’s smoking status to a periodontal risk prediction model.

Implementing a course in computational thinking during residency using R

Furquan Pathan, MD1, Sary Beidas, MD, MBI, FACP, PMP1
1GME Orange Park Medical Center, Orange Park, FL

Introduction
A widening chasm exists between what future healthcare providers are learning and the actual health care environment needs.[1,2,3] HITECH Act was introduced in 2010 to facilitate adoption of electronic health records, since then the majority if not all residency programs have adopted clinical information systems (CIS).[4] Hence, new skills and competencies are needed if healthcare providers are to effectively leverage these technologies for patient care, education and research. In particular, there is a gap in statistical analysis, visualization of data skills, and computational thinking. R is an open source application that is widely used in academia and addresses the identified gaps in education pertaining to statistics, visualization science, and computational thinking. [5,6] Because ACGME requires residents and faculty to participate in scholarly activities, we developed an introductory curriculum for R in an internal medicine residency.[7]

Methods:
The curriculum is administered using a “flipped” classroom method to residents during at the PGY-I level. In brief, the intervention is administered through prerecorded videos (8-10 minutes), classroom lectures (1 hour each) demonstrating specific skills in using R to analyze datasets, and one-on-one sessions during each resident’s research rotation, where an instructor helps the resident solve problems in a clinical data set in R. To measure the effectiveness of the course content and delivery, we administered a pre and post course survey to assess their baseline level of understanding and also to receive feedback.

Results:
Three out of ten residents have completed the introductory portion of the course. The overall reception of the course was positive in the pre-course survey, with learners showing a high level of motivation to continue expanding their knowledge in R for use in clinical problem solving and decision support. The post-course survey noted that the residents found the course moderately difficult, with no previous exposure to programming or computational thinking. A major challenge for the residents was interacting with the command line interface especially adapting to the new syntax to execute functions.

Conclusion:
Residents have the capacity and are eager to learn computational skills. The clinical curriculum can be modified to accommodate an introductory course in statistics, data, and visualization to achieve these goals. Future plans will focus on developing and personalizing course content to support resident education and needs.

Cues for PE Diagnosis in the Emergency Department: A Sociotechnical Systems Approach for Clinical Decision Support

Brian W. Patterson\textsuperscript{1,2}, MD MPH, Erkin Otles\textsuperscript{1}, MS, Ann Schoofs Hundt\textsuperscript{2}, PhD, Peter Hoonakker\textsuperscript{2}, PhD, Shashank Ravi\textsuperscript{1}, MD, and Pascale Carayon\textsuperscript{2,3}, PhD

\textsuperscript{1} Department of Emergency Medicine, University of Wisconsin School of Medicine and Public Health
\textsuperscript{2} Center for Quality and Productivity Improvement, University of Wisconsin-Madison
\textsuperscript{3} Department of Industrial and Systems Engineering, University of Wisconsin-Madison

Pulmonary embolus (PE) is among the most challenging diagnoses made in the emergency department (ED). While missed or delayed diagnosis of PE is a major problem in the ED\textsuperscript{1}, overtreatment, which subjects patients to harm from radiation, overdiagnosis, and increased cost, is also a concern\textsuperscript{2}. Health information technology, such as clinical decision support, has the potential to reduce diagnostic errors and support the diagnostic process.\textsuperscript{3} However, this requires that the technology be useful and usable, and fit within the clinical workflow, providing justification for a sociotechnical systems approach.\textsuperscript{4} The purpose of this study is to understand cues in the PE diagnosis process in the ED sociotechnical system and to compare these cues to the information available in the EHR. This will help in defining design requirements for a clinical decision support for PE diagnosis in the ED.

Using the Critical Decision Method,\textsuperscript{5} we interviewed 16 attending physicians and residents in three EDs of two academic medical centers and one community hospital. The total duration of the interviews was over 12 hours. Using an iterative qualitative content analysis, we identified 4 categories of cues: (1) patient signs and symptoms (e.g., leg swelling, chest pain), (2) patient risk factors (e.g., immobilization, surgery or trauma, cancer), (3) explicit risk scoring (e.g., PERC), and (4) clinical judgment. We then mapped these cues to information available in the EHR at one of the participating hospitals. About 80-90\% of the cues may be available in the EHR; many of them rely on the physical exam and information obtained by talking to the patient. This finding underlines the need to identify the various roles involved in obtaining, documenting and reviewing the information that informs the PE diagnostic process. The PE diagnostic process in the ED is distributed across multiple roles, individuals and technologies in a sometimes chaotic and often busy physical and organizational environment. Our findings highlight the potential for decision support tools to aid providers by collecting data already available in the EHR in disparate areas of the workflow and highlighting relevant cues for providers at the time of diagnostic decision making.

Evaluation of UMLS Term Coverage for Echocardiogram Measures

Olga V. Patterson, PhD1,2, Matthew S. Freiberg, MD, MSc3, Cynthia A. Brandt, MD, MPH4,5, Scott L. DuVall, PhD 1,2
1VA Salt Lake City Health Care System; 2University of Utah, Salt Lake City, UT, USA; 3Vanderbilt University Medical Center, Nashville, TN, USA; 4Connecticut VA Healthcare System; 5Yale University, West Haven, CT, USA

Abstract
The Unified Medical Language System (UMLS) is a widely used resource for concept identification systems that link phrases found in text to the concept entries in the UMLS. Building a natural language processing (NLP) system for the purposes of echocardiogram measures extraction from unstructured clinical notes requires a comprehensive lexicon. Our previous effort resulted in a custom lexicon that contained 408 entries for 27 concepts typically found in echocardiogram reports. Using interactive MetaMap, we determined UMLS coverage of the terms in the lexicon by searching for the lexicon entries in UMLS. Overall term coverage was measured at 43.9%.

Background
Since the first days of inception of the Unified Medical Language System (UMLS) multiple efforts have been performed to determine the limits of UMLS term coverage.1,2 These studies agree that while the UMLS concept coverage varies across clinical subdomains, it generally higher than the term coverage. The U.S. Department of Veterans Affairs Corporate Data Warehouse (CDW) is a national data repository comprising data from several Veterans Health Administration (VHA) clinical and administrative systems. With a large number of facilities within VHA, the unstructured data in CDW shows a high level of variability across different facilities and time. As a part of a larger NLP system development project, we built a custom lexicon to be used for term identification of echocardiogram measures in clinical notes.3

Method and Results
Using a previously described term extraction method, we obtained a custom lexicon containing 502 terms for 74 concepts. The project focused on 27 concepts decided by domain experts as the target concepts for the study, which combined had 408 terms. Each of these terms was searched in UMLS version 2013 using interactive MetaMap application offered by the National Library of Medicine. We did not use UMLS Metathesaurus Browser because MetaMap offers phase segmentation, word disambiguation, and filtering functionalities that minimize the number of ambiguous results as well as enable composite concept matches. For each of the 27 concepts in our custom lexicon, we counted the number of terms that had 1) a single mapping with a) an exact match; b) a composite concept match; 2) multiple mappings with a) at least one exact match; b) at least one composite concept match; 3) a) one or more mappings with all of them being incorrect mappings; or b) no mappings.

Out of 408 terms, only 54 terms (13.2%) had an unambiguous match to a simple or composite concept in the UMLS. Another 125 terms (30.6%) were ambiguously mapped to multiple concepts but at least one of them matched the targeted concept. 229 terms (56.1%) were either mapped to unrelated concepts or were not mapped to any concepts.

Discussion
UMLS is frequently used as a single source of terms for concept identification in NLP systems. Our study indicates that UMLS provides only 43.9% coverage of terms used in the VHA clinical notes to describe echocardiogram measures. In order for an NLP system to achieve a high level of recall in concept identification of echocardiogram measures, a custom lexicon derived from the data is required. While the UMLS contains at least one entry for each of the targeted concepts (simple or composite), the synonym set lacks all spelling variations found in clinical notes.

NDC Properties in RxNorm

Lee Peters, M.S. and Olivier Bodenreider, M.D., PhD
U.S. National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA
{lee.peters|olivier.bodenreider}@nih.gov

Motivation
The National Drug Code (NDC) is a universal product identifier for human drugs in the United States. NDCs can be found on drug packaging and are listed on the Food and Drug Administration (FDA) Structured Product Labels (SPLs). NDCs are used by pharmacists for inventory management and for drug information exchange, as well as in claims data. From a clinical perspective, however, NDCs are too detailed (e.g., packaging information) and need to be mapped to clinical drugs or ingredients (e.g., for medication reconciliation). It is therefore not surprising that the most used query from users in the RxNorm Application Program Interface (API) [https://rxnav.nlm.nih.gov/RxNormAPis.html] is to map NDCs to the corresponding RxNorm concepts. RxNorm currently contains over 200,000 NDCs, most of which come from SPLs and the rest from First Data Bank. However, until recently, the RxNorm API did not expose the properties associated with NDC (extracted from SPLs). The new API function described here now provides this information.

NDC Properties
NDCs are multi-segment identifiers, with codes for manufacturer, drug, and packaging information. NDCs come in multiple flavors, namely 3-segment, 2-segment (manufacturer-drug), and an 11-digit format combining the 3 segments. NDCs are associated with other codes, such as the Abbreviated New Drug Application (ANDA) code and the identifier for the SPL (“SPL set id”). Other information linked to the NDC include pill characteristics (e.g., color, shape, size), as well administrative information (e.g., marketing category, labeler, schedule). The RxNorm API function getNDCProperties takes as input an NDC (any flavor), an SPL set id or an RxNorm identifier and returns the properties associated with the NDC (for all NDCs from SPLs). While most of the properties are extracted from RxNorm, packaging information is acquired from DailyMed. NDC properties for 0781-1506-10 (Atenolol 50 MG Oral Tablet) are listed in Table 1.

Use Cases
The RxNorm API function getNDCProperties was designed to support several use cases.
- Finding the NDC properties for a clinical or branded drug. For a clinical or branded drug in RxNorm, the NDC properties of all the NDCs for that drug can be returned from a single call to the API.
- Finding the NDCs and properties for a Structured Product Label. The API function will return all the NDCs and their properties for a given Structured Product Label.
- Finding the characteristics of oral solid dose form medications (pills). The NDC properties returned include color, shape, size, and imprint code.
- Finding the labeler/manufacturer information for a drug. For a given NDC, the labeler/manufacturer is returned. By specifying an RxNorm identifier as input, the labeler/manufacturer information is returned for each associated NDC.

Use of Freetext Clinical Reports for Prediction of 30-Day Psychiatric Readmissions

Jose Posada, MS1,3, Lingyun Shi, MS1, Ye Ye, MS1, Neal Ryan, MD2, Frank Ghinassi, MD PhD2, PhD, Henk Harkema, PhD4, Fuchiang (Rich) Tsui, PhD1
1Department of Biomedical Informatics and 2Department of Psychiatry University of Pittsburgh, Pittsburgh, PA; 3Electronics and Telecommunication Engineer Program Universidad Autonoma del Caribe, Barranquilla, Colombia; 4Nuance Communications®, Pittsburgh, PA)

Abstract: We assessed the contribution of free-text clinical reports in predicting 30-day psychiatric readmissions. We extracted 5,495 clinical findings from 491 psychiatric visits during one month using cTAKES and identified top predictive terms using feature selection. We built a Bayesian classifier using the leave-one-out cross-fold validation (LOOCV) approach. The model had an area under receiver operating characteristic curve (AUROC) of 0.75 (95% CI 0.66-0.84). Our findings indicate that clinical reports appear to be valuable in predicting 30-day psychiatric readmissions.

Introduction: According to the substance abuse and mental health services administration (SAMHSA) 43.1 million of adults (18.1%) in the US have experienced some form of mental illness1. Hospitalizations for psychiatric illnesses are increasing at a faster rate than any other type of hospitalization1. For hospitalized psychiatric patients, 15% of all discharged patients are readmitted within 30 days and these readmissions are associated with higher costs than any other readmission cause1. Moreover, CMS releases individual hospital readmission rates to the public as an indicator of quality of care. One of the key steps to reduce 30-day readmission rates is to identify patients at high risk of 30-day readmission; however, existing studies2 have used only structured psychiatric data (e.g., demographics) and have achieved AUROCs less than 0.63. In this study, we hypothesize that unstructured clinical reports can be utilized to better predict 30-day psychiatric readmissions.

Methods: We retrieved all the clinical reports from one month of inpatient visits at the Western Psychiatric Institute and Clinic of the University of Pittsburgh Medical Center (UPMC) during December 2007. We used the visits from the following month (January 2008) to determine readmission cases. We utilized cTAKES3, an open source natural language processing tool, to extract signs and symptoms from the clinical reports and encode them into one of three values: Present, Absent and Missing. To predict readmission visits, we employed a naïve Bayesian (NB) classifier because it can handle uncertainty and has performed well in our prior work4. We used LOOCV to evaluate the classifier performance. We chose the top 50 features automatically ranked by information gain to train the classifier, which was based on the balance between model complexity and available sample size.

Results: The pilot dataset comprised 941 clinical reports from 491 inpatient visits (36 readmission cases and 455 controls; 7.3% readmission rate). cTAKES extracted 5,495 unique clinical findings from the reports. The dataset comprised three report types: discharge summaries (47.5%), history and physical (52.2%), and progress notes (0.3%). The final classifier had an AUROC of 0.75 (95% CI 0.66-0.84). Top-performing features included feeling suicidal, hallucinations and group psychotherapy. These features were also identified as key factors for readmissions in a prior study by Machado5.

Conclusion: In this pilot study, we found that free-text clinical reports appear to be valuable in predicting 30-day psychiatric readmissions with AUROC 0.75. The limitation of the study is the small number of readmission cases. We plan to collect more cases, refine cTAKES, and retest our hypothesis in a larger scale study.

Systemic identification of analytes tracked as outcomes in RPM clinical trials

Gouri Prakash, BE, MISM, PGDCR

1 CitiusTech Inc., USA

Abstract

Remote Patient Monitoring (RPM) technology facilitates delivery of care outside conventional clinical settings, such as the patient’s home. Waived lab tests provide opportunity to conduct a limited amount of self-monitoring. This poster evaluates the extent to which RPM clinical trials measure values of analytes designated as waived.

Introduction

RPM technologies support or enable care models that reduce avoidable re-admissions, promote transition of patient care from the hospital to home and empower patients with chronic conditions to regularly monitor the severity of their illness. RPM clinical studies evaluate the efficacy with which RPM technology improves clinical and financial outcomes. In order to assess clinical outcomes, some of these trials measure values of one or more analytes. This study was undertaken to systemically identify the analytes measured during the conduct of RPM clinical studies and to systemically identify which of these analytes were also on the list of waived analytes. Waived analytes by definition can be measured by lab tests that are approved by the FDA for home-based use. The objective of the study was to gain insight into the utilization of analytes on the waived list in RPM clinical studies.

Methods

The keyword “Remote Patient Monitoring” was used to retrieve studies from the ClinicalTrials.gov portal. The result set comprised of 238 clinical studies. The information provided in the outcomes field for each study was parsed to isolate analytes that were measured during the conduct of trials. The Component field in the LOINC dataset was used for the detection of analytes embedded within the outcomes section for each study. This list of analytes was parsed further to identify whether any of these analytes were designated as waived which was done by leveraging the he list of waived analytes as a reference to arrive at the matches between the two lists.

Results and Discussion

Out of 238 clinical trials, there were 27 trials that measured analytes designated as “waived”. 20 of these 27 trials (74%) evaluated the efficacy of RPM in improving outcomes for diabetic patients (Type 1 diabetes, Type 2 diabetes or gestational diabetes). The analytes measured to evaluate these outcomes were glucose, HbA1c, lipid profile, inclusive of cholesterol and triglycerides, and in one case fructosamine - all of which have been designated as waived by the FDA. Out of 123 waived analytes, there were 13 analytes (10.56%) that were measured to evaluate clinical outcomes in RPM clinical studies. From an informatics standpoint, as the outcomes of RPM clinical studies was provided in natural language, the LOINC dataset and the waived analyte list served as controlled vocabularies, in the detection of waived analytes embedded within the outcomes of interest in RPM clinical studies.

From a clinical standpoint, since waived lab tests by definition have regulatory approval for home-based use, these tests can potentially be leveraged in the model of care enabled by RPM. Match on just 13 analytes indicates under-utilization of waived lab tests within the model of care enabled by RPM. More than two-thirds of the analytes on the waived list comprise of biomarkers of normal biological processes, which implies that these waived tests can be used for monitoring purposes. Alternatively, a hybrid model of care which makes use of tenets of RPM and is enabled by the availability of waived tests can be hypothesized. For example, although none of the RPM clinical studies measured outcomes for patients suffering from gout, care providers can put such patients on care plans designed to self-monitor the levels of uric acid, a waived analyte. Waived lab tests can potentially scale the model of care enabled by RPM for newer target patient populations and improve the efficacy of the existing model of care.

Usability of a Provider-Facing Breast Cancer Prevention Toolbox

Jordan L. Price, BS¹, William Ueng, BS¹, Austin M. Coe, BA¹, Raven David, BA², Meghna Trivedi, MD², Katherine D. Crew, MD¹,²,³, MS, Rita Kukafka, DrPH, MA¹,²

¹Mailman School of Public Health, Columbia University, New York, NY; ²College of Physicians and Surgeons, Columbia University, New York, NY; ³Herbert Irving Comprehensive Cancer Center, Columbia University, New York, NY

We developed a provider-facing toolbox for breast cancer risk assessment and prevention in the primary care setting. The toolbox informs providers about the risks and benefits of genetic testing and chemoprevention and facilitates patient engagement. We conducted usability testing to identify themes related to ease of use, content, and navigation. Further evaluation in a controlled trial will determine if the toolbox improves the identification and referral of women at increased risk for breast cancer.

Introduction

Breast cancer poses a public health burden as the most commonly diagnosed and second leading cause of cancer-related deaths among women in the United States. Several known risk factors affect breast cancer development, and primary care providers (PCPs) may employ risk assessment tools to calculate patient risk. However, available tools and prevention methods are not routinely employed in practice. This study aims to assess the usability of a provider-facing Breast Cancer Prevention Toolbox targeted for providers in the primary care setting.

Methods

The toolbox provides modules on chemoprevention and genetic testing consisting of key concepts, guidelines, and multimedia case-based learning. The “My Patients” section displays relevant information for patients at high breast cancer risk. The patient’s 5-year risk according to the Gail model is shown with a link to a patient-generated action plan with family history, patient-identified pros and cons for risk-appropriate preventive services, and action items. The toolbox can be accessed through the electronic health record or directly on the web. Seven PCPs were identified through Columbia University Medical Center (CUMC) in New York, NY. Testing sessions were recorded and lasted approximately one hour during which subjects were asked to “think aloud” while navigating the toolbox. A monitor facilitated each study while an observer documented comments and reactions. Qualitative data analysis promoted the identification of themes related to the program’s Ease of Use, Content, and Navigation.

Results

The identified issues in each of the thematic areas are summarized in the table (Table 1) below.

Table 1. Themes identified and addressed during the usability studies specific to the toolbox.

Conclusion

The toolbox addresses a gap in PCP breast cancer risk assessment and prevention management. The themes we identified provide insight to achieve optimal user engagement. Further evaluation in a controlled trial will determine if the toolbox improves the identification and referral of women at increased risk for breast cancer.
A platform for rapid data sharing and visualization to contribute towards future epidemic preparedness within communities in Sierra Leone

Nuri Purswani, PhD, Meenal Pore, PhD, Purity Mugambi, BSc, Samuel Karumba, BSc, Kala Fleming, PhD, Reginald Bryant, PhD

1IBM Research Africa, Catholic University of Eastern Africa, Nairobi, Kenya

*Equal contributors to this work

Introduction

A vital lesson learned from the 2014 Ebola outbreak in West Africa is the need to develop tools that enable government agencies and NGOs to rapidly share data in the event of an emergency. In Sierra Leone, the majority of data in health facilities is collected through paper forms: a time-consuming process that often leads to information of dubious quality. In addition, health facilities often do not report essential information, which hinders the process of data-driven decision-making in policy. The gradual transition towards mobile-based data collection platforms provides a promising opportunity for improving data quality. Furthermore, datasets from different organizations (e.g., NGOs and Government) need to be interoperable so as to enable end users to quickly obtain insights from different reports without the need for expert knowledge or long delays manipulating files before information is available for action.

Architecture

To address the challenges above, we have developed a web-based platform enabling the following key functionalities: ingestion of tabular data, unstructured text management (mobile) and real-time API integration with mobile collection platforms like Open Data Kit, Commcare and Kobo Toolbox; geotagging, deduplication and matching of related fields across multiple datasets (to match multiple naming conventions to the same location); visualization dashboards for uploaded datasets and in-built analytics to enable data exploration; alerts dashboard to flag areas in risk based on user defined indicators (i.e. the user selects indicators and the system triggers alarms based on pre-defined conditions) and natural language processing tools to generate word clouds and provide rapid situational awareness in different parts of the country.

We developed back-end analytics to flag important pieces of information for epidemic preparedness in Sierra Leone. The analytics are broken down into: (1) A trigger system flagging alerts at health facilities when diseases such as measles, yellow fever, typhoid or maternal deaths are reported; (2) An alarm system for infection detection and prevention and also for the detection of events that relate to un-sufficient or deficient control structures, inventories or practices; (3) An alarm system detecting section death alerts that exceed predetermined threshold (e.g., 17 deaths per 1000 population per month). In addition, the developed analytics also flag health facilities that are not reporting data consistently. Finally, to verify reports from health facilities, we developed a dashboard that enables officers to produce real-time reports automatically geotagged through the KoBo Toolbox app. The real-time information input by users is visualized through a second dashboard that contains a word cloud and highlights key topics reported by date and geography.

Pilot

The pilot for the tool is currently taking place in Sierra Leone. We will present the results during the workshop.

S2CR3UM: A Solution to the In Silico Relevance, Reliability & Reproducibility Conundrum

Sarah B. Putney, JD, MA, Andrew White, PhD, Janos Hajagos, PhD, Joel H. Saltz, MD, PhD, Jonas Almeida, PhD, Mary. M. Saltz, MD; Department of Biomedical Informatics, Stony Brook School of Medicine, Stony Brook, NY

Introduction
Informaticists face daunting challenges with data management. Stony Brook Department of Biomedical Informatics created a quality control program to improve reliability, reproducibility, and relevance of data products.

Methods and Objectives:
We defined two synergistic goals for this project: a) to develop, implement, and iterate on a Toolkit for Quality improvement and ongoing quality control (QC) for data analytics; and b) to transform the culture to support a nimble and productive team. The program meta-process is organized around defined roles and responsibilities, and coordinated across time and technical systems, to deliver data products meeting scientific standards of relevance, reliability, and reproducibility. People & Communications: Roles and responsibilities were defined for the team and all developed tools and shared ideas for process improvements, based in part on The Checklist Manifesto. Building on this foundation, the group drafted of a core set of checklists to guide workflow and to promote accuracy and consistency. Borrowing from the model of agile software development, a rapid cycle of work-review-correct/revise, a set of “scrum”s (informal but focused meetings) began: thrice-weekly scrums where developers report on current work; more inclusive weekly scrums at which project priorities are set and data products in process are critiqued; and a weekly “super” scrum for program leaders. Program leaders reinforce expectations for attendance and participation. Systems for Data, Code & Data Products: A shared infrastructure was adopted to promote interoperability, retrieval, version control, reproducibility, etc. OpenProject (https://www.openproject.org/) is used for project management with projects and tasks defined using a simple structured format (Problem, Materials, Methods, Observations, Conclusions, Application.). Github (https://github.com/) is the designated repository to store software code for work in process and finalized. Analogously, BOX (https://www.box.com/) serves as the repository of data products at all stages of development, made searchable through a naming convention that included task #, completeness level, a 4-5 word description of the product, and file format. Links to storage of final products and code are placed in the OpenProject tracker. A 5 level grading system, with a checklist for each completeness level, was developed. The final and most complete level (5), includes criteria such as references to data provenance, a cross check for data veracity, the number of populations and subgroups analyzed, and geographic or service provider scope. Interactive tools for data visualization and exploration, such as integration of patient addresses to Google Street View were developed to help guide understanding of results. Standard templates are used to promote brand identity and consistency. Monthly project review meetings are conducted, engaging subject matter experts as needed, to ensure relevance and completeness of data products. Observations: Nine months after implementation review shows new data products to be easily retrieved, consistent, reproducible and well branded. This effort encompassed dataset testing and validation to ensure accuracy of combined in patient and outpatient data including laboratory test, location and medication information. Insights gained in this dataset quality process allowed us to collaborate with Cerner to optimize usefulness of the information obtained from our newly deployed Healthe EDW data warehouse and to target a variety of quality efforts including infection control, systematic targeting of Clostridium difficile (C. diff) testing along with analysis of Suffolk County New York population patient health quality indicator and readmissions related metrics. Challenges include consistent adhere to standards and checklists, but changes in workflow have made consistent QI a vital part of departmental culture.

Conclusion
We conclude that by changing culture around data quality and by using a Toolkit for Quality, scientific integrity and in silico quality control can converge in a manageable, affordable, and productive workflow in an academic setting.

Topic Visualization of Online Cancer Discussion Forums
Jin Qu, BS, Annie T. Chen, PhD
Department of Biomedical Informatics and Medical Education, School of Medicine, University of Washington, Seattle, Washington, USA

Abstract
Online cancer discussion forums are a rich source of health information and can potentially have a great impact upon people’s medical decision-making. However, given the dynamic nature of online discussion data, it is a challenge to extract valuable insights from these data. We present a prototype visualization to aid exploration of people’s online information and support exchanges.

Introduction
Recent literature has observed that social media and online communities are reshaping the healthcare landscape. As people’s interest in seeking and exchanging online health information increase, it is of great importance to develop a high-level understanding of this information, including topics that draw the most attention, and differences among online communities. We have leveraged text mining and visualization techniques to prototype a visualization tool that facilitates exploration of topics in online cancer-related discussions.

Methods
Data Collection: We used Wget to extract webpages from CancerCompass, a website featuring cancer-related message boards. Our corpus is comprised of 152,378 posts (from July, 2001 to February, 2016), covering a wide range of topics including cancer diagnosis, treatment and recovery.

Data Processing and Topic Mining: Discussion content was extracted from the raw HTML files and pre-processed using BeautifulSoup. We then utilized MALLET to perform topic mining using Latent Dirichlet Allocation (LDA). In addition to the default stop word list, the top 100 highest frequency words were removed from the corpus to increase topic differentiation. This list is available upon request.

Data Visualization: The visualization was developed using d3.js. We set three design goals:
1. To visually represent topic prevalence. The topics are represented using circles, where the radius of each circle is proportional to the proportion of each topic within the corpus. The use of circle size to indicate prevalence has been used in previous visualizations of textual data including discussion forums and newsgroups.
2. To facilitate association of topics by semantic category. Different colors are used to represent topic categories: e.g. body, habits, information, and medical events.
3. To provide detailed summary statistics and links to posts associated with each topic. When a user hovers over a circle, summary information and a hyperlink list to posts will be displayed (in progress).

Preliminary Results
A visualization of the Head and Neck Cancers message board is displayed in Figure 1. Discussion about feeling is the most prevalent, followed by spirituality, doctors, lymph and treatment effects.

Conclusion
We have demonstrated a visualization tool to present text mining results. This tool can be used by researchers and health consumers to explore the dynamics of people’s online health information and support exchange behaviors. This tool can also be used by patients, caregivers, and biomedical informaticians in shared decision-making contexts.

Mobile Maternal Health Applications in Developing Countries

Yuri Quintana¹, Ph.D., Jennifer McWirther², Ph.D., Melek Somai¹, MD MPH, Michelle Hacker¹, ScD, MSPH, James Gray¹, MD,
¹Beth Israel Deaconess Medical Center, Boston, MA, USA
²University of Guelph, Guelph, Ontario, Canada

Introduction

A long-term goal for maternal and newborn health is to prevent and reduce newborn deaths and morbidities. In 2013, 4.6 million children died (74% of all under-5 deaths) within the first year of life¹. An estimated² 270,000 newborns die during the first 28 days of life every year from congenital anomalies. To address this global health problem, the United Nations (http://www.un.org) included maternal health in their Millennium goals and the new Sustainable Development Goals. Governments, non-profit groups and research groups worldwide have launched initiatives to improve outcomes. Mobile technologies hold the potential to improve maternal and newborn health by supporting access to education, improving coordinated care, and facilitating patient support. Some of these systems have been designed to improve maternal outcomes such as increasing patient visits for antenatal care, improving healthier behavior in patients such as avoiding smoking and alcohol, and improving vaccination rates of newborns.

Method

We searched the literature for any intervention delivered during pregnancy or up the first 28 days, where the intervention was delivered digitally (not voice alone) via mobile phone or smart phone. The effect of the mobile intervention had to be discernable from other intervention components. Computerized literature searches were performed with no date or language delimiter using the following literature databases: PubMed/MEDLINE (NCBI), Embase (Elsevier), Cumulative Index to Nursing and Allied Health Literature (EBSCO), Cochrane Central Register of Controlled Clinical Trials (EBSCO), Web of Science (Thomson), Popline (K4Health). The search was focused on mobile applications on mobile devices and platforms for maternal health. The search was constrained to the title and abstract words and controlled vocabulary terms, when available, and to peer-reviewed journal papers. One author completed the electronic search. All items in the final list were reviewed by two or more authors.

Observations and Discussion

We found 1,680 references using the search strategy of which 32 met our inclusion criteria. Of these, the studies used the mobile phone applications for: reporting test results from clinics to patients via mobile apps (n=1), patient reminders for upcoming clinic visits via mobile alerts (n=5), patient-reported medical status (n=5), patient education via mobiles for behavior change (n=21). The sample size of participants in the studies ranged from 68 to 2550. There were mixed findings for the utility of mobile health applications in the context of maternal and child health. A wide range of hardware- and software-based technologies have been developed to address various aspects of maternal and newborn health. Despite the many programs and publications, very few studies took the form of randomized control trials. Implementation problems included, for example: lack of availability of mobile phones by patients in some developing countries; issues around staff training and incentives; and a lack of health literacy measurements for educational content. Studies, and the applications considered within, were also largely uninformed by health behavior models or theories. Evaluation problems included not having a large enough sample size for statistical significance, a high number of dropouts and the lack of qualitative measures or validated assessment tools.

Conclusions

A variety of economic, geopolitical, sociocultural, and technical factors need to be addressed to achieve successful deployments of mobile maternal health applications and platforms. Future studies seeking to evaluate such tools should use randomized control trials in order to understand effects. The success of these systems is very much dependent on the design and implementation that is appropriate for local contexts.

Serious digital game for heart failure self-management by older adults: A pilot study

Kavita Radhakrishnan, RN PhD MSEE, Paul Toprac, PhD, Matt O'Hair, MA, Paul Bradley RN MSN, Miyong Kim RN PhD FAAN, Mike Mackert, PhD

1The University of Texas, Austin, TX, USA; 2The University of Texas Game and Multimedia Applications (GAMMA), Austin, TX, US

Introduction

Effective self-management of heart failure (HF) which has an estimated worldwide prevalence of over 23 to 41 million can lower mortality and hospitalization rates. Serious games as a modality is yet to be explored for disease management among older adults. In this abstract, we present the development and testing of a serious game prototype by an inter-disciplinary team from nursing, computer game programming, usability science and communication for improving HF self-management knowledge and efficacy among older adults.

Method

The game genre of casino slots was selected based on a survey of 34 community based HF nurses on their and their patients’ preferences for playing digital games. HF education content adapted from the Heart Failure Society of America (HFSA) evidence-based guidelines and tailored to low literacy levels was placed strategically throughout the game using game-based instruction strategies. Participants 55 years or older and admitted with a HF diagnosis were recruited from three out-patient HF clinics based in central Texas, USA. Usability of the digital game was tested on seven HF individuals through guided observations by a trained Research Assistant, and a game usability questionnaire influenced by the Serious Game Usability Evaluation and the interest / enjoyment subscale of the Intrinsic Motivation Inventory (IMI) questionnaires. During the beta-testing of the game with 19 participants over four weeks, a pretest-posttest design was used to test improvement in HF knowledge and self-management which was measured using validated instruments of the Atlanta Heart Failure knowledge Test (AHFKT) and Self Care Heart Failure Index (SCHFI). A post-game survey was used to assess participant perceptions on the game. The study received institutional review board approval from the University of Texas – Austin.

Results and Evaluation

Of the seven community-residing older adults (57% females) with HF who participated in the usability testing of the digital game, 100% found the game easy to play, 100% found it enjoyable and 86% found it helpful to learn about HF. Of the 19 participants in the beta-testing of the game (90% were males, 84% were Caucasian, 72% lacked a degree, 58% older than 70 years age, 58% diagnosed with heart failure for more than 10 years), 90% found the game interesting, enjoyable and easy to play. Participants with lower education level preferred games to any other medium for receiving information (p= 0.02). Playing our game resulted in significant improvement in HF knowledge (p=0.007), non-significant improvement in HF self-maintenance (p=0.11) and no difference in HF self-confidence scores.

Discussion

Developing a serious game that is satisfying and acceptable to older adults with HF is feasible. Moreover, game-based instruction was established as an effective manner to impart knowledge on chronic diseases such as heart failure, especially for participants with lower education levels. The next steps include studies to explore the impact of gamification principles for HF self-management behavior modification and improving older adults’ heart failure outcomes, including self-management, re-hospitalizations, and quality of life.

Parsing complex microbiology data for secondary use

Protiva Rahman, BS¹, Albert M. Lai, PhD¹, Courtney L. Hebert, MD, MS²,³

¹Department of Computer Science and Engineering, ²Department of Biomedical Informatics, ³Department of Internal Medicine, The Ohio State University, Columbus, OH

Introduction

Clinical microbiology culture and antibiotic susceptibility data are a rich source of information required for a variety of secondary use applications such as epidemiologic studies of antimicrobial resistance. Our study team is working on using clinical microbiology data to develop antibiotic prescribing clinical decision support.¹ Unfortunately, culture and antibiotic susceptibility results are often reported in complex, semi structured or free text form, making it difficult to use them for analysis. Cultures from abdominal-biliary (AB) sources are especially complex because there are multiple types of cultures results (e.g. anaerobic, fungal) and a wide variety of organisms. Prior work in this area has focused on rule-based approaches, natural language processing, and often on blood cultures.²,³ The objective of this project was to parse and annotate each unique organism name from a free text field of AB cultures and identify any antibiotic susceptibility results or evidence of resistance mechanisms (e.g. presence of penicillinase production) that occur in this free text field. By annotating the organisms with a unique concept identifier we are able to add additional, useful information to the dataset, such as Gram staining, type of growth patterns, and family.

Methods

Adult patients admitted to an inpatient unit with a diagnosis of AB infection, with a positive culture from a relevant site in the first 4 days of their hospitalization to The Ohio State Wexner Medical Center from 1/1/2009 to 1/1/2014 were included for a total of 625 patients and 1023 unique cultures. The UMLS metathesaurus⁴ was used to identify organism name. Our method included: 1) Tokenizing the result text and removing. 2) Using regular expressions to extract colony count and other culture data (e.g., resistance mechanisms). 3) If a token did not match any predefined regular expression, we checked to see if it matched the concept type of ‘bacteria, virus or yeast’ in the UMLS. If it did we continued consuming tokens to find the longest matching string that matched the semantic type identifier for a pathogen. 4) In the case where an organism was not fully speciated (e.g. Escherchia/Citrobacter), we assigned the code for the common parent. 5) If the token matched the UMLS semantic type of “Antibiotic,” we look at the surrounding tokens with a span of two to see if they match a set of positive words: [e.g., confirmed, produces, covers] or a set of negative words: [e.g., negative, resistant] and accordingly assigned true or false. We developed our algorithm on 300 cultures and tested it on the remaining 723. Our subject matter expert (CH) manually validated a set of 200 parsed results, for which we report the precision (true positive/(true positive + false positive)), recall (true positive/(true positive+false positive)) and F1 score (2*precision*recall / (precision + recall)).

Results

For identifying the correct organism precision was 0.91, recall 0.95, and F1 0.93. Penicillinase production was identified and related to the correct organism with a precision of 1, recall 0.95, and F1 0.97. Free text antibiotic susceptibilities were identified and related to the correct organism with a precision of 0.92, recall 0.93, and F1 of 0.93. The major challenges we faced were in dealing with not fully speciated organisms and relating parsed data to the correct organism in a poly-microbial infection.

Conclusion

We achieved high F1 scores using our technique of longest matching and regular expressions customized to our data. While some techniques are specific to our data, the ideas can be replicated for other free text microbiology data. This kind of work is vital in order to use these complex data for secondary use applications.

**Rural Health Informatics: Using EHR Data for Systems Based Improvements in the Emergency Department**  
**Gilbert H Ramirez, MD., James P Killeen, MD.**  
**University of California, San Diego**

**Introduction:** El Centro Regional Medical Center is a safety net hospital with an annual census of 52,000. In 2015, one out of every 25 patients left the emergency department without evaluation by a physician. This is double the rate of the previous year. This represents a symptom of increased waiting times, patient volume and is a risk to hospital safety.

**Methods:** Using hospital EHR data and physician billing data we plotted arrival and screening curves for the patient census. These curves were compared with time to bed and average expected physician workflows. We adjusted this data to model intake workflows as patients per hour. We assumed an inefficient system when curves did not intersect. From the combination of these curves, assumptions of physician workflow, fatigue and department triage efficiency were made. This data was used to make staffing and workflow adjustments to the intake process. Over the next few months we will observe the difference in left without being seen rates after implementation.

**Results:** From the model, we were able to identify areas that required systems based process improvements. During the morning hours a large patient surge quickly overwhelms the intake process of the emergency department. In addition, physicians are unable to meet screening demands despite working beyond their expected capacity. From these observations, we implemented a new triage and provider staffing model. After a two-month adjustment period the left without being seen rates will be compared. We hypothesize that the model is useful as an easy data-driven tool to identify targets to reduce left without being seen rates in the emergency department.

![Figure 1. Identifying need for provider staffing.](image)

**Conclusion:** Hospitals with access to limited data streams can still identify and target process improvements. These simple models can potentially avert risk and improve patient care by re-allocating limited resources to periods of need. Ways to quickly and transparently identify these targets may improve access to patient care in these communities.
Patient Identity Matching for Health Information Exchange between Poison Control Centers and Emergency Departments

Pallavi Ranade-Kharkar, PhDc, MS1,2, Darren Mann, BS1, Heather Bennett MPA, Barbara Crouch, PharmD, MSPH2, Guilherme Del Fiol, MS, PhD2, Sidney N. Thornton, PhD1,2, Mollie Cummins, PhD, RN, FAAN2
1Intermountain Healthcare, Murray, UT; 2University of Utah, Salt Lake City, UT;

Introduction
Poison control centers (PCCs) routinely collaborate with emergency departments (EDs) to provide care for patients exposed to poisoning. However, PCCs and EDs use disparate information systems, communicate using a telephone-based process and do not routinely share data electronically1. Electronic health information exchange (HIE) has the potential to improve the current process by enabling appropriate and timely routing of information, shared documentation for patients, and addressing ambiguity through exchange of standardized documents. Patient identity matching is both a crucial first step and a known barrier in HIE2. Automated patient identity matching based on demographic data collected by PCCs is the optimal workflow. However, the completeness and validity of PCC data for the purpose of patient identity matching is unknown. The objective of this project is to determine the feasibility of automated patient identity matching between the Utah Poison Control Center (UPCC) and Intermountain Healthcare EDs.

Method
We performed Cross-Community Patient Discovery (XCPD) transactions for successful PCC referrals to Intermountain Healthcare EDs across the State of Utah, that occurred in the year 2015 (n=1154), in order to determine the extent of successful patient identity matching between UPCC and the EMR at the EDs. In a successful PCC referral to an ED, the PCC recommends that a patient go to the ED for further medical evaluation and treatment, and the patient complies with that recommendation. Therefore, all cases in the sample involved patients known to Intermountain Healthcare. We calculated the number and percentage of cases with a successful XCPD match, and conducted a manual review of the dataset with unsuccessful match, to determine the cause.

Results and Discussion
The patient attributes currently captured in ToxiCALL® result in only 7% of the patients matching between the UPCC and the EMR at the EDs. Manual review of the dataset revealed that the addresses included the city, state and zip code and did not include the street address for 100% of the cases. Patient date of birth (DOB) was captured for 305 (26.64%) records only. The phone number was captured for the caller and not the patient for the entire dataset. While it is likely that the phone number of the caller matches that of the patient in a subset of the cases, it is unlikely that it matches for all cases. All of the matched records included the patient DOB. We concluded that the primary reasons for a low match rate included: 1) missing DOB; 2) incomplete address; and 3) phone number captured for the caller (instead of the patient). Going forward, the UPCC staff will be trained in an enhanced workflow where the distinguishable characteristics for a patient match, namely, patient DOB, address and phone number are captured consistently, in a standard format. We will re-assess the extent of successful patient identity matching after workflow modification, and a deferred patient linkage process will be used to resolve patient identities for the exceptional cases in which automated patient identity matching is not successful.

Conclusion
Data quality of patient demographics at the intake of poisoning cases is critical to patient identity matching between PCCs and EMRs at the EDs. Low patient identity match rates can be remedied by improved workflow and training to capture the distinguishable characteristics for a patient match. Analyzing HIE barriers and facilitators at design time while connecting heterogeneous systems not designed for HIE, can improve feasibility and efficiency of HIE.

Detecting Anomalies in Alert Firing in Clinical Decision Support (CDS) Systems using Anomaly/Outlier Detection Techniques

Soumi Ray, PhD¹, Dustin McEvoy, BS², Jan Marie Andersen, MS², Adam Wright, PhD²
¹Northeastern University, Boston, MA; ²Brigham and Women’s Hospital, Boston, MA

Introduction
Anomaly detection techniques are commonly used in many different domains such as credit card fraud, data/network security, and meteorology. CDS systems which facilitate clinicians in their decision making process suffer from malfunctioning alerts which often go undetected for months or even years before being recognized. We propose the application of two algorithms for detection of anomalous triggering of alerts within CDS.

Method
Anomalies can be generally classified into two classes: point and breakout anomaly. Point anomaly refers to a sudden spike or drop in time series. Breakout is characterized by two steady states and an intermediate transition period. Point anomalies can be detected using the Seasonal Hybrid Extreme Studentized Deviate algorithm (S-H-ESD)¹. This algorithm approximates the underlying trend in a long-term time series using a piecewise median method. Breakout anomalies can be detected using a novel statistical technique, called E-Divisive with Median (EDM)². Alerts originating from Brigham and Women’s electronic health records are used in this study. Point anomaly detection was applied to alerts originating from patients with coronary artery disease who were not on aspirin (a deviation from US Preventive Services Task Force recommendation). Breakout detection was applied to alerts originating from immunocompromised adults <65 years old who did not receive Pneumococcal Conjugate Vaccine (PCV) according to existing guidelines.

Result
Figure1(a) shows the point anomalies detected by S-H-ESD, which start around 23rd May 2012. These anomalies were identified and validated as a malfunction in the drug classification service, which caused the rule to fire for all patients with CAD even if they were already taking Aspirin. In Figure1(b) the red dotted lines denote the start time of breakouts detected by the EDM and the ordinates correspond to the approximate mean of the previous window. We compute the pairwise p-value using Wilcoxon test shown in blue above the red dotted line, which gives an estimate of the magnitude of the shift at that corresponding timestamp based on data in the time intervals (determined by start times of breakouts) immediately preceding and succeeding that breakout time. During the first mean-shift around 22nd July 2015, a change was noticed in PCV alert firing. Changes in the rule designed to fire PCV alert even for patients already vaccinated, could potentially explain this breakout.

Conclusion
We used two novel anomaly detection algorithms on alert firing data and preliminary results show that they are able to detect the approximate dates of anomalous alert triggers which correspond to known CDS system malfunctions. These algorithms could aid early detection, but further testing on other CDS alerts is needed for validation.

Utilization of Cost Effective Tools for Queries on Healthcare System Stress

Taylor Read MS\textsuperscript{1}, Elizabeth White\textsuperscript{1}, Neelima Karipineni MD, MMSc\textsuperscript{1,2,3}, Maksim Ignatov\textsuperscript{1}, Mahesh Shanmugam\textsuperscript{1}, Beatriz Rocha MD, PhD\textsuperscript{1,2,3}, J Perren Cobb MD\textsuperscript{4}, Saverio Maviglia MD, MS\textsuperscript{1,2,3}, Roberto Rocha MD, PhD\textsuperscript{1,2,3}, Sarah Collins RN, PhD\textsuperscript{1,2,3}

\textsuperscript{1}Brigham and Women’s Hospital, Boston, MA; \textsuperscript{2}Harvard Medical School, Boston, MA; \textsuperscript{3}Partners Healthcare System, Wellesley, MA; \textsuperscript{4}University of Southern California, Los Angeles, CA

Introduction
National preparedness efforts for public health emergencies are important in order to address challenges to healthcare and communications systems. The United States Critical Illness and Injury Trials Program for Emergency Preparedness, in partnership with the Office of the Assistant Secretary for Preparedness and Response, aims to increase the capacity for multi-site, prospective data collection during emergent events. Success is dependent on the management of large participant lists using widely-available and open-source software including REDCap and an analytics platform. We implement these technologies for queries on healthcare system stress across the U.S. Our specific aim is to configure open-source tools for complete and rapid data collection and reporting of system stress.

Methods
REDCap is a secure, web based data collection application used to build and manage online surveys, which can be sent to participants by email, and data collection instruments, which require a REDCap user account\textsuperscript{1}. Piwik is an open-source web analytics platform that provides weekly reports on REDCap usage. We defined specific requirements for our project and how we intended to use the open-source software solutions. These requirements were evaluated against the existing feature in each open-source tool and we reached out to user-communities to better understand existing solutions and configurations, as needed. In the instances that the open-source tools could not achieve our specific requirements we leveraged open APIs to configure our own solution. The infrastructure is developed to meet requirements for rapid content configuration and deployment to a large database of participants within 24 hours. A tool that meets these requirements could be used for non-emergent events as well.

Results
The query on healthcare system stress was designed as a REDCap survey and 354 participants’ names, emails, unique identifiers, and responses were managed via the Participant List REDCap feature. By inputting a unique identifier we were able to pre-populate survey responses using information participants provided previously, track participants’ responses, and send reminder emails (see Figure 1). We sent 289 automated reminder emails to participants who had yet to respond and observed an increased rate of responses per hour: 4 responses per hour compared to 1 response per hour prior to reminders being sent. We identified the requirement to represent geographical distribution of participants visually and developed a geographical visualization tool integrated with REDCap. The visualization tool uses real-time data and overlays responses with population density maps and creates the 3 color-coded maps necessary to represent participation. The analytics platform was used to track website visits (n = 178) and length of each visit (average 498 seconds). We additionally collected data on participant actions performed, participant city, device type, and Internet browser.

Conclusion
We successfully fulfilled all of our project requirements except for an ideal solution to pre-populate fields using demographic participant list data. Our REDCap survey configuration is limited to surveys and requires a consistent participant identifier across all projects on a server. More configurations are necessary to find an efficient way of pre-populating additional field types, not limited to text boxes, at the project level instead of at the server level. In comparison we were able to easily find open source tools that we could configure for our usage analytic needs.

Improving Pain Assessment in Medical Intensive Care Unit Through Natural Language Processing

Douglas Redd, PhD¹,²,⁵, Cynthia Brandt, MD, MPH,³,⁴, Kathleen Akgün, MD, MS³,⁴, Jinqiu Kuang, MS¹,⁵, Qing Zeng-Treitler, PhD¹,²
¹VA Salt Lake City Health Care System; ²Medical Informatics Center, George Washington University; ³Department of Medicine, Section of General Internal Medicine, VA Connecticut Healthcare System; ⁴Department of Medicine, Section of General Internal Medicine, Yale University School of Medicine, New Haven, Connecticut; ⁵Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah

Introduction
Medical intensive care unit (MICU) admissions are increasing for older adults, especially towards the end of life (EOL). Among MICU patients with a high risk of death, pain is reported by up to 80% of patients and is often moderate to severe in intensity. Inadequate symptom management is consistently identified as an area for improvement amongst MICU survivors as well as family members.

Sensitive, validated tools for measuring pain are readily available for use in the MICU. These tools can be used to enter pain assessments into the electronic health record (EHR) as structured or unstructured data. Inpatient pain assessments are routinely entered as unstructured data. Development of future interventions to improve the quality of pain assessment and management depends on developing an accurate approach to extracting pain assessments from unstructured MICU data. We are developing a pain score extractor for this purpose.

Background
As is common practice, pain assessment in our collection of MICU data is measured on a scale of 0 to 10. In this collection, however, an extra code of 99 is included to indicate that a score could not be obtained (e.g. when a patient is unable to respond). A commonly used method for information extraction of this type of data is the use of regular expressions. Creation and maintenance of collections of regular expressions can be cumbersome and brittle, and requires specialized knowledge of the regular expression language. For this reason, we employ the Regular Expression Discovery for Extraction (REDEX) algorithm, a supervised learning algorithm for automated discovery of regular expressions. This approach has been used successfully in other studies for extracting temporal expressions, body weight, and METs values.

Methods
Documents containing the keywords “pain” and “score” were retrieved using the Voogo application within the VA Informatics and Computing Infrastructure (VINCI) system. These documents were split into snippets (the matched keyword and the surrounding context), resulting in 3862 snippets. These snippets were human annotated to indicate pain scores. A REDEx model was trained using these snippets, with precision .90, recall 0.94, specificity 0.90, f-measure 0.92, and accuracy 0.92. This model was then applied to a random sample of 1000 MICU unstructured documents from an approximation of the VA Musculoskeletal Diagnosis (MSD) cohort. Pain scores were extracted from these documents using the REDEx model. Pain scores were also queried from structured data for the same patients and the same date as the unstructured documents for comparison.

Results & Discussion
815 pain scores were extracted from the unstructured data, while 4063 pain scores were available from structured data for the same MICU patients at the same time. This represents a 20% increase in the number of pain score observations over structured data alone. This demonstrates that the range and representation of pain scores can be substantially increased by including those extracted from unstructured notes in the development of future interventions.
Event Coreference in Support of Temporal Reasoning in Mental Health Notes

Introduction: As part of the development of an NLP engine to assist with clinical reasoning among mental health documents of patients in care for post-traumatic stress disorder (PTSD), we tested the hypothesis that conceptual relatedness between events mentioned in narrative documents can be used to recognize mentions referring to the same event. For example, the mention “sudden anxiety” occurring in one document of a patient may be a reference to the event described as “panic attack” in another document. The circumstances under which such pairs do and do not have the same referent are examined in this work. Establishing co-reference between event mentions within a single document, or across documents of a given patient is a central method within the temporal reasoning NLP pipeline, MedTARSQI developed for this project. Merging event information between co-referring event mentions provides opportunity to assign more precise temporal information to all instances of the same event, and to other event members of temporal relations (e.g., BEFORE E2) within an event sequence. With each iteration of event-merging between co-referring event mentions, and consequent temporal relation assignment along each event sequence, a greater number of events can be anchored by temporal values. This in turn results in a decrease in interval lengths that constrain the temporal interpretation of events within a sequence that are not anchored by temporal values. That is, we have a more precise temporal interpretation of Event, in the relation [E1 BEFORE E2] if we know that Event1 occurred at a given time-date. This submission lays the groundwork for identifying co-referring events as candidates for merging temporal information of distinct event mentions.

Methods: From a cohort of over 3,000 veterans receiving care for PTSD, we selected a random set of 58 patients having at least 3 mental health narrative notes. A corpus of 368 mental healthcare notes from this selection was used to conduct an event co-reference detection test. To detect events in the corpus, we ran YTEX, a searchable database tool underwritten by the NLP engine cTAKES. We filtered the terms detected by YTEX by matching to spans of text that were annotated for PTSD symptoms and treatments. The database functionality of YTEX was used to group event mentions within each patient dataset by the concept code within the UMLS that each mapped to. Within each patient dataset, terms recognized by YTEX which mapped to the same concept code, or a daughter concept code were placed in a “synonym set” as coreference candidates. These terms were then assigned an event profile feature set composed of an event classification, an association with a temporal expression, and an event domain. Event pairs within each synonym set were determined to be co-referent if and only if their event profiles contained the same values for each feature; otherwise, the pair was determined non-referent. We compared the co-referent/ non-referent assignment of each pair in the synonym sets for 12 patients in the study sample against human review of the sets.

Results: YTEX identified a total of 6,820 token strings, mapping to 154,017 possible concepts from the mental healthcare note corpus (368 notes). Forty-eight patient datasets had terms forming synonym sets, with a total of 5,736 concepts determined to be events. Pairs of events from 12 patient datasets were reviewed as referent or not co-referent and compared against the assignment of synonym-set-with-constraints, with a rate of 74.2% agreement, where agreement is a binary measure for each event pair presented: co-referent or not co-referent.

Discussion: In conducting the human review of candidate event pairs, we spotted pairs that were wrongly determined to be co-referring by the features in the event profile. One error type stemmed from the failure to distinguish hypothetical from experienced events; another resulted from events with distinct participants, as occurring with trauma exposure caused by witnessing as opposed to experiencing. These error types could be corrected with a finer-grained event classification system.

Limitations: The cohort was selected by numbers of notes, rather than distributing across a demographically representative group. This study does not account for the proportion of event pairs that were not recognized as possible coreferences (False Negative pairs) where one member of the pair was not identified as an event.

Conclusion: Using event recognition and conceptual relatedness among event terms can reliably determine coreference relations with a small set of features to constrain the assignment. This aids in achieving event sequentialization among narrative notes.

**Pediatric Inpatient Burden and Comorbidities of Bullous Pemphigoid in the United States**

Ziyou Ren, BS¹,², Jonathan I. Silverberg, MD, PhD, MPH¹

¹ Department of Dermatology, Northwestern University Feinberg School of Medicine, Chicago, IL 60611; ² The Graduate School, Northwestern University, Chicago, IL 60611.

**Introduction**

Bullous pemphigoid (BP) is an autoimmune blistering disorder associated with substantial morbidity. The incidence and prevalence of BP have been reported to be between 0.2 and 3 per 100,000 person years.¹ Previous studies showed that BP was more common in older age groups and associated with female sex.²,³ Analyses based on National Inpatient Data showed that patients with a primary (mean ± std error: 75.9±0.3 yr) diagnosis of BP were significantly older than those without a diagnosis of BP (57.0±0.1 yr); 87.7% of with a primary diagnosis of BP were age 60 years or older. Therefore, few large-scale epidemiological studies have examined risk factors for BP for the pediatric patients. We hypothesized that pediatric patients with BP would have higher rates of comorbid neurologic disorders, as well as autoimmune, infectious and cardiovascular disorders than adults patients. We further hypothesized that the combined disability of BP and associated comorbidities would contribute towards higher rates of hospitalization in pediatric patients with BP compared to those without BP.

**Method**

The 2002 – 2012 Nationwide Inpatient Sample (NIS) provided by the Healthcare Cost and Utilization Project (HCUP) from the Agency for Healthcare Research and Quality (AHRQ) was analyzed. The databases were searched for a primary and/or secondary diagnosis of BP using ICD-9-CM codes and were categorized by age. Univariate and multivariate linear regression and logistic models were constructed to analyze the risk factors and comorbid disorder association.

**Result**

The total incident rates of BP were 16 for primary and 20 for secondary diagnosis of BP out of 13 million pediatric patients. We found that social conditions as well as hospital conditions were significantly associated with pediatric patients with BP. Pediatric patients in a teaching hospital would have a (odds ratios [95% confident interval] 6.2[1.3-30.0]) higher risk of BP than those not. Furthermore, they would have a 0.2[0.07-0.5] lower risk of BP if they came from lower income family than higher income family. For comorbidity profile, pediatric patients with 2-5 and more than 6 chronic diseases experienced 13.5[5.9-31.0] and 40.2 [13.1-123.5] times more hazard than patients with 0-1 chronic diseases. Out of 130 comorbidities tested, 20 showed significant associations with BP in pediatric patients. Specifically, pediatric patients would be exposed to a higher risk with hypertension 63.4[14.6-275.4], deficiency anemias 17.1[7.2-40.5] and bacterial infection 14.5[6.1-34.5].

**Conclusion**

There appeared to be economic and healthcare disparities with respect to BP, such that pediatric patients from rich family appeared to have higher odds of hospitalization of BP in teaching hospitals. Furthermore, pediatric patients with BP experienced much higher risks of autoimmune, infectious and cardiovascular comorbidities than both pediatric patients without BP and adult patients with BP.

*Corresponding author: iychoi@catholic.ac.kr

Backgrounds and aims: The number of Smartphone users is increasing in worldwide and 40 million people (78.6%) have Smartphone in South Korea. The explosive usage of Smartphone leads negative results such as Smartphone addiction. This study aims to explore the feasibility of screening and diagnosis of pathological Smartphone use and addiction using mobile technology.

Methods: We developed smart healthcare platform for Smartphone addiction patients (MindsCare system). The MindsCare system was developed to gain Smartphone use pattern to prevent excessive use. It was developed using open source software and calculated time of usage and data for power consumption including Central Processing Unit (CPU), Wireless fidelity (Wi-Fi)/Cellular data, and Liquid Crystal Display (LCD). We collected data from 24 people who agreed to participate in the experiments. They were allocated to the addiction group and control group by using Korean Smartphone addiction proneness scale for adults. We collected time spent for smart phone applications for four weeks and analyzed the Smartphone use pattern by application categories.

Results: Average Smartphone usage time is 3.5 hours for addiction group and 1.3 hours for control group. The mostly used application category for addiction group and control group is Social Network Service (SNS), entertainment, game and web browser. The daily average time for SNS is different as 33 minutes for addiction group and 19.6 minutes for control group. Entertainment is 13.5 minutes for addiction group and 9.7 minutes for control group.

Conclusions: The mobile application system is useful for screening and diagnosis of pathological Smartphone use and addiction. Further development and research will be conducted to improve the effectiveness of the mobile application system.
PubMed ‘Early Alerts’: Towards Better Precision of Literature Searching for Pharmacovigilance Information Based on an Assessment of Relevance Feedback

Anna Ripple, MLS¹; Alfred Sorbello, DO, MPH²; Shahrukh Haider, DDS, MPH²; Olivier Bodenreider MD, PhD¹

¹Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, 8600 Rockville Pike, Bethesda, MD 20894, USA; ²US Food and Drug Administration, Center for Drug Evaluation and Research, 10903 New Hampshire Avenue, Silver Spring, MD 20993, USA

**Background:** The PubMed ‘Early Alerts’ provide FDA regulatory reviewers with weekly topical searches of the most recently submitted citations to PubMed/MEDLINE to support prospective detection of emerging adverse drug events for specific drugs. We seek to increase the precision of electronic searching based on an assessment of relevance feedback for a subset of retrieved citations for the antidiabetic medications.

**Methods:** Using a search query optimized for recall and focusing on the titles, abstracts, and keywords, four regulatory evaluators assessed 30 citations each for relevance to drug safety and efficacy drawn from a random sample of 120 of the most recently deposited reports (i.e., not yet indexed). Candidate precision terms were identified by significant word frequency analysis (excluding stopwords) using Word Counter Tool, a free online word counter. We performed a differential frequency analysis of text word occurrences for the relevant compared to non-relevant citations.

**Results:** Based on reviewers’ feedback, half of the reports in the 120 citation random sample were assessed as relevant to safety, efficacy, or both safety and efficacy, whereas the remainder were considered non-relevant for both safety and efficacy. The candidate precision words ‘efficacy’, ‘safety’, ‘adverse’, and ‘risk’ were identified by expert opinion from the titles or abstracts of the relevant citations among frequently occurring words (see Table 1 below). The text words ‘efficacy’, ‘safety’, and ‘risk’ had no title occurrences in the non-relevant citations. However, ‘risk’ and ‘safety’ are not discriminant, because they also occurred in the abstracts of non-relevant citations, leaving ‘adverse’ as the only candidate precision word derived from the abstract field. Analysis of the keywords field did not yield any candidate precision text words.

</table>

**Conclusions:** We identified several candidate text words to potentially increase the precision of our literature search strategy for pharmacovigilance information, but further validation is required. Small citation sample size and restriction to only the title, abstract, and keywords fields may have contributed to the limited capacity to identify such candidate precision words. Future research is planned involving a larger group of citations, a broader set of drugs and the application of more sophisticated analytical techniques such as term frequency-inverse document frequency to detect text words that may enhance the precision of the PubMed ‘Early Alerts’ as a tool to complement other ongoing pharmacovigilance activities at FDA.

Use of a market segmentation method to validate user types of SHUTi, an Internet-delivered intervention for insomnia.

Authors:, Ritterband, L, PhD¹, Sturz, V, MS², Chow. P., PhD³, Lord, H., MS¹, Thorndike, F., PhD¹, Cohn, W, PhD².

¹Dept. of Psychiatry and Neurobehavioral Sciences, Center for Behavioral Health & Technology
²Dept. of Public Health Sciences
University of Virginia, Charlottesville, Virginia

Background: Given increased barriers to accessing health care, Internet-delivered interventions have increasingly become an option in the delivery of health services, particularly in behavioral health. Hundreds of these web-based treatment programs exist in various stages of development, evaluation, commercialization, or implementation. These interventions are typically defined as self-guided, tailored, interactive, and engaging interventions modeled after effective face-to-face treatments but provided via the Internet. Unfortunately, most commercially available programs have little scientific basis or empirical validity, and even fewer have been evaluated to understand who might be best served by this type of approach.

Methodology: This is the first study to use the Tailored Educational Approaches for Consumer Health (TEACH) model¹ to segment users of an Internet intervention for insomnia (Sleep Healthy Using The Internet or SHUTi)² based on users’ personal characteristics and preferences for health information. Participants were administered the TEACH measure at baseline as part of a large RCT testing the efficacy of the insomnia intervention in comparison to online patient education in a population seeking help online for chronic insomnia. The TEACH measure was given to determine each participant’s strongest affiliation with one of the eight previously validated segments

Evaluation Results: SHUTi participants (n=151) were primarily affiliated with two segments, Segment 4: “Unhealthy, Ask-the-doctor” (72.2%) and Segment 1: “Health Conscious, Browsers” (20.5%). Very few participants were categorized as affiliated with the other segments (7.3%). Segment 4 is characterized as needing information that is credible, available via a healthcare provider and requiring less reading. Segment 1 is characterized as needing information delivered by the Internet provided at a higher reading level and comprehensively. Both of these segments are reasonably expected to seek out and engage in health interventions, including online interventions. As reported previously, participants achieved substantial clinical health benefit³ suggesting that Segments 1 and 4 can benefit from an Internet-delivered intervention.

Conclusions: This data confirms that there are certain types of people who seek out and engage in self-help digital health interventions more often than other user types. In conjunction with previously presented outcome data³, this data highlights that these types of users can perform well in an online health intervention, but future research needs to evaluate both how to better recruit individuals who fall in other segments and are thus under-represented as well as how to adapt interventions to meet a diverse set of users. Finally, new research must test whether individuals in other segments, once recruited, can achieve the same health benefits as their peers in Segments 1 and 4, or whether only certain segments do well with digital health interventions.

Improving Inclusion of Comparison Studies in Radiology Interpretations

Catherine C. Roberts, M.D.¹, Shirley A. Loprino, R.T.(R)¹, Elaine M. Comstock, R.T.(R)(CT)¹
¹Mayo Clinic, Scottsdale, AZ

Introduction
A comprehensive satisfaction survey of physicians that refer patients for imaging at our institution revealed an opportunity for improvement regarding the use of prior comparison studies in the interpretation of new studies. This feedback about the suboptimal use of comparison studies was received for all radiology subspecialties in our practice (ex. neuroradiology, chest radiology). Comparing with prior imaging is a very useful adjunct in assessing the chronicity of imaging findings and thus limiting the provided differential diagnosis. This has a direct impact on patient care since broad differential diagnoses, as well as indeterminate findings, typically warrant additional imaging or clinical investigation, some of which may be avoided. Failing to compare radiological studies to prior studies can cause unneeded procedures and additional imaging for patients, exposes the institution to legal risk, and can delay appropriate patient care.

Methods
The target was to have > 80% of radiology interpretations at our institution either compare to a prior study when available or document that there were no prior studies for comparison. This was an arbitrary goal that left opportunity for physician discretion to not compare if they did not feel it would add value. The radiology imaging electronic medical record was searched using the Softek Illuminate InSite program to establish the rate of documentation of comparison studies in all types of radiology reports. All radiology reports in the designated time period were searched for containing any form of the word compare (comparison, comparisons, compare, compared, compares), prior(s), change or since. Reports using the word “since” were manually reviewed to confirm that the word was used in reference to comparing with a prior exam.

Results
At baseline, 63% (13,421 out of 21,216) of radiology reports generated in a single month included some reference to a prior study. The denominator was the number of reports containing the trigger words. There were no false positives. Numerous factors contributing to the gap in quality of care were identified and addressed. Four Plan-Do-Study-Act (PDSA) quality improvement cycles were undertaken that implemented a number of changes, which included alterations in workflow, automated image retrieval, and generation of voice recognition software templates. Of note, the first intervention of simply informing the different radiology divisions of their performance was entirely unsuccessful in producing change. After the fourth PDSA cycle, compliance increased to 84.7% (14,638/17,273).

Since searching for, retrieving, and reviewing prior studies takes time to complete, our countermeasure was that our report turnaround time (time from images available to report finalized) would not increase by more than 10%. Having radiology reports rapidly available to referring physician is a high satisfier for the referring physicians and is, of course, very important for timely patient care. We found no significant change (p-value = 0.71) between the average report turnaround times at baseline (129 minutes) and at the completion of the project (115 minutes), indicating no adverse effect of the project interventions to increase the use of comparison radiographic studies in interpretations.

Conclusion
Our radiologists have a tremendous amount of pride in their work. It can be difficult to ask people to change, since this is often taken as a criticism regarding their prior work. It is of utmost importance to approach changes such as these with a receptive customer-centered attitude. A combination of behavioral and technologic changes in workflow led to a successful project to improve the quality of our patient care.
Developing Standards for Usability in Electronic Health Records: Challenges and Opportunities

Mitra A. Rocca, Dipl. Inform. Med1, Rebecca Meehan, Ph.D.2, John Ritter, MSc.3, Gary Dickinson4, Kandace Kelly5, Lauralee Barrett6, Ethan Budreau7, Constance Johnson8, Ph.D., FAAN

1Food and Drug Administration, Silver Spring, MD; 2Kent State University, Kent, OH; 3Health Level Seven, Ann Harbor, Michigan; 4CentriHealth, Los Angeles, CA; 5 6 7EPIC, Verona, WI; 8Duke University, Durham, NC

Abstract

The Health Level Seven (HL7) Electronic Health Record System (EHR-S) usability project is an ambitious collaborative effort that addresses the importance of usability in EHR-S and the challenges of developing standards. The goal of this project is to translate existing, well established usability guidelines and health information management principles into functional criteria for EHR-S.

Introduction

Views of what usability is, and how to improve EHR usability vary across stakeholder groups. Usability is defined as how useful, usable, and satisfying a system is for the intended users to accomplish goals in the work domain by performing certain sequences of tasks1. There have been many advances made to improve EHR usability, yet, they are often implemented in silos or shared in a fragmented way, preventing feedback from different stakeholders. This poster will present the collaborative effort of the HL7 EHR-S Usability work group to highlight the importance of EHR usability standards, the process of developing standards to improve EHR usability and the approach for implementation. The HL7 EHR-S Usability workgroup focuses on translating existing, well established usability guidelines and health information management principles into functional criteria complete and develop two functional profiles: 1. User Centered Design Functional Profile 2. Systems Usability Design.

Methods

EHR usability is one of the most important issues influencing safety outcomes of patients in today’s healthcare environment. In order to achieve the project goals, the work group:

1) Conducted an environmental scan by reviewing the literature and government agencies guidelines (e.g. NISTR 78042, ONC SHARP-C3, HIMSS EHR Usability Taskforce4).
2) Using the NISTIR 7804 report as a basic guide, the workgroup compared the heuristics already developed to determine any missing heuristics within the NISTIR 7804.
3) Developed the EHR usability heuristics and framework that can result in an EHR-S Usability functional profile complete with functions, conformance criteria and examples for the HL7 balloting process.

Results

The work group members addressed the comments resulted from the HL7 ballot process and plan to ballot the revised EHR usability functional profile as an informative ballot in the HL7 September 2016 ballot cycle.

Conclusion

Usability standards need to be a critical aspect of EHR user interface design to ensure that healthcare providers can use these systems in an effective, efficient, safe and satisfying manner.

Future Plans

The HL7 EHR-S Usability work group aims at providing the developed standard for accrediting EHR systems.

Are Boston Healthcare Center Websites Linguistically Accessible?

Jorge A. Rodriguez, MD, Sanja Percac-Lima, MD, PhD
Massachusetts General Hospital, 55 Fruit St., Boston, MA 02114

Introduction
The Internet has become a significant source of health information, with nearly 87% of Americans having access to the Internet1. The availability of linguistically appropriate content is critical to providing patients with access to health information. While accessible health content is important for English-speaking patients, it becomes paramount for Limited English Proficient (LEP) patients. Much like the health disparities among racial, educational, and economical lines, language disparities have been associated with negative health outcomes2. The LEP population is growing, with 20% of the US population speaking a language other than English at home and 8.6% defined as being LEP. In Boston, 12% of the population is LEP3. Furthermore, homepages are the online face of healthcare centers and access points for all patients4. Thus, with this context in mind, we sought to evaluate the language accessibility of healthcare center websites in Boston.

Methods
We reviewed the homepages of Boston hospitals and community healthcare centers to identify if there was an option to translate the homepage, and if so, the type of translation method provided and the number of available languages. We categorized the translations as automated (i.e. Google Translate), single translated homepage, and entire separate translated website. After we categorized each health center, we mapped their translation capacity to the percent LEP population in their neighborhood.

Results
We reviewed 45 homepages, 20 of which were hospital websites and 25 were community health center websites. Only 44% of homepages had a translation option available. When we looked at the type of translation methods, we found that 60% of the homepages had automated translation services, primarily Google translate, 15% had a single translated homepage in specific languages, and only the Dana-Farber had a separate translated website in Spanish. The number of available languages ranged from 1 to 83. Among the 10 neighborhoods with >33% LEP population, only 50% of the healthcare centers had a translation option available.

Conclusion
Hospital websites serve as access points for the communities they serve. However, despite the linguistic diversity of Boston neighborhoods, many of the hospitals and community centers do not provide translated versions of their websites. With the shift of health information to the Internet, the inability to access healthcare center websites serves to further extend health disparities that already exist for LEP patients. We plan on extending this type of review to the state of MA and other major cities in the US.

Towards automatic discovery of Genes related to Human Placenta

Laritza M. Rodriguez, MD, PhD, Stephanie M. Morrison, MPH, Kathleen Greenberg, PhD, Dina Demner Fushman, MD, PhD

Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction

The human placenta is the most important organ in human pregnancy. Its functionality influences maternal and fetal health and development and impacts future health for both mother and baby1. With the advancement of genetic and molecular sciences, it has become possible to study placental biology during pregnancy.

Discovery of gene pathways and biochemical mechanisms that help explain disease causality can be facilitated by automated extraction of relevant information from the biomedical literature2. One essential step in understanding complex pathways has been the compilation of disease-specific gene candidates extracted from the literature. Data analysis then makes it possible to create candidate gene assays and translate the results to the wet bench for biochemical research.

Our goal is to extract genes, gene pathways, biomarkers, and related events from the human placenta literature to create a specialized human placenta gene repository, and to identify pathways that can uncover target genes and gene therapies for pregnancy-related diseases. Here we present the first phase of the study: extraction of gene mentions from text.

Methods

The document collection was retrieved from PubMed® using search filters and the following search terms: placenta, gene, biomarker, polymorphism, enzyme, preeclampsia, hypertension, diabetes, growth restriction. The tailored search returned 428 papers. To identify specific gene mentions from titles and abstracts we used the NLM MetaMap 20143 restricting processing to semantic type Gene. We then manually classified the extracted gene names into: 1) specific gene mentions (e.g. CDKN1A), 2) general genetic terms (e.g. Growth Factor Gene), and 3) errors (e.g. PREECLAMPSIA, SUSCEPTIBILITY TO).

Results

In the 428 retrieved abstracts, MetaMap identified 413 with Gene mentions. Overall, MetaMap identified 826 distinct gene names in titles and abstracts in the collection. Of these, we classified 753 as specific gene mentions, 71 as general genetic terms, and 2 as errors. Examples of the most frequent mentions by type are: Specific Gene: NLRP5 gene (178), NCR3 wt allele (83), CD8A wt allele (83), CD69 wt allele (71), PGF gene (26), LEP gene (18); General genetic terms: Genes (246), Alleles (51), Genome (37), Human gene (34); Errors: Genes, vif (50), PREECLAMPSIA, SUSCEPTIBILITY TO (2).

Conclusions

Our preliminary analysis shows that the placenta literature contains enough specific gene mentions to warrant further text mining on the genes of interest to identify pathways, biomarkers, and relationships between placenta gene expression and maternal and/or fetal diseases, ultimately identifying predictors of diseases that may clinically manifest only later in life.

Family History by Other Names: A Preliminary Comparison of Structured and Free-Text Sources in the Electronic Health Record

Paul T. Rosenau, MD, MS¹, Diantha B. Howard MA, MS¹, Genevieve B. Melton, MD, PhD², Elizabeth S. Chen, PhD³
¹University of Vermont College of Medicine, Burlington, VT; ²University of Minnesota, Minneapolis, MN; ³Brown University, Providence, RI

Introduction

Family history (FH) data documented in electronic health record (EHR) systems have the potential to inform studies of heritable determinants of health and disease. A unique aspect of pediatric documentation is its common reference to birth history, a potentially rich source of maternal FH data¹. We sought to characterize structured and free-text sources of FH data in the enterprise EHR used at the University of Vermont Children’s Hospital (Epic Systems Corporation, Verona, WI) with respect to variability and redundancy of FH documentation.

Methods

We compared FH data from two sources: 1) the FH section of the History ‘Activity’ (“FH Activity”), a set of updatable, structured fields accessible from a variety of clinical contexts, and 2) free-text History and Physical (H&P) notes that document inpatient admissions. Records of patients born January-March 2010 who were admitted to the hospital at least three times before their fifth birthday were considered eligible. FH data were manually abstracted from all H&P notes signed by an attending physician within 48 hours of admission into pairs of discrete observations (e.g., presence of a disease) about family member relations. Observation-relation pairs, or “statements”, were compared to the FH Activity data with respect to novelty; concept granularity; and frequency of relations and clinical topics referenced by the statements. The relative novelty of statements were scored in terms of their granularity (general vs. specific), scope (inclusion or absence of associated attributes), and semantic vs. syntactic equivalence. Patient-specific statements were compared across encounters and against FH Activity data available at the time of the patient’s last hospital encounter. Statements were scored as partially-novel if they differed from all other patient-specific statements and FH Activity data by at least one dimension and this difference produced a net increase in granularity or scope specification.

Results

Fourteen patients met inclusion criteria, contributing twelve sets of FH Activity data and 68 notes from 53 hospital admissions. FH Activities and H&P notes contained 50 FH entries and 459 statements, respectively. All notes contained statements except for four of the five surgical H&P notes. Frequency of statements varied by hospital unit. Admissions to the neonatal intensive care unit (NICU) generated by far the highest number of statements per patient admission (13.1±7.3.), a result of note duplication. The proportion of partial novelty ranged from 84% in the newborn nursery (NN), to 19% in the pediatric intensive care unit (PICU). The general topics covered by FH statements also varied by unit. For example, common PICU subjects were Cardiovascular (59.3%), Gastrointestinal (14.8%), Statements of Uncertainty (14.8%), and Infectious Disease (7.4%). In contrast, the top NN statements pertained to Infectious Disease (43.6%), Mental Health (14.1%), Hematological (11.5%), and Endocrine (9.0%). Female relations were noted to be much more frequent than males. For newborn admissions the female to male relations ratio was 72:1; for non-newborn admissions, this ratio was 1.4:1.

Discussion

In this small dataset, H&P notes contained unique FH data the frequency, novelty and subject of which varied by hospital unit. Birth history data found in birth admission notes were a particularly rich source of maternal FH. This study represents an initial step toward characterizing a pediatric FH dataset from a commercial EHR in an academic health center using a methods that may be generalizable to other EHR systems and institutions.

Acknowledgment: This work was supported in part by National Library of Medicine grant R01LM011364.

Patient Record Linkage Between Two Academic Health Centers

Mindy K. Ross, MD\(^1\), Douglas S. Bell, MD\(^1\)

\(^1\)University of California Los Angeles, Los Angeles, Ca USA

Introduction

Clinical research requires complete data on patient treatment and outcomes. However, many patients receive their care from multiple provider organizations and fragmentation of care can adversely impact research on this data. The Los Angeles Data Resource (LADR) is a growing regional collaborative of six health systems in Los Angeles, California that was created to facilitate multi-center clinical and comparative effectiveness research. In order to accurately identify patient cohorts for these applications, it is important to connect disjointed patient records between these healthcare systems.

Eventually, we aim to match patients across institutions utilizing private record linkage, which obviates the need to release patient-identifying information. An example of this is the application developed at Northwestern University, Distributed Common Identity for the Integration of Regional Health Data (DCIFIRHD)(1) using a “one-way hash” algorithm. The accuracy of private record linkage algorithms across systems can be measured by comparison with manually reviewed charts serving as the “gold standard.” However, manual review is resource demanding, which limits the population size for validation studies. The Epic Care Everywhere module imports records on a patient from other health care organizations if a matching patient can be identified at the other institution. We seek to assess the potential to use patient linkages created in Care Everywhere between the UCLA and Cedars-Sinai Health Systems as a gold standard for evaluating alternative private record linkage algorithms.

Methods

We conducted a preliminary exploration of the patient matching data available from the Epic Care Everywhere implementations at UCLA and Cedars-Sinai Health System. At Cedars-Sinai, Care Everywhere is configured to automatically query nearby institutions for patient matches at the time of patient appointments; at UCLA, Care Everywhere queries need to be explicitly triggered.

Results

From November 2014 until September 2015, there were 274,723 query attempts from Cedars-Sinai to UCLA. During this time period, there were 7,347 queries from UCLA to Cedars-Sinai. Queries from Cedars-Sinai to UCLA reveal 207,630 counts labeled as “unsuccessful” and 4,449 queries that were “unsuccessful” from UCLA to Cedars-Sinai. The reasons listed for “unsuccessful” queries are: no matching patients, multiple high threshold matches, multiple patient identification numbers assigned, multiple low threshold matches found, potential match found but patient has no clinical encounters, potential match found but the demographics match score was too low, patient missing Care Everywhere identification number, patient not participating in Care Everywhere, and query timed out.

Discussion

Patient match results generated by Care Everywhere include multiple indeterminate values. The underlying causes of indeterminate results need to be understood before Care Everywhere matches can serve as a gold standard for evaluating other patient linkage algorithms. The next steps are to determine how many of the queries are unique patient matches, manually review 500 patient queries from each institution, and determine the sensitivity and specificity of the Care Everywhere tool.

Conclusion

We will be able to determine if Epic Systems’s Care Everywhere tool can be used as a surrogate gold standard in place of manual patient query result review.

Confidence in Methodologies to Accurately Predict Risk Stratification in Primary Care Practices
Rachel L. Ross, BA, Bhavaya Sachdeva, MPH, Jesse H. Wagner, MA, Lindsey Watson, Jennifer Hall, MPH, David Cameron, Deborah J. Cohen, PhD, David A. Dorr, MD, MS Oregon Health & Science University, Portland, OR, USA

Introduction. Primary care risk stratification is a process where practices apply an algorithm to assign their patients into risk categories based on factors that may contribute to negative health outcomes. Risk stratification (RS) in primary care is crucial to improving outcomes of high-cost, high-needs patients, tailoring interventions for these patients, and controlling healthcare costs. This study will develop a maximum value/minimum complexity approach to RS using a mixed-methods approach. The qualitative arm includes an analysis of online survey responses and follow-up semi-structured interviews. This early analysis of the qualitative work sought to understand the impact of practice characteristics, especially sociotechnical framework elements, on perceptions of RS.

Methods. The survey included questions such as percentage of patients actively risk stratified, changes in RS methodology, type of approach, challenges, and 9 point Likert scale questions to assess success of RS implementation. From a subset of 79 practices that were invited to complete a survey, 65 individual survey responses were received. We assessed these for staff confidence in RS methodologies across practices varying in size, location, and ownership. Data were analyzed by coding as percent positive responses (7-9 on Likert scale) versus other responses, and differences tested by Fisher’s Exact Test. Then, 10 individuals representing 6 practices were interviewed regarding their RS approach. Transcripts were coded using Atlas.ti™ software as relevant themes emerged. Codes relating to the sociotechnical framework were identified, and we analyzed their relationships to other pertinent codes. Correlation coefficients (r) were calculated on how codes co-vary.

Results. As seen in Table 1, our Fisher’s Exact Test revealed that practices’ agreement with the RS scores generated by their algorithm differed significantly by practice ownership, with independent practices more confident, but not by size or location. Independently owned practices are more likely to agree with RS scores and have greater confidence than practices that are part of a system. An analysis of the transcript data demonstrated that quotes coded with “EHR/HIT” co-occurred most frequently with “Risk Stratification Workflow” (c=0.18), “Changing Approach” (c=0.1), and “Computer-based algorithms” (c=0.11). An example of a co-occurrence between “EHR/HIT” and “Risk Stratification Workflow” is the following excerpt: ”I think part of it is the technology. Part of it, on the provider’s side, is encouraging more standardization and approach for a particular group of people...when I came here...a number of these things weren’t fully developed. Though we have been tackling each of those issues since then, you know, human beings are involved so it’s a...[chuckles]...it can be quite a journey, I think, to get there.” Additional quotes, highlighting each co-occurrence, will be provided.

</tbody>
</table>

Conclusion. Practices may have more control over their RS process when they are not owned by a system, which could lead to greater agreement with their scoring. Interviewees revealed rich understanding of the complexity of workflow, approach, and technology, consistent with the sociotechnical framework. Further analysis is needed to elucidate the reason for the survey findings and interpret the impact of the co-occurrences found in the qualitative interviews.
Redesigning Chart Rounds in Radiation Oncology

Adam Rule, MS¹, Erin Gillespie, MD², Nadir Weibel, PhD¹, Todd Pawlikci, PhD²

¹Design Lab, UC San Diego, La Jolla, CA; ²School of Medicine, Department of Radiation Medicine and Applied Sciences, UC San Diego, La Jolla, CA

Introduction: Peer review is widely accepted as a useful and necessary form of quality assurance in radiation oncology [1] and many facilities conduct weekly, practice-wide chart rounds to collaboratively review treatment plans for all new patients. However, there is little evidence that current methods of peer review improve quality of care [2]. At a typical chart rounds meeting plans are discussed for an average of just 3 minutes [3], changed only 4-12% of the time [4], and are often reviewed after treatment has begun [5]. In short, chart rounds do not afford rapid and thorough peer review.

Redesigning Peer Review: To redesign peer review in radiation oncology, we assembled a team of radiation oncologists, physicists, and designers at UC San Diego for two half-day workshops. Participants used design thinking [6] to guide the workshops, which encourages thoroughly defining the problem before brainstorming and testing solutions. In the first workshop, participants identified four goals of peer review, mapped how peer review is currently conducted at UC San Diego based on experience and extensive observation, and consolidated observations into “How might we...” statements that captured key areas where peer review could be improved. During the second workshop, participants brainstormed solutions to these design prompts for further prototyping and testing.

Results: Four goals of peer review were identified including:

1. Quality assurance – ensuring patient safety by checking key quality measures of the treatment plan
2. Decision support – helping clinicians make decisions about complex patient cases
3. Education – training residents and senior clinicians on best practices and emerging treatments
4. Team building – fostering a work environment where errors are shared

Participants realized that weekly chart rounds did not provide sufficient time to review quality or appropriateness of all plans and that only certain cases where highly educational. Radiation oncologists at UC San Diego had already limited discussion of routine cases at chart rounds and sought out rapid decision support for difficult cases through mailing lists. Participants recognized these workarounds as an opportunity to provide multi-level peer review and document peer review occurring outside of chart rounds. Participants designed an email review system allowing oncologists to email a treatment plan to a peer for rapid quality checks and decision support. Highly complex or educational cases could then be flagged by the reviewing oncologist for presentation at the next chart rounds. This design seeks to provide peer review for all cases, reduce the time to review, and focus chart rounds meetings on the most profitable cases to discuss.

Leveraging the Electronic Health Record to Investigate Medication Safety Incidents

Alissa L. Russ, PhD\(^1\)\(^-\)\(^3\), Laura G. Militello, MA\(^4\), Peter A. Glassman, MBBS, MSc\(^5\), Karen J. Arthur, PharmD\(^3\), Alan J. Zillich, PharmD\(^1\)\(^,\)\(^2\), Michael Weiner, MD, MPH\(^1\)\(^,\)\(^3\)

\(^1\)Center for Health Information and Communication, Department of Veterans Affairs (VA), Health Services Research and Development Service and Regenstrief Institute, Inc., Indianapolis, IN; \(^2\)College of Pharmacy, Purdue University, West Lafayette, IN; \(^3\)Richard L. Roudebush VA Medical Center, Indianapolis, IN \(^4\)Applied Decision Science, Dayton, OH; \(^5\)VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA.

Introduction
To enhance our understanding of how prescribers and pharmacists recognize and resolve medication safety incidents, we developed a novel approach that integrated cognitive task analysis (CTA) interviews with the electronic health record (EHR). CTA consists of a set of specialized interview and data analysis methods designed to elucidate individuals’ cognitive processes; CTA methods are well-established and help guide informatics designs.\(^1\) This poster describes our methods, the interview guide, and data collection tools.

Methods
We recruited prescribers and pharmacists from a Veterans Affairs Medical Center. Participants reported incidents where they addressed a medication safety problem for any of these categories: 1) adverse drug reaction; 2) drug-drug interaction; and 3) drug-disease interaction involving renal function. Participants submitted incidents via an Incident Card, developed during this study, and incidents within the above categories were eligible for follow-up, CTA interviews. Participants could submit Incident Cards via paper or electronically. The Incident Card captured key data, such as how the participant first identified the problem; resources used to help with decision-making; and actions taken to mitigate safety risks. A physician and pharmacist on the research team reviewed each submission for potential inclusion in subsequent CTA interviews. We integrated CTA with the EHR in a novel manner to expand data capture and used EHR-stimulated recall with participants to aid reconstruction of safety incidents. Interviews were audio recorded for future, qualitative analyses focused on decision-making processes.

Results
We captured 101 incidents; most (79%) were eligible for interviews. After clinical review, we conducted CTA interviews on 60 incidents: 31 submitted by prescribers and 29 by pharmacists. Incidents included 20 adverse drug reactions, 20 drug-drug interactions, and 20 drug-disease cases. Participants consulted the EHR to recount the incident and reconstruct a timeline of events (e.g., days and times when medications were ordered, modified, and discontinued). Participants consulted pharmacy records, progress notes, lab results, allergy documentation, and other EHR data to explain key points that helped them recognize a problem and determine how to respond. In addition, participants accessed records of personal electronic communication that occurred during the course of the incident, to explain statements that influenced their decisions.

Conclusions
To our knowledge, this is the first study to integrate the EHR with in-depth CTA interviews. Incorporating the EHR aided incident selection, enhanced participants’ ability to reconstruct their experience resolving the incident, and expanded data collection. The EHR improved data capture of details that may be difficult for healthcare professionals to recall, such as medication doses and schedules, facilitating data accuracy and completeness. Leveraging the EHR in this manner could enable the use of CTA in a wide variety of health informatics and clinical decision-making studies, and also may help strengthen patient safety root cause analyses.

The Impact of Nurses’ Graph Literacy and Numeracy on Comprehension of Visualized Feedback Information

David Russell PhD¹, Nicole Onorato, BS¹, Yolanda Barrón-Vayá, MS¹, Jacqueline Merrill, PhD, RN², Dawn W Dowding, PhD, RN¹,²

¹Visiting Nurse Service of New York, NY; ²Columbia University School of Nursing, New York, NY

Introduction

Providing performance feedback to clinicians is an important factor in improving health care quality¹ and is a key component of the IHI Triple Aim initiative². Dashboards, a form of Health Information Technology (HIT) which use visualization techniques to summarize performance against metrics, can be used to provide feedback. The aim of this study is to evaluate the relationship between nurses’ graph literacy and their ability to comprehend feedback information related to the care of heart failure patients, presented in a dashboard format.

Methods

A multi-factorial experimental research design using an online survey. Graph literacy was measured using the graph literacy scale³ which was developed specifically for the health domain and measures graph reading skills and comprehension across different types of graphs. Numeracy was measured using the expanded numeracy scale⁴. 129 nurses at a large non-profit home care agency were randomly allocated to an experimental condition where they received visualized information about specific quality indicators (Table 1). Outcomes include knowledge and understanding of the information presented in the visualized dashboard.

Table 1: Experimental Conditions for the Multifactorial Design

<table>
<thead>
<tr>
<th>Experimental Group</th>
<th>Quality Indicator 1</th>
<th>Quality Indicator 2</th>
<th>Quality Indicator 3</th>
<th>Quality Indicator 4</th>
</tr>
</thead>

</tr>
<tr>
<td>4</td>
<td>Spider Graph</td>
<td>Table</td>
<td>Line Graph</td>
<td>Bar Chart</td>
</tr>
</tbody>
</table>

Results

Sampled nurses were diverse in terms of their demographic characteristics and years of nursing experience/education. Nurses answered approximately 10 of the 13 graph literacy items and 7 of the 8 numeracy items correctly—slightly higher than average scores for the U.S. population. There were no significant differences across the four experimental groups in demographic characteristics, numeracy scores, or graph literacy abilities. Nurses’ level of graph comprehension varied by the type of display that was presented, adjusting for the type of question. Significantly higher (p<0.05) graph comprehension was observed for nurses who responded to bar graphs compared to spider graphs, and for tables compared to spider graphs.

Conclusion

Results from this study suggest that nurses’ comprehension of visualized feedback information is influenced by the format in which that feedback appears. Efforts are underway to sample additional nurses from another large, regional home care agency. We will examine how graph literacy and numeracy skills are related to graph comprehension. Results will be used to develop flexible dynamic quality dashboards. Future research will evaluate the effectiveness of dashboards in improving care processes and outcomes.

Abstract

Personal health devices (PHDs) are rapidly developing and issuing in medical domain. This personal health record (PHR) based care management systems can be expected to improve patient engagement and data-driven medical diagnosis in clinical setting. In this study, we designed an exploratory user study of collecting data about physical activity and diet using wearable devices in lifestyle related disease patients and clinicians during 8 weeks. The result of our study shows how patients and clinicians accept PHDs. We have successfully demonstrated the user responses and impacts to evaluate the overall usefulness, usability, and satisfaction of PHR-based health management system.

Introduction

Widespread interest in using PHRs has been reported and their adoption has been increasing. Interactive self-management technology with a variety of chronic health conditions is reported to be acceptable and useful. However, few studies have evaluated the effectiveness and value of PHR applications in clinical point of view. In this study, we aimed to demonstrate the clinician evaluations of PHRs using wearable devices in lifestyle related disease patients who has obesity, hypertension, diabetes, hyperlipidemia, or sleep apnea. The ultimate objective of the study is to derive healthcare management service contents and features in a clinical setting.

Methods and Results

We utilized activity tracker (Fitbit, Misfit) to collect individual physical activity data and developed a smartphone applications to record every meals and daily logs. We also monitored data collecting in web administer environment. Patients with lifestyle related disease were participated the study, and asked to use wearable devices for two months. Lifestyle related disease experts were also recruited in the experiment. For patients and clinicians, paper based survey, interview, and workflow observations were processed to monitor and evaluate the study. During the study period, personal health data based clinical diagnosis and recommendations were done in outpatient visit, two times.

The developed diet-log app successfully collected daily meal information, and with the personalized physical activity data, clinicians were able to promote physical activity by the patients. The varied compliance of the participants enabled evaluation of administrative features of the PHR based health management including the generation of participation surveys, and user interviews. We found that data recording compliance and patient expectations to their care providers, as well as clinicians PHR based interventions.

Conclusion

We have developed an innovative testing approach to collect and demonstrate the user interactions of PHRs using wearable devices in lifestyle related disease patients. We have successfully derived the features of PHR service contents and consumer responses, and satisfaction of using wearable devices and PHR-based self-management system.

Using patient photos to reduce wrong-patient order entry: Providers’ perspective

Hojjat Salmasian, MD MPH PhD1,2, Jason Adelman, MD MS1,2, Robert A Green, MD MS1,2, David K Vawdrey, PhD1,2
1NewYork-Presbyterian Hospital, New York, NY; 2Columbia University, New York, NY

Introduction

Wrong-patient order entry is an important safety concern that has been estimated to occur in approximately 1/1000 orders placed by prescribers.1,2 Evidence suggests that displaying patients’ photographs in an Electronic Health Record (EHR) system can reduce these errors, and the Office of the National Coordinator for Health IT (ONC) recommends this as a best practice.3,4 However, little is known about the providers’ perspectives of patient photographs being displayed in EHR systems. To assess this question, we conducted a survey of prescribers who were newly introduced to patient photographs displayed in an EHR system to elicit their perceptions of the impact of this process.

Methods

Display of patient photographs was added to an existing patient identification alert for a sample of patients as a pilot project in October 2015. Photographs were taken after obtaining verbal consent, and were displayed when prescribers placed orders for these patients. Prescribers who received identification alerts with photographs were identified using the EHR logs and an anonymous survey was sent to them via email. The survey was delivered using a HIPAA-compliant platform in case any answers accidentally contained patient information, but it was designed in a way that would not ask for any identifiable information about the patients or prescribers. Survey questions focused on prescribers’ demographic information, their experience with the existing patient verification alert, and their perceptions of the new addition of patient photographs displayed within the verification alert.

Results

During the pilot, 57 patients had their photographs taken, and 472 prescribers who cared for these patients were displayed the patient verification alert with photograph. All of these prescribers received the survey, and 103 surveys were completed. Most respondents were resident physicians (43%), nurses (22%) or attending physicians (12%). The majority of respondents reported seeing a patient’s photograph 1 to 5 times (86%). Most (59%) believed the existing patient identification alert without patient photographs was helpful in reducing wrong-patient order entry errors. Additionally, 72% of respondents expressed that adding photographs to this identification alert was at least a moderate improvement, and 25% of prescribers stated this enhanced alert with photographs prevented them from placing orders for the wrong patient. We found no association between the prescriber’s role (nurse, resident, attending) and his or her opinion about the impact of the patient verification alert (Fisher’s p-value = 0.114) or the enhanced alert with patient photographs (p-value = 0.275).

Conclusion

Adding photographs to our existing patient verification alert was perceived positively by residents, nurses and attending physicians, and many prescribers expressed that it prevented them from placing orders for the wrong patient. These findings are consistent with previously published research and a national best practice,3,4 and are informative in the implementation of a hospital-wide process for acquiring and displaying patient photographs. Future research should focus on rigorously quantifying the impact of displaying patient photographs in reducing wrong-patient order entry errors.

A Comparative Model of Participatory User Centered Design Methods (pUCD) for Adolescent Health Technologies

Savitha Sangameswaran, MS1, Cynthia M. LeRouge, PhD1, Anne M. Turner, MD, MPH, MLIS1, Torree Malasanos MD2

1University of Washington, Seattle, WA; 2 Kiwee Health, LLC, Gainesville, FL

Introduction
Recent calls from the popular press and academe encourage visionaries, developers, and decision-makers to embrace a human-centered focus by engaging users and stakeholders in the design and selection of health technologies (HIT). Participatory User Centered Design (pUCD) is an approach for gathering information on needs and preferences that can integrate the user’s voice and interaction early and throughout the design process. The UCD domain has evolved into a wide collection of different methods. It is not clear which specific methods under the UCD umbrella are most befitting to health care contexts and with specific groups of targeted users (e.g., adolescents), nor do we have structured guidance on criteria for methodological choice and design in deploying these methods for the development and selection of HIT targeting adolescent users. As digital natives and given the increase in chronic disease in adolescents, understanding which specific pUCD methods are most effective in engaging adolescents is critical for effective design and thereby successful HIT to actualize the promise that HIT may offer this target group. The purpose of this study is to provide structured guidance to researchers and developers on the criteria for methodological choice in deploying pUCD methods for the development and selection of HIT involving adolescent users

Methods
To identify the available methods, we utilized existing toolkits (identified from comprehensive review studies1 and two schools of UCD methodology (Design Thinking and Double Diamond). pUCD Methods were identified and defined with care not to duplicate the same method addressed in the literature under different terminology. The research team then used the Framework for Comparing Assessments of Usability Testing Methods for Children2 (only known UCD framework to target youths) as a lens from which to analyze and develop direction for pUCD methodological choices with adolescents. The model includes the following dimensions: a) Assessment Criteria (e.g., robustness of the method), b) Usability Testing Method Characteristics (e.g., number of participants), and c) Children Characteristics (e.g., trustworthiness of self-report). The purpose of the Framework is not to guide a classification or even a meta-analysis of User Centered Design, but to serve as a way to structure the problem space of selecting appropriate methods. The research team of seasoned pUCD researchers worked collaboratively on assessing analysis and design stage methods (where an understanding of the users’ needs, preferences, and capabilities, as well as creative possibilities, are explored) using the Framework as a guide.

Results
Our resultant Comparative Model of pUCD Methods for Adolescents consists of 22 individual (12 including interviews, user diary, story sharing) and group (10, including focus groups and body mapping) methods. In cases where one activity had distinct activity options (e.g., immersive workshop), we treated each option as a separate pUCD activity. In reviewing these methods, we noted some UCD activities were focused on activities that the design team could do (e.g., brainstorming). In the spirit of pUCD, where possible and practical, we adapted these activities to interactions with potential users. Our results provide structured guidance in the form of a Comparative Model of pUCD Methods for Adolescents

Conclusion
The Framework for Comparing pUCD Methods for Adolescents addresses existing needs by delineating and refining pUCD methodologies in the context of HIT for adolescents to inform and motivate those involved in HIT design, selection and research and move towards a more patient engaged HIT model.

Use of a Web-based Survey to Identify Symptom Frequency and Intensity Reporting of Persons Living with HIV with HANA Conditions

Rebecca Schnall, PhD, MPH, RN-BC1, Sabina Hirshfield, PhD2, Karolynn Siegel, PhD3, Lena M. Milian, BSN1, Heidi Castillo, MPhil, BSN, RN1, Hwayoung Cho, MSN, RN1
1Columbia University, School of Nursing, NY, NY; 2Public Health Solutions, NY, NY; 3Columbia University, Mailman School of Public Health, NY, NY

Introduction

HIV has evolved from an acute to a chronic illness largely and as a result, people living with HIV (PLWH) are living longer (1). As PLWH age, they are developing chronic illnesses and co-morbid conditions that are often seen in older HIV negative patients (2). Fifty to sixty percent of deaths in HIV-infected persons occur from HIV-associated non-AIDS (HANA) causes and people suffering from these conditions are more likely to be affected by adverse symptoms (3). An individual’s ability to identify and self-manage symptoms of HIV illness has been shown to improve patient outcomes and quality of life (4). The goal of our work was to identify the most frequently reported symptoms for PLWH with HANA conditions and integrate them into an existing web-based self-management system (VIP).

Methods

We conducted an anonymous online survey with 82 PLWH with HANA conditions to inquire about their symptom frequency and intensity in the past 30 days. Study participants were recruited from POZ.com, Craig’s List and Facebook.com (the largest online social networking site). In our survey, we asked participants to report 1) In the past 30 days, which of the following symptoms made it difficult to carry out your daily activities? 2) In the past 30 days, how much did the symptom interfere with your day to day activities?

Results

Demographics of survey participants are reported in Table 1. The top ten most frequently reported symptoms included: 1) Fatigue, 2) Muscle aches/ pains, 3) Difficulty falling asleep, 4) Anxiety, 5) Depression, 6) Neuropathy, 7) Difficulty remembering things, 8) Difficulty staying asleep, 9) Shortness of breath and 10) Decreased sex drive. The ten most intense symptoms were: 1) Fatigue, 2) Muscle aches/ pains, 3) Difficulty falling asleep, 4) Neuropathy 5) Depression, 6) Difficulty staying asleep, 7) Anxiety, 8) Difficulty remembering things, 9) Shortness of breath and 10) Decreased sex drive.

Conclusion

This study is introducing a novel research design, recruitment from online social networking sites, to study daily symptoms of PLWH, which is data that we can't get from clinical data or clinic-based surveying of this population. Findings from our survey regarding what self-care strategies they used to try to ameliorate these symptoms will be incorporated into the existing VIP system which will result in the VIP-HANA system. The VIP-HANA system will deliver these strategies to PLWH with HANA conditions.

Usability Evaluation of an Evidence-based Dental Patient Case Simulator

Kelsey M. Schwei, PhD¹, Kate L. Thomas, MA², Vijayakumar Thirumalai, BTech³, Chris Enstad BS³, Kim Johnson, MDH³, Andrew Schmidt, MS⁴, Olga Godlevsky, BA⁴, Neil Johnson, DDS,PhD⁵, Bill Rush, PhD⁴, Amit Acharya, BDS,MS,PhD¹,²

¹Institute for Oral and Systemic Health, Marshfield Clinic, Marshfield, WI; ²Biomedical Informatics Research Center, Marshfield Clinic, Marshfield, WI; ³HealthPartners Institute, Bloomington, MN; ⁴HealthPartners Dental Group, Bloomington, MN

Abstract

Dental Decision Simulation (DDSim) was developed by HealthPartners Institute (HPI) to aid dentists in their continued education of the latest evidence-based approaches to practice. The abstract provides a brief description of the formal usability evaluation of DDSim conducted by the study team.

Introduction

Innovative methods are needed to further educate dentists in the latest evidence-based practice. Incorporating evidence-based dentistry (EBD) into practice is currently taught in dental school curricula, but dentists face barriers to incorporating new research into their daily practice. DDSim, a novel web-based, patient case simulator for dentists to practice evidence-based care, was developed by HPI. The objective of this study was to conduct a formal usability evaluation of DDSim to discover any design issues and whether it was intuitive to dentists before planning for implementation.

Methods

A convenience sample of fifteen practicing United States dentists was recruited to participate in the study. The participants completed think aloud usability studies to discover inconsistencies or usability issues with DDSim. Usability analysts observed and recorded participants attempting to complete a treatment plan of varying complexity (hard, medium, and easy) on DDSim. Participants then completed an exit interview consisting of the System Usability Scale (SUS) survey¹ and product reaction cards from the Microsoft Desirability Toolkit.² The recordings were analyzed for themes on usability issues. SUS scores were calculated from the survey and user-selected terms from the reaction cards were counted.

Results

Participants earned an average of 23% of possible points for their respective case (hard average: 18%; medium average: 12%; easy average: 40%). Participants rated DDSim with an average SUS score of 50.8, which corresponds to a letter grade C when all SUS scores were curved like test grades. The most common terms selected from the reaction cards included complex, frustrating, usable, annoying, comprehensive, confusing, hard to use, organized, and unattractive.

Discussion

Much of the functionality of DDSim needs a redesign to ensure completion of desired actions. Participants did not earn many points while completing their cases because they only treated their given patient’s chief complaint. A majority of points in all cases were earned for treating issues the patient did not mention. Participants expressed enthusiasm for EBD, but they found the user interface of DDSim to be complex and the length of patient cases to be prohibitive to success. Further work on the interface of DDSim is needed to refine the system to make it more usable for dentists.

An Evaluation of ‘Definite’ Anaphylaxis Drug Allergy Alert Overrides in Both Inpatient and Outpatient Settings

Diane L Seger, RPh1,2, Sarah P Slight, MPharm, PhD, PGDip1,3, Elizabeth R Silvers, BA1,2, Mary G Amato, PharmD, MPH1,4, Julie M Fiskio, BS1,2, Adrian Wong, PharmD1,4, Patrick E Beeler, MD1,5, David W Bates, MD, MSc1,6

1The Center for Patient Safety Research and Practice, Division of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA; 2Partners HealthCare, Wellesley, MA; 3School of Medicine, Pharmacy and Health, The University of Durham, Stockton on Tees, Durham, UK; 4MCPHS University, Boston, MA; 5Research Center for Medical Informatics, University Hospital, Zurich, Switzerland; 6Harvard Medical School, Boston, MA

Abstract: Surprisingly drug allergy interaction (DAI) alerts that warn against the reaction ‘anaphylaxis’ are being overridden. We found 1,271/1,851 (68.7%) and 142/226 (62.8%) DAI anaphylaxis alerts were overridden in the inpatient and outpatient setting, respectively. A sample of these overrides where the medication being ordered was an exact match to the allergen listed (definite match) was assessed and the majority found to be appropriate.

Introduction: Clinical decision support (CDS) systems are designed to provide real-time guidance and support to providers at the point of prescribing. Drug allergy interaction (DAI) alerts are generated when a known adverse sensitivity-inducing substance is prescribed. Anaphylaxis is a serious life-threatening allergic reaction and typically a red flag for providers. However, a recent study at our institution showed that providers overrode the majority of DAI alerts including those that warned against ‘anaphylaxis.’ This study aimed to determine the reasons why providers overrode these alerts and whether these overrides were appropriate.

Methods: All DAI alerts, specifically those relating to the documented reaction of ‘anaphylaxis’, were analyzed for inpatients at Brigham and Women’s Hospital and 36 primary care practices affiliated with Partners HealthCare between January 2009 and December 2011. These interruptive alerts suggested a life-threatening reaction and gave the provider the option of either ‘cancelling’ the order or ‘overriding’ the alert. A total of 1,851 inpatient DAI alerts and 226 outpatient DAI alerts were collected. Data included the name of the drug and allergen that triggered the DAI alert, and the reasons that the provider gave for overriding the alert. A research pharmacist reviewed patient’ s charts to assess the appropriateness of these overrides that were classified as ‘definite’, i.e., where the medication being ordered was the same as the allergen listed, according to a predetermined set of criteria.

Results: Among the 1,851 anaphylaxis DAI alerts in the inpatient setting, 202 (11%) were classified as ‘definite’; in the outpatient setting, we found a total of 226 anaphylaxis DAI with 20 (9%) classified as ‘definite’. The rate of definite anaphylaxis DAI overrides was 46% (93/202) in the inpatient setting and 70% (14/20) in the outpatient setting. The appropriateness rate of the definite DAI overrides for inpatients was 83.9% (78/93) and 100% (14/14) for outpatients. The most common reason for overriding these alerts in the inpatient setting was “administered per desensitization protocol” (64) and for the outpatient setting, “patient does not have this allergy -will d/c pre-existing allergy”(8). There were 15 DAI inpatient overrides found to be inappropriate. Twelve (80%) of these overrides were intercepted by pharmacy so the patient never received the medication, while the remaining overrides were for prochlorperazine suppositories as needed, which the patients never received.

Conclusion: The rate of overrides for ‘definite’ anaphylaxis DAI alerts were found to be high but appropriate for the majority (83.9%) or all (100%) of the overrides in the inpatient and outpatient setting, respectively. Inappropriate drug allergy alerts at best can waste clinicians’ time, and the information contained in patients’ drug allergy lists should be kept updated.

Introduction
Sentence segmentation, a critical natural language processing (NLP) task, has a profound effect on downstream processing tasks, because most clinical NLP tasks are applied at the sentential level. Most sentence segmenters are developed using non-clinical text and do not segment clinical text well due to clinical text’s telegraphic style e.g., non-standard grammar, short forms, and missing punctuations. Machine learning-based segmenters trained on one clinical corpus may not perform consistently well on other corpora. On the other hand, rule-based segmenters leveraging regular expressions are rule-order-dependent, which makes the rule maintenance onerous and processing cumbersome once the rules are enriched. We present an easily adaptable, efficient, and extremely accurate sentence segmenter well suited to clinical NLP. We tested our system against three popular sentence segmenters.

Method
RuSH (Rule-based Segmentation using Hashing) leverages a nested hash table data structure to execute simultaneous rule processing, which reduces the impact of the rule-base growth on execution time and eliminates the effect of rule order on accuracy. Training and testing sets were prepared using the SemEval-2015 task 14 dataset, including 431 clinical notes of four types: discharge summaries, electrocardiogram, echocardiogram, and radiology reports. Sentence annotation was made by one annotator and reviewed by another two annotators. We randomly split the documents for training (50%) and testing (50%). The training set was used to develop RuSH rules (732 rules), as well as retrain the cTAKES segmenter model to ensure a fair comparison between the two systems. The testing set was used to evaluate the five approaches: RuSH, Stanford CoreNLP, GATE RegexSentenceSplitter, cTAKES segmenter using its default model and the retrained model. Sentence boundary detection performance was assessed using precision, recall, F1-score, and run time (overall run time and normalized run time by rule size).

Results
Our results demonstrate a notable accuracy improvement by RuSH over the other four approaches. In terms of normalized run time, RuSH demonstrates superior efficiency over GATE (100 rules) and Stanford CoreNLP (16 rules).

* Using cTAKES default segmenter model, **using model retrained with our annotated training set. ms = milliseconds

Conclusion
RuSH is an efficient, reliable, and adaptive sentence segmentation solution that can be used in an NLP pipeline either in-line or to pre-annotate clinical texts. Our purpose is to compare RuSH with other off-the-shelf solutions. Although GATE’s splitter can be optimized through customizing rules, it is difficult to handle hundreds of rules because of the aforementioned ordering issue. By adding and/or removing a small portion of rules, RuSH can quickly be adapted to other corpora. The sentence annotations will be made available upon request with SemEval data access approval.
Disease Connections at RGD

Mary Shimoyama PhD, Stanley Laulederkind PhD, Jeff De Pons BS, Marek Tutaj MS, Victoria Petri PhD, G. Thomas Hayman PhD, Shur-Jen Wang PhD, Jennifer R. Smith MS, Jyothi Thota MS, Omid Ghiasvand MS, Monika Tutaj PhD, Melinda R. Dwinell PhD

Abstract

An integrative software platform at the Rat Genome Database provides researchers with software tools to explore and analyze human, rat and mouse genes for disease association. Users can easily retrieve gene sets associated with single or multiple diseases and further filter by those common functions such as drug interactions or pathway participation. Resulting data subsets can be analyzed for genomic variation and additional functional features and connections.

Introduction

The Rat Genome Database (RGD) (rgd.mcw.edu) integrates comprehensive genetic and genomic data for rat, human and mouse and provides a variety of software tools to explore, analyze and visualize this data. In addition to complete gene datasets for all three organisms, variant data for Human and Rat are also available along with predictions of impact and known disease relationships for the variants. Disease-gene associations are curated from published human and rat literature using an enhanced ontology based on the Disease Ontology, MEDIC, OMIM with additions from RGD staff. RGD also provides multiple types of annotations for genes including drug/chemical-gene interactions, pathway and disease (Table). This data provides the basis for innovative software tools that allow researchers to identify subsets of genes associated with particular diseases and make connections among gene sets through commonalities in function.

Data Exploration and Analysis Tools

OLGA-Object List Generator and Analyzer, is a tool that allows users to create human, rat or mouse gene lists through easy to create complex queries using genomic regions, symbol lists or disease, pathway, drug or other functional searches. Multiple lists can be generated and a final list generated by combining lists, subtracting one from another or identifying the union of the lists. The resulting gene subset can then be downloaded or submitted to additional tools to identify variants within the genes and predicted effects or to a genome viewer to visualize location or to the Gene Annotator. The Gene Annotator provides comprehensive reports for each gene, analyzes common functional features among the genes using a distribution presentation or heatmap tool for further investigation.

Conclusion

RGD provides complete catalogues of rat, human and mouse genes and comprehensive functional annotations that can be mined, explored and analyzed using a suite of innovative tools.
Comprehensive Evaluation of Univariate and Multivariate Distributions for Machine Learning With Microbiome Data

Ali Shojaee Bakhtiari, PhD, Alexander V. Alekseyenko, PhD
Program for Human Microbiome Research, The Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC

Introduction

Human body is host to complex microbial communities collectively known as the microbiomes. The human microbiome has comparable number of cells to the number of our own cells. This additional genetic pool of the microbiome provides us with an extended metabolic and genetic capability not present in our own genome (1), and is a potential source of pathognomonic relationships in diseases. This can be exemplified in the recent linkage of the microbiome to obesity and inflammatory bowel disease.

The data for microbiome studies come from high-throughput sequencing. In particular, a marker gene sequencing assay based on 16S rRNA gene, allows for rapid and extensive identification of the microbiota. The data from this assay comes in the form of short sequences of the variants of the 16S rRNA gene present in the analyzed specimen. These sequences are processed by specialized pipelines to create standard sample-feature matrices for subsequent machine learning analysis. The minimal feature of such analyses is an operational taxonomical unit (OTU), which can be thought of as representing an underlying microbial species. The data matrix, therefore, contains counts of observed OTUs in each sample. The data are typically high-dimensional and sparse. We evaluate statistical distributions for modeling the OTU frequency vectors to recommend the most suitable ones.

Materials and Methods

We approach the problem of finding appropriate distributions for modeling the microbiome data by evaluating an extensive array of univariate and multivariate distributions to model count data of typical microbiome datasets in the model selection framework. The following univariate distributions are considered in this benchmark: Poisson, Negative binomial, Poisson Inverse Gaussian. In addition, we consider the zero inflated versions of these distributions. We use Akaike information criterion (AIC), Bayesian information criterion (BIC) and Deviance information criterion (DIC) for model comparison.

In our multivariate analyses of the data, we focus on Dirichlet-Multinomial and Beta-Liouville multinomial distributions as the two main distributions capable to account for OTU overdispersion and. The first author has shown the relative strength of the Beta-Liouville distribution compared with Dirichlet distribution in modeling of discrete count data (4).

Our benchmarking dataset consists of the data from 300 healthy participants of the Human Microbiome Project. These subjects have been sampled at 18 distinct body sites to capture the diversity of the human microbiota. A total of approximately 5,000 samples have been collected. ~45,000 individual OTUs are present in these data. We apply our methods to each OTU or the entire community in multivariate case at each body site to determine the best model(s).

Conclusion

As no single distribution has been determined to be unanimously superior, we recommend that appropriate distribution be determined empirically. We provide the set of distributions of microbiome count data utilized in this analysis as an R package: Empirical univariate and multivariate modeling for microbiome data (EUMM). The software is capable of automatically finding the optimal distribution for the provided dataset using specified model selection criterion.

Comparing Clinical Decision Support of a Homegrown Versus a Vendor Electronic Health Record System

Elizabeth R. Silvers, BA1,2, Diane L. Seger, RPh1,2, Adrian Wong, PharmD1,3, Mary G. Amato, PharmD, MPH1,3, Sarah P. Slight, MPharm, PhD, PGDip1,4, Patrick E. Beeler, MD1,5, Julie M. Fiskio, BS1,2, David W. Bates, MD, MSc1,6

Introduction: Evidence suggests that CDS improves patient care, but the amount of improvement achieved is typically a fraction of what is possible. Our institution recently adopted a vendor-based system after using a homegrown EHR system for over 20 years. While the new system has medication CDS in place, it is not considered to be as user-centered as our previous homegrown EHR. We were interested in targeting providers who had used both systems and exploring their views on the design of alerts displayed in both systems. We felt that this could help identify potential areas of improvement.

Methods: We approached providers who frequently overrode medication CDS alerts (n=1,770) in the inpatient setting between January 2009 and December 2011 and interacted with the vendor system upon its deployment in May 2015. A research pharmacist trained in effective academic-detailing techniques conducted these sessions, which were tailored to each provider’s particular overrides. Graphical materials including performance level data were presented to each provider and used as the basis for a two-way discussion. A robust and complete analysis using a qualitative analytic tool (NVivo 11 for Windows) of the data was carried out, and key concepts related to views on alert functionality and specific prescribing behavior were identified.

Results: We conducted a total of 35 sessions, which included a diverse group of providers of varying professional backgrounds including physicians, physician assistants, nurse practitioners, and pharmacists. Providers felt several aspects of the CDS in the vendor system were less effective than the homegrown EHR system including the timing and tiering of alerts. Most providers felt the lack of tiering of CDS in the vendor system increased their alert fatigue in comparison with the homegrown EHR. They also found the presentation of all alerts at the time of signing an order, as opposed to at the time of ordering, to be overwhelming. Many agreed that drug-drug interactions (DDI) should be considered high priority in the vendor system as in the homegrown system. CDS of renal-based alerts outside of labeling renal insufficiency was rarely offered, whereas the homegrown EHR offered dose and frequency adjustments and appropriate alternatives, which caused providers to often refer to outside resources to make informed decisions. Distinguishing between true drug allergies and intolerances in the new EHR was an improvement, though many were unaware of this functionality. Providers suggested that the new vendor system incorporate alert tiering and draw attention to serious reactions and contraindications through the use of hard stops.

Conclusions: A number of insights surrounding alert functionality in both EHR systems were identified. Regarding DDIs and renal-based alerts, providers felt the homegrown system provided more useful information. Most were unaware that the vendor system distinguished between true drug allergies and intolerances: therefore attention should be drawn to this feature in provider training. Providers felt they overrode more alerts and experienced greater alert fatigue using the new system, though ascertaining these alert override rates is beyond the scope of the current study. These findings will form the basis for several recommendations to senior management on how to improve the vendor system. By incorporating a more robust CDS system, the vendor EHR could more effectively help clinicians with their decision making and deliver safer patient care.

Introduction

Metadata-driven information systems provide end users with the ability to manage information models that otherwise require developers to write code. Metadata-driven design also allows for auto-creation of forms and data display interfaces as well as the use of common data elements. Use of research Common Data Elements is increasingly being encouraged by funding agencies (1). CDEs have the potential to increase the harmonization of data collected in clinical trial management systems. National Institute of Dental and Craniofacial Research (NIDCR) Office of the Clinical Director (OCD) oversees many clinical trials and needs to manage the lifecycle of these trials effectively. This requires a flexible data model that also supports data collection in a standardized way.

Material and methods

To enable effective management of clinical trials data by the NIDCR OCD we created a web service that allows the end users to model their data using a metadata-driven approach. This tool is integrated with National Institutes of Health National Library of Medicine’s Common Data Elements (CDE) repository so the users can incorporate CDEs into their data models with ease. The web service is created using open source technologies, including Linux Ubuntu, Apache, PostgreSQL, Ruby on Rails web framework (2), Bootstrap, and JQuery. The system allows complex type specific validation rules to be defined for each CDE. For example a text field may have a regex-based validation where as an integer field may have a range defined as the validation rule. Fields may have more than one validation rule set which allows the value domain for each user defined field or CDE to be precisely defined.

Results and Discussion

The web service is now being used at the NIDCR OCD to manage 34 clinical trials. Since its inception, data managers and research nurses have used the service to create data models. A total of 17,415 CDEs from (https://cde.nlm.nih.gov/home) have been integrated into user defined fields and can be used while designing new tables and forms. A central user defined field repository contains all published fields from individual projects as well as imported common data elements from public repositories such as the NLM.

Conclusion

A metadata-driven system allows seamless integration of common data elements into data models designed by end users and minimizes the need for programmer involvement in information system design.

Developing an Electronic Health Record-Based Cohort of Patients with Inflammatory Bowel Diseases for Observational Patient-Centered Outcomes Research

Siddharth Singh, MD, MS1; Paulina Paul, MS1; Chun-Nan Hsu, PhD1; Lucila Ohno-Machado, MD, PhD1,2

1University of California San Diego, La Jolla, CA and 2San Diego Veteran’s Administration Health System, San Diego, CA

Introduction

Observational research in inflammatory bowel diseases (IBD) has traditionally been limited by small sample size and event rates (in single-center studies) or lack of detailed phenotype analysis (in administrative health claims databases). We propose to overcome these barriers by creating a large contemporary electronic health record (EHR)-based cohort of patients with IBD seen across any of the five University of California (UC) medical campuses, which combines structured (and codified) data with NLP-derived phenotype data, utilizing the platform developed for the patient-centered SCAlable National Network for Effectiveness Research (pSCANNER),1 a clinical data research network that is part of PCORnet. A combination of structured and narrative data has been shown to have superior performance to identify and characterize patients in “phenotyping” activities for numerous diseases.

Balancing sensitivity and specificity

The cohort for this study will be identified using a sequential two-step process as shown in the Figure. In the first step, we will screen all records using ICD-9 codes for Crohn’s disease (CD) (ICD 9 555.x) and ulcerative colitis (ICD 9 556.x), to identify a large cohort of patients with a potential diagnosis of IBD. To assess feasibility we used the UC Research eXchange Data Explorer (powered by SHRINE) to estimate a total of 23,296 potential patients with IBD, of whom 5,726 (24.6%) appear to have been treated with anti-TNF agents. From a cohort derived from pSCANNER, we will develop an algorithm, based on structured data elements, to more accurately identify patients with CD and UC. Structured data elements include: number of ICD-9 codes for CD and/or UC, diagnostic codes for competing diagnosis (irritable bowel syndrome, diverticulitis), codes for inpatient hospitalization, gastroenterologist visit or endoscopic procedure, diagnostic codes for CD or UC-related complications (intestinal fistula, stricture, perianal fistula or abscess), procedural codes for abdominal or perianal surgery (using Current Procedural Technology – CPT codes), laboratory values for elevated inflammatory markers (such as C-reactive protein), and prescription of IBD-related medications in the EMR prescription program. However, there are limitations related to use of only structured data elements for IBD diagnosis. Hence, to improve upon our approach to identifying patients with IBD, we will analyze narrative text (within clinical notes, endoscopy reports, etc.), using NLP techniques to augment the identification process of IBD patients. The accuracy of the combined models at various specificity levels will be calculated using a hierarchical generalized linear model, and the overall prediction performance evaluated based on the area under the receiver operating characteristic curve (AUC), using a training set of randomly selected 500 patients with IBD. This will be initially validated in an independent test set of 100 patients for whom manual chart review will be completed.

In summary, our approach combining structured and narrative data, using NLP algorithms, will help to identify and characterize a large, EHR-based contemporary cohort of IBD patients across the UC system for use in observational comparative effectiveness and patient-centered outcomes research.

Pilot Evaluation of Usability and Acceptability of a Mobile Application for Congestive Heart Failure Readmission Reduction: The HealthPal Project

Minal A. Singhee, MS¹, Rema Padman, PhD¹, Sriram Iyengar, PhD², Daniel Gartner, PhD³, Robert Monte, MBA⁴, Ashley Ketterer, MHA⁴, Brianna Scott, MS⁴, Angelo Baiocchi, RPh⁴
¹Carnegie Mellon University, Pittsburgh, PA, USA; ²Texas A & M University, College Station, TX, USA; ³Cardiff University, Cardiff, United Kingdom; ⁴Veterans Engineering Resource Center, VA Pittsburgh Health System, Pittsburgh, PA, USA

Introduction

Congestive Heart Failure (CHF) is a major chronic condition characterized by the inability of the heart to pump sufficient blood to the body. CHF readmission is a critical contributor to the burgeoning healthcare cost¹. Drawing on social cognitive theory and persuasive computing technology, we have developed HealthPal, a customizable, multimedia-rich post-discharge education, follow-up and monitoring application for CHF that uses an innovative technology platform called guideVue for creating and publishing apps on mobile devices². The aim is to help CHF patients understand their condition better, improve knowledge and enable self-efficacy in post-discharge self-health management to potentially reduce the risk of readmissions. This study is a preliminary evaluation of the factors associated with the usability, acceptability and workflow aspects of HealthPal.

Methodology

We developed a fixed protocol for the exploration of the app via interviews with all the stakeholders. This included the Think Aloud Protocol³, a quiz to understand the content and ease of use of the application and a survey to obtain feedback from users. Multiple analyses were performed to understand the usability, acceptability and workflow features of the app, including qualitative analysis of the aggregated free text responses in the Think Aloud Protocol and content quiz, a quantitative analysis of the survey via summary statistics and Key Log Sequence Analysis of app navigation. Figure 1 shows a complete exploration flow to test user’s navigation patterns and completeness of their app exploration to analyze workflow. We encoded the five major sections of the application as follows: a. Exercise, b. Blood Pressure, c. Cholesterol, d. Risk, e. Resources

Results

In-person interview results from 30 stakeholders including patients, physicians, nurses, case managers and social workers indicate that the app is very informative and easy to use. Table 1 summarizes the average scores from patients’ feedback tested on a scale of 1 to 5. Users suggested improvements in the layout of the app to make it more accessible, and recommendations for desirable interactivity functions in a future version.

Conclusion

Patients and clinicians reported positive experiences with the interactive mobile technology. Future extensions of HealthPal will incorporate additional interactive features and voice recognition capabilities to facilitate personalized patient-provider interactions.

Tracking Risk of Acute Mental Status Change in VA Hospitals

Stacey L Slager, BA, MS1,2, Bryan Gibson PT, PhD, 1,2 Teresa P Taft, BEd1,2, Nancy Staggers, RN, PhD1,2, Charlene R Weir, RN, PhD

1Biomedical Informatics, University of Utah, Salt Lake City UT; 2 George E. Whalen Veterans Affairs Medical Center, Salt Lake City, UT

Introduction

Nurses spend more time with the patient than any other care provider and are responsible for the bulk of patient care. Thus, they are most likely to notice when the patient is experiencing an acute mental status change (AMSC), referring to changes in brain function, such as confusion, loss of alertness, loss of orientation, defects in judgement or thought, unusual or strange behavior, poor regulation of emotions and other functions. Acute mental status changes can have a significant impact on patient care in terms of symptom management, patient safety, and staffing; therefore monitoring changes in mental status, initiating preventative actions and mitigating harm requires effective coordination between clinical roles. Formal assessments for AMSC and tracking that information over time is lacking. Well-defined data from patient assessment for AMSC can aid development of decision support in a learning health organization.

Methods

Semi structured interviews were conducted with 58 Nurse Managers (NM) of acute medicine floors across regional areas of Veteran’s Affairs hospitals in the US. Our purpose was to characterize nurses’ medication management information needs, documentation and communication processes associated with identifying and monitoring AMSC in inpatient settings. We asked questions about admission assessment and documentation of AMSC; identifying patients at risk by formal assessment or otherwise; interventions for patients at risk and associated policies regarding risk; and documentation and planning at the ward/institution level. The interviews were analyzed with descriptive statistics.

Findings

When asked how mental status was assessed upon admission, 49(84.5%) nurse managers said it was part of the nursing admission process. Only 7(12.0%) reported a formal assessment other than orientation, such as with the Confusion Assessment Method (CAM). Most NMs (n=54, 93.1%) documented orientation in the nursing admission template. Risk for delirium was identified by: Admission diagnosis, prior diagnosis, prior delirium (n=24, 41.4%) with clinical judgement (n=10, 17.2%) and flagging of behavioral history (n=6, 10.3%) being the next most common method approaches. While the assessment of patients for AMSC is somewhat informal, it is a key aspect to making nursing assignments (n=46, 79.3%). The majority of NMs did not know if AMSC was tracked on an institutional or ward level, but they do track related measures (e.g. sitters, falls, etc.) (24, 41.4%). Table 1 highlights additional results.

Table 1. selected results from Nurse Manager interview

| Used a specific tool for delirium assessment | 6(10.3%) | Said there was a policy for contacting physicians if patient at risk for delirium 8(13.8%) |
| No formal risk assessment for delirium | 44(75.9%) | Interventions for patients at risk of delirium: 16 unique interventions mentioned |
| Documented delirium risk in CPRS 8(13.8%) | | |
| Notifies physician when change in cognition, behavior | 36(62.1%), 21(36.2%) | Do charge nurses have separate report of AMSC? Yes 22(37.9%) No 29(50%) |

Discussion

Mental status assessment is limited largely to orientation and no policies are in place that uses risk measurement to drive increased monitoring. Identifying risk appears to not be a formal process.

A Literature Review of The Approaches Used to Train Qualified Prescribers to Use Computerized Provider Order Entry Systems

Clare Brown, MPharm¹,², Katie Reygate, MPharm PGDip³, Ann Sleg, MPharm⁴,⁵, Jamie J. Coleman, MD MA⁵, Sarah K. Pontefract⁵, MPharm PGDip⁵, David W. Bates MD, MSc⁶,⁷,⁸, Andrew K. Husband, PhD¹, Neil Watson MBA MSc², Sarah P. Slight, PhD¹,²,⁶

¹School of Medicine, Pharmacy and Health, Durham University, U.K. ²Newcastle upon Tyne hospitals NHS Foundation Trust, U.K.; ³Health Education KSS Pharmacy, U.K.; ⁴eHealth Research Group, Centre for population health sciences, University of Edinburgh, U.K.; ⁵College of Medical and Dental Sciences, University of Birmingham, Birmingham, U.K.; ⁶The Center for Patient Safety Research and Practice, Division of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, USA; ⁷Harvard Medical School, Boston, MA, USA; ⁸Harvard School of Public Health, Boston, MA, USA.

Abstract: Studies have suggested that insufficient training is associated with suboptimal use of Computerized Provider Order Entry (CPOE) systems. We conducted a literature review to describe the approaches used to train qualified prescribers on these systems, whether online methods in particular were used and to identify whether they included the challenges of using these systems. A number of different approaches were used to train prescribers, including demonstrations, practical exercises and ward-based training. Educating prescribers about the pitfalls and challenges of CPOE systems was rarely discussed.

Introduction: Computerized Provider Order Entry (CPOE) systems have been associated with potential benefits over paper-based systems, including improved patient safety. A key element of the implementation and on-going use of these systems is ensuring that users are, and remain, sufficiently trained to use them effectively. Studies have suggested that insufficient training is associated with suboptimal use.¹ We sought to describe the approaches used to train qualified prescribers to use CPOE systems, whether online methods in particular were used, and to identify whether they covered the pitfalls and challenges of using these systems.

Methods: We performed a literature review, using a systematic approach. Three large databases: Cumulative Index Nursing and Allied Health Literature (CINAHL), Embase and Medline were searched. We did not restrict the timeframe for these searches in any of the respective databases. Articles that explored the training of qualified prescribers (medical and non-medical practitioners) on systems in both inpatient or outpatient settings were included. Reference lists of included articles were also examined. A narrative synthesis of all eligible studies was undertaken.

Results: Our database search returned 1,155 publications. After reviewing the titles, abstracts and full text, a total of seven were included. One further article was identified from the reference list search. A variety of training methods were used, such as: demonstrations; expertise-specific exercises aimed at addressing commonly encountered prescribing errors (e.g. prescribing an antibiotic at non-standard times); and assessments, which allowed users to monitor their own progress. Super-users played a valuable role in providing ward-level support and reducing the need for external training, with potential cost-savings. Web-based demonstrations were used in one study. A team at the University of Victoria in Canada developed an online portal that housed a range of simulated versions of electronic health record systems, where individuals could prescribe for fictitious patients. Educating prescribers about the challenges and pitfalls of CPOE was rarely discussed and a comparison between methods was lacking.

Conclusion: We identified few articles related to the training of prescribers on the use of CPOE systems. Approaches used include demonstrations, practical exercises and ward-based training. Using a combination of approaches was considered important. Online learning may facilitate the training of a large number of users, offering them the opportunity to practice and become familiar with the system at a convenient time and place.

Needs Assessment: A Subscription-based Laboratory Notification System

Benjamin H. Slovis MD¹,², Hojjat Salmasian MD MPH PhD¹,³, Gilad Kuperman, MD PhD¹,³, David K. Vawdrey PhD¹,³

1. Department of Biomedical Informatics, Columbia University, NY, NY, 2. Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, NY, NY, 3. Quality and Patient Safety, New York-Presbyterian Hospital, NY, NY

Introduction
The delayed review of laboratory results is potentially harmful. Established processes (e.g. phone-calls) provide notification of critical laboratory values, however physician awareness of non-critical and normal results also affects clinical decision-making. Previously described notification systems have demonstrated improved physician responses to critical results, yet few studies have documented subscription-based notifications. Allowing providers control of notifications for laboratory results may reduce delays in patient care. We propose a tool to provide near-real-time notifications of laboratory results through text-page and email, via subscription at the time of order-entry. This system will allow clinicians to subscribe to individual tests and receive notifications when results are available. To inform the function of the system, we solicited input from resident physicians.

Methods
A survey instrument created with Qualtrics software (Qualtrics, Provo, UT) was distributed via email to all house-staff in the medicine and pediatrics residencies to determine the perceived usefulness of a subscription-based laboratory notification system. The survey included questions regarding the frequency of lab order and review, perceived barriers to result review and physician opinions on our proposal. Responses were analyzed using descriptive statistics and qualitative responses were coded to generalized themes.

Results
A total of 63 residents responded to the survey, accounting for 29% of the 216 eligible house-staff. The majority (87%: 55/63) of the respondents reported repeatedly reviewing labs throughout the day, with 60% of these repeatedly checking labs more than 5 times per day. (Table 1). Sixty-two percent (39/63) of respondents reported frustration from repeatedly checking lab results, while 63% (40/63) reported that repeatedly checking results caused delays in clinical care. When asked about our proposed tool, 59% (37/63) of respondent reported they would find it useful. When asked about preferred methods of notification, 83% (52/63) of respondents reported that they would carry a pager, with only 41% (26/63) stating they would prefer SMS and 16% (10/63) preferring email. The majority of residents (53%) who responded to questions regarding how notifications would affect patient care implied it would save time in their clinical workflow. (Table 2)

</tbody>
</table>

Conclusion
Our respondents were generally dissatisfied by the current state of result review in the EHR, and were accepting of our proposed subscription-based laboratory result notification system. The next steps in our research are to deploy the notification system and evaluated whether its use reduces time between available results and physician awareness.
eMeasure Certification: Validating Logic for Electronic Clinical Quality Measure (eCQM) Reporting
Anne Marie Smith, RN, BSN, MSHSA1, Ben Hamlin, MPH1
1National Committee for Quality Assurance (NCQA), Washington, DC

Abstract
NCQA developed an electronic process to verify a software package has the electronic clinical quality measures (eCQMs) correctly programmed and the resulting Quality Reporting Document Architecture (QRDA) Category 1 file is correctly generated. NCQA is certifying systems that produce these QRDA 1 files to provide data for quality reporting.

Introduction
The eMeasure certification process is designed to validate measure-specific software code for extracting the correct electronic health record (EHR) data as defined by CMS eCQM specifications. NCQA’s system offers more robust testing than other systems, because it tests many more cases per measure and includes testing for negative events. These measure-specific tests use a black-box testing model to create a comprehensive set of measure scenarios based on the eMeasure specifications and known measure-specific programming errors. The goal of certification is to pre-approve the integrity of the software code to ensure its adherence to measure specifications and its ability to accurately produce comparable results.

Methods
NCQA creates unique sets of sample data or "test decks," for each eCQM, developed from randomly generated patient-level test data. Each test deck contains between 800-1000 individual patients designed specifically to test each measure’s initial population, denominator, exceptions, exclusion and numerator inclusion logic. The test data also includes negative testing, or testing for data not applicable to the measure. Test decks are generated from flow diagrams that allow NCQA to mark the portions of the measure to which each sample patient applies. A vendor seeking NCQA certification process a test deck through their measure code and returns results for each patient in the test data. The vendor results for each patient are then compared to the expected results to determine if the vendor software code computes the measure correctly. NCQA also validates the vendor’s ability to report the correct results in the QRDA Categories I and III standard document format. Multiple test decks are created for each eMeasure in order to correct errors identified from each pass of the deck through the vendor code. Each measure is tested individually using Continuity of Care Documents (CCDs). Each vendor that completes certification receives a final certification report and seal which indicates the measures certified.

Results
NCQA has completed this process with 3 vendors and beta tested with a 4th. Every vendor had to make adjustments to their measure calculation logic to match NCQA’s expected results. Common errors included age calculation errors, missing results of lab tests, vendor defined exclusions not in measure specification, misspelled elements in the QRDA file, and codes not included in the value set but present in calculation. Vendors were most challenged in the certification process by measures containing an index event for denominator eligibility or those containing specific timing linked to a denominator event in order to determine numerator compliance.

Conclusion
Vendors who achieve certification will improve the precision and long-term data comparability while also having pre-approved data, which may reduce costly chart reviews.
Human Factors Analysis of Look-Alike/Sound-Alike Medication Errors

Katrina H. Smith1, Aaron Z. Hettinger, MD MS1,2, Allan Fong, MS1, Maryann E. Amirshahi, PharmD MD MPH2,3, Grace M. Tran, MS1, Erica L. Savage1

1MedStar Health National Center for Human Factors in Healthcare, Washington, DC; 2Georgetown University School of Medicine, Washington, DC; 3MedStar Washington Hospital Center, Washington, DC

Introduction
Look-Alike/Sound-Alike (LA/SA) medication errors have been estimated to account for approximately 25% of all medication errors1. In order to recognize these errors, the Institute for Safe Medication Practices (ISMP) maintains a list of the most common LA/SA name pairs that have the potential to be confused2. Given the great potential for these events to result in patient harm, a human factors analysis of the frequency and sources of LA/SA errors was undertaken.

Methods
In an effort to develop potential solutions for preventing LA/SA medication incidents, a patient safety event database was reviewed to understand the contributing factors leading to medication cases involving LA/SA drug names. The database, containing roughly 90,000 incident reports over a 3-year span, consists of frontline staff self-reported near misses or harm events in an academic healthcare system. The free text narrative field of the reports was searched using all 399 unique keyword pairs from the ISMP list of confused drug names2. An additional search was performed using approximate string matching to account for spelling mistakes3. Each case narrative was reviewed independently by two subject matter experts (AZH, MEA) and categorized according to one of four phases in the medication use system: 1) documentation, 2) ordering, 3) dispensing, or 4) administration of medication. Error severity level was also determined based on standard toxicology outcome definitions, taking into account both anticipated and actual patient outcomes. Cases of disagreement were discussed until consensus was reached.

Results
A total of 131 initial events were retrieved, of which 82 incidents met inclusion criteria consistent with a LA/SA error. These 82 incidents represent 12 different entities within a single health system. Five of these 131 events (4%) produced an initial disagreement between reviewers, and only one required discussion between reviewers before reaching a consensus. The most common LA/SA medication pairs in the analysis were oxycontin-oxycodone (20%), hydroxyzine-hydralazine (12%), ceftriaxone-cefazolin (11%), prednisone-prednisolone (9%), sulfasalazine-sulfadiazine (7%), hydromorphone-morphine (6%), oxycodone-hydrocodone (6%), dopamine-dobutamine (5%), and risperidone-ropinirole (5%). These pairs accounted for 80% of identified errors. Analysis by date indicated a mean of 2.48 events per month (standard deviation 1.84) over the 33-month period, and a range of 0-7 events per month. The most common reporters were pharmacists (45%), registered nurses (38%), and administration/management staff (9%). The most common errors phase was dispensing (50%), followed by ordering (26%), administration (21%), and documentation (4%). Severity level categorized 46% of events as moderate, 41% as mild, 7% as severe, and 1% as critical. Near misses accounted for 61% of events, while 39% of reported errors reached the patient. Of those events that reached the patient, 9% resulted in temporary harm, while the other 91% resulted in no harm.

Discussion and Conclusion
Initial analysis of the LA/SA medication errors confirms that further exploration is warranted, particularly within the dispensing phase. Future research will review the common themes and discuss the vulnerabilities in medication practices with the health system’s pharmacy team. This will provide a deeper understanding of workflow practices and additional insights into trends within specific facilities. Potential human factors solutions will be formulated with the pharmacy team to develop system-based improvements that will prevent the occurrence of LA/SA errors.

Categorization of Patient Health Goals Elicited During Home Care Admission

Paulina Sockolow DrPH MBA MS¹, Kavita Radhakrishnan RN PhD MSEE², Edgar Chou MD, MS¹
¹Drexel University, Philadelphia, PA; ²The University of Texas, Austin, TX

Introduction

Home care agencies (HCA) provide patients with skilled nursing care and ancillary services at home; however, HCA patient rehospitalization rates exceeded 30% for numerous health conditions.¹ In home care, a program of patient self-management goal elicitation with behavioral change decreased hospital readmission and improved health outcome.² Our objective was to categorize elicited patient health goals and identify “clinically informative” goals.

Methods

The research team with a HCA partner examined patient goals that admitting clinicians documented in the point-of-care electronic health record (EHR) during a 5-month pilot project in 2015. Patient goals were available in a text string in a de-identified Excel file that the HCA extracted from their EHR. To develop a coding scheme, a researcher (PS) conducted content analysis on patient goal data: 1-assigned themes to the first 100 patient goals; 2-grouped themes into codes; and 3-specified code categories. A home care nurse (KR) reviewed the coding scheme that PS used to assign a goal code to every 10th patient. Records without a patient goal were tabulated. PS added new codes that emerged to the coding scheme that KR reviewed. Subsequently, KR and the physician researcher (EC) reviewed the coding scheme independently to identify codes that were informative to their disciplines (clinically important).

Results

Of the 1,763 patient records, 18% had no recorded patient goal. After content analysis of 122 records, the coding scheme totaled 20 codes among 3 categories: 12 Health Management (HM); 6 Activities of Daily Living (ADL); and 2 Quality of Life (QoL). In the sample of records with patient goals, there were 1 to 4 goals documented in each record, for a total corpus of 253 goals. Most goals were phrased in clinician vernacular (e.g., “increased ambulation”) and 6 were in a patient’s voice (e.g., “to be able to walk again”). Codes identified as clinically important to both disciplines were equally distributed among the ADL category (6 codes; e.g., ambulation, safety) and the HM category (7 codes; e.g., manage disease process, nutritional status) with no QoL codes selected. There were 5 clinically important codes that also occurred most frequently: safety/falls (ADL, 18%); ambulation (ADL, 9%); ADL activities (ADL, 9%); manage disease process (HM, 9%); knowledge of disease process (HM, 10%).

Discussion

The absence of the patient’s voice and less than universal recording of home care patients’ goals indicated differential clinician documentation of elicited patient goals. Consistent communication of the intent and operationalization of patient goal elicitation may address differential documentation. In addition, clinician training may be advisable to have clinicians understand why they are asking patients about their goals.¹ Findings also suggest that the most frequently occurring codes were codes identified as clinically important for home care nurses and primary care physicians. These findings indicate a shared perspective about the importance of specific clinical information in the treatment of home care patients; however, a Norwegian study found differences in perspectives.³

Conclusions

Research is needed to identify the most effective approach to operationalize patient goal elicitation; clinically important goals using a larger group of clinicians; and optimal dissemination of this information in patient care. Useful research would also be to identify associations between elicited patient goals, nursing interventions, and outcomes.

Health Reform in Minnesota: An Analysis of Complementary Initiatives Implementing Electronic Health Record Technology and Care Coordination

Karen L. Soderberg, MS¹, Sripriya Rajamani, MBBS, PhD, MPH², Douglas R. Wholey, PhD², Martin LaVenture, PhD, MPH, FACMI¹

¹MN Department of Health, St. Paul, MN; ²University of MN, Minneapolis, MN

Introduction

In 2008 the Minnesota Legislature enacted sweeping health reform intended to improve the affordability, access and quality of care to improve the health of Minnesotans¹. Among other initiatives, the law established certification of patient-centered health care homes (HCH). A year prior, another groundbreaking effort was enacted when the Minnesota Legislature passed the interoperable electronic health record (EHR) mandate requiring all health providers in Minnesota to implement interoperable EHR systems by 2015². We examine synergies between these two programs by studying the association between adoption and use of EHRs in primary care clinics and HCH certification.

Findings

By end of 2014 nearly all of Minnesota’s HCH eligible clinics have implemented EHR systems, including 99.7% of certified HCH and 98.9% of not certified clinics. Overall, HCH clinics were better utilizers of EHR systems for the metrics examined in this study: use of clinical decision support functionalities, utilization of patient disease registries, use of EHR data to support quality improvement efforts, electronic exchange of summary care records, and availability of patient portals (Figure 1). Our results differ from other studies of EHR implementation in Patient Centered Medical Homes, which found more variable adoption of care coordination tools than our study found³. A potential source of this difference is the convergence of complementary health reform initiatives in Minnesota has provided opportunity to show distinct differences in the utilization of EHRs among clinics that have committed to EHR adoption and HCH certification. Certified HCHs have more effectively implemented clinical decision support tools that can result in improved care, improved patient safety, and lower costs. Certified HCHs also better utilized electronic patient registries, allowing them to better track patients with chronic conditions in order to improve care, observe outcomes, and monitor progress toward care plan goals.

Conclusion

The rapid uptake in EHR technology, combined with health reform efforts that focus on accountability and care coordination, pose challenges and opportunities for clinical care providers. Challenges include managing changing workflows, training staff, and understanding system capabilities. Opportunities are real-time access to current patient information, use of automated decision support tools, and secure sharing of information with the patient’s entire care team. These findings demonstrate the value that EHRs can bring to achieving coordinated patient care.

Asthma Ascertainment NLP System Portability across Institutions

Sunghwan Sohn, PhD1, Yanshan Wang, PhD1, Chung-Il Wi, MD2, Elizabeth A. Krusemark2, Euijung Ryu, PhD1, Mir H. Ali, MD3, Young J. Juhn, MD2, Hongfang Liu, PhD1
1Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 2Department of Pediatric and Adolescent Medicine, Mayo Clinic, Rochester, MN; 3Department of Pediatrics, Sanford Children’s Hospital, Sioux Falls, SD

Introduction
Clinical NLP systems have proven to be successful in various tasks. However, the performance often varies across institutions. Whenever a NLP system developed in one corpus is applied to another corpus, the questions arise: “how similar are the two corpora?” and if two corpora differ “how does the difference affect the NLP system portability?” In this study we examined similarities of asthma birth cohorts between Mayo Clinic and Sanford Children’s Hospital (SCH) in terms of entire corpus at word-level and asthma-related concepts. Then, we further explored the NLP system portability for asthma ascertainment.

Materials and Methods
The study cohorts were selected randomly from Mayo and SCH patients (n=298 for each) and matched with age (median = 2.3 years). The cosine similarities between Mayo Clinic and SCH corpora were compared using vector representation defined as follows: 1) Corpus: the entire corpus of each institution was compared as a whole using tf-idf (term frequency-inverse document frequency) and latent topic-based vector. The tf-idf for the term t is defined by summation of tf(t)idf(t) for all documents in the corpus divided by total number of documents in the corpus (N), such as ∑tf(t)idf(t)/N. In the latent topic-based vector representation, the topic zk for the corpus C is defined as p(zk|C) = ∑d∈C p(zk|d)/N; 2) Asthma-related concepts: the concepts were extracted and compared. A vector representation of asthma-related concepts for each corpus was created using the definition of cf-idf (concept frequency-inverse document frequency), where we use the concept frequency in the corpus instead of the term frequency.

Results
Table 1 contains the similarities between Mayo Clinic and SCH corpora. Figure 1 shows the distribution of asthma-related concepts between Mayo Clinic and SCH. The NLP asthma ascertainment system was originally developed on the Mayo’s sick child cohort and tested on the Mayo’s late-preterm cohort with an F-score of 0.762. The current NLP system has been refined on the late-preterm cohort. However, it has not been elevated yet on the held-out test set. The out of box NLP system was applied to the SCH cohort and produced an F-score of 0.813.

Discussion
The entire corpus similarity was merely mediocre showing the different nature between the two corpora in the word level. However, the NLP system for asthma ascertainment is largely dependent on asthma-related concepts and therefore we believe that concept-wise similarities are more important as an estimate of the NLP system portability than the word-level similarity. The direct comparison of the NLP system performance has not been performed due to the lack of Mayo Clinic’s gold standard annotation. However, we believe that the comparison to the previous study shows a reasonable insight about the performance in SCH. The Mayo Clinic and SCH corpus were relatively homogeneous in concepts that show a good potential for the NLP system portability. However, a proper adjustment will be necessary to deal with intrinsic corpus heterogeneity in order to produce the desirable performance of asthma ascertainment.

Automated Extraction of Disease Activity Component Measures From Electronic Medical Records Using Natural Language Processing

Brett R. South, MS, PhD1,2, Shobhit Mehrotra1,2, Chris Leng, MS, Chao-Chin Lu, PhD1,2, Brian C. Sauer, PhD1, Grant W. Cannon, MD1
1VA Salt Lake City VA Health Care System, Salt Lake City, Utah, 2University of Utah, Department of Biomedical Informatics, Salt Lake City, Utah

Abstract Chart Review is often used to obtain patient data only found in clinical texts such as patient outcomes or measures of disease activity. These efforts have high cost and may be less efficient than using natural language processing (NLP). Automating retrieval of disease activity score measures would be a significant benefit for pharmaco-epidemiologic research on rheumatoid arthritis (RA). We evaluate a rules-based NLP approach to extract disease activity scores from VA clinical documents.

Introduction The Veterans Affairs rheumatoid arthritis (VARA) registry is a multi-center observational study of RA patients collecting data from 12 VHA medical centers including 28 joint disease activity score (DAS28) using manual chart review. This method of retrospective data collection is inefficient and automated NLP extraction of DAS28 scores that are entered by providers during a patient encounter using a semi-structured note template would be a great advance. NLP systems have shown promise in reducing labor-intensive chart review tasks such as quality assessment1, risk assessment2, cohort generation3, and for extracting RA disease activity4.

Methods We constructed a development set of 472 clinical documents for VA Salt Lake City VARA patients (n=207) between January 1, 2015 and September 30, 2015. This set was used to train a rules-based NLP system to extract three DAS28 core measures: tender joint count (TJC), swollen joint count (SJC), and patient global assessment (PtGA). A validation set was constructed using 484 clinical documents from the same site for VARA patients (n=214) seen in clinic between April 1, 2014 and December 31, 2014. We evaluate system performance metrics (accuracy and precision) comparing NLP outputs against clinical gold standard data obtained from the VARA registry by manual review.

Results Accuracy and precision calculated using the validation set and treating the VARA registry as the clinical gold standard for each of the three DAS28 core measures was: TJC (93%, 100%), SJC (92.1%, 100%), and PtGA (92.1%, 99.8%). NLP failures were all explained by situations where incorrect note templates were used or where the template was modified.

Conclusion The development of an NLP system to electronically retrieve disease activity measures would be a significant benefit for pharmaco-epidemiologic research on rheumatoid arthritis (RA). Our process was successful at retrieving DAS28 components from clinical documents and can be implemented in an automated way to reduce chart review burden. Future directions will apply these methods to other VARA sites and automate population of NLP retrieved data into the VARA registry.

Contrasting Autism Subgroup Genotypes Using Frequent Pattern Mining

Matt Spencer¹, Chi-Ren Shyu, PhD¹,²,³,⁴

¹Informatics Institute, ²Department of Computer Science, ³School of Medicine, ⁴Department of Electrical and Computer Engineering, University of Missouri, Columbia, MO

The etiology of autism spectrum disorder (ASD) remains poorly understood, imposing an obstacle to the diagnosis and treatment of people with the disorder. Genome-wide association studies (GWAS) have identified isolated gene candidates that are only minimally associated with the disorder¹, so recent studies emphasize the effects of interacting single nucleotide polymorphisms (SNPs)². Most studies search for genetic causes of autism as a whole, rarely considering that autism may be an assortment of many disorders with similar phenotypes. If this is the case, then sets of SNPs may contribute to specific subdivisions of the disorder. Here we apply the idea of interacting SNPs to identify genetic differences between potential subpopulations of autism.

We analyzed the Simons Foundation Autism Research Initiative (SFARI) dataset comprising over 2600 families, a larger population than most autism studies. SNP microarray genotype data and phenotype classification data (demographics, behavioral phenotypes, etc.) are available describing the proband, both parents, and siblings for each family. Thus, every affected individual is contrasted by unaffected individuals with many of the same SNPs. We exploit this to focus our analysis to the combinations of multiple SNPs (multi-SNPs) unique to the individual with autism in each family.

Frequent pattern mining is a useful method for identifying combinations of genotypes that may be related to notable phenotypes, especially since genotype data introduces far too many variables for a regression analysis. We previously implemented a frequent pattern mining package in Apache Spark³, allowing us to utilize a distributed computing environment to address the computational challenge of testing combinations of many genetic loci. This software identified multi-SNPs that are frequently observed in individuals with autism.

We developed a workflow that allows us to highlight multi-SNPs that show a significant difference in prevalence between two subpopulations. After stratifying a population according to phenotype classifications, we calculate the occurrence of multi-SNPs in each subpopulation using the frequent pattern mining package described above; these are subsequently filtered when the multi-SNP is not unique to the proband within each family. The populations are then contrasted by comparing the frequency of occurrence of each multi-SNP in either group.

Our preliminary study contrasts probands with and without substantial physical abnormalities. We focus on variations in genes that have been studied in the context of autism, a total of 740 genes derived from the AutDB database⁴. We identified 55 multi-SNPs that have at least a five-fold difference in prevalence in these populations, providing candidate genes for further investigation into the underlying genetic distinction between the groups. This method is being utilized in ongoing research to compare other subpopulations of the Simons dataset.

We aim to use this method to uncover distinctions between subpopulations of autistic children and provide candidate genes that are associated with specific phenotypes for further investigation. This may lead to a better understanding of the mechanisms that produce individual phenotypes and may even provide evidence that a subpopulation should be considered a separate disorder, allowing for more specific diagnosis and treatment of each group. Although the etiology of autism is complex and will not be explained through any single effort, an emphasis on multi-SNPs allows this method to suggest contribution from genes that would otherwise be overlooked by conventional GWAS methods.

Smartphone-platforms Apps and Medical Disciplines serving Mobile-Health

Basile Spyropoulos\textsuperscript{1,2} PhD, Maria Bania\textsuperscript{2} BSc, Irini Mathe\textsuperscript{2} BSc, Stavros Miloulis\textsuperscript{2} BSc, Georg Tziokas\textsuperscript{2} BSc, Kostas Proestos\textsuperscript{2} BSc, Iliana Gerakou\textsuperscript{2} BSc, Manolis Kapernaros\textsuperscript{2} BSc
\textsuperscript{1}Technological Educational Institute (TEI) of Athens, GR, \textsuperscript{2}University of Athens, GR

Abstract

A “3-dimensional project” is presented addressing, firstly, cardinal medical-managerial m-Health aspects, secondly, evaluating currently available Smartphone-OS/platforms and finally attempting to design Apps to be employed in important m-Health Medical Specialties. It is based on the outcomes of a novel, innovative and collective final-examination approach, in the MSc.-Course “Medical Information Technology and Telemedicine”, for the seven Students of the common Graduate-program “Information Technologies in Medicine and Biology” of the University of Athens and the TEI of Athens, based on extended reviews of Patent Applications and other Papers.

Introduction

Mobile-health is a term used in Medical Practice, supported by mobile devices, collecting clinical data, healthcare-information, allowing for real-time monitoring of vital signs etc. The Internet of Things (IoT) holds a great potential to meet yet unmet needs of Healthcare, however, IoT technologies demand further R & D. In this paper, we attempt to predict the potential of the combination of these emerging approaches, as reflected mainly on Patent Documents.

Methods and Resources

The most important aspects of m-Health have been approached as a “triplet” of components including (Table 1):

\begin{itemize}
  \item Medical-managerial m-Health aspects as Health-vigilance, Safety, Market-trends, Providers’ Liability etc.
  \item The advancement of the OS/platforms developed, as reflected on relevant published Patent-Documents.
  \item An attempt to design Apps, based on similar principles, to support m-Health related Medical Specialties.
\end{itemize}

328 m-Health relevant Patent Applications (PA) have been retrieved and evaluated, by employing the esp\@cenet search-engine of the European Patent Organization (EPO) and a detailed mapping has been created (2000-2016).

Results

The group has focused on the most urgent or promising issues and aspects of m-Health as presented in Table 1.

Table 1. An overview of the three major components of the collective project presented.

Analyzing Similarities in Handoff Communication Content between Residents and Nurses

Vignesh Srinivasana, Thomas Kannampallilb, Trevor Cohena, Joanna Abrahama
a University of Illinois at Chicago, Chicago, IL, United States; b University of Texas School of Biomedical Informatics, Houston, TX, United States

Abstract
Past empirical handoff research has emphasized the importance of developing shared understanding among various clinicians (physicians, nurses) for streamlining the handoff process. We compared the degree of content overlap between the content of communication of handoff between residents and nurses using two methods: first, using a standardized Jaccard’s coefficient, and second, using human raters. We found significant association between the two methods ($r=0.54$) suggesting that Jaccard’s coefficient is a reliable measure for analyzing clinical content.

Introduction
Handoffs are primarily a communication activity that involve a transfer of patient information, responsibility, and authority between clinicians. A vast majority of handoff tools are designed to promote discipline-specific communication. While recent studies have emphasized the importance of building an interdisciplinary ontology for handoff communication, we have identified two gaps in the current handoff research: (1) a lack of understanding of the potential overlap in the content of communication between disciplines; and (2) lack of an analytical method that can identify this content overlap between disciplines. However, no reliable methods, besides human coding, exists for establishing the overlap between content. In this paper, we compare the human coded transcripts of overlap with Jaccard’s coefficient to evaluate its appropriateness as a metric for investigating content overlap.

Method
The study was conducted in an Internal Medicine unit of a large academic hospital in Midwestern United States that has over 13,000 hospital encounters per year. Handoffs between outgoing and incoming residents/nurses occurred every day at shift changes. Resident and nurse handoffs of 10 random patients were shadowed and audio-recorded. Transcripts of residents ($n=10$) and nurses ($n=10$) were segmented along the clinical content categories based on a previously developed handoff content coding framework (that includes identifying information, code status, allergies, disposition, medical history, active problems, assessment of active problems, pending labs/procedures, medications/treatments, tasks/to do, family)². Human rating was provided by two clinical experts (1 resident and 1 nurse): For each pair of transcripts (resident and nurse), the rater indicated how similar they perceived the transcripts were on a five-point scale with 1 indicating “no similarity” and 5 indicating “high similarity” (this was done for each content category). These pairs of documents were blinded and randomized to all coders. Jaccard’s coefficient has been used to effectively measure the similarity between words with high stability. Next, for each pair of documents, we computed the Jaccard’s coefficient. The ratings obtained from human coding and the Jaccard’s method were then compared using Pearson’s correlation.

Results & Discussion
We obtained a moderately high degree of correlation between the two rating methods ($r=0.54$). While we had a relatively small set of documents, the Jaccard’s coefficient achieves a good correlation with human judgement. The results clearly show that the Jaccard’s coefficient, which is widely used for comparing the similarity and diversity of sample datasets, is a reliable measure to evaluate similarity in communication content between disciplines.

Most Common Allergen Terms in the DoD and VA
Developing a Baseline Set of Allergen Terms for the C-CDA Using RxNorm "Ingredient" Level Abstraction

Karl J. Stiller PharmD, David A. Parker MD, Brett A. Marquard, BS, Margaret A. Marshburn, RN, Sharon L. Moore, BS, Steven F. Kator MD, Norman E. Stone III MD

DoD/VA Interagency Program Office, Rosslyn, VA

Objective
Determine the most common allergen terms recorded in the Departments of Defense (DoD) and Veterans Affairs (VA) electronic health records, with a goal of improving semantic interoperability for drug-allergen clinical decision support, and establishing a baseline set of terms for the Consolidated Clinical Document Architecture (C-CDA).

Methods
The enterprise data stores of the DoD and VA were queried for all allergen terms and corresponding frequency of use. Medication terms were mapped to RxNorm Concept Unique Identifier (RxCUI); Medication classes were mapped to the National Drug File - Reference Terminology (NDF-RT). Medications were then abstracted to the RxCUI "Ingredient" level. The DoD and VA lists were merged to a single list using RxCUI and NDF-RT as the common keys. The list was rank-ordered by combined frequency of use and the 95% usage list was calculated.

Results
601,666 recorded allergies to medications or medication classes were analyzed. The DoD data store contained a dictionary of 103,862 terms, of which 4,339 terms were used at least once. 446 terms represented 95% of all recorded allergens. The VA data store contained 2,298 terms, all of which were used at least once. 305 terms represented 95% of all recorded allergens. Combined, the Departments’ lists contained 498 unique medication and medication class allergen terms. The top 3 allergen terms were Penicillin, Lisinopril, and Sulfonamides (medication class), representing 14%, 8%, and 7% of all recorded allergens, respectively.

Conclusion
Relatively few allergen terms comprise the majority of recorded allergens in the DoD and VA. Agreement on this limited set of common allergen terms could simplify achievement of semantic interoperability in this important domain of health data.

Is More eHealth System Use Better for Cancer Patients and Family Caregivers? A Literature Review

Wu-Chen Su, M.S., Ming-Yuan Chih, Ph.D.
College of Health Sciences, University of Kentucky, Lexington, Kentucky, USA

Abstract
We aim to review eHealth literature for cancer patients and their family caregivers, and summarize differential eHealth system use effects. 2595 articles were searched, and 12 that met the exclusion/inclusion criteria were reviewed. The review demonstrated that more system use were associated with improved health outcomes. However, further studies are needed to provide stronger evidence and application of differential eHealth use effects.

Introduction
EHealth has been shown to support cancer patients and their family caregivers. However, such interventions do not always lead to predictable outcomes due to different system use. Increasingly, researchers went beyond reporting randomized trial results by examining the impact of system use on the effects of eHealth interventions. We aim to provide a review of these studies and summarize the reported differential system use effects.

Methods
In February 2016, the authors searched PubMed using these broadly defined eHealth terms: “((Internet OR web* OR smartphone* OR "mobile app") AND (therapy OR “self-help” OR intervention)) OR eHealth OR mHealth OR telehealth OR telemedicine OR [Mesh] "telehealth" } AND Cancer” and found 2595 research articles. After excluding articles that met the criteria: 1) non-full text, 2) non-English, 3) not eHealth interventions for cancer patients or caregivers, and 4) not reporting system use and users’ physical, psychological and social health outcomes, 12 papers were included. Types of cancer, intervention, study period, correlations between users’ characteristics and system use, and correlations between users’ health outcomes and system use were summarized.

Results
Of these 12 articles, 11 were published after 2010; nine conducted in the U.S. Seven articles focused on breast cancer, while the rest covered mixed cancers (including prostate, colorectal, and lung). Cancer patients and survivors were the main target populations. Only one study included family caregivers. The main studied eHealth interventions included online social support groups (6), decision aids (3), expert consultation (1) and the combination of them (2). All interventions were web-based. Most studies (8) lasted for more than four months. All studies allowed participants to use eHealth interventions freely without required or prescribed amount of use. Nevertheless, one study made the eHealth intervention available to both randomized groups but provided the study group participants structured approaches to encourage more system use. Four studies reported the correlations between users’ characteristics (e.g., psychological status at pretest, demographics and treatment history) and the level of system use. The cancer knowledge, mental illness status and perceived social support at pre-test stage are important factors to predict the level of system use. For instance, the high-use group participants were often those who reported poor psychosocial status at pretest than those in the low-use group. These 12 articles reported a total of 30 unique system use measures, including 13 basic system use measures (e.g., logins, time spent, and page views) and 17 advanced system engagement measures (e.g., posts and votes). Overall, more system use has been associated with improved physical outcomes (e.g., length of survival), psychological outcomes (e.g., depression and anxiety), self-efficacy, knowledge, behavioral outcomes (e.g., intention and attitude) and social outcomes (e.g., bonding and social support). However, two studies reported the relations between the level of system use and health related outcomes were not statistically significant, and two studies found negative impact of system use: 1) more page views were found to be related to less favorable attitude toward cancer screening tests; and 2) those who were instructed to post more emotional, informational, and companionate support messages in an online support group reported higher depression and anxiety afterwards. Detailed findings were provided here (http://tinyurl.com/hq3sebg).

Conclusion
In conclusion, several eHealth use measures and their differential effects on health outcomes of cancer patients and caregivers were found and summarized. Further studies should focus on providing stronger evidence (ideally via randomized trial design) of such a dose (system use)-response (health outcomes) relationship. Additionally, the knowledge of differential system use effects may provide the basis for the design of a more effective eHealth intervention that facilitates beneficial system use behavior of cancer patients and their family caregivers.

Abstract
The Pediatric Research using Integrated Sensor Monitoring Systems (PRISMS) program was launched in 2015 to develop sensor-based, integrated health monitoring systems for measuring environmental, physiological, and behavioral factors in epidemiological studies of pediatric asthma. PRISMS will develop an open platform and associated suite of tools to enable a comprehensive spectrum of biomedical research into chronic diseases in pediatric populations. We describe the PRISMS program goals, operations, and organization, and informatics challenges.

Introduction
The NIH launched a cross-institute initiative to examine the effects of the environment on children’s health, including the Pediatric Research using Integrated Sensor Monitoring Systems (PRISMS) Program¹. As part of its mission NIBIB conducts research and development of new bioengineering techniques and devices to improve the detection, treatment, and prevention of disease, including technologies for disease detection and assessment of health status.

Problem addressed/purpose
Pediatric asthma is complex, with interactions between environmental, physiological, and behavioral factors. In PRISMS, researchers will develop a variety of novel sensors, sensor-based integrated health monitoring systems, and an interoperable data management platform to make environmental and health data available to epidemiologists and clinical researchers. The integrated effort will offer new insights into non-invasive health monitoring and pediatric asthma research. PRISMS is organized to address several informatics challenges.

Program organization
Sensor Development Centers develop new sensors or redesign existing sensors to monitor environmental stressors and physiological parameters correlated with pediatric asthma. Informatics Platform Centers manage secure data acquisition and processing, integration of sensor data with other data sources, and secure transmittal to the Data and Software Coordination and Integration Center, which verifies data quality, harmonize data into a consistent model, and supports analysis. Key challenges to be addressed in the PRISMS Program include developing robust measurement devices to collect environmental and behavioral data. Devices must be feasible and acceptable for study participants and investigators to use. Informatics platforms must be flexible, interoperable repositories that embrace diverse approaches to environmental and behavioral measurement; calculate interim measures such as multiple asthma severity scores; and must be generalizable to other types of environmental epidemiology studies. The platforms must accommodate mobile health (mHealth) approaches and must be scalable for large multi-center studies. Other challenges include managing uncertainty and diverse quality inherent in sensor data, the need to integrate data collected at multiple levels of granularity and timing, and information models and standards that may not adequately encompass the detail needed for sensor-intensive research.

Conclusion
Developing a sensor-based, integrated health monitoring system for measuring environmental effects on health offers challenges that require informatics innovations, methods and tools. Pediatric asthma research is likely to benefit from the comprehensive spectrum of biomedical informatics efforts developed through the PRISMS program.

Never-Ending Medical Learning

Douglas A. Talbert, PhD; William Eberle, PhD; Mei Liu, PhD

1Tennessee Tech. Univ., Cookeville, TN; 2Univ. of Kansas Med. Center, Kansas City, KS

Introduction and Background

Effective collection and application of healthcare experience data presents an ongoing challenge to the quality and cost of healthcare delivery in the United States and has contributed the Institute of Medicine’s (IOM) development of a vision for a continuously learning health care system to “promote and enable continuous and real-time improvement in both the effectiveness and efficiency of care.” In support of this vision, we have designed and implemented an early stage prototype that seeks to apply recent developments in never-ending machine learning to healthcare. We call this prototype the Never-Ending Medical Operative (NEMO).

The never-ending machine learning paradigm seeks to construct computer programs that, like people, learn many different types of knowledge from years of diverse experience, make use of previously learned knowledge to learn new types of knowledge, and use skills such as self-reflection to sustain continuous learning and avoid performance plateaus.

NEMO was inspired and informed by CMU’s Never-Ending Language Learner (NELL). NELL was designed to explore the application of never-ending learning to the task of reading the web by pursuing just two goals: (1) read the web to improve the quantity and quality of its knowledgebase and (2) learn to read better. Like people, NELL employs multiple strategies to achieve these goals in an ongoing, continuous manner.

Prototype Design and Implementation

Our NEMO prototype implements a step toward never-ending learning, in which semi-autonomous, adaptive learning is directed by domain experts and user feedback regarding system output. Figure 1 shows NEMO’s high-level architecture. The Client Web App is the primary user interface and is where domain experts direct and give feedback on NEMO’s learning. The AI Controller is responsible for the learning as well as adapting in response to user feedback. The Data Loader pulls a subset of records from the i2b2-based KUMC clinical data repository and stores them in the Data Mart. The Data Mart holds a subset of patient data to be used by the learners, the questions posed by the domain experts will pose, and the user feedback.

Next Steps

This prototype is the first step toward NEMO’s long-term vision of being a collection of intelligent agents that cooperatively contribute to an ever-learning computational healthcare support environment. The evaluation of this prototype will focus primarily on its ability to successfully implement semi-autonomous, adaptive learning in a medical domain. Subsequently, the scope of NEMO will expand to include work on how NEMO selects which knowledge to pursue and how NEMO can enrich its knowledge and influence health and healthcare through interactions with patients and providers.

Fitbit™ Fitness Tracking Ease of Use and Utility: Preliminary Findings for Potential Use in Clinical Care

David P. Taylor, PhD1; Nathan C. Hulse, PhD1,2; Chaitanya K. Mynam, MS1; Bhanu Iyer1; Matthew H. Ebert, MS1; Jason P. Gagner, MBA1; Peter J. Haug, MD1,2
1Homer Warner Center, Intermountain Healthcare, Salt Lake City, UT; 2University of Utah, Salt Lake City, UT

Introduction

Sedentary behavior is an increasing problem and a contributor to obesity, chronic disease, and rising healthcare costs. Fitness tracking may help individuals more accurately monitor and increase physical activity levels. Tracking other lifestyle aspects such as diet and sleep may also provide benefits. As part of a diabetes prevention program at Intermountain Healthcare we built tools, utilizing Fitbit’s API, to help patients share their Fitbit data and provide care team access to summarized views of the data. We are reporting preliminary findings on the ease of use and utility of the Fitbit system in a sample of test subjects prior to its use with actual patients.

Methods

We produced iterative designs for the web-based tools using input from clinicians. After implementation, 6 medical informaticists used Fitbit devices to test the system. We interviewed participants at 9 months after data were first collected with follow-ups at 22 months. The main goals of the interviews were to assess the ease of use of the Fitbit system and determine the utility that the participants derived from it. We accessed summarized data on physical activity, sleep, diet and weight through the data review tool to assess how often and how consistently test subjects were tracking.

Results

The web-based patient enrollment and fitness data review tools were successfully implemented in a production environment. The enrollment tool was available through the Intermountain patient portal, My Health. An automated nightly call retrieved any new or changed Fitbit data for participants through the API. The fitness data review tool displayed summarized views of the data for authorized care team members. Over 22 months, test subjects tracked steps 73% of possible days with a daily average of 10,383 steps. Four of six test subjects continued to use the system regularly at 22 months. Sleep and diet tracking features were not well used (19% of nights for sleep and 1% of days for diet tracking). No participants reported body weight using Fitbit more than once or twice.

Discussion

Overall, test subjects regarded the Fitbit system as worthwhile in motivating them and/or reinforcing fitness habits, particularly for step-oriented activities that required no manual effort to track besides remembering to wear the device. Any tracking activity that requires effort, such as manually entering data, is much harder to maintain. It is obvious that individuals have different sources of motivation to engage in and track physical activity. With regard to tracking, some individuals may have more internal sources of motivation while others prefer competition, status, or other social benefits. Others may respond to monetary rewards or prizes that are more tangible. In this study the social features (e.g., comparisons with peers) were motivating to some but not others. We anticipate that a variety of methods—reminders, incentives, and frequent communication between patients and care team members may be necessary to help sustain patients’ efforts in fitness tracking. Although medical informaticists may not be representative of the general population, what we learned is still valuable. If informaticists are not willing to use a certain set of features consistently, it seems unlikely a less tech-savvy population would either.

Conclusion

The ability to acquire data from systems such as Fitbit provides interesting opportunities to integrate fitness tracking into clinical care. We have demonstrated it is possible for individuals to maintain consistent tracking habits over a period of months, or even years. However, there is still a question whether a fitness tracking device on its own, without any additional incentives or affiliated coaching, will demonstrate a significant improvement in fitness outcomes in most individuals. Until systems become even more automated and easy to use, individuals may need additional incentives and outside support to form and maintain tracking habits to reach health goals. Additionally, as more patient-generated data become available for clinical use, there are interesting questions about the utility of these data, how to summarize them appropriately, which members of the care team should review and act on them, and where these activities fit in clinical workflow.
Relieving Operational Burdens of Participants in Inter-organizational Care Coordination

Sidney N. Thornton, PhD¹-², Shan He, PhD³, Iona Thraen, PhD²³, Deepthi Rajeev, PhD⁴
¹Intermountain Healthcare, Salt Lake City, UT; ²University of Utah, Salt Lake City, UT; ³Utah Department of Health, Salt Lake City, UT; ⁴HealthInsight, Salt Lake City, UT

Introduction

Provider organizations within the Utah geographical region have demonstrated a willingness to participate in inter-organizational care coordination projects that improve the health of patients for whom they share treatment. Care coordination by definition spans multiple patient encounters and potentially multiple provider organizations using disparate EHR systems and connectivity networks. Many pilot care coordination projects are underway from provider, payer, and public health sectors¹. The current investment to participate in a care coordination project is substantial and requires both technology and personnel. The question under investigation by the Utah community is what aspects of care coordination can be pooled centrally. Policy constraints in the community favor a federated model but precedence exists for centralized repositories².

Methods

Active projects of care coordination were collected from stakeholders including initiatives funded privately and through public grants. The convenient sample of fourteen use cases of care coordination represented clinical, public health, patient engagement, and payment reform sponsorship. The technical interoperability requirements along with the workflow implications of data exchange and integration were analyzed for common functional components. Optimal integration strategies were evaluated based on existing and proposed data sharing policies and agreements, and were evaluated based on scalability for future care coordination scenarios. Gaps in policy were identified and escalated to the community governance committees for assistance.

Results

Potential economies of shared care coordination utilities and services are identified for the following electronic maintenance and discovery transactions: patient identity proofing and identity verification; patient designated proxy and legal care representation; patient’s current care team by role and active status; care team providers’ delivery preference and connectivity details; and care coordination logic (trigger recognition, service orchestration, and system and patient-registered device notification). The shared utilities and services will be hosted centrally and available for consumption by all participating stakeholders. Maturity and readiness of the proposed services are variable with most experience in the patient identity space. Standard, interoperable definitions and models for care teams are not widely implemented particularly when integrated with patient portals. Significant policy and technology gaps exist for sharing patient proxy information.

Discussion

A trade-off exists between scalable workflow automation and the operational burdens associated with care coordination. Larger organizations with more advanced clinical exchange functionality will require scalable automation to ensure replicable and standardized data behavior, while smaller facilities may tolerate manual processes in the beginning. Some independent facilities will find economies and operational relief through the state designated clinical exchange authority that will have full access to the envisioned shared services and utilities for care coordination. Limitations of the process include the breadth of the convenient sample of scenarios and a reasonable evaluation methodology for national scalability. Near term refinements of policy are being organized.

Development of Test Topics for Cohort Identification

Tamara Timmons, M.D.1, Stephen Wu, Ph.D. 1, William Hersh, M.D. 1
Oregon Health and Science University, Portland, Oregon

Introduction

Patient cohorts are a fundamental component for many types of biomedical research. Our long-term goal is to develop sound information retrieval (IR) methods for patient-level cohort identification from clinical text. To evaluate these methods while protecting patient privacy, we have begun creating a secure, intra-institutional resource using the Cranfield approach for evaluation of a cohort retrieval task: creating a test collection with three components: a collection of documents, a set of topics, and relevance assessments. In this abstract, we focus on the subject of topics, describing our development process and the considerations and challenges specific to their use in patient-level clinical IR.

Test topic development

The topic development process had 3 main steps: 1. definition of topic format, 2. selection of representative sources, and 3. abstraction of source documentation into topic contents.

Topics are provided in 3 different formats for possible queries: 1) summary statement; 2) brief summary and clinical – a shorter summary statement plus a mock clinical case incorporating a patient and scenario which typify the topic criteria; 3) brief summary plus structured data – a summary statement plus criteria list. This format is similar to topics in some TREC ad hoc collections, and both reflect varying user approaches1.

We aimed to have 50 topics in our set, an adequate set size to achieve evaluation measure stability2. For use as topics, we considered 60 cohorts from sources representative of different use cases for cohort identification such as clinical study recruitment or quality measure reporting. The resulting topics are drawn from 5 sources: OHSU’s research data warehouse (RDW) (29 topics), Mayo Clinic’s RDW (2 topics), Phenotype KnowledgeBase (PheKB) (7 topics), Rochester Epidemiology Project (REP) (9 topics), and the National Quality Forum (NQF) (12 topics). Similar topics were merged (1 OHSU/REP, 2 OHSU/PheKB), and 1 was excluded (non-patient cohort).

Topics vary in eligibility criteria, but a few contained extensive lists of criteria, or multiple combinations of different criteria satisfying overall eligibility. For practical reasons, these topics required simplification by removing criteria less integral to the topic’s objective.

Development of such topics requires consideration of many factors that influence the results. In developing test topics for this project, such factors included: variation in topic criteria complexity, maintaining applicability to multiple use cases, and creating multiple representations of each topic.

Real-Time Patient Satisfaction Surveys via an Emergency Department Portal

Marc Tobias, MD¹, Julie Westover, BS¹, Daria Ferro, MD¹, Joseph J Zorc, MD, MSCE¹

¹The Children’s Hospital of Philadelphia, Philadelphia, PA, USA

Background: The standard methods for measuring patient satisfaction in healthcare settings are limited as they are typically completed well after the encounter and have low response rates. Methods to capture patient feedback in real-time would allow clinical teams to respond and improve care prior to discharge.

Aim Statement: We assessed use of a website to measure patient satisfaction during an Emergency Department (ED) visit. We compared two methods for survey administration: 1. Invitation by research associates (RAs) to participate in providing feedback, and 2. Self-guided completion by families using their own device via a web portal (BYOD).

Methods: We created a web portal (http://ed.chop.edu) that patients and their families can access while receiving their ED care (Figure 1). A link to a RedCap™ patient satisfaction survey was offered through this web portal as a method to measure satisfaction. RAs also randomly selected patient rooms to administer an identical survey. The survey measured overall satisfaction and specific elements of care on a 1 (worst) to 7 (best) Likert scale.

Outcomes: During the evaluation period starting January 2016, RAs administered 324 complete surveys and there were 41 complete BYOD surveys. Ongoing data collection is in progress for both groups. The median overall satisfaction for the RA surveys was 7 out of 7 (IQR 6-7) with a mean of 6.6 (95% CI 6.5-6.7); 13.3% (95% CI 9.8-17.5%) of these surveys provided free-text comments that were deemed actionable. For the pilot BYOD surveys, the overall satisfaction ratings median was 7 out of 7 (IQR 5-7) with a mean of 5.9 (95% CI 5.4-6.4) and 51.2% (95% CI 35.1-67.1%) surveys contained actionable free-text comments (Figure 2).

Conclusion: Preliminary results suggest that real-time satisfaction surveys administered by RAs measure a high degree of satisfaction with relatively few actionable comments. Pilot surveys completed spontaneously by families using their own devices showed lower satisfaction with more actionable free-text comments. Further data will be available for presentation at the meeting.

Operationalizing Best Practice for First Follow-up Visit after Discharge from a Well-Baby Nursery
Michael Totzke, Catherine Staes PhD, Julie Shakib D.O. MPH,
Department of Biomedical Informatics, School of Medicine, University of Utah, Salt Lake City

Background
The American Academy of Pediatrics (AAP) Bright Futures guidelines for the timing of the first well-child visit (WCV) after discharge from a Well Baby Nursery (WBN) recommend that the visit occur within 48 hours of discharge for newborns with a WBN length of stay of <48 hours, and within 3 to 5 days for those with a WBN length of stay of >48 hours.¹ The purpose of these early WCVs is to detect conditions that may cause readmission in the first weeks after birth. Recommendations that the first outpatient visit occur within a few days after discharge differ from the previous standard practice of the first WCV at 2 to 4 weeks of age.² A recent large retrospective study by Shakib et al. demonstrated that completing the first WCV in compliance with the AAP guidelines was associated with a 15% reduction in the rate of readmissions compared with a later first WCV.³ We hypothesized that adding a “recommender” module or application within the electronic medical record (EHR), such as a best practice alert (BPA), may help to improve compliance with the AAP guidelines and prevent newborn hospital readmissions. The logic that would determine best practice could be integrated into an EHR as a set of rules that could function as a type of “recommender” to a clinician in the nursery.

Methods

Process modeling
To understand the processes and the logic of a clinician’s workflow involved after the birth of a baby, as the mother and baby are being observed and preparing for discharge, I interviewed Dr. Julie Shakib, medical director of the Well Baby and Intermediate Nurseries at the University of Utah Healthcare. Dr. Shakib described each step in the process flow that a pediatrician goes through when documenting the first follow-up appointment using the Epic EHR system.

Operationalizing business logic
The logic was documented which describes all the data needed to be captured in the workflow involved in the processes of setting a first follow-up appointment. The logic was placed in sequential order and then reviewed and refined with Dr. Shakib by adding clinical criteria that would influence the timing of the first appointment. We compiled a list of clinical criteria and diagnoses, and their associated ICD-9 codes, that might appear in the problem list portion of the EHR and which might change the scheduled time of discharge as well as the scheduled first follow-up appointment.

Discussion
A problem with the current process of documenting the first follow-up appointment is evident when discharge planning begins. In the Epic EHR, when a pediatrician initially wants to document a patient’s discharge information, they first have to enter the name of the outpatient pediatrician before they can even see the discharge form. An improvement to this process would be to present the discharge information, including the anticipated first follow-up date and time, to the pediatrician the first time they click on the discharge form. Getting the information with less effort and in less time will help the process move more smoothly.

There are several foreseeable scenarios that might hinder the ability to make the appointment within the recommended time frame. For example, the recommended date and time might fall on a weekend. Saturdays are sometimes possible appointment days, but pediatric clinics are generally not open for appointments on Sundays. In these cases, the attending pediatrician could use their judgement to decide if the baby could be seen on the following Monday, or would need to be seen earlier. This decision could be documented as free text in the discharge note or, better yet, as a structured comment in a new data field added to the discharge tab so the rationale is more easily computable.

References

Introduction
Patients presenting to the emergency department (ED) with life-threatening aortic dissections (AAD) can be challenging to diagnose. Though the time-sensitive condition is rare, these patients are at high risk for death; therefore delays in diagnosis must be avoided. AAD symptoms can be vague and may mimic other conditions such as acute coronary syndrome or abdominal pain. Our team examined a population-based ED database to identify presenting symptoms of patients diagnosed with AAD to enhance current clinical decision rules. Upon review of the data, we noted that the patient records included AAD in all 11 diagnosis (dx) positions (from 1-primary, to 2-secondary…to position 11). Prior to analyzing symptom data, we had to differentiate patients with life-threatening AAD from those with a history of AAD. The purpose of this study was to develop a case definition for ED visits attributable to AAD by determining the accuracy of including visits with AAD dx in secondary or tertiary positions.

Methods
We obtained ED visit data for 2008-12 from a statewide ED database which accounted for 99.5% of all visits to North Carolina (NC) EDs. Included were visits with an ICD-9-CM code for AAD (441.00-441.03) in any dx position. We then grouped the visits into 11 strata based on the dx position containing the AAD code. We also conducted a manual chart review of a stratified random sample (AAD in dx positions 1-11) of 2008-12 visits to an academic medical center ED in NC. A trained research nurse manually reviewed the full EHR record for each patient to determine whether the visit was attributable to AAD or a history of AAD.

Results
2841 (0.01%) of the 22.4 million ED visits in NC had an AAD dx, distributed across all 11 dx positions (Table 1).

31 charts with dx 441.00-441.03 were reviewed. 16 (52%) of the visits, with AAD in positions 1-3, were for life-threatening AAD (Table 2). The remaining 15 had unrelated primary dx, plus a history of aortic dissection in the past.

<th>Primary Dx</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>786.5 chest pain</td>
<td>790.7 bacteremia</td>
</tr>
</tbody>
</table>

Conclusions
Our findings suggest that patients with an AAD dx in the second or third dx position may have life-threatening AAD but are more likely to have a previous history of AAD. The availability of large clinical datasets can facilitate research that is otherwise impractical, but accurate case definitions are required for appropriate use of these data.

Logical Rules for the Automated Ordering of Isolation Precautions

Jacob S. Tripp, PhD¹, Cherie Frame, RN, MSN, CIC², Crissy Elliott, MBA, MT (ASCP), CIC², Gisele G. Borsato, MS¹, Rebecca Farr, BS³
¹Homer Warner Center for Informatics Research; ²Infection Prevention; ³Nursing Operations;
Intermountain Healthcare, Salt Lake City, UT

Hospital-acquired infections (HAI) are one of the most common adverse events experienced by hospitalized patients. These infections include Methicillin-resistant Staphylococcus aureus (MRSA), Vancomycin-resistant enterococci (VRE), and other multidrug resistant organisms (MDRO), as well as many other less well-known diseases. The Centers for Disease Control and Prevention (CDC) maintains a list of isolation guidelines for nearly 250 infectious diseases.¹ As the numbers and types of infectious diseases are varied and often rare, Intermountain Healthcare has a history of using Computerized Decision Support (CDS) to aid clinicians in selecting appropriate isolation precautions for patients. In 2015, in connection with the implementation of a new electronic health record (EHR) installation, a team of infection control practitioners and engineers developed a set of logical rules to determine when patients needed to be placed on isolation precautions, and to automatically place orders for these isolation precautions, attempting to account for each disease in the CDC isolation guidelines.

These rules make use of a variety of clinical data elements to determine when isolation precautions are needed and the type of isolation to be ordered. The data elements used include a patient’s problem list, diagnoses, test orders, lab results, and data charted by nurses. Some examples of the rules are rules that: check a patient’s problem list upon admission for a history of MDRO infections; order isolation for patients who are diagnosed with hepatitis A or E and who also have evidence in their chart of having diarrhea or incontinence; order isolation precautions for pediatric patients for whom a rapid RSV (respiratory syncytial virus) test has been ordered; isolate incontinent patients with positive stool culture results; order isolation for patients with recent travel history to West Africa; isolate patients for whom nurses have charted evidence of rash, headache, fever, and photophobia, as this combination of symptoms may be an indication of meningitis. As of March 3, 2016, 113 logical rules for ordering isolation precautions had been created. Rules are continuously created and refined based on clinician feedback.

As a preliminary evaluation of these rules and the automated orders, a four-month sample of isolation orders at the largest hospital currently using them was studied. Between November 1, 2015 and February 29, 2016, there were 5030 orders for isolation precautions placed, with the most common reasons for isolation being MDRO-related (54% of orders). While the rules are intended to cover any situation when a patient would need to have isolation precautions ordered, nurses using the system can still order isolation manually any time they feel that it is needed. However, manual isolation orders made up only 3% of all isolation orders during the study period. While some isolation precautions are only needed for a limited time, and it is natural for them to be discontinued at some point during the patient’s hospital stay, 511 (10%) of the orders for isolation precautions were discontinued within 24 hours of their being ordered. Some of these orders, tied to lab test orders, were likely discontinued when those tests came back negative, but some of the orders may have been discontinued because they were unnecessary or inappropriate. Further analysis of discontinued orders may give helpful information in refining the rule logic.

This change, going from 100% of isolation orders being user-generated to 97% of isolation orders being system-generated, represents a major change in infection prevention workflow and merits further study to more fully understand its impact on HAI and other aspects of infection prevention.

Intravenous immunoglobulin stewardship using an electronic tool
Demetra Tsapepas, PharmD1,2, Hojjat Salmasian, MD MPH PhD1,2, David K. Vawdrey, PhD1,2
1NewYork-Presbyterian Hospital, New York, NY; 2Columbia University, New York, NY

Introduction
Healthcare organizations utilize electronic clinical decision support (CDS) to optimize medication use and safety. Preconfigured order sets may facilitate standardized treatment, encourage adherence to a particular care pathway, and optimize medication use--particularly for expensive medications. Intravenous Immunoglobulin (IVIG) has powerful therapeutic effects and is used across a wide spectrum of disease states. IVIG is a costly medication (several hundred dollars/dose) and its broad use constitutes a large expenditure for many healthcare organizations. Carefully implemented order sets may encourage evidence-based or institution-specific care through the influence on provider behavior.

Methods
In phases, an IVIG order set was designed and implemented in our electronic health record (EHR) during 2013. In the first phase, prescribers recorded an indication for IVIG in a free-text format. This crowd-sourced list of indications was then used in the second phase to develop a coded list of appropriate indications for IVIG. The order set would automatically calculate the appropriate dose of IVIG for 53 distinct conditions, adjusting for patient’s weight as needed. Although prescribers were allowed to place orders for IVIG through other routes (e.g., direct ordering for pediatric patients), the order set was the primary method for placing IVIG orders. Each condition was listed for prescribers to choose through a drop-down menu which subsequently populated the medication form including recommended dosage. Prescribers could manually override the recommended dosage while placing the order. We measured the utilization of the order set, and the rate of compliance with the guideline-recommended dosage, by querying 2.5 years of data from the EHR system. The study was conducted at NewYork-Presbyterian Hospital/Columbia University Medical Center and was approved by the institutional review board.

Results
During the 2.5-year study period, 1,039 orders were placed for IVIG, of which 814 were placed through the order set (78%). We limited our study sample to those where the patient’s height and weight was available at the time of order entry (N=724). The most common indications selected were various forms of transplant rejection, followed by Guillain Barre Syndrome, idiopathic thrombocytopenic purpura (ITP), and hypogammaglobulinemia. Using a tolerance range of ± 30% of the recommended dose, only 8% of orders placed for one group of indications (hypogammaglobulinemia) were for higher doses than recommended, although a notable fraction of orders were at a dosage lower than recommended (31%). Further analysis confirmed that overdosing was uncommon in orders placed for other indications using the order set.

Conclusion
An iteratively designed order set was commonly used by clinicians placing orders for IVIG and was associated with good compliance with the guideline recommended dosage. Overdosing of IVIG was rare in orders placed using the order set, although under-dosing remained relatively frequent. Our future research includes qualitative analysis of these orders to understand the reasons for noncompliance, an evaluation of the impact of underdosing on patient outcomes, and development of further enhancements to the order set accordingly.

Feature Engineering Alternatives for Natural Language Phenotype Classifiers
Clayton A. Turner, Paul E. Anderson, PhD, Alexander D. Jacobs, Cassios K. Marques, Jihad S. Obeid, MD
College of Charleston, Charleston, SC, Medical University of South Carolina, Charleston, SC

Introduction: Mining electronic health records (EHR) for known disease phenotypes allows automated identification of patients in the absence of International Classification of Diseases 9th revision (ICD-9) codes. This phenotype classification task can be automated using Natural Language Processing (NLP) techniques along with pattern recognition machine learning (ML) algorithms. The key to finding these patterns is translating plain text into quantifiable entities that could be used as features for ML. The classic technique for this is bag-of-words (BOWs). Another well documented method is to use UMLS Concept Unique Identifiers (CUIs) mapping with ML. The aim of this research is to evaluate the performance of these two approaches with various classifiers to identify patients with Systemic Lupus Erythematosus (SLE). A sub-aim is to determine which classification algorithms are better suited for each observed methodology, BOWs and CUIs.

Methods: With IRB approval, we obtained clinical notes for 322 patients with SLE diagnosis and 340 controls from the Rheumatology Clinic, a gold standard created by clinicians at MUSC. We filtered the notes for all patients, controls and SLE-diagnosed patients, to those only containing the partial word “rheumatol”, in order to enrich the text with more relevant notes to SLE (48,313 post-filtering). Classification using ICD-9 codes was used as a baseline metric. We created data manipulation scripts to transform the text notes to BOWs. The cTAKES/YTEX pipeline was used to produce CUIs. The variable importance extracted from the Random Forests classifier was utilized for feature selection. The output was subjected to ML algorithms using customized Theano and scikit-learn libraries: Neural Networks (NN) with 1 hidden layer, Random Forests, Naive Bayes and Support Vector Machines (SVM) with a radial basis function kernel. Performance was measured by calculating accuracy through cross validation and an external test set. The cross validated set contained its own training and test set (90%/10%) and the external set was created through a random sampling of 50 controls and 50 SLE patients.

Results: Table 1 shows the results of various combinations of approaches and classifiers along with the results based on ICD-9 codes.

Discussion: Currently cohort identification in EHRs is most commonly achieved using ICD-9 billing codes. In our dataset we used ICD-9 as a baseline and were able to achieve 90% accuracy. The NN performance was much better using CUIs, according to the cross validation and external test set accuracies. This is presumed to be due to CUIs providing more refined and contextual patterns than simple word frequencies in BOWs for the NN to recognize. We hypothesize that with more training data and a deeper network, the NN would perform more effectively with BOWs. The relatively good performance of Random Forests with BOW is consistent with historical performance of these classifiers with BOW. It is important to note that in our experience generating the CUIs was much more resource intensive than generating BOWs, rendering this Random Forest performance with BOW fairly desirable. The “rheumatol” filtering on the notes removed a large amount of noise from the data, allowing each classifier to train more effectively. The naive bayes algorithm was included as a baseline as it operates on the assumption that features are independent when, in this context, words and concepts together are very dependent upon each other. Lastly, SVMs are often an effective classifier for convoluted patterns in textual datasets.

Conclusion: Our results suggest that a shallow NN with CUIs performed best as a classifier, however the overhead in generating CUIs has to be balanced with the almost equally good performance using the Random Forests classifier with BOWs, though the Random Forests did not perform as well on the external set. Our examinations on the feature sets generated by these techniques suggest CUIs are more generalizable than BOWs, as well. Future considerations include: examining the performance of these classifiers on different portions of clinical notes e.g. chief complaint, history of present illness, family history, assessment and plan; and applying these algorithms to phenotyping in other disease states for a variety of uses cases, such as clinical trials eligibility and genotype-phenotype studies.

Implementation Strategies to Address Information-related Barriers for Community Pharmacies Participating in a Statewide Pharmacy Care Management Network

Kea Turner, MPH, MA1, Christopher M. Shea, PhD, MA, MPA1
1. University of North Carolina-Chapel Hill, Gillings School of Global Public Health, Chapel Hill, NC

Introduction. Approximately 250 community pharmacies in North Carolina are participating in a pharmacy care management network designed to improve care quality and reduce cost of care.1 Pharmacies in the network are implementing changes needed to provide enhanced clinical services, such as comprehensive assessments of medications, and coordinate care with primary care physicians and other providers. Previous work has identified information-related barriers pharmacies in the network are facing, such as challenges with learning a new documentation system and integrating documentation within workflow.2

Objective. The goal of this study is to systematically document implementation strategies that network staff and program collaborators are employing to assist community pharmacies with addressing information-related barriers to implementing enhanced clinical services and improving care coordination. This documentation will facilitate evaluation of the implementation strategies and dissemination of effective strategies to other networks.

Methods. We are in the process of conducting 15 one-hour interviews with network staff and program collaborators (i.e., network operational staff, university research team members) who are employing implementation strategies to assist participating community pharmacies with addressing information-related barriers. Interviews are being conducted using a semi-structured interview guide based on Powell et al.’s compilation of implementation strategies3, which defines 73 possible implementation strategies, and Proctor et al.’s guidance for specifying implementation strategies, which provides guidance for documenting the strategies in detail using a template.4

Results. Preliminary results indicate that community pharmacists experience information-related barriers, such as difficulty locating patient data and obtaining medication information from primary care providers. To address these barriers, network staff and program collaborators have employed a number of implementation strategies, such as developing and implementing tools for quality monitoring, developing and organizing quality-monitoring systems, conducting educational outreach visits, assessing change readiness, and conducting audit and feedback.

Discussion. The interviews have yielded detailed information about the implementation strategies being employed. Also, preliminary feedback from interviewees suggests that strategies such as audit and feedback, tools for quality monitoring, and educational outreach visits may facilitate effective information use by community pharmacies. However, systematic evaluation of each strategy is needed to determine impact on implementation of the enhanced services. The documentation conducted during this study will facilitate evaluation of the strategies.

Conclusion. When introducing clinical services within community pharmacies, documenting implementation strategies employed to address information-related barriers is important for evaluating the implementation approach, promoting efficient use of implementation resources, and ultimately supporting successful practice change.

About the authors. Dr. Christopher Shea and PhD student Kea Turner are currently working with Community Care of North Carolina to evaluate implementation of a pharmacy care management network in NC.

Understanding Technology Requirements to Support Chronic Disease Care: The Longitudinal Care Plan Cycle

Kim M. Unertl, PhD, MS1, Christopher L. Simpson, MA1, Laurie L. Novak, PhD1
1Department of Biomedical Informatics, Vanderbilt University, Nashville, TN, USA

Introduction

Optimizing chronic disease care is a substantial and growing challenge for the healthcare system, with a need to shift from episodic acute care delivery approaches towards longitudinal perspectives on health. Transformational approaches such as the Chronic Care Model include health information technology as important components in chronic disease management. However, too little is known about specific technology requirements to support chronic disease work processes and information needs, a major barrier to designing usable and useful technology.

Methodology

The study was set in an academic-community collaboration that had a goal of creating a Medical Home Model for individuals with sickle cell disease (SCD) from birth through adulthood. Researchers collected data from May 2012-July 2014 using non-participant and participant observation, informal interviews, and artifact and spatial data collection. Data collection was open-ended and continued until a point of data saturation was reached. Data were analyzed using a Grounded Theory approach, with iterative cycles of progressively more focused coding.

Results

As data collection progressed, strong themes emerged around longitudinal care planning. Managing the health of an individual with a complex chronic disease is a shared process among the individual, informal caregivers, and healthcare teams. We observed the development of collaborative plans for health management, key work activities that occurred without formal comprehensive support from the existing health information technology infrastructure. Based on our data we developed a six-stage collaborative work process model, the Longitudinal Care Plan Cycle (Figure).

Discussion and Conclusion

Developing and acting on a longitudinal care plan for individuals with a chronic disease is more than a single event. Instead, the process is complex and continuous and involves many actors. The Longitudinal Care Plan Cycle supplements existing approaches such as the Chronic Care Model and the Medical Home Model to assist with identifying specific process-oriented technology requirements. Requirements for health IT to support longitudinal care plan processes include: communication tools for boundary-crossing collaboration, temporally-oriented longitudinal planning elements, data visualization of health status over time, and collection and analysis of patient-specific barriers to health management.

Structured Information Displays for the Comparison of Clinical Trials

Prasad Unni¹, MD, Jiantao Bian¹, MS, Charlene Weir¹,², BS, PhD, RN, Guilherme Del Fiol¹, MD, PhD

¹Biomedical Informatics, University of Utah, Salt Lake City UT; ²George E. Whalen Veterans Affairs Medical Center, Salt Lake City, UT

Introduction

Clinicians raise information needs during patient consultations that are often not met. Evidence from randomized controlled trials (RCT) is an important source to help clinicians meet their information needs. Yet, this evidence source is underutilized due to the significant effort required to judge relevance and interpret results of RCTs for a specific patient. Murlow et al. proposed that tabular displays can help systematic reviewers, patients, and providers integrate research findings into practice¹.

In our previous study that investigated alternative information displays for RCT reports, we found that clinicians favored a structured, tabular display vs. narrative abstracts². However, clinicians still found the tabular display somewhat overwhelming. To address this issue, we designed different displays focused on two steps in the RCT information seeking process: relevance judgment and interpretation of study results.

Methods

We followed a user-centred design process, which included multiple iterations within our team of students, informatics researchers and clinicians. We used NinjaMock®, a low-fidelity prototyping tool to design, and HTML, CSS, JavaScript to build a fully interactive prototype. After several cycles of feedback and redesign, we exposed the prototype to a group of clinicians for broader informal feedback. For the prototype, we manually extracted relevant information from a set of clinical trials and “hard-coded” into a JSON file used by the prototype.

Results

The resulting prototype (Demo link: https://goo.gl/Ins9ig) provides users with four layers of interaction. The first three layers are designed to facilitate efficient relevance judgment and the fourth layer provides a tabular comparison for the interpretation of study results. The first layer clusters search results into studies that have similar patient characteristics and interventions. The second and third layers are used to “zoom into” a selected cluster and select individual RCTs for comparison. The final layer (Figure 1) uses a tabular format to present RCT details, which can be compared among RCTs. Similar attributes across RCTs, are displayed in the same row to allow direct comparison.

Discussion

The proposed tool is a departure from traditional approaches to the visualization of search results for RCT reports. Unlike narrative abstracts, our information display was explicitly designed to facilitate two distinct and critical steps in the information-seeking process: relevance judgement and study interpretation. After further refinement based on clinician input, we plan to conduct a formative evaluation of the information display, comparing with traditional narrative formats.

Temporal Annotation of Swedish Intensive Care Notes

Sumithra Velupillai, PhD¹, Rebecka Weegar, MSc², Maria Kvist, PhD²,³
¹KTH, Sweden; ²Stockholm University, Sweden; ³Karolinska University Hospital, Sweden

Abstract
We describe the creation of a corpus of Swedish intensive care unit (ICU) notes annotated for temporal expressions.

Introduction
To better understand disease and care progression, automated extraction of time expressions can help build models for temporal inference. TimeML¹ is a model for semantic annotation of text for enabling temporal reasoning, which has been adapted to the clinical domain for English²,³. Our long-term goal is to develop a state-of-the-art temporal reasoning system for Swedish clinical text that extracts temporal relations between events and time expressions.

Methods and Materials
Clinical notes from an ICU in Stockholm, Sweden were used. The HeidelTime⁴ system was adapted to develop Swedish clinical time expression (TIMEX3) resources. An iterative process was employed: 1) automated pre-annotation, 2) manual identification of errors and missing expressions (domain expert, A1). Inter-Annotator Agreement (IAA) was calculated on a final test set (17 notes), annotated by A1 and A2 (NLP researcher), using precision, recall and F-measure, exact and overlap span, per TIMEX3 type and overall micro- and macro-average.

Results
Over 1800 TIMEX3s were identified (1834 A1, 1864 A2). One note=one patient’s entire ICU documentation. Overall micro-average IAA is high (86% F1), Table 1. Date is the most common type. Prepostexp (expressions about operations) yields highest IAA, indicating unambiguous expressions. Frequency results in most discrepancies. The notes contain a wide variety of time information, i.e. the resulting terms are likely useful also in non-ICU notes.

Table 1. Results: TIMEX3 annotations in Swedish ICU notes compared between annotators A1 and A2.

<td>0.89/0.91</td>
<td>0.82/0.92</td>
<td>0.84/0.91</td>
</tr>
</tbody>
</table>

Discussion and Conclusion
We present a Swedish clinical corpus annotated for TIMEX3s. Our IAA results are comparable to previous studies, (73%/87% (exact/overlap)² and 80%/³ F1). We have created Swedish lexical resources with clinically specific time expressions that will be useful for the development of clinical temporal reasoning systems also in other domains.

Cajun Codefest 4.0 on SMART-on-FHIR apps for Diabetes

Kavishwar B. Wagholikar, MBBS PhD 1,2, Rahul Jain, MPH CPHIM3, Eliel Oliveira, MBA MS3, Henry Chu, PhD PE4, Harshal Shah 5, Joshua Mandel, MD 1,6, Jeffery Klann, PhD 1,2, Sohail Rao, MD, MA, D.Phil 7, Kenneth D. Mandl, MD MPH 1,6, Shawn N. Murphy, MD PhD 1,2, Thomas Carton, PhD, MS 3

1Massachusetts General Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3Louisiana Public Health Institute, New Orleans, LA; 4University of Louisiana at Lafayette; 5Persistent Systems, India; 6Children’s Hospital Boston, Boston, MA; 7Ochsner Health System, LA

Introduction

Clinical Data Research Networks (CDRNs) sponsored by Patient-Centered Outcomes Research Institute (PCORI) widely use the infrastructure developed by the ‘informatics for integrating biology and the bedside’ (i2b2) project to store data. i2b2 has developed a FHIR interface, to facilitate development of reusable apps that can be shared across the CDRNs. However, there is a lack of expertise in the clinical IT community to develop apps using SMART on FHIR.

In order to spur the development of programming skills for these upcoming technologies the authors collaborated to conduct Cajun Code Fest 4.0 (CCF), posing a challenge for development of Diabetes apps. We constructed a platform for CCF in the REACHnet data center hosting data for 300 real patients diagnosed with Diabetes. This data was anonymized by date-shifting and by substituting the patient identifier. A FHIR endpoint was made available to CCF participants on their signing of a confidentiality agreement with REACHnet. Education videos were developed which provide an introduction to the FHIR api. These resources are published online and are freely available at http://www.cajuncodefest.org/index.php/event-info/data-release. For executing the Code Fest, we created parallel tracks for engagement and for infrastructure.

Engagement

REACHnet partnered with CCF on the fourth iteration of their annual health coding competition. We gave seminars on health informatics at UL Lafayette’s Informatics Research Institute to prospective CCF participants in October and November. Next, we organized a connect-a-thon at Ochsner Health System in New Orleans, LA on December 11th, 2015 to empower CCF and other regional developers. To kick start the CodeFest, subject matter experts engaged 40 participants on a range of topic including the learning health system, SMART Health IT technology, FHIR, HAPI, patient centered outcomes research, and how to access REACHnet’s data infrastructure to compete in Cajun Code Fest. The event was recorded and shared on social media. Connect-a-thon attendees were encouraged to compete in CCF by submitting a concept paper in February of 2016 with final judging being in April of 2016. Attendees were provided confidentiality agreement to access the FHIR API at REACHnet's data center. A REACHnet Clinical Innovation Committee was created to facilitate app ideation and link CCF competitors with subject matter experts in clinician science, medical care, and population health; and to support award adjudication.

Infrastructure

REACHnet deployed an API for the development of reusable apps by CCF that draws from the PCORnet Common Data Model V 2.0. REACHnet availed its data center and created an i2b2 instance with 300 real patients. The dates were shifted at the patient level by REACHnet to deidentify the data in consultation with national privacy experts. The FHIR cell i2b2 plugin was installed in REACHnet’s i2b2 instance to support SMART on FHIR. A demo application was created to validate the functionality of a reusable app that leverages SMART on FHIR on i2b2 in accessing the PCORnet CDM. OAuth user access tokens were created to authenticate calls to the FHIR API.

It is expected that 5-7 teams will move on to be judged for a CCF award leading to entrepreneurial and incubation services. The competition will yield apps that are of value to health systems, researchers, and patients. The educational artifacts created for the Code fest participants will serve as a useful starting point for developers.

Acknowledgements: Research, dissemination, and engagement for the REACHnet connect-a-thon and its associated data infrastructure was supported in part by grant CDRN-1306-04864 from the Patient Centered Outcomes Research Institute, and partly by R00LM011575 from NLM, and R01GM104303 from NIGMS.
Planning a Learning Health System Evaluation: The Multiple Sclerosis Partners Advancing Technology and Health Solutions (MS PATHS) Initiative

J.S. Wald, MD1, J.E. Richardson, PhD1, M. Ashok, PhD1, J.R. Webb, MS1, B.H. Blumenfeld, MD1, A. Ortiz, MS1, R. Bailey1, G. Phillips, PhD2, J.R. Williams, PhD2, R. Rudick, MD2

1RTI International, Research Triangle Park, Raleigh, NC; 2Biogen, Cambridge, MA

Introduction
Multiple Sclerosis Partners Advancing Technology and Health Solutions (MS PATHS) is a Learning Health System demonstration project sponsored by Biogen in collaboration with 10 healthcare institutions in the United States and Europe. MS PATHS aims to integrate technology into routine MS care to standardize the collection of clinical data in order to learn from routine clinical practice and generate insights that one day may be used to inform decision making at the point of care. MS PATHS leverages a new iPad-based patient self-administered assessment tool, the Multiple Sclerosis Performance Test (MSPT), to objectively quantify major motor, visual, and cognitive symptoms; implements standardized acquisition sequences of magnetic resonance imaging to enable quantitative image analysis; and employs other technologies that form an informatics infrastructure for de-identifying and pooling patient data across multiple institutions. RTI International is conducting a program evaluation of the MS PATHS demonstration project funded by Biogen. This poster presents the comprehensive plan for the program evaluation of this important and complex initiative.

Methods
We developed an evaluation plan (EP) using an adapted version of the Consolidated Framework for Implementation Research1. EP development included: 1) a literature review to identify relevant outcomes and measures, 2) discussions with MS PATHS sponsors at Biogen and leadership at participating institutions, and 3) a measurement strategy using an evaluation planning matrix (EPM) that maps program goals and success indicators to specific metrics. Using the EPM, we developed surveys, interview guides, and tracking metrics, leveraging established instruments where possible. The draft program EP was reviewed by six key opinion leaders unaffiliated with the project, Biogen sponsors, and site leadership, who were invited to review and critique the draft. The RTI institutional review board confirmed this work was considered program evaluation, not research.

Results
The EP is driven by three overarching evaluation questions: 1) How successful is the MS PATHS implementation at each institution? 2) What collaboration is taking place among network institutions to support research, improve implementations, and promote mutual learning? 3) How is research productivity growing as a result of MS PATHS, and what would accelerate further growth? The EP calls for mixed methods data collection using surveys, semi-structured interviews, site visit observations, document analyses, and system tracking data. Data collection at each institution is timed to coincide with early implementation (2-3 months post-go-live) and routine use (after 8-10 months), with annual follow-up visits in the remaining 36 month period.

Constructs guide data collection and analysis. Institution implementation constructs include alignment of MS PATHS with institution clinical and business priorities; access to and perceived value of training; the reach of the tools (# of patients, # of assessments); value of MSPT data in direct clinical care; and the patient experience of care. Network constructs include collaboration across institutions to accelerate problem-solving; data coordination; and effective governance. Research productivity constructs include growth in research capacity (e.g. data contributions); indicators of high data quality (e.g. accuracy, completeness, availability); research activity (e.g. patient cohort queries, extracts, protocols); and dissemination (e.g. presentations, publications).

Discussion
The EP highlighted several timing-related items to consider during data collection and analysis. First, data collection at each institution should be timed to align site implementation phase if possible. Second, research activities such as data capture precede other indications of research productivity, so early assessment must take this into account. Third, the EP itself is likely to evolve as additional institutions, including European institutions, are live. Fourth, site implementations are a moving target, suggesting that multiple data collection time points will be helpful.

Healthcare Providers’ Usage of an Interactive Case Simulation Tool for HIV Patient Mental Health Screening in a Statewide Clinical Education Program

Dongwen Wang, PhD
Arizona State University, Scottsdale, AZ

Abstract

We conducted a pilot study to analyze the usage of an interactive case simulation tool (ICST) by healthcare providers for mental health screening in HIV patients. We identified specific usage patterns and verified their generalizability. Future development of ICSTs should consider such patterns for customized tool design and effective dissemination.

Introduction

Dissemination of clinical evidence to healthcare providers is an essential requirement for translation of biomedical research into patient care. We have demonstrated in previous studies that: (a) interactive case simulation tools (ICSTs) can be used as an effective channel for knowledge dissemination; and (b) there are specific patterns in clinicians’ usage of ICSTs, as shown in a case study of an ICST for insomnia screening and treatment in HIV patients. Here we report a study: (a) to analyze clinicians’ usage patterns on a different ICST for mental health screening in HIV patients; and (b) to verify the common ICST usage patterns by comparing the findings from this study with the previous one on insomnia ICST. The results from this study will help identify the generalizable usage patterns across different ICSTs, and direct future development of such tools for more effective and targeted knowledge dissemination.

Methods

We conducted the study within the New York State (NYS) HIV-HCV-STD Clinical Education Initiative (CEI) online education program (www.ceitraining.org). Both ICSTs in the current and the previous studies were part of CEI’s repository of online educational resources. To ensure a fair comparison, we selected the same study period (from April 3, 2012 to October 15, 2012) and queried the usage tracking database for data collection. Parameters for usage pattern analysis included: (a) new vs. returning users, (b) access through web browsers vs. native apps, and (c) access from large-screen equipment (desktops, tablets, etc.) vs. small-screen hand-held devices (smartphones, iPods, etc.). Usage analyses of specific ICST sections were based on the same classifications in the previous study, i.e., “recommendations”, “sample cases”, and “user-defined cases”. We used Chi-Square test to examine the statistical significance between the usage groups.

Results

We recorded a total of 386 user visits to the mental health screening ICST during the study period. Among them, 381 (98.70%) were from new users and 5 (1.30%) from returning users. Regarding the platform, 283 (73.32%) visits came from native apps, while the remaining 103 (26.68%) were through web browsers. In terms of screen size, 144 (37.31%) visits originated from large-screen equipment and 242 (62.69%) were from small-screen devices. Pattern analyses found that: (a) visits to “sample cases” and “user-defined cases” were more likely from small-screen users (p=0.001), (b) visits to “sample cases” and “user-defined cases” were more likely from app users (p<0.001), and (c) small-screen users were more likely to access the resources through native apps (p<0.001). These findings reconfirmed the usage patterns identified from the previous study of the insomnia ICST. Although we also found that returning users were more likely to use large-screen equipment and to access the resources through web browsers, the sample size in specific usage context was too small to make any valid statistical inferences.

Conclusion

Initial analyses have shown that certain patterns of healthcare providers’ usage of ICST can be generalized to multiple clinical problems. Future development of ICSTs should consider these usage contexts and patterns for customized tool design and more effective knowledge dissemination.

Medication Recommendation for Chronic Diseases with Comorbidities Using Electronic Medical Records

Liqin Wang, MS¹,², Peter J. Haug, MD¹,²
¹Department of Biomedical Informatics, University of Utah, Salt Lake City, UT, USA;
²Intermountain Healthcare, Salt Lake City, UT, USA

Objective: The goal of this study is to identify effective medications among a number of related drugs for chronic diseases with comorbidities, and to identify medications potentially causing adverse events when prescribing them to patient with comorbidities.

Background: Healthcare providers are likely to consider a number of drugs when developing a treatment plan for their patients. For example, diuretics, β-blockers, calcium-channel blockers, and ACE inhibitors, are classes of drugs used for treating heart failure. An important assumption is that medications may affect different subpopulations (e.g., patients with comorbidities) differently. FDA-approved indications or clinical practice guidelines may lack the details to determine how well the medications treat patients with a typical circumstances, especially special population like the elderly or those having multiple comorbidities, while practical data stored in the electronic medical records could be very useful by supplementing evidence missed from these sources. For chronic diseases, the treatment is usually long-term; a medication which is not effective in a certain subgroup will be stopped quickly and more effective medication will end up with more frequent prescriptions. This could statistically differentiate the effective medications from those not effective medications with well-defined diagnostic groups. It is important to identify the most effective medications for patient subgroups among those medications with similar indications in order to reduce poor medication adherence and potential adverse events. In this study, we intend to extract and sort medications for the treatment of chronic diseases with and without common comorbidities. We will identify those comorbidities that result significant differences in the patterns of prescription choice compared to patients with no such comorbidities. Identification of these comorbidity-associated differences may be useful in identifying the need for changes when prescribing medications to patients with those phenotypes.

Methods: In the initial stage of the study, we explored the chronic heart failure (CHF) population with different comorbidities using the data from the Intermountain Healthcare enterprise data warehouse (EDW). We first extracted a CHF-pertinent, pharmaceutical treatment vocabulary as a reference from a heart failure ontology.¹ We then identified a range of CHF-pertinent comorbidities from the biomedical literature and verified their frequency of occurrence in the CHF population from the EDW. For each comorbidity, we exploited association mining algorithms (e.g., support, chi-square, and interest) to extract and rank the medications related to the CHF with and without comorbidity. Extracted medications not directly included in or being members of the reference vocabulary were excluded from the analysis. Thereafter, we compared the rankings of CHF-pertinent medications for populations with and without certain comorbidity, and analyzed changes in the ranks of the same medications from the two subpopulations.

Results/Conclusion: We totally retrieved 186 pharmaceutical treatment terms as a reference. We initially tested our approach on five non-cardiac comorbidities: diabetes mellitus, chronic kidney disease, asthma, arthritis, and depression. We obtained two lists of ranked medications for each comorbidity: one is for CHF with comorbidity, and the other is for CHF with no comorbidity. Although the majority of the medications were ranked differently in two compared lists, furosemide was ranked as top 1 medication in most lists. By comparing the ranked medications between the paired lists, we identified some medications dropped significantly in their ranking from the subpopulation with comorbidities as compared to the non-comorbid subpopulation. There were (1) lisinopril, potassium chloride, spironolactone, and warfarin for the comorbidity of kidney disease; (2) isosorbide and clopidogrel for the asthma comorbidity; (3) metalazone, warfarin, isosorbide, and torsemide for the arthritis comorbidity; and (4) amiodarone, warfarin, isosorbide, and lisinopril for the depression comorbidity. These medications will be further analyzed to investigate their potential for adverse reactions in the affected subgroups. The lists of ranked medications from this study may prove to be useful for recommending pharmaceutical choices for CHF patients with comorbidities.

Discovering Associations between Problem List and Practice Setting

Liwei Wang, MD, PhD, Dingcheng Li, PhD, Majid Rastegar-Mojarad, MSc, Hongfang Liu, PhD

Department of health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN, U.S.

Abstract

The problem list has a potential to help practitioners to provide customized care to a patient. However, it remains an open question on how to leverage problem lists in different practice settings for providers to provide tailored care. In this study, we aim to investigate the associations between the problem list and practice settings using the longitude data from Mayo Clinic EHRs, through natural language processing (NLP) and topic modeling techniques.

Introduction

The Health Information Technology for Economic and Clinical Health Act (HITECH) has greatly accelerated the adoption of electronic health records (EHRs) with the promise of better clinical decisions and patients’ outcomes. One of the core criteria for “Meaningful Use” of EHRs is to have a problem list which lists the most important health problems facing a patient. The problem list was first introduced by Weed in 1968 in his promotion for a Problem-Oriented Medical Record (POMR) 1. As important communication vehicles, problem lists are supposed to play an indispensable role in clinical practices. However, it remains an open question on how to leverage problem lists in different practice settings for providers to provide tailored care. In this study, we aim to investigate the associations between the problem list and practice settings using the longitude data from Mayo Clinic EHRs, through natural language processing (NLP) and topic modeling techniques.

Method

The collection of clinical documents used in our analysis consists of clinical notes for a cohort of patients receiving their primary care at Mayo Clinic, spanning a period of 15 years (1998–2013), and covering both inpatient and outpatient settings. Problems in those documents are generally itemized entries as either phrases (e.g., Allergic rhinitis/vasomotor rhinitis) or short sentences (e.g., Her asthma appeared to be very mild). We used the NLP method from our previous study to process the problem list, extract problems and normalize them to codes from the unified Medical Language Systems (UMLS). Then we kept the codes that mapped to the CORE Problem List Subset codes. According to the features of settings in Mayo Clinic notes and extended values of HL7/LOINC DO, we further aggregated them into 73 settings.

We used R package “topicmodels” to build our topic model. To choose the optimal topics in our dataset, we calculate the log likelihood values with the number of topics varied from 5 to 150 by 5, and then investigated the performance by comparing the log likelihood value, of which the highest indicates the optimal number of topics. And the result returns 65 as the optimal topics. Then we fit an LDA model with 65 topics using Gibbs sampling with a burn-in of 1000 iterations.

Initial Results

Figure 1 shows the histograms of the topics for all 73 settings. Fig. 1A shows the histogram of the frequency of the most likely topics for documents from 73 settings. The dataset is divided into 65 categories (topics), and the frequency (document number) difference of various topics could be observed. For example, for all documents, topic 15, 33 and 5 are most frequent. Topic 15 represents a theme of “patient laboratory tests”, topic 33 “surgery”, and topic 5 “pain”. Fig 1B shows the histogram of frequency of top 3 topics in 73 settings, and there are no significant frequency difference for most topics except topic 1 and topic 2.

Future work

We would choose representative problem concepts of each setting with statistical significance, and evaluate the accuracy in new clinical notes.

Auditing Tree-like Organ Systems in the FMA Using Network Motifs

Lucy L. Wang, MS\(^1\), Eli Grunblatt\(^2\), Mark E. Whipple, MD, MS\(^1,3\)

\(^1\)Department of Biomedical Informatics and Medical Education
\(^2\)Medical Scientist Training Program
\(^3\)Department of Otolaryngology-Head and Neck Surgery
University of Washington, Seattle, WA

The Foundational Model of Anatomy (FMA) ontology forms the basis of many biological and physiological models involving human anatomy.\(^1\) A graphical analysis of tree-like organ systems in the FMA reveals highly-recurrent network motifs. One such motif is the wing formation, consisting of a superclass anatomical entity and its relationship to its two subclasses in the left- and right-side body. This is shown in Figure 1a, where a series of arterial trunks have symmetric left and right subclasses. A double wing formation is a fully connected pair of wings, showing continuity between the two superclass nodes, and between the respective left and right nodes. This motif exists in FMA organ systems that display bilateral symmetry and connectivity (i.e. continuity, flow, or attachment).

Figure 1. (a) A portion of the arterial tree from the FMA, (b) a double wing formation and five broken double wing formations (i-v). Black lines show connectivity relationships; gray lines show subclass relationships. Red nodes are superclasses; blue nodes are left and right subclasses.

Figure 1b documents several broken double wing formations, which can be identified computationally by searching the connected graph of each organ system. From the FMA, we generated organ system views of three vascular trees: the systemic arterial, systemic venous, and lymphatic systems. Unique instances of broken formations are detected for each vascular tree (Table 1) and are especially prevalent in the lymphatics.

Table 1. Broken double wing formations for each of the three FMA vascular tree organs.

This work builds on the use of bilateral symmetry\(^2\) and organ-specific applications\(^3\) to audit the FMA, and focuses on cases of recurring graph motifs. Inconsistencies in content can be discovered by applying this technique to relevant organ systems, allowing for increasingly computational audits of the FMA ontology. This method may also be generalizable to other resources, such as the anatomical portion of SNOMED-CT and the cross-species anatomical ontology Uberon, or another ontology in which structural relationships are reflected in the structure of the resource.

Research reported in this abstract was supported by the National Library Of Medicine Training Grant T15LM007442.

A Part-Of-Speech Weighting Scheme for Medical Information Retrieval

Yanshan Wang, PhD1, Stephen T. Wu, PhD2, Dingcheng Li, PhD1, Hongfang Liu, PhD1
1Mayo Clinic, Rochester, MN; 2Oregon Health & Science University, Portland, OR

Introduction

Over the past decade, the amount of health information has increased exponentially in the form of computerized Electronic Health Records (EHRs). The second use of EHRs has facilitated healthcare solutions and clinical decision making, from which physicians and patients have been tremendously benefited in the clinical practice. As the EHR repository becomes larger, however, it becomes more intractable to search the preferred health information in the current systems. Information retrieval (IR), an interdisciplinary research field of information science and computer science, has become a crucial technology to find textual information. Since the EHRs are also narrative textual data, IR has become an essential part of the modern EHR systems.

Methods

In this study, we propose an automatic Part-of-Speech (POS) based query term weighting scheme for two widely used IR models, Bag-of-Word (BoW) model and the Markov Random Field (MRF) model, which are named POS-BoW and POS-MRF, respectively. The motivation is that the Natural Language Processing (NLP) techniques, specifically, POS tagging, would strengthen the conventional IR models to improve the retrieval performance in the clinical domain. The posterior ranking functions of POS-BoW and POS-MRF are defined as:

\[ r_{\text{POS-BoW}}(Q, D) = \sum_{\tau \in \mathcal{T}} \sum_{q \in \tau} \lambda_q f(c, q, D) \]

and

\[ r_{\text{POS-MRF}}(Q, D) = \sum_{c \in (T, O, U)} \theta_c \sum_{\tau \in \mathcal{T}} \sum_{q \in \tau} \lambda_q f(c, q, D) \]

respectively, where \( D \) denotes document set, \( Q \) query set, \( \mathcal{T} = \{1, 2, ..., \tau\} \) the POS category set, \( c \in \{T, O, U\} \) is a set of cliques, \( T \) the single term cliques, \( O \) the ordered term cliques, \( U \) the unordered term cliques, \( \lambda = \{\lambda_1, \lambda_2, ..., \lambda_\tau\} \) is the weight vector for terms with distinct POS categories, and \( f(c, q, D) \) the feature functions over clique \( c \) for query \( q \). Figure 1 depicts an example of graphical models of POS-BoW and POS-MRF with three query terms. In order to decide the weight, we employ a supervised machine learning algorithm. This algorithm is a cyclic coordinate method where golden section line search algorithm is applied along each coordinate to optimize the Mean Average Precision (MAP) defined objective function.

Results

The effectiveness of the proposed approach was verified on a twofold cross validation using TREC 2011 and 2012 Medical Records tracks. Language Models with Dirichlet Smoothing was used in the feature function. The experimental results are listed in Table 1.

Table 1. Average results on the TREC 2011 and 2012 Medical Records tracks.

Conclusion

The experimental results are consistent with our hypothesis that the NLP techniques, specifically POS tagging, could enhance IR models and improve the retrieval performance in the clinical domain.
Personal Health Record Self-Scheduling by Patients Decreases No-Show Rates and Operational Efficiency in Primary Care and Specialty Follow-Up Visits

Michael A Wassef, MD,1 Bret Wagner, BS,3 Joshua Russow, BS,3 David C Kaelber, MD, PhD, MPH1,2

1School of Medicine, 2Center for Clinical Informatics Research and Education, The MetroHealth System, Case Western Reserve University, Cleveland, OH, 3Huron Healthcare, Huron Consulting Group, Madison, WI

Background
The MetroHealth System (MHS) (Cleveland OH) has over 40% of its socio-economically diverse patients signed up for its personal health record (PHR) tethered to its Epic (Verona WI) electronic health record (EHR). One of the features in the PHR is patient appointment self-scheduling. Self-scheduling allows the patient to select and reserve the date, time, and location for an appointment that is most convenient for the patient in real-time. MHS deployed PHR self-scheduling for primary care follow-up appointments in 2013 and for follow-up specialty appointments in 2015. Here we evaluated various PHR self-scheduling measures across different EHR departments and estimated operational efficiency, increased revenue, and cost savings attributed to self-scheduling.

Methods
Using scheduling information from our Epic EHR, we examined no show rates, cancellation rates, adoption rates of self-scheduling, and time spent scheduling appointments for primary care (from 2013-2015) and specialty (from 2015) follow-up visits both for self-scheduled and non-self-scheduled appointments, by provider specialty. De-identified Press Ganey patient satisfaction scores for appointments were also examined.

Results
11,807 appointments (90% primary care and 10% specialty appointments) (1.5% of all potentially self-schedulable appointment) were self-scheduled through the PHR from 2013-2015. Self-scheduling rates ranged from 0-9% (by provider specialty). Appointments to dermatologists, optometrist, and gynecologists had the highest self-scheduling rates. Self-scheduled appointments had 14% lower no show rates with primary care providers and 5% lower with specialists; combined no-show rate declined by 9% (p<0.0002 compared to non-self-scheduled appointments). Annualized, at the current decrease in no show rates, over 300 additional appointments, totaling an estimated $15,000 (based on conservative estimate of $50 net revenue for a follow-up visit) in additional net revenue occurred throughout MHS because of self-scheduling. Cancellation rates were higher among patients that self-scheduled (28% in primary care and 30% in specialty care) compared to those that did not self-schedule (13% and 14%, respectively), with p<0.05 for both groups. An estimated average of approximately 4 minutes of staff time (based on time-motion study) were needed to help a patient who does not self-schedule an appointment. Therefore, to date, self-scheduling has saved approximately $16,000 in staff scheduling (estimated staff rates of $20/hr). Almost 1/3 of self-scheduled appointments were made outside of normal business hours (evenings, nights, and weekends) when staff is unavailable. Press Ganey patient satisfaction scores between self-scheduled and non-self-scheduled visit were examined, but there were no statistically significant differences. The rate of self-scheduled appointments doubled annually. We estimate that for each 1% absolute increase in percent of total appointments that are self-scheduled annually that translates into at least $10,000 in increase revenue from decrease in no-show rates and at least $10,000 operational cost savings from enhanced operational efficiency for the MetroHealth System.

Discussion
Real-time, patient visit self-scheduling through a PHR is a growing EHR tethered PHR administrative function. No show rates decreased, probably because of a combination of more favorable initial appointment for the patient and increased ease of cancelling (hence higher cancellation rates) and rescheduling through self-scheduling (cancellations are better than no shows because of ability to reschedule). Also, significant operational staff savings occur because of self-service and better service because of the ability to self-schedule at any time of the day or night.

Conclusion
PHR enabled self-scheduling optimizes use of healthcare resources, both directly by decreasing no show rates and indirectly by saving scheduling staff time and allowing for scheduling outside of regular business hours. Patient appointment self-scheduling can save tens of thousands of dollars even when the percent of appointments self-scheduled is relatively low. As PHR adoption and use increases, appointment self-scheduling could save hundreds of thousands or even millions of dollars annually for large healthcare systems as the majority of follow-up appointments are self-scheduled.
Export data from i2b2 using the new download data web client plugin

Nich Wattanasin, MS¹, Taowei David Wang, PhD¹, Bhaswati Ghosh, MS¹, Reeta Metta¹, Vivian Gainer, MS¹, Shawn N. Murphy, MD, PhD¹²
¹Partners Healthcare, Boston, MA; ²Massachusetts General Hospital, Boston, MA

Abstract

The Informatics for Integrating Biology and the Bedside (i2b2) platform is a framework enabling clinical research and data analysis at more than one-hundred healthcare institutions worldwide. The modularized architecture of i2b2 fosters the rapid creation of plugins to support clinical research needs. At Partners Healthcare, we have developed an i2b2 web client plugin that facilitates the aggregation and exporting of data from i2b2 into CSV format.

Introduction

The i2b2 software has been successfully deployed at more than one-hundred academic medical centers and health care institutions worldwide. The framework provides tools that allow researchers to easily query the data stored in i2b2 at their local site. The i2b2 web client query tool supports Boolean logic-type queries that enables investigators to obtain aggregate counts of patients matching a particular criteria, such as demographics, diagnoses, medications, laboratory values, etc. The modularized design of i2b2 and the fostering of an open source community has led to collaborative projects such as the Shared Health Research Information Network (SHRINE). SHRINE makes it possible to connect any number of i2b2 deployments together to create powerful research networks. Investigators in this instance are able to execute federated queries across multiple participating i2b2 sites to support multi-site clinical research. In both the i2b2 and SHRINE, there is a need for researchers to be able to extract data quickly to continue a necessary patient review process after running an appropriate query.

Methods & Results

At Partners Healthcare, we have developed a web client plugin that enables the exporting of aggregated patient data as a Comma Separated Value (CSV) file. The user first selects a previous query that represents their desired patient cohort. Next, the user selects health-related criteria such as demographics, diagnoses, medications, and/or labs to define the columns of the CSV file. Finally, for each criteria, the user specifies the aggregation method that they desire for that particular column. For instance, an investigator using i2b2 to find suitable patients as part of the clinical trials patient recruitment process would be able to create and download a CSV of patients to review. The investigator could start with a query representing patients with a particular disease. Then, they could choose various medications and lab values, for example, as columns of the CSV output, specifying aggregation preferences such as the existence of a medication, most frequent lab value, or the latest data of a specific disease observation. The resulting CSV output is a single patient per row with the aforementioned specified columns.

Conclusion

The new i2b2 web client plugin has been deployed in Partners Healthcare’s Biobank Portal (Figure 1), an i2b2 implementation bridging clinical research informatics and phenotyping analyses together with the requesting of Biobank samples, such as DNA, plasma, and serum. Researchers using the Biobank Portal use the plugin to obtain a CSV file to review patients that match a criteria to request Biobank samples for. Furthermore, the plugin is intended to help support the facilitation of finding suitable patients for clinical trials across multiple sites using SHRINE as part of the Accrual to Clinical Trials (ACT) project.

Figure 1. Biobank Portal with the new Download Data plugin
Finding Evaluation Frameworks for Complex Health IT Implementations
Jennifer R. Webb, MA, Joshua E. Richardson, PhD, MS, MLIS, Mahima Ashok, PhD, MS, Barry H. Blumenfeld, MD, MS, Jonathan S. Wald, MD, MPH
RTI International, Research Triangle Park, NC

Introduction
In order to plan a program evaluation for a Learning Health System demonstration project at 10 academic centers, we conducted a literature search to identify frameworks to evaluate complex health IT implementations. We developed two research questions: 1) What frameworks for evaluation planning have addressed complex health IT implementations?; and 2) Of those frameworks, what outcomes and measures have been used to assess the success of complex system interventions?

Methods
In partnership with a librarian, we identified multiple National Library of Medicine Medical Subject Heading (MeSH) terms and keywords associated with three high level concepts: evaluation, health IT, and implementations/studies (Table 1). Using 10 different multiple-line search queries using Boolean operators “OR” and “AND” to combine the MeSH terms, we obtained results using PubMed and EMBASE literature databases, and gray literature databases Google Scholar and the New York Academy of Medicine Grey Literature Report Database. Abstracts from the resulting 96 unique citations including two from gray literature were screened for recency (years 2005-2016), English language, human research, adult populations, and relevancy to the two research questions, eliminating 82 citations to arrive at 14 preliminary articles. Following project leader review we abstracted the final set of 7 articles to identify frameworks, their elements, environments where they were applied, and reported evaluation metrics.

</tbody>
</table>

† = Medical Subject Heading (MeSH) terms

Results
The literature review identified 7 articles that described applied or general frameworks for evaluating complex health IT implementations, including the Consolidated Framework for Implementation Research (CFIR) and Adapted CFIR, the Health IT Reference-based Evaluation Framework (HITREF), the Fit between Individuals, Task, and Technology (FIT) framework, and other unnamed frameworks. The frameworks cover a range of health IT implementation areas including IT adoption, effectiveness of health IT interventions, system development, comparative effectiveness research, and process redesign. Applied settings included a hospital, geriatric center, community health network, and one that addressed multiple settings. Three identified metrics including: end user surveys and time-to-event analyses for clinical alerts. Each framework describes constructs or outcomes for use in a health IT implementation evaluation and lessons learned in using the framework. Although multiple frameworks were identified, some key literature according to experts were not captured in the search including Psek et al. (2015) and Sittig and Singh (2010)†‡.

Discussion
While our detailed search strategy using keywords and MeSH terms identified a number of evaluation frameworks, it also missed some important evaluation framework resources within and outside of published literature. This may reflect poor categorization of concepts and common keywords related to complex health IT implementations. We recommend that researchers supplement search strategies with websites including the EDM forum (http://www.edm-forum.org), CFIR Technical Assistance website (http://cfirguide.org), and the Health Services Research Information Central (HSRIC) website (https://www.nlm.nih.gov/hsrinfo/) that provide useful information and resources for informing evaluation planning of complex health IT implementations.

Using Semantic Groupings to Support Clinical Trial Medical Condition Search: A Case Study on Diabetic Complications

Duo (Helen) Wei

Computer Science and Information Systems – BUSN
Stockton University, Galloway, NJ 08205

Abstract
Due to the large volume of clinical trial protocols achieved in ClinicalTrials.gov, it becomes increasingly difficult for patients to find their desirable trials. To expedite the search process, one way is to formulate search queries with standard vocabulary, such as SNOMED or MeSH. Patients can use a medical term and its neighboring terms to formulate their search query keywords. However, this exhaustive search method is time consuming and labor intensive. In this research, we propose to use our previously developed semantic uniformity group (SUG) of SNOMED, which is based on concepts’ properties and hierarchical configuration, to help patients find clinical trials more efficiently.

Introduction
ClinicalTrials.gov is one of the primary sources of information on clinical trials that receives hundreds of thousands of visitors every month. It is routinely used by patients to find clinical trials. The search queries can be grouped into combinations of keywords related to “condition”, “location,” and “treatment” [1]. “Location” and “treatment” are relatively easily to be identified, but “condition” is sometimes very difficult to be described, especially, when patients try to specify a “condition” with a medical terminology with high granularity. One of the options for the patients to formulate their search queries is with the help of the standard vocabulary, such as SNOMED CT. Typically, patients first try to use a medical term in SNOMED CT and its neighboring terms (i.e. its parents, children, siblings) to formulate their search query keywords. However, this exhaustive search method is time consuming and labor intensive, and sometimes, they search in vain since there is a large gap between what they may be looking for and what is available. In this research, we propose a method to use our previously developed semantic uniformity group (SUG) [2] of the SNOMED, which is based on concepts’ properties and hierarchical configuration, to help patients find clinical trials more efficiently.

Method
First, SUGs are generated, which is defined as the maximal set of SNOMED concepts with the exact same set of relationships and sharing the same lowest common ancestor (LCA) within the particular SNOMED IS-A hierarchy. Our assumption is that concepts in the same SUG share same semantics and thus can be used as alternative keywords for retrieval. Second, based on the patients query content, we identify which SUG the concept belongs to. Third, clinical trials are retrieved via the ClinicalTrials.gov API with all members of the SUG as the keywords. Fourth, merge all search results. Fifth, we compare the search results using our method with traditional “exhaustive” search method.

Results
Our method has been applied to the search of “Diabetic complications.” A total of 21 SUGs are generate for concepts with finding site as their relationship for SNOMED (07/2015), where “Diabetic complication” is located in one of the SUGs. There are 13 members in this SUG and we retrieved 1,335 clinical trial protocols with the members as keywords. As a comparison, if we apply “exhaustive” search, then as many as 3,970 protocols are retrieve, which is almost three times if we use SUG members. The search result will be evaluated by patients and domain experts.

Discussion and Conclusion
In conclusion, the SUGs are perceived to be more efficient to support clinical trial search than traditional exhaustive standard vocabulary keyword search, since it significantly condensed search results. We will calculate precision and recall to verify our assumption. Additionally, future research can compare the results using SUGs with that using synonyms-based search method.

A Study of Active Learning for Document Selection in Clinical Named Entity Recognition

Qiang Wei, M.S.¹, Yukun Chen, Ph.D.², Sungrim Moon, Ph.D.¹, Trevor Cohen, M.B.Ch.B., Ph.D.¹, Hua Xu, Ph.D.¹

¹School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA; ²Pieces Technologies Inc., Dallas, TX, USA

Introduction

Effectiveness of machine-learning (ML), a widely used strategy in natural language processing, is largely dependent on the availability of high-quality training data, requiring manual annotations by skilled professionals that can be slow and expensive. It is important to select the most informative sample for annotation to build a high performance ML model. Most of the previous work in active learning (AL) methods apply AL strategies at the sentence level to reduce annotation cost in applying ML methods. Here, we propose AL strategies for named entity recognition at the document level using the i2b2 2010 dataset.

Method

The i2b2 2010 dataset includes 826 annotated clinical notes, of which 477 were used as training set and 349 were the evaluation set. Our program adds a document from unlabeled set to labeled set in each round. The program trains a conditional random field model based on the labeled set and uses the model to evaluate the selection. We used uncertainty-based and diversity-based querying in our study. Uncertainty-based querying uses entropy of entities to measure the uncertainty of labeling the document. Diversity-based querying selects the most representative document in unlabeled set. Random querying and document length-based querying were the baseline.

Result

We used six methods in our study. We generated learning curves of F1 score vs. number of documents (DN) and F1 score vs. number of words (WN) and evaluated our methods. We used area under curve (AUC) as a score for each method (Table 1). Word entropy method had better AUC score for F1 vs. DN than the baseline methods. Normalized word entropy method had the best AUC score of F1 vs. WN amongst all the tested methods.

Table 1. AUC score of learning curve.

<table>
<thead>
<tr>
<th>AUC Score</th>
<th>Random</th>
<th>Document length</th>
<th>Word entropy</th>
<th>Normalized word entropy</th>
<th>Normalized entity entropy</th>
<th>Similarity</th>
</tr>
</thead>
<tbody>
<tr>
<td>F1 vs. DN</td>
<td>0.909</td>
<td>0.919</td>
<td>0.922</td>
<td>0.916</td>
<td>0.905</td>
<td>0.912</td>
</tr>
<tr>
<td>F1 vs. WN</td>
<td>0.908</td>
<td>0.901</td>
<td>0.903</td>
<td>0.910</td>
<td>0.905</td>
<td>0.893</td>
</tr>
</tbody>
</table>

Discussion

In general, the length-based methods performed better on DN as compared to the WN. An explanation may be that longer documents include many informative words, but also have increased number of uninformative words. The entity entropy method considers uncertainty of the entity but ignores the non-entity in a document, causing the lower score. Normalized word entropy method uses the entropies of the entity and the non-entity as well as the length of the document, resulting in the best overall score. The longer document is likely to have a higher Jaccard similarity coefficient, causing similarity-based method to perform worse on WN.

Conclusion

We propose novel active learning methods for named entity recognition task at the document level that can improve machine-learning model performance within limited manual annotation.

Using the hierarchical structure of the Medical Subject Headings (MeSH) for automatic MeSH term assignment

Wei Wei, MS, Zhanglong Ji, MS, Lucila Ohno-Machado, MD, PhD
University of California, San Diego, San Diego, CA, USA

Introduction
The hierarchical structure of controlled vocabularies and ontologies has been previously employed in automatic data annotation, such as automatic Medical Subject Headings (MeSH) term assignment. MeSH Now, a MeSH term assignment algorithm developed by the National Library of Medicine (NLM), served as a baseline model for the 2015 BioASQ Challenge (see: http://www.bioasq.org). However, this algorithm does not use the hierarchical structure of MeSH. Our aim was to improve the performance of MeSH Now using this type of information.

Method and Preliminary Results
Given an article, MeSH Now ranks candidate MeSH terms collected from similar articles. Our ranking function considers the contribution of relations (i.e., parents, children, and siblings) to the selection and ranking of potential candidates. For example, if a child of a candidate MeSH term is frequently observed in similar articles, the ranking score of this candidate term is increased accordingly. We followed MeSH Now and used its objective function,

\[ L(Y, G) = - \sum_{i=1}^{n} \Pr(y_i) \log \Pr(g_i) \]  

where \( Y \) is the gold standard, \( y_i = 1 \) if this candidate term is appropriate and \( y_i = 0 \) otherwise; \( G \) is the set of ranking scores; \( i \) indicates the \( i^{th} \) candidate; \( n \) is the number of candidates. In the new ranking function \[2\], a candidate \( x^t \) or one of its related terms, \( x^lr \), is represented by \( m \) features. In the preliminary study, we used two dominant features: (1) the number of similar articles in which this term appears; and (2) the sum of similarity scores of articles in (1).

\[ g_i = \sum_{l=1}^{m} w_l \cdot x^l_i + \lambda \sum_{l=1}^{R} \sum_{i=1}^{m} k_l \cdot x^lr_i \]  

where \( g_i \) is the ranking score of candidate \( x^i \), \( x^l_i \) is the \( l^{th} \) feature; \( w_l \) is the weight of \( x^l_i \); \( x^lr_i \) is the \( l^{th} \) feature of \( x^lr_i \); \( k_l \) is the weight of \( x^lr_i \); \( R \) is the number of relations of \( x^i \); \( \lambda \) is the weight of the contribution of relations.

We explored the contribution of relations using the same training and evaluation data as those used by MeSH Now.

</tbody>
</table>

Conclusion and Future Work
Siblings of candidates slightly improve the model performance, but not by a significant extent, because the occurrences of parent/child/sibling terms are not frequent enough in similar articles. Perhaps deeper structure information (e.g. edge number) will be necessary improve performance in a significant way. This study was supported in part by bioCADDIE grant NIH/BD2K - U24AI117966.

Use of an Interface Terminology for Evaluating Terminology Coverage for a Clinical Decision Support System

Asli Weitkamp, PhD¹, Sina Madani, MD, PhD¹, Trent S. Rosenbloom, MD, MS²
¹Department of Health Informatics Technologies & Services¹;
²Department of Biomedical Informatics, Nashville, TN

Introduction
Clinical terminologies play an important and foundational role in clinical decision support systems (CDSS). Accurate classification of clinical findings is critical for a predictable response from CDSS, while a lack of standardized terminology coverage can become a barrier to deploying and using such systems efficiently. Use of these terminologies can be limited to the manual processes required for identifying and maintaining appropriate linkages to CDSS content. Leveraging interface terminologies designed to represent commonly occurring clinical entities and relationships among them could improve the process of curating CDSS items.

An interface terminology designed to represent clinical problems in a problem knowledge base (PKB) has been in use for a problem list module at the Vanderbilt University Medical Center since 2011. This terminology was designed to contain commonly observed clinical findings, to represent them using general medical terms, and to map to SNOMED CT to support interoperability with other systems. We used existing data in the PKB to identify level of granularities required to represent clinical findings that are used to specify the rules in one of our CDSS modules.

Methods
As part of CDSS rule engine criteria, we identified 12 diseases that, if identified in the outpatient clinical problem lists, resulted in alerts being generated for healthcare providers using the electronic health record systems. We measured PKB usage data, extracted the child concepts of the 12 diseases, and measured their usage in the problem list between 2011 and 2016. We then compared the percentage of usage between the parent and child concepts.

Results
We were able to expand the original list of 12 disease concepts to 175 by including child concepts, based on their usage in PKB (Figure 1). The additional “more granular” child concepts comprised 17% of the total usage of all 175 concepts in the problem list module. The percentage of the child concepts usage, compared to their parent concepts, varied from 0.44% (Coronary Arteriosclerosis) to 100% (Sickling cell disorder) with an average of 25% (Figure 1).

Discussion
SNOMED CT disorder axiom contains clinical concepts that are usually sufficient to be used in clinical decision support applications typically used at the point of care. However, such concepts usually contain more granular child concepts and exposing them all, compared to the actual usage at the point of care, would not only be redundant but also cause a computational explosion of the concepts represented to the providers. On the other hand, based on the CDSS protocols some distinction may need to be made between different subtypes of a given concept (like acute asthma versus chronic asthma). While it can be argued that SNOMED CT has the capability of post coordination in such instances there are still technical difficulties in implementation of this feature in CDSS modules. Therefore, it is important to identify and represent child concepts quickly and objectively for CDSS terminology modules.

Figure 1. Comparison between the usages of 12 disorder concepts together with their children selected for a CDSS module
ItRunsInMyFamily Social Network for Family Health History: Project Update
Brandon M. Welch, MS, PhD,1 Ayesha Aziz, PhD,1 Joshua Schiffman, MD,2
1Medical University of South Carolina, Charleston, SC,
2University of Utah, Salt Lake City, UT

Introduction
Family health history (FHx) is one of the most important tools available for genetic diagnosis and disease risk assessment,1 and is the most consistent risk factor for almost all human diseases. Half of all families display a positive FHx for one or more common chronic diseases.2 Unfortunately, FHx is often inadequately collected in a clinical setting as clinicians are typically hindered by limited time, inadequate reimbursement, and lack of expertise related to genetics and FHx.1 As a result, FHx is discussed with only half of new patients and less than a quarter of return patients.3 As such, a comprehensive FHx data collection and documentation may be best accomplished outside the timeframe of a physician office visit.1 As a result, several researchers and organizations, such as the Surgeon General, have built patient-oriented tools to help individuals collect and record their own FHx. However, these tools tend to be difficult to use, disease specific, collect limited structured data, have limited interoperability, and lack useful clinical decision support. Furthermore, these FHx tools require the patient to recall all their relatives’ health information, which results in inaccuracies and data gaps, particularly in 2nd and 3rd degree relatives. In general, patient-oriented FHx collection tools have had limited adoption and impact outside of research settings.

Approach
To overcome the challenges of current patient-oriented FHx collection tools, clinicians and informaticists at the University of Utah and the Medical University of South Carolina are currently developing an online social network platform called ItRunsInMyFamily. This website will allow individuals to record their own health information and link up with relatives to exchange health information to create a more comprehensive and accurate FHx. ItRunsInMyFamily will leverage both popular social networking techniques and health information technology approaches to help individuals and their relatives collect and share health information with each other. At its core, ItRunsInMyFamily is being developed as a Meaningful Use-aligned, standards-based personal health record (PHR). The platform will use social network techniques to generate a family pedigree of available health information. ItRunsInMyFamily will be a free resource that also provides basic care recommendations (e.g. talk to your doctor about your risk for disease X) to individuals. Clinicians would also be able to access their patients’ FHx information and receive personalized risk assessments and care guidelines for their patients.

Discussion
In this poster, we will describe an update and description of our technical architecture, informatics standards used, the user interface designs, and approaches to data privacy & security being incorporated in the development of ItRunsInMyFamily. A beta version of the site is expected to be available for AMIA 2016.

Conclusion
We believe that an online platform using social networking technology which helps individuals share and discuss their health information with relatives will create a more comprehensive and accurate FHx than current approaches.

Improving the Workflow of Curbside Consultation by Using Unstructured Clinical Notes - a Natural Language and Machine Learning-based Approach

Wei-Hung Weng, MD¹,², Avni M. Khatri, BS², Kavishwar B. Wagholikar, MBBS, PhD²,³, Adam B. Cohen, MD⁴, Henry C. Chueh, MD²,³
¹Department of Biomedical Informatics, Harvard Medical School, Boston, MA; ²Laboratory of Computer Science, ³Department of Medicine, ⁴Department of Neurology, Massachusetts General Hospital, Boston, MA.

While caring for patients, physicians often encounter clinical questions beyond their expertise. To resolve these questions, physicians refer the patient to a relevant specialist. But often the physicians tend to reach out to the specialist themselves using phone and email. Such informal discussions are defined as curbside consultations. It is challenging, however, to find a relevant specialist for curbside consultation. Consequently, the curbside consultations can be inappropriate, time-consuming, and even unsafe for patients.

To resolve these problems, expert recommendation systems (ERS) have been developed to identify suitable specialists, who can appropriately answer the clinical problem. Yet ERS have not been widely used clinically due to lack of performance. As such, natural language processing (NLP) and machine learning (ML) have been shown to improve the validity of ERS by identifying biomedical experts. In this study, our objective is to develop an NLP and ML-based clinical ERS.

We hypothesize that an NLP-ML model trained on clinical notes mapped to specialties and authors can be repurposed as an accurate ERS. We will develop NLP-ML software and model based on clinical notes from Massachusetts General Hospital that can predict the specialty and the author of a given note. To evaluate the performance of the model for the ERS task of identifying the appropriate specialty and specialist given a clinical question, we will then construct a gold standard by interviewing the clinical specialists. The participating specialists will be requested to provide questions, which have been consulted in curbside consultations. The specialists will also provide the name of the domain experts that appropriately resolved the question. For evaluation, the questions provided by the specialists will be input into the NLP-ML model, and the output will be compared to the expert-list provided by the specialists. Figure 1 gives the framework of the study.

UMLS concepts in the clinical notes will be extracted using NLP tools. The concepts along with the specialties or author names will be fed into supervised ML algorithm for modeling, and the model performance can be evaluated using normalized discounted cumulative gain (NDCG). To apply the model to an ERS task, we will use the NLP tool to extract UMLS concepts from the gold standard questions. The concepts will be input into the model to obtain a ranked list of specialists. The list will be compared against the gold standard and evaluated by NDCG. We will explore different feature extraction and ML techniques to optimize the model. For preliminary work, we have developed an NLP-ML pipeline for predicting the medical domain from a clinical note, using 431 publicly available notes in iDASH repository. Cross-validation revealed that NDCG improved from 0.905 with baseline bag-of-words to 0.985 with UMLS concepts and maximum entropy algorithm (table 1). We adopted UMLS concepts to reduce dimensionality and capture semantically related concepts inside the content. Linear SVM, random forest, and maximum entropy algorithms were selected for effective NLP tasks.

The NLP-ML approach may enhance the real-time ERS, and ultimately optimize the workflow of curbside consultation, save time for physicians and improve patient care.

³University of Houston, Houston, TX

Abstract
The long-term goal of our research is to enhance the consultation process for women undergoing breast reconstruction surgery. The purpose of the current study was to conduct focus groups to evaluate patient experiences related to the breast consultation process and to obtain feedback on components of our prototype decision support system.

Purpose
The long-term goal of our research is to enhance the consultation process for women undergoing breast reconstruction surgery. Our vision is a decision support system that will enable breast cancer patients, in consultation with their healthcare providers, to choose a reconstruction strategy with maximal potential to optimize psychosocial adjustment. This system for shared decision-making will use quantitative models to tailor the presentation of patient-specific information about breast reconstruction outcomes. The purpose of the current study was to conduct focus groups to evaluate patient experiences related to the breast consultation process and to obtain feedback on components of our prototype decision support system.

Methodology
The study sample was drawn from patients seeking treatment at The University of Texas MD Anderson Cancer Center and from local breast cancer support groups in the surrounding Houston area. A trained facilitator used a semi-structured interview guide to conduct each focus group (Figure 1). Notes and audio recordings of the group discussion were transcribed and analyzed with two basic approaches: qualitative/ethnographic summary and a systematic coding via content analysis.

Results
Twenty-one women participated in one of six focus group. Each focus group contained between 2-5 participants. Several key themes related to visualization emerged from the focus groups: (1) Women mostly preferred to see their own image rather than the image of someone else; (2) 2D images were described as more natural looking and strongly preferred by all participants when compared to 3D still images; (3) 3D still images were described negatively in all groups: used terms like “creepy” “weird” “bionic” “Halloween;” (4) Smooth and mesh textures were poorly received; (5) Video and interactive 3D photo were very well received by all groups.

Conclusions
Interactive photos and videos appear to show particular promise for helping patients to understand possible appearance outcomes from breast reconstruction.
Getting to the Right ICD-10 Code: A Multifaceted Approach

Nancy Whipple, BSN, MS, MM\(^1\), Harley Ramelson, MD, MPH\(^{1,2,3}\)

\(^1\)Partners HealthCare System Inc, Wellesley MA; \(^2\)Harvard Medical School, Boston, MA; \(^3\)Brigham and Women’s Hospital, Boston, MA

The transition from the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) to ICD-10-CM coding system for billing claims codes occurred on October 1, 2015. Several components essential to the successful transition to ICD10 included adequate education and training, proper selection of software vendors and tools, exhaustive internal and external quality assurance testing, and proper change management processes and communications. This poster describes the changes we made to our EHR software system to support our clinicians in selecting an appropriate and specific diagnostic ICD-10 code for ambulatory practices.

One of the primary goals of our ICD-10 project was to optimize the process of selecting an appropriate ICD-10 diagnosis code by both presenting pertinent clinical questions important to the selection of a specific ICD-10 code and minimizing the number of mouse-clicks and screen changes. Based on a user-centered iterative design feedback process, we offered the ability to select an ICD-10 code in a variety of ways: Search, Favorites, Templates, Past Patient Data, and Past Encounter Data.

**Search:** Users can enter one or more text terms and be presented with a set of matching results tailored\(^1\), when appropriate, to a patient’s age, sex and medical history. These results contain root codes and/or specific billable ICD-10 codes. A root code is one that encompasses a group of related ICD-10 codes, is not billable, and requires further refinement to greater specificity to get to a billable code. From this result list, if a user selects a billable ICD-10 code, that code is added immediately to the encounter; if a user selects a root code, additional questions are presented. Basically, each question represents an additional character in the refined code. The questions are based on the National Library of Medicine’s mapping rules to ICD-10 and were enhanced and customized to cover a greater number of ICD-10 codes and to be more efficient from a clinical standpoint. Due to dependencies among questions, branching logic was instituted so that an answer to one question would affect the subsequent questions and answer sets presented to the user. The question screen is interactive so that if the clinician changes a response to any question, the screen reflects the updated valid questions and answers.

**Favorites:** The user or practice can create a list of commonly used diagnosis codes and access these at the time of documenting billing codes. **Templates:** Templates are collections of a variety of billing codes and information important for actions performed at the end of a visit. These include diagnosis codes, procedure codes, orders, E&M codes, follow-up information, referrals and educational materials to provide to the patient. Templates can be tailored to specific visit types (e.g. a 6 month well baby visit) or conditions (e.g. diabetes follow up visit), or can be based on age/sex of a patient (e.g. male adult senior annual exam). **Past Patient Data:** Users can use the patient’s current list of problems to get to a matching ICD-10 code or set of codes. This is accomplished using maps between SNOMED-CT and one or more corresponding ICD-10 codes. In addition, ICD-9 diagnosis codes added prior to Oct. 1, 2015, can be selected and a corresponding ICD-10 code will be added to the current encounter. Subsequent to this date, a reverse chronological list of previously selected ICD-10 codes for that patient can be accessed and one or more codes can be selected and added to the current encounter. **Past Encounter Data:** Diagnoses and individual elements of previous encounters can be selected and “copied forward” to the current encounter. The clinician can also copy the entire previous encounter in a single step.

Data from Oct 2015 to March 2016 showed that clinicians were employing many of the tools we provided. There was a significant increase in the number of favorite lists created. We also found a high correlation between the codes in templates and in favorite lists and codes entered in encounters.

Modifying a Case Report Form to Collect Anonymous and Consistent Data

Elizabeth White\textsuperscript{1}, Sarah Collins RN, PhD\textsuperscript{1,2}, Beatriz H. Rocha MD, PhD\textsuperscript{1,2}, Neelima Karipineni MD, MMSc\textsuperscript{1,2}, Taylor Read MS\textsuperscript{1}, Saverio Maviglia MD, MS\textsuperscript{1,2}, J Perren Cobb MD\textsuperscript{3}, Roberto A. Rocha MD, PhD\textsuperscript{1,2}

\textsuperscript{1}Brigham and Women’s Hospital, Boston, MA; \textsuperscript{2}Harvard Medical School, Boston, MA; \textsuperscript{3}University of Southern California, Los Angeles, CA

Introduction

In multi-site studies involving data transfer, the security of patients’ protected health information (PHI) is vitally important. Many strategies exist to de-identify study data \cite{1}, but when patient identifiers are not necessary to achieve study aims, it is more efficient to refrain from collecting PHI. The objective of this project was to implement an existing case report form (CRF) with specific modifications to remove PHI and preserve data integrity. These modifications should streamline data transfers while maintaining the ability to answer key research questions.

Methods

We used a validated paper CRF\textsuperscript{1} and implemented it in electronic form using Research Electronic Data Capture (REDCap). REDCap is a secure, web based data collection application \cite{2}. After implementing the electronic CRF (eCRF), data fields were reviewed to determine which ones constituted PHI and which ones required modification to promote data consistency. The identified fields were deleted or modified to address these needs, and in the case of data consistency, several fields were also added. The resulting eCRF was tested and validated by a team of informatics and clinical subject matter experts (SMEs).

Results

To remove PHI from the eCRF, 10 changes were made. Seven of the changed fields were dates, of which 3 were deleted and 4 were modified to a time reference format rather than an exact date. As a result of the changes to date format, 2 fields became unnecessary and were deleted. Patient medical record number (MRN) was removed from the eCRF and replaced with an automatically generated REDCap identification number. To improve data reliability, 27 additional changes were made to the eCRF. Nine fields were added to prevent data loss or resolve ambiguities. After these changes, 1 field became redundant and was deleted. Finally, 17 fields were modified in either the field label or answer choices in order to provide more clarity to the user regarding what data was being asked for and what units were required. Seven of these modifications were to replace the answer choice “NA,” which our SMEs determined to be ambiguous, with “Data not available.” An example of each type of change is shown in Table 1.

\begin{table}
\centering
\begin{tabular}{|l|l|l|l|l|}
\hline
Original Field Label & Original Answer Format & Modified Field Label & Modified Answer Format & Reason for Modification \\
\hline
Symptom onset date of first/earliest symptom & DD-MM-YYYY & Onset of first/earliest symptom & 1, 0-1 day before admission | 2, 2-3 days before admission | 3, 4-5 days before admission | 4, 5 days or more before admission | 999, unknown & Remove PHI \\
\hline
Other & 2, YES - Confirmed | 1, YES - Probable | 0, NO & Other Infectious Respiratory Diagnosis & [not modified] & Improve data reliability \\
\hline
\end{tabular}
\caption{Examples of changes to eCRF to remove PHI and improve data reliability}
\end{table}

Conclusion

Our objectives were met through this process, which took approximately 20 hours of total effort. With these modifications, participating sites have obtained expedited IRB approval and data collection is about to begin. We will monitor the effort required to complete the eCRF, as well as suggestions for improvement. Once the study is concluded, we plan to compare the data obtained with this revised eCRF with data from sites using the original CRF.

Towards A Better Cancer Care Through The Use Of A Chemotherapy Ordering Information System: Transferable Lessons Learnt

Nilmini Wickramasinghe 1,3, Peter Haddad 1,3, Stephen Vaughan3, Jonathan L. Schaffer2

1Deakin University, Melbourne, Victoria, Australia, USA, 2 Cleveland Clinic, Cleveland, Ohio, 3Epworth HealthCare, Melbourne, Victoria, Australia

Abstract

Today, cancer is one of the most prevalent diseases. Cancer treatment regimens are complex, are associated with high risks and often have unwanted side effects. The outcomes of a longitudinal study to evaluate the impact of using an American computerized physician order entry (CPOE) system to improve cancer care outcomes in an Australian not-for-profit tertiary healthcare environment are presented. Results indicate that while the system is necessary it is not sufficient to provide superior care. Finally, lessons learned are presented.

Introduction

Cancer is one of the most common chronic diseases in today’s modern society. The treatment regimens used to treat cancers are complex, associated with high risks and often have unwanted side effects and complications. Within cancer services, the administration of chemotherapy is typically a major component in the treatment plan. The use of a computerised physician order entry (CPOE) system as a chemotherapy ordering system (COS) for the planning, ordering, dispensing and administration of these cytotoxic drugs should improve the quality, safety and efficiency of this process. A major consideration is the effectiveness of the implementation of such a system, the facilitators and barriers to this process, as well as how to address them. These points form the central focus of this study.

The Proposed Model

Actor Network Theory [1] and Agency Theory [2] were combined to provide the theoretical lens and guide the systematic literature review to explore the key points necessary to successfully implement the COS (chemotherapy ordering system) in the Australian not-for-profit tertiary healthcare environment. Combining the results from the preceding literature synthesis with an initial assessment of the data, the conceptual model was developed (Figure 1).

Methods and Materials

Methods: The study adopts a multi method approach that is predominately qualitative using semi-structured interviews, focus groups and survey techniques to gather critical information.

Materials: An online survey was designed, developed and then validated to assess usability and acceptance of the COS and data triangulation was adopted to ensure internal and external validity. Specifically, the survey targeted three categories of healthcare professionals and executives as follows: Oncologists, Executives and Casual Users and COS Daily Users.

Results:
The COS was found to be necessary for many elements of care and administration, i.e.; EMR elements available to track clinical documentation in concert with ordering and results documentation, but not sufficient to provide superior care. A key challenge relating to poor goal aligned behavior emerged. Agency Theory underscores the importance of engaging users to ensure strong goal alignment between their tasks and their interactions with the system and the hospital's goals and objectives [13], yet this was poorly addressed in the specific context. Key lessons include the need to engage with all users, to appropriately design training as well as effecting thoughtful change management and organization culture/subculture modification changes.

Conclusions:
The adoption and implementation of COS requires a holistic perspective during each phase of design and implementation. Adequate attention to the health ecosystem, the system structure, the delivery operations and the satisfaction of all the respective users e.g., oncologists, nurses, pharmacists, GPs and administrators as well as the nested clinical structures should be addressed.

E-prescriptions and Problem Lists: Looking for Indications Using the Open-Source MEDI Medication-Indication Matching Resource

Taylor Woodroof, PharmD; Wing Liu, PharmD; Scott D. Nelson, PharmD, MS

1Vanderbilt University Medical Center, Nashville, TN

Introduction
When performing medication reconciliation and medication therapy management, it is critical that prescribed medications are reconciled with indications on the patient’s problem list and that untreated diagnoses are re-evaluated. However, these reconciliation processes are dependent on the completeness of the medication and problem lists, and could be aided by automated matching. The purpose of this study was to estimate the proportion of e-prescribed medications at our facility with a potential indication listed on the patient’s problem list using the open-source medication-indication matching resource MEDI (MEDication Indication) to infer probable matches.

Methods
We analyzed a de-identified dataset of medications e-prescribed from 1/1/2015 to 6/30/2015 at Vanderbilt University Medical Center (VUMC). To be included in the study, patients have to have established care at VUMC, defined as ≥2 visits in the past year and ≥1 e-prescribed medication. We matched e-prescriptions to potential indications on the problem list using MEDI (MEDI_01212013), which integrates medication indication information from four public medication resources, RxNorm, Side Effect Resource (SIDER) 2, MedlinePlus, and Wikipedia.1 To improve precision of the medication-indication pairs, we separately analyzed the MEDI High Precision Subset (HPS) (MEDI_01212013_HPS), which is a smaller set of medication-indication pairs found within RxNorm, or at least two of the other three resources. We mapped prescription medication codes from First Databank to RxNorm generic drug ingredient names (RxCUI, TTY=IN). Prescriptions were excluded if they consisted of multiple ingredients or did not map to RxNorm. In order to match diagnosis on the problem list to the MEDI dataset, we mapped SNOMED CT problems to ICD-9 codes. We established a gold-standard to evaluate the MEDI precision and recall by having two pharmacists independently manually review e-prescriptions and problem lists from 30 randomly selected patients. Disagreements were resolved by discussion and consensus. For analysis, we calculated precision, recall, and descriptive statistics.

Results
Out of 62,191 patients included in the study, there were 270,045 electronic prescriptions sent. 61.3% of electronic prescriptions had an indication match within the patient problem lists, whereas only 37.5% had a match using MEDI-HPS. Using MEDI, patients had an average of 1.3 medications match to prescribed indications and 0.44 medications using MEDI-HPS. For comparison, the final dataset contained an average of 4.3 prescribed medications per patient. For the gold-standard comparison, the reviewers had an inter-rater reliability of 0.81. The precision of MEDI compared to the gold standard was 55.8% with a recall of 61.4%; whereas MEDI-HPS had a precision of 85.2% and recall of 95.8%. The top-20 most frequently e-prescribed medications had an indication match 61% (n=47,892) of the time using MEDI, with only 36.8% (n=28,735) having an indication using MEDI-HPS. Secondary analysis excluding medication prescribed with a day supply <14 days gave slightly better, yet similar results (data not shown).

Conclusions
We were not able to match indications from the patient problem list for the majority of e-prescribed medications with an acceptable level of precision (MEDI-HPS). Manual review showed that MEDI-HPS has a higher precision and recall than MEDI. This marks the first use of MEDI-HPS matching e-prescribed medications with indications. Given its high precision and recall after manual review, this study suggests that many problem lists (and potentially medication lists) are incomplete in the EHR, emphasizing the difficulty, and potential beneficial use cases, of using an automated medication-indication matching resource such as MEDI-HPS.

Effect of Alcohol Prohibition on Drug-related Mortality

James A. Woodward, B.A.¹, Ray H. Hylock, PhD¹, Qiang Wu, PhD¹, Xiaoming Zeng, PhD¹
¹East Carolina University, Greenville, NC

Overview

Since 2000, overall mortality rates in the United States have decreased 16.6%¹ (Figure 1) while drug-related mortality rates have increased 137%². This research investigates how the county alcohol prohibition status (i.e. whether alcohol sales are completely prohibited (dry counties), completely permitted (wet counties), or there is some regulation of alcohol sales (mixed counties)) is related to increased drug related mortality rates. We performed a policy level literature search that revealed evidence of a positive relationship between alcohol prohibition and meth lab seizures³, but found no research directly related to alcohol prohibition and drug-related mortality.

Methods

County and State name, county FIPS code and alcohol prohibition status were parsed from the national alcohol prohibition map SVG file. The wet-dry status, Census data, and CDC mortality datasets were created, normalized and merged in SAS, which was also used for descriptive and analytical statistical analyses.

Results

Our analysis reveals that dry counties consistently have higher mortality rates than both mixed and wet counties through all years of the analysis (2002-2014) and that dry counties have statistically higher odds of having high drug mortality rates (>20 drug related mortality rate) than wet or mixed counties (Figure 2).

Restoring line breaks in Epic-derived clinical notes

Stephen T. Wu, PhD1,2, Allison Sliter1, Meikun Wang1, Tamara Timmons, MD1, Steven Bedrick, PhD1

1Oregon Health & Science University, Portland, OR; 2Mayo Clinic, Rochester, MN

Introduction

Secondary use of the Electronic Health Records (EHRs) is challenging for multiple reasons. Unfortunately, with such vast amounts of heterogeneous data, small design decisions in the implementation of a system can have wide-ranging impact on the viability of the data for downstream processes.

In the early stages of a patient-level information retrieval (IR) and natural language processing (NLP) project at Oregon Health & Science University, we discovered that data originating in free-text note fields had been modified, and all line-ending characters had been replaced with a variable number of whitespaces. This profoundly affects a number of downstream NLP tasks, such as section detection, as well as any analysis of semi-structured data such as lists, tables, etc. that may have been present in the notes. Further investigation of these errors pointed back to the Extract-Transform-Load (ETL) processes within the Epic EHR that produces the standard Clarity database; thus, this transformation of line endings is a barrier to local IR and NLP research, and also to secondary use of clinical notes in any institution using the same Epic ETL process.

Methods

Inspired by previous approaches to sentence detection (1), we developed a conditional random field (CRF) model (2), using the CRF++ package, to restore line breaks on data extracted from Epic's Clarity. For each word \(w_i\) in clinical text, we sought to predict whether the following delineation should be a <space> or a <new line>.

Features for the CRF classifier were developed on a small development set of "synthetic" line-break data. Namely, we took a de-identified data set (from a non-Epic EHR) with original line breaks preserved, then removed line breaks. We could then compare the original line breaks with those hypothesized by our classifier.

In this development data, we noted that the appearance of line breaks was highly correlated with other textual features in close proximity. Our basic feature set included case information, the presence or absence of punctuation medially or token-finally, and whether or not the token contained digits. In addition to this, we included secondary features that were combinations of these features, and calculated these features in 2-to-6-word contexts around a candidate line ending location. We built a classifier to predict which white space characters between tokens might have originally been a newline character. We found that 4-gram contexts were the most successful.

Evaluation and Deployment

For evaluations, we annotated 450 line-break-less Epic clinical notes, introducing 11,140 line breaks. We performed cross-validation tests on this data, resulting in scores of 96.5%, 87.5%, and 91.7% for Precision, Recall, and F1-score. This performance on real data was lower than on synthetic development set, but it is still an important improvement over the existing lack of line break data in Epic-derived clinical text.

We parallelized the line break-restorer and ran it on 10,111,930 clinical notes to be used in a new IR collection (3). Future work includes improved feature extraction, a characterization of performance on different types of EHR text (e.g., Pathology vs. Radiology reports), and making our line-break restorer available open-source to other institutions with similar issues arising from their Clarity databases.

What Can Neural Networks Learn from Unlabeled Clinical Narratives?
Yonghui Wu, PhD1, Jun Xu, PhD1, Yaoyun Zhang, PhD1, Hua Xu, PhD1
1School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

Introduction: Word embeddings can capture abundant semantic relations to extend the current applications of natural language processing (NLP). Researchers have applied word embeddings in the clinical domain and reported performance improvements in many clinical NLP tasks. However, there is no research to examine the details of semantic relations captured from clinical narratives, as it's a non-trivial and challenging task in general. A good interpretation of the "black box" (word embeddings) can help people better understanding why neural word embeddings could help and what is captured in the real-valued numbers. This study attempts to interpret the details of semantic relations captured from large clinical narratives using neural networks. We looked into word embeddings trained from a 2.2 G clinical narrative corpus and examined the semantic relations. Our results showed that in addition to the conventional semantic relations defined by linguistics, such as the word prefix/suffix, part of speech tags (POS), the word embeddings also captured more complex semantic relations (medications, body locations, and even complex logical relations, such as $WED<$"father"$, "$mother"> \approx WED<$"wife"$, "$husband">$, where "WED" denotes "word embedding distance", which is defined as the cosine-similarity score between two word vectors).

Methods: In our previous work1, we trained word embeddings from 2.2 G unlabeled clinical narratives from MIMIC II corpus using a neural network. The training corpus was composed of various types of notes, including discharge, radiology, ECG, and ECHO notes. All the words with frequency great or equal to 5 (about 41,000 words) were used. We applied t-Distributed Stochastic Neighbor Embedding (t-SNE) algorithm to calculate the neighbors and generate word cloud visualization, where words formed various clusters according to the distance to its neighbors. Then, we examine the word clusters and tried to label the semantic relations among the words within each cluster. For example, the label “plural/singular” was assigned to the cluster containing the plural form and singular form of a word. Finally, we compared our results with the semantic relations reported in the previous research to compare the differences and report new findings.

Results: Although clinical narratives are often criticized as ungrammatical and telegraphic, we found that the neural networks captured many reasonable semantic relations. Table 1 shows some examples of captured semantic relations. As shown in Table 1, the word embeddings captured not only the relations defined by linguistics, such as words with the same prefix/suffix, POS, but also medical and complex relations. Figure 1 shows the visualization of a complex relation: $WED<$"father"$, "$mother"> \approx WED<$"wife"$, "$husband">$, similar to the <"king"$, "$queen"> and <"man"$, "$woman"> relation reported in the general English domain.

Diabetes Self-Management Applications: Focus Group Findings from Elderly Diabetic Patients

Qing Ye, MS\textsuperscript{1}, Suzanne A. Boren, MHA, PhD\textsuperscript{1,2}, Uzma Khan, MD\textsuperscript{3}, Min Soon Kim, PhD\textsuperscript{1,2}

\textsuperscript{1}Informatics Institute; \textsuperscript{2}Department of Health Management and Informatics; \textsuperscript{3}Department of Medicine, University of Missouri, Columbia, MO

Abstract

We conducted two focus groups with 10 older diabetic patients to identify barriers in functionality and usability of mobile diabetes self-management apps. We collected demographics and diabetes self-management app experiences. They completed a set of diabetes management tasks using nine representative diabetes self-management apps on iPad. Descriptive statistics and thematic analysis were used. We found current diabetes apps are not usable and do not fulfill the needs of older diabetic patients for self-management.

Introduction

The prevalence of diabetes is increasing, and 25% of Americans above 65 years old have diabetes. The number of diabetes self-management (DSM) applications available has risen. However, we do not know whether these apps provide effective DSM for elderly diabetic patients. The purpose of this study was to identify barriers in usability and functionality related to the needs of elderly diabetic patients for DSM apps.

Methods

We conducted two focus groups with 10 older diabetic patients. After the multi-step review process, 73 iOS apps were identified eligible. We selected apps on the basis of app ratings, number of reviews, and presence of seven principles by the American Association of Diabetes Educators (AADE7) Self-Care Behaviors\textsuperscript{TM}. The seven behaviors are Healthy Eating, Being Active, Monitoring, Taking Medication, Problem Solving, Reducing Risks, and Healthy Coping. Nine apps were selected and installed on iPads: MySugr Diabetes Logbook, GoMealsHD, DiabetesConnect, Diabetes Pilot HD, Tactio Health, Diabetes App Lite, ezbdz, Daily Carb Premium, Diabetes in Check. We collected demographics, diabetes history, Single item literacy screener question (SILS, 1-5), and prior experience using smart mobile devices and DSM apps. SILS scores greater than 2 are considered positive, indicating some difficulty with reading health related material. The participants were asked to perform self-management tasks related to Healthy Eating, Problem Solving, and Healthy Coping, which are the critical principles for improving self-care behaviors. We collected their preferences, issues, and needs of DSM app features. System Usability Scale (SUS, 0-100) was used to measure usability. Descriptive statistics and thematic analysis were used to identify barriers elder patients encountered as they interacted with the DSM apps.

Results

The average age of participants was 67 years old. Of the 10 participants, six were male. All participants were white. Six of them were Type 1 diabetes and four were type 2 diabetes. The average diabetes history was 27 years. Most participants had high health literacy (SILS=1.8). More than half of the participants had used smart mobile devices for over one year, however nearly all participants had never used diabetes apps to help them manage their condition. The features that participants liked most for their DSM were documentation, information, and goal setting. Most participants thought these apps helped them gain the skills of counting carbohydrates (72%), setting goals for a healthy lifestyle (62%), and reading food labels (51%) in Healthy Eating, and recognizing and reacting to high or low blood sugar levels (70%) in Problem Solving. On the other hand, participants thought these apps did not help gain the skills of motivate exercise/meditate (16%) and pursue hobbies (32%) to deal with stress, anxiety or depression in Healthy Coping. Thematic analysis revealed that usability was their primary concern about DSM apps in managing diabetes conditions (i.e. complicated layout, not easy to use, and not useful). The average score of the SUS was 49 (SD=28), which was considered not acceptable. Besides the usability issue, participants considered presence of documentation functionality and cost as important factors when they decided to download diabetes apps.

Conclusion

Older diabetes patients would like to choose apps that are easy to use, allow documentation of glucose levels, diet and physical activity. This study suggests current DSM apps do not provide meaningful features for self-management and may not fulfill the needs of elderly diabetic patients. Future diabetes apps designed for diabetic users should be easy to use for older patients also.
A Review of Mobile Phone-based Interventions and Applications for Medication Adherence

Po-Yin Yen, RN, PhD, Jessica M. Garvey Smith, BS, Michelle P. Zhou, Megan Chamberlain, Xiaonan Ji, MS, Albert M. Lai, PhD
Department of Biomedical Informatics, The Ohio State University, Columbus, OH

Abstract
Medication non-adherence is a critical problem, resulting in poor clinical outcomes and wasteful spending. We reviewed 803 articles in PubMed and found 80 relevant studies with mobile phone interventions. We also reviewed 10 free mobile applications with the highest downloads and user ratings. We identified limitations and gaps for future research.

Introduction
In 2010, $100-300 billion of US spending on healthcare costs was due to medication non-adherence, leading to re-hospitalizations, mortality, and multiple morbidity.\(^1,2\) Portable technology such as smartphones has the potential to improve medication adherence with reminders and educational messages.\(^3\) The purpose of the study was to review the effectiveness of such an mobile phone intervention and identify gaps for future research.

Methods
We searched in PubMed with the following search strategy: ((Medication Adherence[MeSH Terms] OR "medication adherence" OR "medication compliance") AND (technology OR application OR "mobile phone" OR smartphone). The inclusion criteria was that studies must utilize mobile phones as an intervention. We also searched in Google Play for free medication adherence applications with the highest number of downloads and at least 4-star user ratings. We investigated study design, trial length, study population, outcomes, and mobile phone features used for medication adherence.

Results
A total of 803 articles were found in PubMed; Only 80 studies were included with a mobile phone intervention for medication adherence. Of the 80 studies, 66 (82.5%) solely used text/voice messages or personal phone call as reminders and educational messages; only 14 (17.5%) used smartphone applications with advanced features, such as adherence monitoring and health status tracking (e.g., blood pressure, glucose, weight). The most common study populations are HIV, followed by diabetes and general non-specific population. Most studies conducted randomized controlled trials with less than 6 months intervention; Only 12 studies followed up with study subjects for 1-2 years. 42 (52.5%) found the mobile phone-based intervention effective, 13 (16.2%) found the intervention inconclusive, 10 (12.5%) found no improvement, and 15 (18.8%) with pending results. In addition, we reviewed 10 free mobile applications. The most common features included reminders, management of dependents/multiple accounts, inventory tracking, medication adherence on-time records, adherence tracking, important contact information, usage of medication pictures or icons, and health conduction tracking. We did not find any research regarding the effectiveness or usability of these applications.

Conclusion
Patients with chronic conditions are likely to stop taking their medication within the first year.\(^2\) Medication adherence research should aim to conduct studies for more than one year. Smartphone applications with advanced features were perceived useful, but lacked long-term and effectiveness studies. A medication adherence intervention could be simple text messages or complex smartphone applications, economic or costly monitoring systems (e.g., electronic pill trays/bottles). In order to benefit the majority of patients, there is a need to investigate cost-effective solutions. Further research should include long-term adherence trials, usability and feature comparative studies, and application development for complex and multiple medication regimens.

Vision-Based Hand Hygiene Monitoring in Hospitals

Serena Yeung, MS1, Alexandre Alahi, PhD1, Albert Haque, BS1, Boya Peng, BS1, Zelun Luo, BS1, Amit Singh, MD2, Terry Platchek, MD2, Arnold Milstein, MD1, Li Fei-Fei, PhD1

1Stanford University, Stanford, CA; 2Lucile Packard Children's Hospital Stanford, Stanford, CA

Introduction

Recently, much progress has been made in machine learning-based interpretation of clinical data for decision support and knowledge discovery. These works have reasoned on data such as electronic medical records and radiographic images. However, a valuable source of clinical data that is still underexplored is visual data capturing patient experience and environment during health care episodes such as hospital stays. Such data can contain rich information about patient condition, and the occurrence and characteristics of clinical care activities.

In this work, we interpret visual clinical data for the application of health care-associated infection (HCAI) prevention, which is a challenging and costly problem for hospitals in the United States1. Proper hand hygiene is known to play an important role in preventing HCAI2. We introduce an approach for monitoring hand hygiene compliance using machine learning-based interpretation of visual recording of the environment. Specifically, we propose to deploy privacy-safe depth sensors in hospitals to capture the physical space near hand hygiene dispensers, and use computer vision methods to detect hand hygiene actions.

Method and Experiments

We use a convolutional neural network3 to detect whether hand hygiene occurs in a video frame. The network consists of 2 convolutional layers and 2 fully connected layers, with a binary classification output, and we optimize it using stochastic gradient descent. We collected a pilot dataset of 20 hours of depth signals (Figure 1), and achieve 0.450 average precision (AP) on full images, and 0.937 AP on cropped regions around dispensers.

We additionally introduce a novel, viewpoint-invariant method for 3D human pose estimation that can localize hands in the video frame to associate the actions with specific persons. Our model is a recurrent convolutional neural network that takes an image as input and outputs human pose, i.e. locations of a set of body parts. While previous methods4 have been able to accurately estimate pose from frontal views, our model uses recurrent error feedback5 in a viewpoint invariant framework to achieve strong pose estimation from arbitrary and challenging viewpoints such as a top-down view over a hand hygiene dispenser. Our method achieves 73% localization accuracy of left hands and 65% of right hands, where a detection is correct if the localization error is less than 10cm.

Conclusion

We have demonstrated the use of image-based and human pose-based computer vision methods for monitoring hand hygiene compliance. Future work involves demonstrating these methods at large scale in hospital environments, implementing real-time interventions based on the monitoring, and measuring their effect on compliance.

Annotation of Tumor Reference Resolution and Tumor Characteristics for Cancer Liver Stage Prediction

Wen-wai Yim¹, Tyler Denman², Sharon W. Kwan, MD²,³, Meliha Yetisgen, PhD¹,⁴
¹Biomedical and Health Informatics, ²School of Medicine, ³Department of Radiology, ⁴Department of Linguistics, University of Washington, Seattle, WA

Introduction
Despite availability of new treatments, deaths due to liver cancer, one of the leading causes of cancer-related deaths worldwide, have continued to increase in the United States. More than 80% of patients do not survive past 5 years. Various co-morbidities, lifestyle, and genetic diversity are associated with the disease; thus, optimization of treatment strategies to personal characteristics remains challenging. We target evidence-based research in this area, by concentrating on automatic cancer stage classification. The premise is that cancer stages, calculated based on individual characteristics and linked to successful treatments and outcomes, may inform future clinical decisions. Tumor information, such as number and size, are typical cancer stage parameters, which require reasoning over multiple sentences. Therefore, reference resolution, which determines which mentions in text refer to the same real world entities, is an important part in cancer stage determination. In this abstract, we present our annotation of tumor reference resolution and tumor characteristics used to calculate liver cancer stages.

Annotation
Our goal of automatic stage classification for three liver cancer staging systems (AJCC—the American Joint Committee on Cancer, BCLC—the Barcelona Clinic Liver Cancer, and CLIP—the Cancer of the Liver Italian Program) necessitates identification of a few general tumor-related stage parameters. Based on our staging systems, we identified three tumor-related relevant parameters: (1) tumor number, (2) tumor size, and (3) invasion of >50% of the liver. However, these values are not only non-explicitly stated in reports, they require reasoning over multiple sentences. For example, as shown in Figure 1, arriving at the relevant parameters (1-3) requires understanding co-referring statements and correctly aggregating.

We annotated reference resolution and tumor characteristics for a corpus of 101 abdomen radiology reports from University of Washington hepatocellular carcinoma patients, which was previously annotated for tumor events [1]. Reference resolution annotations were marked using brat, a web-based annotation software. The two types of reference resolution annotations included: (a) coreference relations, directionless link amongst two or more references of the same entity, e.g. line-29-Lesion-1 and line-38-lesion, and (b) particularization relations, a directed relation between a generalized reference to more specific reference, e.g. line-37-focal-lesions to line-38-lesion. The summarized tumor characteristics (1-3) mentioned above were annotated per document. Tumor numbers for benign, indeterminate, and unknown malignancy were also marked (instead of only malignant tumors). Thus, for Figure 1, the document annotations include the following: (#-malignant-tumors:2), (#-indeterminate-tumors:1), (#-benign-tumors:0), (#-unk-tumors:0), (size: 3.6cm), and (>50%:no).

Inter-annotator agreement for 20 documents, annotated by a medical student and biomedical student for reference resolution, showed an agreement of 0.94 F1 (MUC) for coreference and 0.84 F1 for particularization relations. Agreement for tumor characteristics was at 0.91 F1.

Future Work
We are building an automatic system for reference resolution and tumor characteristic annotation. We will include these pieces into our overall cancer stage prediction system, though our methods are generalizable to other systems.

Visualization of Topics from Twitter and Focus Groups as the Foundation for Insights about Dementia Caregiving

Sunmoo Yoon, PhD1, Niurka Suero-Tejeda1, Blake Hunter, PhD, Suzanne Bakken, PhD1
1 Columbia Univ. Medical Center, NY, 2Dept. Math Sci, Claremont McKenna College, CA

Abstract
The study aims to illustrate application of mining and visualization techniques for insights about dementia caregiving.

Introduction
Approximately 47.5 million suffer from dementia. Informal caregivers such as their family members experience burden and need support for their self-management tasks and skills including emotional, medical and role management of the individual with dementia as well as themselves. Mining social media may provide novel insights of support strategies for dementia caregivers. The study purpose is to illustrate application of mining and visualization techniques as a foundation for insights about dementia caregiving.

Methods
Using NCapture, we randomly extracted Tweets mentioning dementia (n=73564) or demencia (n=2501) from Tweet corpora collected daily from Sep 2015 to Jan 2016. We applied Latent Dirichlet allocation (LDA)-based topic modeling1 to identify topics from the Tweet corpus after preprocessing with R. The authors with a native speaker analyzed focus group data by human coding of English and Spanish verbatim transcripts and visualized the topics using network diagrams.

Results
Figure 1 displays topics from English and Spanish Tweets and focus group data.

Figure 1. Topics from English and Spanish Tweets and focus group data

Conclusion
Application of mining and visualization techniques provide the foundation for research team insights regarding dementia caregiving and self-management needs for the person with dementia and the dementia caregiver. The findings will be applied for future targeted intervention development for Hispanic dementia caregivers.

Using Topic Models to Analyze Concepts for New MeSH Terms

Zhiguo Yu, MS1, Todd R. Johnson, PhD1
1The University of Texas School of Biomedical Informatics at Houston, Houston, TX

Abstract

In this poster, we present a way to use Topic Models to analyze the evolution of concepts for new MeSH terms. By computing the correspondences between the MeSH terms and the topics generated from PubMed citations published in each year, we show that there are topics that are more and more similar to the MeSH terms along the years. When the MeSH term was introduced, a correspondence score around 0.75 was reached.

Introduction

Medical Subject Heading (MeSH) is one of the source vocabularies in UMLS with the primary purpose of supporting indexing, cataloging, and retrieval of biomedical articles in MEDLINE. A small group of indexing staff at the NLM are responsible for revising and updating the MeSH vocabulary. However, NLM does not retrospectively re-index MEDLINE citations with new MeSH terms. Therefore, the timing to introduce a new concept to MeSH vocabulary is crucial. Unlike MeSH terms, which are manually created, topic models can automatically extract semantic themes based on a subset of documents. Such themes may uncover a specific set of topics for a particular domain or sub-domain, which may not exist in MeSH. In our previous work, we introduced a correspondence matrix (figure 1) between topics generated using Latent Dirichlet Allocation (LDA) and MeSH terms. Each topic generated by LDA is a distribution over all of the unique words in the corpus. We represented each MeSH term as a distribution of the words contained in the documents to which it had been assigned. A similarity score was then computed between each pair of topic and MeSH. Figure 1 provides an illustrative correspondence matrix. Here, Topic 2 is the corresponding topic for MeSH 2.

Figure 1. Correspondence Matrix.

To analyze the evolution of concepts for new MeSH terms over time, we used 3368 titles and abstracts returned from the PubMed query, ‘J Biomed Inform’[Journal] OR ‘J Am Med Inform Assoc’[Journal]’. We picked two MeSH terms, ‘Data Mining’ and ‘Electronic Health Records’, which were both introduced in 2010. We created each of these two MeSH terms’ word vectors using all the citations indexed with this MeSH term within the query results. For each year, we used LDA to generate topics based on the citations published in and before this year. Then we computed the correspondences between topics and these two MeSH terms for each year. We chose the highest corresponding (similarity) score for each year to determine whether we could find similar concepts prior to the introduction of the new terms. Figures 2 and 3 show how the highest similarity score varies and improves over time. There are topics that are more and more similar to the two terms over time. From these two examples, we see there are topics in 2008 and 2009 that have the same similarity score as the topics of 2010, in which those two MeSH terms were introduced. In both cases, a correspondence score around 0.75 was reached at the time the new terms were introduced.

Figure 2. Topic evolution for ‘Data Mining’. Figure 3. Topic evolution for ‘EHR’

Drew University of Medicine and Science, Los Angeles, CA; 4Los Angeles Biomedical Institute at Harbor UCLA Medical Center, Torrance, CA, 5Cedars-Sinai Medical Center, Los Angeles, CA

Introduction

The NIH Common Data Elements (CDEs) is an initiative spanning the NIH institutes to develop standardized elements for inclusion in research data collection instruments. Its ultimate aim is to make data collected by different research projects more comparable, so that data from multiple studies can be pooled more easily for reanalysis. One of the oldest and best-developed of the CDE initiatives, the National Institute of Neurological Disorders and Stroke (NINDS) CDE currently contains 16,000+ unique variables derived from more than 550 instruments.

For this study, we evaluated the extent to which the variables collected by a major stroke research study using REDCap, a software system used for implementing standardized research data collection, were or could be represented using the NINDS CDEs. We explored the extent to which the CDEs encompassed the data needed for the stroke study and the extent to which investigators might need help in finding appropriate CDEs.

Methods

The REDCap forms from a UCLA neurology study that utilized NINDS CDEs were examined. The study contained 1,331 REDCap fields. Of these, 468 fields were excluded from our analysis because they were duplicates of other fields that were translated into Spanish, and an additional 507 fields were excluded because they did not capture discrete subject variables (e.g. instructions for the interviewer, flow control, modifiers of other variables, etc.). The remaining 361 discrete patient variables were evaluated by four reviewers to determine whether an NINDS CDE was used or could have been used. NINDS CDEs were searched using an Excel file downloaded from the CDE website in Summer, 2015. When possible, each study variable was matched to an NINDS CDE, and the closeness of the match was categorized. To define the match process and match types, the first 129 of the 361 discrete variables were reviewed by each reviewer, in sets of 20-40 items at a time, with comparisons of match and consensus-setting meetings after each set. After consensus match definitions were agreed upon, the remaining 232 variables were then each evaluated independently by two of the four reviewers. A fifth reviewer adjudicated disagreements between reviewers on the CDE match and match type. Cohen’s κ was calculated to measure inter-rater agreement.

Results

Of the 361 discrete patient variables captured by the study, a closely related CDE was found for 117 (32%). Of these, 20 (17%) used a CDE item unmodified, 59 (50%) used a CDE with minor modifications, and 38 (32%) were items that had an unused potential CDE equivalent. Of the 244 without a closely related CDE, 56 (23%) could be matched to a partially related and 58 (24%) to a distantly related CDE. Focusing on the 232 study variables that were independently evaluated, reviewers agreed on 43% of match types, and inter-rater reliability was fair (Cohen’s κ = 0.264; 95% CI [0.201, 0.328]). In choosing a specific CDE (or no CDE), reviewers agreed for 53% of the study variables.

Discussion & Conclusion

Preliminary analysis indicates that investigators succeeded in using NINDS CDEs but that the CDEs need expansion given that a closely related CDE was found for only 32% of study variables. Although the 16,000+ CDEs are categorized into nine domains, the domains are not defined. Clearly defined domains and improved organization of the CDEs would facilitate the identification of the appropriate standard when it is available. Poor agreement between reviewers is a reflection of the cumbersome task of searching the 16,000+ variables in the NINDS CDEs that are grouped into nine undefined domains.
Reading Leadership: Improving Participation in an Introduction to Health Informatics Course

Iris Zachary, PhD, MS, CTR\textsuperscript{1}, Suzanne A. Boren, MHA, PhD\textsuperscript{1}
\textsuperscript{1}Department of Health Management and Informatics,
University of Missouri, Columbia, MO

Abstract

We evaluated the opportunity to improve participation in an introduction to health informatics course by incorporating four engagement strategies and offering in class and online discussion opportunities. Offering multiple methods of participation led to 100\% of students participating in the discussions.

Introduction

The purpose is to evaluate the process of student led discussion on peer reviewed health informatics articles by offering more than one method of participation in an Introduction to Health Informatics course. Previous students had provided general feedback that there was not enough time in class to fully discuss each article. Some students had cited barriers to successfully joining the in class discussion with their peers. We have incorporated four engagement strategies, 1) intellectual engagement by having the student pose two questions that are discussed by the class, 2) behavioral engagement by having student led discussion, 3) social engagement by engaging discussion among the students, and 4) cultural engagement by giving students different modalities they can voice their opinions either in class or online, however they feel more safe to participate and confident in terms of language barriers.

Methods

Each student in the Introduction to Health Informatics course was required to complete the reading leadership assignment. Reading leadership consisted of each student leading the discussion of an article from the peer reviewed published literature related to course topics. Students were provided with a pre-approved article list and were required to read all articles. Students wrote a 150-200 word summary and two discussion questions posted to a discussion forum in the course management system, made a three minute oral summary, and led a discussion lasting up to a maximum of 10 minutes. (Students could participate by responding to the discussion questions orally during the class discussion and by responding online in the discussion forum for up to 24 hours following class. Participation in the oral discussion in class was tracked by one of the course instructors as it occurred. Online discussion was read and tracked the next day. Comparisons were made between in class and online discussions participation rates.

Results

Thirty-nine (39) students were enrolled in the course and participated in reading leadership discussion throughout the semester. Thirty-two (32) or 82\% of the in-class reading leadership discussions lasted the full 10 minutes. All students participated in at least one of the discussion modalities: 32 students participated in discussion in class, 34 students participated in discussion on line, 27 students participated in both in class and online discussion. A total of 365 comments (average of 9.4 comments per student) were made in class and 306 comments (average of 7.8 comments per student) were made online.

Conclusion

Providing the opportunity for students to participate in the discussions orally in class and in writing online immediately following class expanded participation by seven students (18\%) to achieve 100\% of students participating in class discussion. Offering multiple methods of participation enabled all students to participate and many students to participate more than they would have with only one method.
Answering patients’ questions using expert-vetted online resources: A case study of diabetes

Abstract
It is not clear if expert-vetted online resources cover the information needs of patients. Collected patients’ questions of diabetes, we evaluated three expert-vetted online resources (WebMD, MedlinePlus, and UpToDate) with respect to the content coverage and time required to find information when ignoring the language use difference. Among three online resources, WebMD received the highest coverage with the least amount of time in finding answers.

Introduction
An increasing number of patients seek medical information online. Expert-vetted knowledge online resources such as UpToDate have been created by medical authorities to provide new and accurate health and disease information which have a great potential to provide the right information for patients. However, it is not clear if they contain the information needed by the patients. In this study, we evaluated three expert-vetted online resources (WebMD-WMD, MedlinePlus-MLP, and UpToDate-UTD) with respect to the content coverage and time required to find information when ignoring the language use difference.

Methods
190 questions were obtained from a healthcare data analytics challenge in ICHI2015-IEEE International Conference on Healthcare Informatics. Two experts with medical background read the questions, identified keywords to be used for searching the content to answer these questions from the three resources. For each question, the time used to retrieve was recorded, and the answer on each question was assessed on a six-category rating scale ranging from 0 (none), to 5 (complete and comprehensive answer matching with question). One expert searched the three resources for all 190 questions and the results were analyzed. While the other expert searched 50 questions randomly selected from those 190 questions and the results were used to evaluate the consistency by calculating the weighted κ value (Cohen’s kappa coefficient) of scores and time in the same 50 questions from the two experts.

Results
The comparison of scores between the three groups (Figure 1) showed that three group scores were all more than 4. The score of MLP (4.02±1.04) was remarkably lower (p<0.05) than that of UTD (4.53±0.77) and WMD group (4.58±0.67). No statistical difference was observed between UTD and WMD group. In comparison with WMD (1.00±0.75), UTD (1.42±1.00) group took remarkably longer time (p<0.05) while MLP (1.07±0.74) was not statistically significant comparable to WMD (Figure 2). The kappa values greater than zero (κ>0) indicated that the two experts had the consistency for the results. Among three online resources, WebMD received the highest coverage with the least amount of time in finding answers.

Data-Driven System for Perioperative Acuity Prediction

Linda Zhang, BS\textsuperscript{1}, Daniel Fabbri PhD\textsuperscript{1}, Jonathan P. Wanderer MD, MPhil\textsuperscript{1,2}
\textsuperscript{1}Departments of Biomedical Informatics\textsuperscript{1}, and Anesthesiology\textsuperscript{2} Vanderbilt University, Nashville, Tennessee

The American Society of Anesthesiologist’s’ (ASA) Physical Status classification is a subjective assessment of a patient’s overall health. It is a widely used grading system for preoperative health in surgical patients, and consists of six classes of increasing severity [1]. Associations of ASA score with postoperative outcomes have been reported in literature [1]. Even though ASA score has been shown to be a predictor of postoperative outcome, there is considerable variation in the ASA classification allocation [1]. It is up to the anesthesiologists to subjectively rate the patients’ preoperative health. Though there are definitions for the class allocations in the ASA scale, the definitions do not detail the diseases and conditions for patients in each class. Despite that, the ASA scale is considered reliable. A study recent study performed in 2014 shows that the ASA scale has moderate inter-rater reliability in clinical practice [2]. The biggest discrepancy in scores is between ASA class 2 and 3.

Since ASA score is an important indicator for outcomes, it is important that scores for patients are consistent. There would be less variability if the method of evaluating ASA score was not so subjective. In this study, we attempt to solve the problem of predicting the ASA score of patients using a reproducible, data-driven automated system. Using data from the Vanderbilt Perioperative Data Warehouse, which houses data from the perioperative environment at Vanderbilt University Medical Center, we develop a model to predict the ASA score of a patient. We use supervised machine learning techniques to develop a system that mines the underlying factors that determine if a patient belongs in ASA class 1-2, or ASA class 3-5.

The machine learning techniques that we test in our study were logistic regression, random forest, and deep neural networks. We first chose features for the ASA prediction classifier. The features were age, body mass index (BMI), service category that the patient was in, if the patient previously had surgery, home medications, prior inpatient ICD9 codes and history of outpatient ICD9 codes. We incorporated temporality into the ICD9 features by sectioning codes into stretches of time for which they were placed. From these features, we tested different combinations of features and created a combined classifier. The final features we selected were age, BMI, service, medication class, inpatient ICD9 hierarchy, and outpatient ICD9 classes. We also compared the combined classifier to classifiers using a single feature (i.e. ASA prediction with only age). We used logistic regression and random forest to test these, measuring performance with 5-folds cross validation (Figure 1).

![Figure 1. Logistic regression and random forest results for single categories of features and combined categories](image)

We then used deep neural networks to make predictions from the features in the combined classifier. The best network that we developed used 3 layers and 800 units, and achieved an AUC of \(0.874\pm0.0024\). In conclusion, we have found that it is possible to predict the AUC of patients using data from the EMR and achieve a high AUC.

An Integration of Cooperative Learning into Undergraduate Medical Informatics Class with Service Learning Components

Jiangyuan Zhou, PhD1, Duo (Helen) Wei, PhD2

1 School of General Studies, Stockton University, Galloway, NJ 08205, USA; 2 Computer Science and Information Systems – BUSN, Stockton University, Galloway, NJ 08205, USA

Abstract
Service learning module in undergraduate Medical Informatics class provides educational and outreach activities and builds a mutually beneficial relation with healthcare community partner. However, student learning outcome result shows that students were lack of teamwork skills with their classmates when participating community service. In response to this problem, a cooperative learning method was introduced into the Medical Informatics class with service learning components. Students are encouraged to work together as a team to improve community participants’ awareness of the usage of Smartphone Apps to assist in managing their chronic diseases. The pre- and post- class surveys show positive results. Students welcome this method and confirmed the benefit of this cooperative learning approach in Medical Informatics education.

Introduction
Service learning module was introduced to an undergraduate Medical Informatics class in a four-year state university to develop community awareness, communication, and critical thinking skills in 2012. An assessment tool was developed with 20 items on Engagement, Learning, Communication, Collaboration and Critical Thinking to assess the students’ performance in this service learning course by collecting the observations from community partners, instructor, classmates and student themselves. The results show that the main barrier for this medical informatics class was the teamwork skills among classmates. So a cooperative learning method was introduced into the Medical Informatics with service learning component in 2015. The service learning project was designed to have a common goal for the entire class to increase community awareness of using Smartphone Apps to assist in managing chronic disease. Students are assigned to small groups with various tasks, such as organizing workshop, developing survey, creating posters, and collecting/analyzing data. They worked together as a team and wrote self-reflection papers. At the end of the semester, students are expected to present their tasks and their self-reflections. The study aims to evaluate the effects of this Medical Informatics course with the introduction of cooperative learning[1] method.

Methods
Student performance scores on teamwork skills of four classes from 2012 to 2015 (in total of 114 students) were compared. Variance analysis was used to determine the difference among four groups. Pre- and Post- course surveys on the integration of cooperative learning method into the Medical Informatics class were conducted to determine students’ perceptions about the integration of cooperative learning with medical informatics class with service learning components.

Results
The average scores of the one groups (2015, 35 students) after the integration are higher than the other three groups (2012, 2013, 2014, in total 79 students). Variance analysis showed there were difference among the four groups (p<0.05). Pre- and Post- survey shows that “integrating cooperative learning method in medical informatics class is helpful.” With students’ average rating of 9.4 out of 10.0.

Discussions
Medical informatics is interdisciplinary in nature. Therefore, it make sense to seek a way to let students work together to achieve a common goal. The integration of cooperative learning into Medical Informatics with service learning components seems to be a useful approach to foster teamwork spirits. A large sample with controlled trial is desirable to confirm the effects. Also, the integration of cooperative learning into a Medical Informatics without service learning components is also worth trying.

Extracting Laboratory Eligibility Criteria Data Elements from IRB Protocols Using Natural Language Processing

Vivienne J. Zhu, MD, MS, Elizabeth A. Marshall, MD, MS, Randall W. Alexander, Sherly Roy Yesudhas, Leslie A. Lenert, MD, MS
Biomedical Informatics Center at Medical University of South Carolina, Charleston, SC

Abstract: We developed and evaluated the performance of a natural language processing (NLP) approach for translating laboratory eligibility criteria within IRB protocols into a structured format. A total of 718 IRB approved clinical trial protocols were used to iteratively develop lexicon and NLP algorithms to extract data elements (lab test name, equation, value, and unit). By manual review of 180 testing documents, our NLP approach scored 94.5% for precision, 90.2% for recall, and 92.3% for F-measure.

Background: Laboratory eligibility criteria are important benchmarks for identifying potential patients to participate in clinical research. However, laboratory eligibility criteria are commonly documented as narratives within research protocols. Usually, manual review of these protocols is required to translate such free text criteria into computerized programs in order to query medical records to identify potential subjects. A potential approach to automate the process of screening for eligibility is to use natural language processing (NLP) techniques to extract relevant data elements from free text laboratory eligibility requirements for comparison to existing structured data. In this study, we evaluate the feasibility and performance of NLP in this context.

Method: The data resource for this study is research eligibility criteria records from the electronic Institutional Review Board (eIRB) system at the Medical University of South Carolina (MUSC). A total of 898 research criteria (inclusion and exclusion) records from 898 complete or approved MUSC IRB protocols for clinical trials between 2010 and 2015 were extracted and prepared for the NLP analysis. We used commercial NLP software (Linguamatics I2E version 4.3, Cambridge, United Kingdom) licensed by MUSC to index, parse, and query each research criterion. We developed a lexicon and a set of NLP queries to capture semantic and syntactic representations of laboratory requirements from free text IRB eligibility criteria for four data elements: 1) protocol number; 2) equation for both mathematic symbol (e.g. “<,” “>,” “=,” etc.) and text presentation (e.g. “greater than,” “less than or equal to,” “at least,” “exceeds,” etc.); 3) lab values accounting for both numeric values and text representations (e.g. “10,000,” “3X,” “two times,” etc.); and 4) lab result unit (e.g. “mg/dl”, “upper limit of normal range,” “ULN,” etc.). A random sample comprised of 75% of the studies’ research criteria (718 documents) was used as training data to iteratively develop the NLP lexicon and queries. The remaining 25% of records (180 documents) were manually analyzed as a gold standard to evaluate the NLP strategy’s performance. We report standard measures: precision (=true positive/(true positive + false positive)); recall (=true positive/(true positive + false negative)); F-measure (=2* (precision * recall)/(precision + recall)).

Results: The top three specified therapeutic areas for MUSC IRB approved clinical trials are cancer (278), cardiovascular (93), and mental health (58). The NLP algorithm processed 180 testing documents within 0.2 seconds. It identified 293 laboratory eligibility criteria from 93 testing documents, and 87 documents had no information about laboratory eligibility criteria. Manual review of all four data elements for each laboratory criterion confirmed 277 positives, and identified 30 criteria that the NLP algorithms did not capture. The overall performance was 94.5% for precision, 90.2% for recall, and 92.3% for F-measure. Table 1 displays the NLP performance of the most common laboratory eligibility criteria.

Conclusion: This study demonstrates that NLP can robustly and accurately extract relevant data elements of laboratory eligibility criteria from free text IRB protocols into a structured format for subsequent comparison to coded data in an electronic health record system for automated eligibility screening.
Evaluating Acceptability and Efficacy of Antidepressant Medications using Patients Comments in Social Media

Maryam Zolnoori1, MS, Timothy B. Patrick2, PhD, Mike Conway3, PhD, Anthony Faiola4, PhD, Jake Luo5, PhD,
1,2,5 University of Wisconsin-Milwaukee, Milwaukee, WI
3University of Utah, Salt Lake City, UT
4Indiana University, Indianapolis, IN

Problem Statement
Patients with depression use the online messaging boards to post self-reports of side effects, effectiveness, and in general their satisfactions for antidepressants. The self-reports of patients experiences provide information that might not be captured in clinical trials. Because of the potential importance of such self-reports, the International Society of Drug Bulletins asserted in 2005 that “patient reporting systems should periodically sample the scattered drug experiences patients reported on the internet”. (Leaman et al., 2010).

Purpose of Study
The purpose of this preliminary study is to evaluate the efficacy and acceptability of the new-generation antidepressants for treatment of depression using patient self-reports on online messaging boards. The study is significant because depression is a periodic, incapacitating condition that is one of the major reasons for disability in developed countries. Approximately 6% of adults annually are affected by depression that is a major cause of suicide and about 9 percent of Americans show symptoms of desperate, regret, and sadness that result in depression (CDC 2014). A meta-analysis was conducted by Cipriani et al. (2009) to rate 11 new-generation antidepressants based on efficacy (treatment the signs and symptoms of depression) and acceptability (the likelihood of continuing an antidepressant medication by a patient). According to the study, the 11 antidepressants ranked from the highest efficacy to the lowest are Remeron, Lexapro, Effexor, Zoloft, Celexa, Wellbutrin, Paxil, Savella, Prozac, Cymbalta, and Luvox. Based on the measure of acceptability, the 11 antidepressants that ranked from the highest to lowest acceptability are Zoloft, Lexapro, Wellbutrin, Celexa, Prozac, Savella, Remeron, Effexor, Paxil, Cymbalta, and Luvox. Since clinical trials, by their nature and purpose, are focused on a limited number of participants selected by inclusion/exclusion criteria (such as demographics, medical condition, and diagnosis), this study may not provide adequate indications of the efficacy and acceptability of antidepressants.

Methods
The methodology of this research consists of two main phases. In the first phase, we used technique of content analysis to measure efficacy and acceptability of the antidepressant medications, and identify side-effects of the 11 new-generation antidepressants. In the second phase, we are going to apply techniques of association rules and co-occurrence to automate the process of extracting the side-effects and measuring the acceptability and efficacy of the antidepressant medications. The output of the first phase of this research is demonstrated in the results section.

Results
The preliminary result of the study showed that, in contrast with the results of the research conducted by Cipriani et al. (2009), the 11 antidepressants ranked, according to patient comments, from the highest efficacy to the lowest are Lexapro, Celexa, Paxil, Luvox, Effexor, Prozac, Zoloft, Wellbutrin, Cymbalta, Remeron, and Savella. In addition, based on the acceptability measure, the 11 antidepressants ranked from the highest to the lowest are Celexa, Lexapro, Prozac, Luvox, Wellbutrin, Zoloft, Paxil, Effexor, Cymbalta, Savella, Remeron. The result indicates, for example, that though Remeron has the highest efficacy in the meta analysis of clinical trials, it is ranked as 10th least efficacious according to the patients comments. In addition, while Zoloft has the highest acceptability according to the meta analysis, the patient comments showed that Celexa has the highest acceptability, not Zoloft.

Conclusion
Analyzing patient comments about antidepressant medications shows that there is important difference between commonly prescribed antidepressants for both measures of efficacy and acceptability. Based on the patients comments Lexapro and Celexa might be the best choice when starting treatment for depression in adults because they have the highest rating for efficacy and acceptability.

Personalized Heart Disease Risk Manager: A Tool for Patients and Clinicians to Manage Cardiovascular Risk

Raja A. Cholan, Jennifer A. Pacheco, Gene Ren, Laura Hickerson, MS, MLS
Dept. of Medical Informatics & Clinical Epidemiology, Oregon Health & Science University, Portland, OR

Acknowledgements: Aditya Rane, Experience Designer

Summary
Heart disease is the leading cause of death in the United States with over 600,000 people dying every year. To help with prevention, the American Heart Association (AHA) and American College of Cardiology (ACC) have developed tools which include risk algorithms and guidelines for healthcare providers to assess atherosclerotic cardiovascular disease (ASCVD) risk. Several of these tools provide treatment recommendations for aspirin, statins, and blood pressure medications, and calculate a patient’s 10 year risk of having heart disease or stroke. In this proposal, we describe the ‘Personalized Heart Disease Risk Manager’ (PHDRM) which aims to deliver personalized healthcare for managing ASCVD risk by (1) incorporating a patient’s environmental, lifestyle, and family history risk factors, (2) highlighting relevant genetic tests for family history associated with ASCVD risk from ClinGen and the Genetic Testing Registry, (3) adding relevant pharmacogenomic tests for aspirin, statins, blood pressure medications, and smoking cessation medications from the Clinical Pharmacogenetics Implementation Consortium (CPIC); and, (4) enhancing the patient-centeredness of education materials in existing ASCVD risk calculators. The PHDRM would act as a decision aid and help clinicians engage patients in targeted conversations regarding treatment options, genetics, behaviors, and environmental factors. It would also help clinicians stratify which patients should get genetic testing for ASCVD risk and/or pharmacogenomics. The PHDRM will help patients understand their cardiovascular risk factors and enhance their ability to make informed decisions. This solution can be incorporated into the point-of-care through bi-directional SMART on FHIR integration via electronic health records and patient portals. An interactive prototype of the PHDRM is available at https://invis.io/957TONK6Q

Background

Problem Definition: Importantly, several ASCVD risk factors are modifiable through lifestyle change or drug therapy, including smoking, high blood pressure, dyslipidemia, diet, exercise, and alcohol consumption. Therefore, patient engagement to achieve successful preventative measures is essential. For ASCVD risk factors not modifiable, such as race/ethnicity, family history and genetics, awareness of high-risk genetic factors is still important for prevention. Several existing ASCVD risk models and associated tools enable identification of select patient ASCVD risk factors, however few consider family history as part of the risk assessment. Additionally, ASCVD risk tools commonly only address risk identification but lack functionality to engage patients in shared-decision making, promote healthy lifestyle over the long-term, or provide resources to that end. Many ASCVD-related guidelines, including those from the American Heart Association (AHA) and American College of Cardiology (ACC), share in common a healthy lifestyle as a foundation for ASCVD prevention. However, functionality to address this healthy lifestyle foundation is lacking in many ASCVD risk tools. In their recent review of the scientific literature relevant to the 2013 ACC/AHA guidelines, Cainzos-Achirica and colleagues propose that healthy lifestyle, and the tools to achieve it, should be “thoroughly addressed in a clinician-patient discussion.” An interactive ASCVD risk assessment tool will not only help identify patient ASCVD risk factors, but also facilitate the clinician-patient discussion about healthy lifestyle, encourage shared-decision making, enable patient-goal setting and progress monitoring, and provide patient resources to help adopt healthy habits. This aligns with the tenants of the National Institutes of Health’s ‘Precision Medicine Initiative’ which places an emphasis on tailoring prevention and treatment efforts that take individual variability into account.
The AMIA Challenge: Our team therefore focused on designing a web-based cardiovascular risk calculator and patient decision aid tool to facilitate conversations between patients and clinicians. Using information gathered from 14 primary care physicians (PCPs) and cardiologists at Oregon Health & Science University (OHSU), Northwestern University, and Mayo Clinic, and 10 potential patients, as well as consultation from experts in shared decision making, data visualization, genetic counseling, and experience design, we propose the ‘Personalized Heart Disease Risk Manager’ (PHDRM). This tool focuses on engaging patients and clinicians in targeted conversations thereby informing the decision-making of both clinicians and patients through enhanced understanding of genetic profiles, treatment, environment, and lifestyles related to improved cardiovascular risk. The PHDRM will have a clinician-only login where clinicians can see clinical, evidence-based information related to genetic information, with the aim of improving clinical interpretability.

Solution Design and Development

Design Process: The Agency for Healthcare Research and Quality (AHRQ) is funding the EvidenceNOW grant initiative that is focused on helping thousands of primary care practices across seven regional cooperatives improve patients’ cardiovascular health, with the aspirational goal to meet national targets on four cardiovascular clinical quality measures. One of our team members is a Health IT practice facilitator working with practices in Oregon on data extraction and quality improvement interventions for these cardiovascular outcomes. The inspiration for the designing the PHDRM came through a qualitative needs assessment (phase 1) through his interactions with clinicians. We identified the following common themes during our phase 1 needs assessment: (1) clinicians and patients do not always agree with blanket guidelines; there needs to be room for clinical judgement and patients’ values and preferences (e.g., patients whose blood pressure readings are high during office visits, but within range in home readings); (2) some clinicians prefer to focus on lifestyle modifications first, such as dieting and exercise, and if there is still a need for improvement after these interventions, then consider treatment options; (3) current risk tools embedded within EHRs do not record ASCVD risk percent as structured data, limiting the ability to write queries and generate reports for stratification; and (4) accessing patient decision aids embedded in EHRs takes a long time, but the subsequent conversations with “defiant” patients is useful.

Once our initial framework was developed, we conducted a more formal needs assessment (phase 2) with additional provider types, and researchers at multiple institutions, and also with potential patients, in which we asked for feedback on our initial concepts and lo-fidelity wireframes (see appendix A for the questions we asked). We met with representatives of the Knight Cardiovascular Institute, Department of Medical Informatics and Clinical Epidemiology, the Oregon Rural Practice-based Research Network at OHSU; representatives from Cardiology, Internal Medicine, Genetic Counseling at Northwestern University; and a cardiologist from Mayo Clinic. From these providers, we learned that while the interviewed providers used the existing ACC/AHA estimator, some were hesitant to use genetic testing, yet they did think that the existing tools could be improved in order to help patients understand their current calculated risk, optimal risk, and be more motivated to make lifestyle changes, to comply with treatment plans, and document their goals. These clinicians would like to see genetic testing used when there is not enough other information to make an informed decision, or when patients are at high risk for well-established genetic risk factors in the Genetic Testing Registry like familial hypercholesterolemia. They also wanted a tool that would allow them to use the limited time they have during appointments to focus on shared decision making for treatment and lifestyle modification plans.

The findings from each of the patient interviews reveal differences in perception of modifiable and unmodifiable ASCVD risk factors. The modifiable risk factors include sociodemographic, lifestyle, and behaviors. For example, two patients were aware that the lack of exercise and consumption of unhealthy foods are harmful to their health but did not have a plan to make changes. Most patients were interested in genetic testing, with most
of those wanting all genetic test results regardless of whether treatment is available or genetic risk is currently fully understood, although at least 1 patient was more interested in genetic testing for another disease area (dementia), not ASCVD. Most patients wanted to know more about what lifestyle modifications they could make to lower their risk and most felt they could use more education and support in order to make those changes.

Following both phases of the needs assessments, we created wireframes using software called Sketch, and created a clickable prototype in a program called Invision. Our prototype simulates the PHDRM as it might appear during a clinician-patient interaction for a fictional persona. Text about patient education was curated by reviewing several existing materials from the Office of the Patient Care Services National Center for Health Promotion and Disease Prevention, Million Hearts, National Institutes of Health, National Heart, Lung, and Blood Institute, Healthwise, and Mayo Clinic. ‘Calculated’ and ‘Optimal’ 10-year ASCVD risk calculations presented in our prototype were generated using the ACC/AHA algorithm for the purposes of our demonstration. We relied on a paper written by Safarova and Kullo which outlines how to screen and treat patients with familial hypercholesterolemia; our patient persona that we created has a family history of high cholesterol, and therefore likely has familial hypercholesterolemia.5

Solution Description: Our proposed solution, as aforementioned, is a web-based heart disease risk calculator and patient decision aid tool named, ‘Personalized Heart Disease Risk Manager’ (PHDRM). The PHDRM tool has four main components: (1) a risk calculator using the 2013 ACC/AHA guideline for the assessment of cardiovascular risk which gives users the ability to set targets and visualize calculated risk compared to optimal risk, (2) patient education materials about family history and genetic screening, treatment, lifestyle, environment for promoting heart health, (3) documentation of patient goals on various pages of the tool, and (4) information about pharmacogenomics when patients and clinicians may want to consider testing for certain genes associated with medications and familial conditions.6

We envision this solution being used during clinical care as a shared decision making tool for primary prevention of ASCVD, primarily for patients aged 40-70, or those otherwise deemed to have a potential higher risk of ASCVD (e.g., patients with diabetes and elevated LDL), as follows see Appendix B.1. for flowchart. First, a week before a patient has a regular check-up appointment with their PCP or cardiologist, the patient will receive an appointment reminder from their EHR patient portal, such as Epic’s MyChart ©, and in that message, there will be instructions to complete any questionnaires before the appointment, with a link to the PHDRM tool as one of those questionnaires (see Appendix B.2. for an example of what this looks like in Epic’s MyChart©). Then, when the patient uses the PHDRM tool, demographic and clinical data will be filled in for the patient from the EHR (using FHIR), the patient will simply fill out their family history and lifestyle behaviors, and click ‘Calculate’ to see their ASCVD risk score. The patient can then review their results, read the educational materials, draft goals to improve their ASCVD risk and write down any questions they may have for their doctor in the PHDRM tool. On the day of their medical visit, the clinician can preview the results and questions in the EHR via the ‘clinician login’ when preparing for the appointment. Additionally, some information, such as updates to family history for example, could be updated in the patient’s record in the EHR via integration through FHIR. During the patient encounter, the clinician and patient can focus on discussing the results and making shared decisions to reduce the patient’s ASCVD risk. If further testing or treatment is ordered, the PHDRM tool will be updated with those test results and treatments as they are entered into the EHR. The patient or provider can then see the updated risk score based on the new treatments and any lifestyle changes that are made. At the patient’s next encounter, the patient and provider can repeat the process again, this time reviewing if goals were met, and if not, discuss any barriers to those goals, and make new goals as needed. In addition, as the CPIC and ClinGen curate new guidelines for pharmacogenomics and other genetic testing for medications and ASCVD risk, we will update our PHDRM tool to incorporate these, with feedback from physicians and potential patients.
Alternative Solutions and Solutions Comparison

Based on our interviews, clinicians who do use ASCVD risk tools at the point of care tend to rely on the ACC/AHA Risk Estimator, or they use ASCVD risk tools embedded within their EHRs that use the ACC/AHA algorithm (e.g., the Kaiser Permanente National Guideline Cardiovascular Risk and Dyslipidemia Management Clinician Guide 2015). The ACC/AHA algorithms require age, gender, race, total cholesterol, HDL, systolic blood pressure, diastolic blood pressure, treatment for blood pressure, diagnosis of diabetes, and smoking status in order to calculate risk. Table 1 summarizes the alternative solutions along with the strengths and weaknesses for each.

Implementation and Dissemination

We have spent over four months developing our current prototype with the input and feedback from both provider and patient stakeholders. We will continue to iteratively improve our tool based on further needs assessments and feedback, and we will add additional features such as improved data visualization regarding risk, and links to other resources. Future builds would include a working standalone version first, then a version that integrates with EHRs via FHIR (both reading data into the tool and writing data back to the EHR data such as risk score and family history), and a version that reads from personal patient mobile health devices via SMART on FHIR (e.g., smartphones, smart watches, home blood pressure monitors).

To disseminate our tool to others we will work with stakeholder groups like eMERGE (electronic Medical Records and Genomics) and Precision Medicine Initiative enrollment centers, organizations such as the ACC, AHA, and AHRQ to promote and get feedback on our tool. We will also work with EHR vendors such as Epic and Cerner to integrate our tool into EHRs.

Evaluation

The proposed PHDRM tool will be evaluated through usability testing, and comparative effectiveness evaluation of similar ASCVD risk tools. Usability testing has been recommended as an important part of the evaluation of health risk communications, and is a recognized method to achieve user-centered improvements in health information, and research-based improvement in web information resources. Usability testing will follow recognized methodologies, allow us to observe actual tool users, and evaluate if the PHDRM tool meets user
needs. Results will enable identification of potential usability problems, and inform redesign and / or improvement of the PHDRM tool.

Our comparative effectiveness analysis will compare the effectiveness of the PHDRM tool against other tools, such as the ACC/AHA risk tools, Mayo Clinic Decision Aid, and potentially other decision aids from Healthwise. The outcome of interest for this comparative effectiveness analysis would be scores from the Decision Conflict Scale, to assess whether the PHDRM helps patients make decisions about their heart health.  

**Conclusion**
Cardiovascular disease is the leading cause of death in the United States and there is growing demand for preventive efforts. There is also demand for tools that help clinicians with parsing through and handling the complexity of clinical and biomedical “Big Data”. We believe that a tool like the Personalized Heart Disease Risk Manager has the potential to deliver personalized cardiovascular healthcare, to help engage patients with clinicians and the data to make informed decisions from knowledge gained from genetic, environmental, and lifestyle information.

CareMax: A Patient-Centric Cancer Treatment Decision and Calendar Tool

Jared Erwin¹, MS, William Kearns¹, Wayne Liang¹, MD, Carolyn A. Paisie¹, PhD
¹Biomedical Informatics and Medical Education, University of Washington, Seattle, WA

Abstract

For pediatric patients with advanced cancers, deciding among treatment options can be a difficult task. Patients and caregivers rely on the advice of their providers who utilize both clinical data and the patient’s wishes and goals to generate personalized treatment recommendations. We present CareMax, an application which supports communication, shared decision-making, and personalized medicine by visualizing treatment options as calendars, allowing direct comparison among treatment options, and matching treatment options to patients’ values and goals.

Prototype: http://kearnsw.com/CareMax/

Introduction

Precision oncology frequently refers to simply matching patients to treatment options based on their cancer type and genetic profile. However, in actual clinical practice, personalized treatment decision-making is a complex, multifaceted endeavor which includes not only the patient’s medical status and tumor genetics, but also their lifestyle, social support, values, goals, and wishes. In pediatric oncology, decision-making takes on additional layers of complexity due to the special role that caregivers (e.g. parents) play in decision-making. The caregiver role also varies across diverse family structures and changes with the age and developmental stage of the patient. Choosing among cancer treatment options involves the complex task of understanding and comparing numerous features (e.g. specific medications, effectiveness, specific side effects, logistical issues), each with a different level of prioritization for different patients. Therefore, pediatric oncology is a particularly well-suited domain to demonstrate the complexities involved in implementing precision medicine.

At Seattle Children’s Hospital (SCH), patients, caregivers, and pediatric oncology medical providers frequently engage in shared decision-making in order to select a cancer treatment regimen among multiple options. These decision-making episodes may occur during a routine clinical encounter, or they may occur during a “care conference”, a meeting dedicated to discussing the implications of treatment options in order to make a decision. Decision-making is often difficult due to complex informational requirements as well as the emotional and psychosocial context of the cancer diagnosis.

Patients, caregivers, and providers have different information needs. Existing informational resources, such as treatment “roadmaps” (a paper form which guides providers in administering the regimen) and chemotherapy side effect handouts, are not in the optimal form to effectively inform decision-making. Existing resources regarding treatment regimens are generally written for medical providers, and they do not provide customized information for specific patients. Any personalized information for specific patients, such as a treatment calendar or a care conference summary document, must be generated manually by providers. Other information, such as the patient and caregivers’ goals and values, is difficult to obtain. Finally, the process of matching patient characteristics, including their clinical findings, genomic alterations, or personal values and goals, to treatment options is a time-intensive, manual process.

Our design provides an innovative approach to precision medicine in oncology by focusing on effective presentation and comparison of complex information across cancer treatment options, supporting patient/caregiver/provider engagement and communication in the shared work of treatment decision-making, and matching patients to personalized treatment options based not only on their cancer subtype, but also their values, goals, and wishes. We will pursue a multi-phase implementation approach, initially focusing on the highest priority functionality based on user needs, then progressively adding functionality with future releases. In phase one, we will implement a treatment calendar template creation tool, a treatment calendar template management system, a patient-specific treatment calendar tool, and a treatment timeline comparison tool. Future releases will implement a patient reported outcomes (PRO)-based regimen rating system, a patient goals and values capture tool, and a patient-to-regimen matching tool.
Our Solution

We initially identified shared decision making for pediatric cancer treatment options as our general domain area of interest. We then utilized semi-structured interviews with medical providers in pediatric oncology to identify user needs, set project goals, and finalize key functionality requirements.

If a patient has advanced cancer, defined as refractory disease (i.e. does not respond to initial treatment) or relapse (i.e. initially responded but then returned), it is often difficult for clinicians to determine which treatment regimens should be recommended. Options may include aggressive experimental therapy with unclear benefit, less aggressive “palliative” chemotherapy without expectation of cure, or palliative care with no chemotherapy. However, there are often no standardized treatment options, and the benefits of experimental therapies are often unknown. Expected prognosis is often low regardless of which regimen is chosen. In some cases, the side effects of cancer therapy are more severe than symptoms the patient may experience if pursuing no treatment.

From interviews with various providers, a common theme was the potential usefulness of a tool that could help patients with advanced cancers, caregivers, and providers make shared treatment decisions. Providers would find it helpful to have a tool which obtains and communicates to the provider the patient and caregivers’ values, goals, and wishes prior to the meeting. They also felt that a tool which organizes treatment options and creates customized treatment calendars would enhance communication. Finally, providers emphasized the importance of having a tool that would not add to their workload, interfere with patient treatment and care, or interfere with the sensitive nature of treatment discussions in advanced cancers.

Prior to meeting with patients and caregivers to make treatment decisions, providers do not know what decision a particular patient or caregivers may make. Values, goals, and wishes, crucial for making treatment decisions, are elicited in real time. Thus, it is difficult determine what written information to prepare in advance. The majority of providers interviewed (7 of 8) did not use any electronic tools to match patients to treatment options or to assist with information retrieval, processing, or decision-making. 1 provider reported searching ClinicalTrials.gov, a database on nationally-funded clinical trials, but they commented that the website was difficult to use. When a treatment option is selected, some providers may choose to generate a custom treatment calendar using standard desktop spreadsheet software, which is then provided to families at a later meeting. However, these calendars are created after the treatment decision and therefore do not play a role in informing decision-making. Finally, some providers may create a written care conference summary which documents what was discussed at the care conference, then provide this to the patient at a later date. Most patients do not receive a calendar or a care conference summary.

Due to privacy considerations, we were not able to interview patients for our first design iteration. Therefore, we relied on literature to provide insight on patients’ information needs. A survey of parents of children with cancer listed nine different information areas in order of priority: (a) treatments and tests, (b) cure, (c) caring for my child, (d) emotional impact, (e) side effects, (f) physical impact, (g) disease, (h) coping with painful procedures, and (i) impact on the family. The calendar functionality aims to address information around the treatment and tests (as far as frequency and duration) and help with caring for the child by giving a tool that makes adherence to the schedule easier.

We pursued an iterative design process which resulted in an interactive prototype. We then conducted focus groups with the same provider participants to demonstrate our prototype and obtain feedback. Overall, participants felt that the prototype has the potential to enhance shared decision regarding cancer treatment options by visualizing complex information and improving communication. Participants emphasized that the tool should focus on patients with advanced cancers due to high decisional complexity in those settings. Participants suggested interface modifications such as colors, layout, textual descriptors, legends, and icons. Lastly, participants suggested and prioritized additional functionality being considered for our tool. For example, participants indicated that having an interface to search treatment options at ClinicalTrials.gov and Cancer.gov was low priority. However, matching patient values to treatment characteristics would be desirable. We have incorporated their feedback into our current prototype and in our plans for future functionality.
We sought to capture patient and caregiver values, goals, and wishes in a quantitative way, which can then be used to algorithmically matched patients to treatment options. We interviewed content area experts (i.e. pediatric oncologists and pediatric palliative care specialists) and conducted a literature search in order to identify survey instruments which could potentially serve as the basis of this algorithm. We were unable to find an instrument which applied directly to our application’s goal. However, we did identify several instruments which could inform the design of our algorithm. Two instruments that are used frequently to support decision making for pediatric cancer patients in palliative and hospice settings are the Decision-Making Tool (DMT)\(^2\) and 5 Wishes\(^1\). Both tools use a qualitative, free text format to capture patient values and preferences, which does not lend itself easily to quantification for matching purposes. 5 Wishes also was designed to be an advanced directive for end of life care, which is a different situation than deciding between cancer treatments. However, the categories of variables captured in these 2 instruments were informative in our design. In the PediQUEST trial, patients with advanced cancer and their parents were administered validated, quantitative patient reported outcome (PRO) and health related quality of life (HRQoL) instruments (e.g. PQ-MSAS\(^4\) and PedsQL\(^5\)) using an electronic system\(^6,7\). Patients and parents were then provided an electronic dashboard which quantified PRO and HRQoL summative measures into 4 domains: Physical, Emotional, Social, and School. The PediQUEST study found that it was feasible to have patients (depending on age) or their parents fill out these instruments on their own in an electronic system; patients, parents, and providers reported being satisfied with receiving summative results via the electronic dashboard. We will pursue the same strategy in the design of the treatment matching functionality, and we will base our algorithm on a modified version of P-Q-MSAS and PedsQL, while incorporating elements of the DMT and 5 Wishes.

### Implementation and Evaluation Plan

There will be four main feature areas and entry points to our initial version of the system. The first area is creating a treatment calendar template which is based on paper-based treatment roadmaps currently in use at SCH. Currently, roadmaps are created through joint effort between physicians and pharmacists for best available therapy (non-research) regimens and clinical trial protocols. The roadmap includes which drugs are to be given at what doses, which tests and procedures to perform, and on which day. This paper based information will be entered into our system by a user we represent by the persona Anne (see Supplementary Material for more information on Anne). Anne directly opens the system and is authenticated using Seattle Children’s credentials over OAuth 2.0. She has access to the currently created templates which she can update, or she can create new templates. Right now Anne is representative of Nurse Practitioners at SCH, as they are the team members currently creating calendars. However, as no patient data access is required, this role could be fulfilled by someone who is not a provider which would lessen the work for providers.

The second area is creating one or more specific treatment calendars for a given patient. The persona performing this task is Ruth. She represents Nurse Practitioners, residents, and even fellows or attendings at SCH who create calendars for their patients. The entry point into the system is different for Ruth as she is doing this task in the context of a given patient. A patient’s record will be accessed in the Cerner electronic medical record (EMR) system as normal and then a new link in that system will launch our application. Patient context and user authentication will be passed to our application with OAuth 2.0 tokens. Our application will launch to calendar view with the patient banner at the top: name, birthdate, and medical record number (MRN). Any existing patient treatment calendars will be available for display and edit. A new treatment calendar for a patient can be created based on an existing template (previously created by Anne). Templates can be found by searching key features (name, therapy, clinical trial, and others) or browsed in a tree structure which is similar to the current organization of therapy roadmaps. Once a start date for the therapy is indicated, a calendar for the patient will be created with default dates based on the template. Ruth can then customize this calendar as necessary.

The third area of functionality is very similar to the second in that Ruth will open treatment calendars for a particular patient and access them via the link on Cerner as before. However, the difference is in the display and purpose of access. This area of use is to display the calendars in a meeting with patients and their families for the purpose of understanding the treatment plan and selecting between multiple treatment options. Multiple views of the treatment schedule will be available. A side by side view of typical calendar displays will allow comparison as well as a horizontal timeline view which gives a high level summary of the treatment. Finally some summary statistics, such as number of required days as an inpatient or total clinic visits, can be viewed.
The final area of functionality and access is the patient access. This will be done via the patient portal where a new link will be available on the portal to launch our application. Again user context and authorization will be passed to the application via tokens. Our patient personas are Jimmy, the cancer patient, and Susan, his mother. In this mode of access Jimmy and Susan can view the calendar or timeline views of any treatment calendars created for them by their providers. They can add individual events to the timeline, such as birthdays or vacations, to help them consider the impact of treatment on those important events. They can also comment on the treatment schedule which will send a notification to their provider; this could be a request to reschedule or a question on what will happen for a particular visit. Here Jimmy or Susan could also request to download .ical files for treatment appointments to integrate the events into their own calendar application. The purpose of the calendars currently created for patients at SCH is to help them with adherence. While we are working to help with decision support we do not want to negatively impact this important purpose of the calendar. Making the calendar digital and able to integrate with current calendar apps which Jimmy or Susan may currently use will hopefully make it even easier to follow the treatment plan. A key point to this feature area is that the application works well on mobile devices.

The next iteration of design and implementation will focus on to two more areas of functionality: patient’s (and their family’s) values and goals and genetic variant information. Users will be able to assign priorities to various values and goals along with open ended prompts and free entry which will allow capturing more in depth information about a patient’s wishes. This information which will be used to facilitate communication between all stakeholders and enable users to map values and goals to treatment plans. The mapping will then facilitate communication of how the treatment plan is personalized to the patient and help explain the recommended treatment plan. Reprioritizing, removing, or adding values and goals shall be reflected in the mapping immediately.

Currently, mapping genomic data to specific treatment options has limited use in pediatric oncology. This is a consequence of a limited number of targeted therapies currently available for use in the pediatric realm. While targeted therapies may be utilized in the treatment of adult oncology patients that have specific genetic variants in certain cancers, these drugs are often not yet approved for use in pediatric patients. However, if the patient has a relevant genetic variant which affects treatment decisions, information regarding targeted therapies specific for that individual patient’s genetic variant will be displayed. The type of variant and which drug or regimen it maps to will be shown and explained.

As mentioned we plan to integrate with the SCH EMR system which is Cerner. Some basic patient information will need to be retrieved from Cerner and if possible we would store the treatment calendar in Cerner so that a separate database which contains patient medical data would not be required. A key challenge for the project will be successful integration with Cerner. The planned approach is to use Fast Healthcare Interoperability Resources (FHIR), which is a medical data and web services standard, and the OAuth 2.0 (which conforms to the SMART on FHIR recommendations) authentication standard. Integration with Cerner and the authorization system also allows us to leverage the patient portal when authenticating patients to the application. While Cerner as a product does support FHIR16 more details on how much support SCH has implemented for FHIR and whether or not they allow data to be pushed back into Cerner still needs to be investigated. Building the application using the FHIR standard also increases the ability of the application to be deployed at another location.

Other key challenges in designing our tool include: 1) not interrupting workflow for key stakeholders (e.g. oncology providers, patients, caregivers); and 2) demonstrating sensitivity to each patient’s unique situation, preferences, and needs. Our tool will be made specifically to reduce the work required for oncology providers to prepare for treatment decision-making discussions. From a patient-centered perspective, our approach must remain sensitive to the concerns and environment of patients and their families. Due to privacy considerations, we have not been able to interview patients and caregivers. We have relied primarily on clinicians to serve as imperfect surrogates for the needs of their patients and caregivers.

It has been shown that determining the usability of applications implemented in a clinical setting is crucial for successful implementation11. Previous research has also shown that using multiple methods is more powerful than using a single method alone11. Thus we will use multiple methods for the evaluation of our tool; see Supplementary Material for a detailed description of our evaluation methods for each iteration of our design. We plan to utilize usability testing as we progress through each subsequent phase of development, consulting with providers,
caregivers, and patients as current functionalities are modified and new functionalities are added to ensure that our tool meets the needs of the end-users. In addition to usability studies, we will utilize online surveys to evaluate our proposed design. Additional details of the methods used for conducting surveys is provided in Supplementary Material. Surveys will be distributed at varying time intervals following implementation of our proposed design (e.g. 1 month, 3 months, 6 months, 1 year). We anticipate that data from these surveys will provide insight into how well our proposed design fits the needs of providers as well as elucidating areas for improvement.

We will use a number of different criteria in the evaluation of our proposed design. These criteria include: 1) ease of use; 2) amount of time required to create or customize treatment calendar; 3) missing function(s); 4) point(s) of confusion for user(s); 5) successful implementation. See Supplementary Material for a detailed description of how we will evaluate the effectiveness of our proposed design. Finally, successful implementation will be indicated by responses to the online surveys that users are still using our proposed design several months/years following initial implementation.

Alternative Solutions and/or Features Not Included
Originally we considered a solution focused on assisting providers with conveying genetic information to patients. We envisioned a tool to match patients and treatments based on genetics. However, in many pediatric oncology cases genetics is not the primary deciding factor when deciding on the best treatment for a particular patient. Rather, patient values play a huge role in the choice of treatment, especially in the case of relapse. After our interviews, we decided to go with a patient-facing application that would facilitate patient-provider communication helping patients and providers navigate this challenging time.

One theme commonly expressed by providers during our interview was that patients and their families would ask what treatment a physician would choose if they had to make the choice for their own child. This idea brought up the thought of a feature that showed statistics of prior patients, the choices they had made, and their outcomes. The feedback we received was that it may be coercive thereby negating the goal of developing personalized oncology.

Another area of functionality that would be helpful for providers and patients would be to help them discover other relevant treatments options, usually available clinical trials. The idea we proposed would be to automatically search ClinicalTrials.gov and display a list of trials for which the patient is eligible. Providers thought that it would be an excellent feature if it could be relied on to find an accurate list of trials for a particular patient. We decided not to pursue this functionality because of the technical challenge and the fact that it seemed a more provider centric feature rather than a patient focused feature.

Conclusion
Precision medicine is more than simply matching a patient’s medical data with a diagnosis and treatment. It encompasses that individual’s environment, family, lifestyle, goals, and values. While many healthcare providers are skilled at creating personalized treatment programs which incorporate all of these different elements, it can be very challenging and time-consuming to elicit the necessary information from a patient and then effectively communicate the treatment options and how they fit that individual. In interviewing pediatric oncology providers, we learned about the individualized treatment calendars that were being created and the value that patients and providers gained from them. A dynamic treatment calendar integrated with the electronic health record could be an effective communication tool, engaging patients more in the shared decision-making process. A tool which elicits a patient’s goals and priorities and matches them to treatment options can facilitate conversations with providers about what a patient wants. An electronic calendar makes it easier to share, update and integrate with a patient’s personal calendar for adherence once treatment begins. Our application integrates with the EHR and provides templates for calendar creation in order to fit into the provider’s workflow and reduce redundant work. In conclusion, CareMax enables precision medicine in pediatric oncology by personalizing cancer treatment recommendations toward the values, goals, and wishes of patients and their caregivers.

Abstract
Chronic diseases are the leading cause of disability and death in developed nations. Support for precision medicine in these complex disorders is needed. We propose a self-experimentation approach (SEA) as a mobile game to support precision medicine in chronic disease states. The SEA will be embedded within a learning health system to enable patient empowerment, healthcare provision, and medical knowledge generation.

Introduction
Specific Challenge: Chronic diseases are the leading cause of disability and death in the United States, where half of adults suffer from at least 1 chronic condition (1,2). These conditions are often complex with multiple factors (e.g., exposures, lifestyle, genetics) contributing to treatment response, morbidity risk, and disease prognosis. Given the complexities of chronic disease and resulting therapies, determining an effective, individualized treatment can take time to attain (if attainable). Herein lies an opportunity for precision medicine to advance chronic disease management and improve healthcare for millions of patients nationwide.

Current practice, for chronic disease management, is based on short patient-clinician interactions, where patient symptoms are discussed and clinician expertise is leveraged to direct a patient toward effective treatment and eventually, improved health. Clinicians are given the daunting task of aggregating and processing large amounts of information (e.g., blood work, diagnostic tests, prior conditions, family history, or knowledge about exposures) in a brief patient encounter to develop a treatment plan. This plan may include pharmacotherapy and lifestyle modifications where a patient is responsible to track his or her symptoms in response to treatment. At the next encounter, the treatment plan may be altered based on response to therapy. Personalization of treatment for chronic conditions is achieved slowly (often over months to years) and patients frequently fall between guidelines. Moreover, the time between patient-clinician interactions determines the success or failure of a prescribed therapy leaving much to be desired in current practice.

Several barriers limit precision medicine techniques from providing effective and efficient chronic disease management. First, many patients have difficulty tracking symptoms and communicating changes to clinicians. Some patients may mitigate symptoms while others may exaggerate the situation. Second, the current system depends on patient trust and clinician empathy to be conveyed during brief encounters. Third, treatment plans depend heavily on the clinician knowledge of the disorder and understanding of the patient context and preferences. Finally, accurate and through patient monitoring between encounters, which may be invaluable for treatment modifications, is lost or unreliable for decision-making in a brief patient-clinician encounter. In sum, improved support for personalizing medicine for complex and chronic disorders is needed.

We propose a self-experimentation approach (SEA) nested in a learning health system to support precision medicine for chronic disease states. This system takes input from the patient and clinician alongside other sources to fine-tune treatment through self-experimentation. The SEA will be incorporated within a learning health system to enable patient empowerment, healthcare provision, and medical knowledge generation.

Proposed Solution
Rational: SEA is based on the single-study design approach, where the study subject acts as both the intervention and control (3–5). This approach works well for personalized medicine as experimentation results are optimized to the individual rather than averaged across the population (4,6,7). Karkar et al developed a framework that applied self-experimentation for personalized healthcare with a mobile application for Irritable Bowel Syndrome (3). The results of this study demonstrate the feasibility and potential of this approach in applying personalized medicine to complex disorders. However, self-experimentation has not been fully leveraged to serve personalized medicine in either the scale of people or the number of medical problems (3).
The growing rate of mobile device ownership (68% of US adults) (8) and availability of medical apps for chronic diseases (9,10) make SEA feasible. Specifically, a gaming approach within the proposed framework may greatly support patients’ acceptance and adherence as gaming in health shows promising results (11,12). To ensure sustainability and dissemination of results, SEA should be nested with a learning health system, especially with recent advances in health information management and exchange (13). This integrated and gaming approach has more benefits than isolated apps as most only report measures rather than understand the patient’s unique characteristics and impact on her or his health in continues and robust scientific bases.

System Architecture: SEA has 2 main functions that are supported by multiple stakeholders:
1. Understanding patient characteristics to recommend optimal therapy and behavioral changes
2. Pooling and analyzing of aggregate data in order to update the current medical knowledge

Figure 1 depicts the proposed system with 3 integrated cycles: 1) patient empowerment, 2) healthcare provision, and 3) medical knowledge generation, described below.

![System Architecture of the SEA and learning health system.](image)

**Patient empowerment:** The center of the diagram has the patient and SEA as a game for a specific health condition. First the patient provides input about his or her condition and preferences and the SEA generates the first experiment. Additional input may include EHR, environmental data, wearable devices, or genetic data. Based on these input the SEA then guides the patient through experiment steps and data input as required. In cases where the patient cannot make regular data input, an additional person can provide input. This may be realized in a form of a game where the patient’s avatar has a hypothesis based-mission. As the avatar accomplishes the mission the patient receives feedback. Depending of the patients’ response to the experiment, the SEA provides other missions. On a
continuous basis the generated and collected data can be incorporated into the EHR. The patient empowerment cycle engages the patient by giving him or her responsibility and control over personalizing his or her own treatment.

**Healthcare provision:** The clinician may decide to make adjustments in the SEA to optimally fit the patient’s health condition and to avoid health risks. Data collected and generated by the SEA incorporated into the EHR may alert the clinician of certain risks (e.g., suicidal risk). The healthcare provision cycle ensures proper medical guidance and follow-up.

**Knowledge generation:** Results from many patients can be de-identified and pooled together to inform medical research in disease specific analysis pipelines. By leveraging predictive analytics, various hypotheses can be generated to refine the SEA. In addition, pooled results are available for the research community for further analysis. In both cases, the medical knowledge generated can be used to inform new or refine existing medical guidelines. These guidelines are then fed into the internal logic of the SEA along with EHR and clinical decision support modules. This process represents the knowledge generation cycle by using aggregate results to inform medical guidelines for a specific condition and patient demographic.

**Data processing and analyses**

**Individual level:** The single-subject study design is used to test the effect of the potential trigger and intervention in one experiment. Minimal of 3 data points during each of the intervention is necessary. Visual analysis, the most common analysis method for single-subject study (5) will be used to analyze the data within a phase. Changes in level, slope and trend will be calculated to describe the stability, variability, and directions of the changes between different phases. Additionally, two-standard deviation band method will be used to assess the variability within each phase. For time-series data, C statistic will be used to estimate the trends of the data.

**Population level:** The built-in data analysis model will be able to handle large scale aggregated data. Based on the population data, we will train models using machine learning and statistical methods to study interesting hypotheses. Phenotyping algorithms will be implemented to identify cohort with certain traits to facilitate clinical research study in the research community. In the meantime, the system provide data export function for users to export the data for their own data analysis.

All information in the SEA will be secured using the best available security protocols and data encryptions. HIPAA and GINA regulations will be considered for patient privacy and de-identification when aggregate-level data are retrieved. As the SEA can be used by subjects located in different states or countries, security regulations will need to be customized. This customization will be guided by a panel of ethical experts and stakeholders in the territories where the SEA is used to ensure ethical and legal adherence.

**Use Case – Major Depressive Disorder (MDD):** A promising application for the SEA is MDD, a complex phenotype affecting 6.7% of adults in the United States (14). MDD is characterized by loss of interest in usual activities or depressed mood accompanied by fatigue, difficulty concentrating, changes in appetite or sleep, feelings of worthlessness, or suicidal thoughts lasting 2 or more weeks (15). Often a chronic illness, MDD can lead to negative outcomes including decreased quality of life, lack of ability to function, negative impact on relationships and work capacity, or even suicide (16).

Finding the right treatment plan for an individual patient with MDD takes fine-tuning and often trial and error. Although over 100 MDD apps exist, providing mood and activity tracking, these apps stand-alone and do not provide personalized interventions based on the patient’s unique condition. MDD treatment generally consists of pharmacotherapy, psychotherapy, and lifestyle modifications (15). The first two categories of treatment (pharmacotherapy and psychotherapy) require psychiatrist or psychologist oversight. Here the SEA can identify optimal treatment based on patient response. In addition, the SEA can provide plans for lifestyle modifications. These functionalities are described below.

**MDD self-experimentation:** Multiple lifestyle modifications are recommended to MDD patients including sleep hygiene, physical activity, diet, mindfulness, or light therapy (15). The most effective lifestyle modifications are the ones that a patient will consistently follow (15). The SEA can effectively identify the optimal lifestyle modification. Through the SEA, a clinician can enter recommendations for changes in lifestyle such as amount of exercise each day, increasing mindfulness, changes to diet (e.g., increasing omega-3 fatty acids or folate), or light therapy. The patient could then input personal preferences about type of activities and duration. The SEA would randomly assign different lifestyle modifications to the patient. A mood and functioning assessment would then be required at the start, halfway through, and at the end of a lifestyle modification plan. Each day the SEA would provide a lifestyle task that falls
within the suggested routine and ask for the patient indicate completion of the task. Taking into account adherence, mood, and functioning results, the app would either suggest a different routine, or provide a similar routine. Once a routine that works well is found, the app continues to provide these suggestions until a decline is noticed. The SEA can also provide clear monitoring of how often a patient is doing with lifestyle modifications, and the gaming aspect can help provide motivation to adhere to the program.

**MDD monitoring:** Currently, mood and how well a patient is functioning is mainly assessed at clinical visits. The SEA can provide a more in-depth picture of a patient’s response to treatment by assessing mood and functionality more regularly. Mood can be assessed through a series of questions within the app. Functionality can be assessed by randomly asking the patient what he or she is doing throughout the day and connecting with wearable technology (e.g. Fitbit).

Results of the self-experimentation alongside mood and functionality assessment will be summarized and reported to the patient and clinician. These data can be used to further inform treatment recommendations in order to find a plan that works for the patient. In addition, results from the experimentation can be fed back into the research community and inform future research by providing details about the patient’s demographics (e.g., body mass index, prior lifestyle, current medications). In this way the SEA aids personalization of treatment for an individual patient and informs treatment of MDD for similar patients.

**Alternative Solutions:** Several additional solutions were considered for SEA for MDD. First, another option could be support for clinician guided experimentation with pharmacotherapy. If first line therapies are not effective it can be difficult to determine which additional option is best. Further research is needed to develop guidelines for second-line pharmacotherapy for MDD, and the SEA could provide this experimentation. Consultation with practicing psychiatrists, however, led us to lean away from this level of experimentation as clinicians may be less likely to use this functionality. Second, we considered supporting psychotherapy experimentation. This layer of treatment often involves developing very specific care plans. Here SEA could provide evidence for what psychotherapy care plans are effective for specific patients. Therapy plans, however, are often very specific to the patient’s symptoms, which may make it difficult to develop general MDD algorithms. Finally, a third alternative solution is targeting the SEA to sub-clinical, or pre-diagnosis patients. Here the app would focus entirely on lifestyle modifications that may help the patient improve symptoms enough to not require medical care. If user symptoms decline, the SEA could recommend the patient seek medical care. This final solution is feasible and could be implemented by making the app available to the general population.

**Implementation and Dissemination**

**Gaming and alternative approaches:** According to the Entertainment Software Association, 63% of households in the U.S. include at least one regular game player, 47% of the players are between 18 and 49 years old. Gamer gender distribution shows that 41% of the players are female (average 44 years old) and 59% are males (average 35 years old) games (17,18). Clearly, games are widely used and accessible across demographics. The SEA leveraged as a game can potentially increase acceptance and usability of the app.

Although games are appealing to many, some individuals may not prefer games, as a result, an alternative representation will be provided that instead uses forms and reports. Following principles of effective system design these reports will incorporate familiar symbols and metaphors (e.g., to-do lists, calendars and reminders) (19).

**User interface design process:** Interviews and focus groups will be held with clinicians and patients to determine what functionalities are desired for a specific use case. Card sorting activities and rapid prototyping with end-users will be employed to develop the patient, clinician, and researcher facing user-interface for the SEA.

**Information exchange:** As the application is required to collect and provide data from/to many separate entities, Health Information Exchange (HIE) will be intensive. To ensure proper syntactic and semantic interoperability the application data representation should follow the commonly used HIE standards such as SNOMED-CT and LOINC. Communication between the EHR and SEA app will use available messaging standards such as HL7-FHIR. In addition, SMART on FHIR create an integral platform that allows data communication among portable healthcare application and the underlying EHRs (20,21).

**Cloud-based data architecture:** The SEA system will use the cloud-based data architecture to store, process, and transmit data. HIPAA protected private (e.g., Center for High Performance Computing at the University of Utah) and public (e.g., Amazon Web Service) clouds will be utilized as SEA service providers.

**Evaluation Plan**
Fully developed versions of the SEA will be evaluated for usability and efficacy. Usability would be assessed based on survey evaluation by end users including clinicians, patients, and researchers working with the phenotype of interest. Efficacy of the SEA for a phenotype of interest would be evaluated by a randomized controlled trial. In this evaluation, patients with the phenotype of interest would be randomly assigned to a treatment plan that uses the SEA or standard clinical care. Comparison of symptoms (patient mood and functionality) would be assessed at initial diagnosis and every month until treatment is no longer needed or for one year. Quality of life (based on mood and functionality assessment) and time to improved symptoms would be compared between the two groups to evaluate the efficacy of the SEA.

**Strengths and Weaknesses**

Our proposed solution has the strength of integrating mobile application with the larger cycle of learning health system. This ensures the benefit for both individual and population level in addition to updating the medical knowledge through providing valuable and structure pool of data. Also, it makes use of the currently available HIE standards to ensure semantic interoperability and avoid redundant or manual data entry as much as possible. The use of the gaming approach supports system acceptance and usability. In addition, this approach fosters patient empowerment and engagement in healthcare process which is considered as the “Blockbuster Drug of the Century” with the aim to improve quality, decrease costs and mitigate disparities (22,23). Here the patient is responsible to understand his or her health condition and participate in finding the optimal treatments or recommended behavioral changes. In conclusion, both the use of games and the integration within a larger learning health system may be considered a valuable addition over the originally developed self-experimentation framework by Karkar et al (3).

The proposed framework still faces some challenges, however. First, the ethical, legal and regulatory framework need more collaborations and discussions among the involved stakeholders. Second, finding HIE standards that capture all concepts may be a challenge and some additional new concepts may need to be proposed to the corresponding standard development organization. Finally, structuring an idea for a game that both fits the SEA and is interesting for the intended population is not a straight-forward task. A thorough review of the currently available games and engagement of intended users and game experts are necessary to reach a useful and usable self-experimentation game.

**Conclusion**

The SEA is an innovative approach to help patients with chronic conditions find therapy that improves their unique conditions. The patient empowerment cycle enables users to take responsibility and control over their conditions. The physician provision cycle improves communication between patient and clinician to ensure shared decision making. The knowledge generation cycle informs future treatment of chronic conditions. This unique integration of SEA with a learning health system can support precision medicine for complex, chronic conditions—potentially improving quality of life for millions of Americans.

Breast Cancer Personal Trajectory Tool
Rebecca A. Marmor, M.D., Elizabeth Epstein, B.A., Meera Reghunathan, B.S., Mitchell Boldin, M.S.
University of California San Diego, San Diego, CA

Abstract

Patients diagnosed with breast cancer face a myriad of treatment decisions. Although there are a variety of resources to help patients make decisions, each is limited in its scope and ability to offer personalized information to users. We propose a personalized decision-making tool that synthesizes data from large trials, granular data from the UCSD Clinical Data Warehouse and qualitative data obtained from online health communities. Information about treatment options and most likely outcomes, will be presented to patients through the lens of their individualized risk factors and prior treatment decisions. We outline our iterative three-phase design process which concludes with a feasibility study.

Introduction

Upon diagnosis of breast cancer, many patients face a variety of treatment decisions, some of which may have significant physical and psychosocial implications.\textsuperscript{1,2} Decision-making in breast cancer is commonly patient-driven. Patients are often required to select from a menu of surgical procedures which include: lumpectomy, mastectomy, contralateral prophylactic mastectomy and/or reconstruction. They might be offered radiation and/or chemotherapy, and asked to take estrogen modulating medications.\textsuperscript{3,4} Patients seek out second opinions and can learn that providers have different recommendations.\textsuperscript{5} They also seek information from peers and online health communities (OHCs).\textsuperscript{6–8} The volume of information can be overwhelming, confusing and sometimes even conflicting. It can be very difficult for patients to predict what their own most likely outcomes are, given their individual risk profile comprised of their current health status, genomic markers and family history. Additionally, past treatment decisions may influence future risk of disease recurrence and metastasis; this knowledge may inform patients’ current decisions.

Figure 1. Sources of Information for Breast Cancer Patients

Information for Breast Cancer Patients

There are three types of information that breast cancer patients commonly use to make treatment decisions: clinical data based on large research trials, anecdotal data from friends and family and data obtained from consultation with health providers (Figure 1). Data from large research trials may provide patients with estimates of risk of local cancer recurrence and overall survival depending on the treatment options they choose. This data is helpful because it can provide long-term follow-up of patients, and is based on large numbers of patients. However, it is limited by its lack of granularity, and may not address more specific questions patients have regarding treatment options.\textsuperscript{9} Also, it may not account for an individual’s specific risk profile. Secondly, patients may consult peers regarding various treatment options. Patients may also seek out similar advice on OHCs.\textsuperscript{10,11} Narratives shared by other patients are often most influential in informing patients’ understanding of how treatments might promote or contradict their idea of health.\textsuperscript{8,12} Numerous studies have explored the benefits of engaging with fellow patients via OHCs about their personal experiences when faced with the same disease.\textsuperscript{13–16} Benefits such as hearing how someone else has coped with the same illness and managed treatment day-to-day provide context and help patients understand their disease beyond medical explanations.\textsuperscript{11} However, patients can have a poor understanding of how their own disease process...
differs from their peers’. As our understanding of cancer is rapidly evolving, with increased emphasis placed on cancer genomics, patients might not be aware of the subtleties of their own disease that affect their prognosis. Similarly, a verbose member of an online health community may complain about her cosmetic outcome following surgery, and create a large volume of posts expressing these views, even though vast majority of community members are satisfied with their outcomes, thus skewing other users’ perceptions of what the most likely outcome is. Finally, information and counseling obtained from health providers may be tailored for an individual’s risk profile and include detailed information about the patient’s current health status, genomic markers and family history. However, information from clinicians might be seen by some patients as untrustworthy, with some patients ultimately preferring to seek out their own information. Information obtained from clinicians also lacks the subjective experience provided by peers and thus might be perceived as less reliable.

Decision Aids
Prior research has been conducted to develop decision aids (DAs) for breast cancer patients. There are several studies confirming the utility of such DAs in decreasing decisional conflict and increasing knowledge and satisfaction. Although providing helpful preliminary data, these decision aids are limited in scope- most address only one treatment decision (e.g. mastectomy v. lumpectomy). None currently support the patient throughout the entire disease course. Additionally, many of these prior DAs have not been updated to reflect recent changes in practice, such as new chemotherapy regimens which may affect outcomes. Perhaps most importantly, no DA currently incorporates information about patient’s subjective experiences in a systematic way, despite the emphasis patients may place on this information when making decisions.

Statement of Problem
Breast cancer patients currently face a wide range of treatment options for their disease. Although there is a plethora of resources available to help them choose among options, these resources are currently limited in their ability to offer personalized information about recurrence risk and survival benefit, based on the patient’s own demographics, health history and tumor characteristics. Additionally, these resources are currently disjointed, addressing a variety of separate concerns and may even sometimes be conflicting. We propose a DA which would incorporate several different types of information, filtered through the lens of a patients’ own unique risk factors, to help patients make treatment decisions.

Alternative Solutions and Designs
Since there are a plethora of resources available for breast cancer patients already, we have carefully considered alternative solutions to this problem. First, we considered merging and updating the content of existing decision-making aids, into a unified aid to support patients throughout their disease course. This solution offered the benefit that many of the pre-existing aids have already undergone validation testing, and have demonstrated efficacy. However, we would still need to repeat validation of this new aid. This solution would also not allow us to incorporate additional data sources, which we believe are vital to decision-making. We also considered working with existing online health communities to refine search capabilities, so that patients could seek out specific treatments and concerns regarding these treatments. This approach offered the advantage of pre-existing large, active and engaged memberships. While this approach may have allowed us to show the frequencies of certain outcomes among community members, it would have not allowed us to superimpose clinical data. This approach is also limited in its ability to provide users with personalized information, tailored to their own risk profile. Even if the search function was refined to such a degree that patients could perform sophisticated searches to answer specific questions, it would be limited by patients’ abilities to recognize users’ disease as similar to their own.

Solution Design and Development

Design Process
We plan to use an iterative, patient-centered design process. The process consists of three stages: 1) Design Requirement Extraction 2) Iterative design and prototype development 3) Evaluation of Trajectory Explorer. We will devise an initial design based on the information obtained in stage one, which will be updated based on feedback obtained throughout the stages from users (Figure 2).
Stage 1: Design Requirement Extraction. We plan to begin our design process by performing in-depth qualitative interviews of breast cancer patients at all stages of treatment. The purpose of these initial interviews is three-fold:  
1) To gain insight into the decision-making process of patients not available in the literature. Specifically, we are interested in what types of decisions were especially difficult for patients to make, what resources they consulted with in order to make those decisions and what they liked/disliked about those resources. For patients who have already made decisions, we will ask them “what they wish they had known,” and for those who are presently in the decision-making process, we will ask them what options they are considering and what information they would like to have available.  
2) To learn about the preferred methods of patients for receiving information. We will ask patients about their comfort level using mobile phones, apps and computers. We will ask about their access to the internet. Finally, we will ask about their comfort interpreting basic statistics including probabilities.  
3) To gain feedback about mockups of the proposed solution, so that we can make changes to improve our design.

We also plan to consult with breast cancer clinicians, to gain insight into the perceptions of providers about the most difficult treatment decisions for patients, and what information they wish they were able to provide patients with that they cannot currently. This part of the process will also include an in-depth literature review of decision-making among breast cancer patients, and prior DAs. We will also conduct brainstorming sessions. At the conclusion of this phase, we will have formulated our design requirements.

Stage 2: Iterative Design and Prototype Development. Our proposed solution is a mobile application (app) that assists in patient decision-making. The app incorporates three distinct data sources for patients, and is readily used by patients during consultations to keep track of information relayed by clinicians. This solution will provide personalized information to users, based on information entered on a personal profile. The app will help users learn about different treatment options for breast cancer, expected benefits of the treatments, given their personal risk factors, and the experiences of other similar patients who have selected the treatments (Appendix A). This information will help patients weigh competing treatment options, and eventually choose one. Finally, it will serve as a repository for users to store additional information they have learned from other sources, including clinicians. We plan to develop a web application with mobile users in mind. A web-based app will have the benefit of being accessible to both iOS and Android users. Moreover, although we believe that users will primarily access the app via smartphone, a web-based app will allow users to access the application via their computer if they do not have a smartphone or if they prefer not to use a smartphone.

Data Components

The three layers of data (Appendix A) we plan to include in our model are:  
1) Clinical Data from large research studies: This will be obtained through literature review, and based on current NCCN guidelines.23 This data will primarily describe risk of local recurrence, distant metastasis and death. When available, we will include individualized risk factors, including BRCA status, age, race and tumor characteristics, to personalize the
information patients receive. This information is limited in granularity, but offers the benefits of large numbers of patients and long follow-up. 2) UCSD Clinical Warehouse Data. Using data from the 8,000 breast cancer patients seen at our local center, we will perform predictive modeling to identify the most likely outcomes for breast cancer patients based on individualized treatment decisions. This data is more granular than that provided by large studies, and may provide information of interest to patients (e.g. what are the chances that I will not be able to complete my course of Tamoxifen? What are the chances I will need an additional surgery to get complete clearance of the tumor following lumpectomy?) The questions we will answer with this data will be largely informed by our patient interviews, and will seek to answer those questions of greatest interest to patients. This data set is smaller than national data, but will allow us to help patients answer questions that may be most important to them. 3) Qualitative Data obtained from online health communities. We have scraped nearly 320,000 posts from two major OHCs (WebMD cancer community, American Cancer Society forum) to assess patients’ questions and needs concerning choosing breast cancer treatments online. We will use these posts to extract patient experiences in quotes and sentiments around treatment options. We will extract breast cancer related terms, the sentiment around the term, and quotes using natural language processing techniques and tools such as Unified Medical Language System24 and Linguistic Inquiry Word Count.25 Additionally, we will perform a keyword search regarding specific patient concerns about various treatments (e.g. burns and radiation, chemotherapy and fertility). We will extract this data, along with demographic information of posters, to provide patients with subjective information from similar patients (e.g. by age, cancer stage, BRCA status, etc.) about cancer treatments. Moreover, users of the app will be able to post their own experiences for other users to view, which will provide additional information for patients. Users will be able to rate posts as helpful so that the most valuable and informative posts are shown preferentially to end users. We will verify the validity and reliability of all data with experienced breast cancer clinicians at the UCSD Comprehensive Breast Cancer Center.

Key Features

In order for the app to educate patients, users will need to be able to engage with it in meaningful ways. The following features will support this engagement. 1) User Profile (Appendix B). Creation of a profile is very important, to ensure customization of information delivered to app users. Users will be invited to share as much information as possible about their health and disease status. However, because additional information about a patient’s stage, tumor characteristics and genetic markers may not be available initially, and the patient’s risk of future cancer-related events will change depending on the past treatment options selected, the profile will serve as an easily accessible centerpiece of the app. Depending on their location on the treatment trajectory, users will be provided with appropriately timed prompts to update their profiles (e.g. a patient who has undergone surgery will be prompted to update her stage and pathology results two weeks after her surgery date). This profile will be the basis of our collaborative filtering system, to ensure that the user is provided with information about similar patients.26 2) Customized Information Displays (Appendix C). Users will be able to customize their displays to see information from any one, or all data sets (e.g. large trials, data warehouse and/or qualitative). This feature will allow them to receive the information they are most interested in. It will also educate patients about the benefits and limitations of each data set, with suggestions about how the given data set may be interpreted. 3) Annotation Mode. To prepare for upcoming visits with providers, patients will be able to compile lists of questions they hope to have answered. Depending on the specialty of the provider, the position of the patient on the treatment trajectory and the patient’s individual health characteristics, the app will suggest appropriate questions for the visit. The patient will be able to add additional questions to the list. At the time of the visit, the patient will be able to take notes with the answers. Additionally, the patient may be able to record the clinician’s answers to the questions and store this in the app.

We will low fidelity mockups of the app with a tool called NinjaMock, which allows for the rapid production of functional and adaptable mockups.27 These affordances are especially important in our iterative design process, because certain characteristics of our solution are subject to change. We will seek out user feedback after each iteration, conducting approximately three interviews and then improving on our design. We will plan to conduct 20-30 interviews total. When we are not receiving any further significant suggestions from users, we will develop a high fidelity, interactive prototype in order to get more detailed user feedback. This design stage will end with usability testing for the final prototype.

Stage 3: Evaluation of Trajectory Explorer. As we will be using an iterative design process, we will be seeking patient and clinician feedback throughout development. Evaluation of our tool will involve a three-phase feasibility study. Formal evaluation of the aid will commence once we have a final working prototype. We will use O’Connor’s Decisional Conflict Scale (DCS), which has been used in multiple previous breast oncologic studies to gauge decisional conflict among patients28. The DCS is composed of 16 items, which assess 5 different subscales:
(1) “Informed”, which evaluates awareness of options, benefits, and risks, (2) “Values Clarity”, which evaluates feelings about benefits and risks, (3) “Support”, which evaluates feelings of support and pressure from others, (4) “Uncertainty”, which evaluates the participant’s confidence, and (5) “Effective Decision”, which measures the likelihood of adhering to the decision.

We propose to evaluate our decision aid using a three-phase approach: Phase I: We will conduct a small pilot study of 30 newly diagnosed patients at our institution, administering our decision aid to all of them one week prior to their first clinic visit. We will assess their response with the DCS and qualitative interviews to ascertain their reactions to the aid, as well as assess how it may be improved. We will incorporate these recommendations into the next version of the tool. Phase II: This phase will incorporate revisions to the aid made based on the results of our phase I study, and include 50-75 newly diagnosed patients at our institution, all of whom will receive the decision aid one week prior to their first clinic visit. We will again administer the DCS, at various points (immediately following their first clinic visit, just prior to surgery, at their first postop clinic visit) along with the FACT-B and EORTC QLQ-30 two validated instruments used assess quality of life among cancer patients. Finally, we will include a survey for patients, to obtain recommendations about how to improve the decision aid. Phase III: This will be a large, randomized, single-blind multi-institutional study to evaluate the efficacy of our DA. Newly diagnosed patients will be randomized to receive either our DA or a traditional DA one week prior to their first clinic visit. Providers will not know which arm of the study patients are in. Again, patients will be assessed with the DCS, FACT-B, EORTC QLQ-30 and a survey to assess their satisfaction with the decision aid. Patients will have access to the tool for one year, and will be assessed with the aforementioned instruments at routine intervals.

Conclusion

Breast cancer is a disease uniquely positioned to benefit from the advances of personalized medicine. Patients, who are often asked to choose from a variety of treatment options, may consult a variety of conflicting and disjointed resources in order to make informed decisions throughout the disease course. We propose the development of a decision aid application, utilizing data from large trials, a single institutional data warehouse and subjective data from OHCs to help patients make informed decisions. This information will be delivered through the lens of the individual patient’s personal risk factors and prior treatments.

Improvement of Patient Reported Depression Outcomes using EMR Integrated Genomics and Mobile Assessment

Anjana Ramnath, MS¹, Timothy A. Green¹³, Diana E. Rickard, MHA, MSHI¹², Lincoln R. Sheets, MD

¹MU Informatics Institute, University of Missouri, Columbia, Missouri, USA; ²Department of Health Management and Informatics, University of Missouri, Columbia, Missouri, USA; ³The Tiger Institute for Health Innovation, Columbia, Missouri, USA.

Abstract

Mobile assessment of patient reported data related to depression, in combination with genomic SNP panels, can provide additional sources of data to help physicians make better treatment plans. In order to be effective as an intervention, these additional data must be integrated into the physician workflow. This study will leverage an existing ambulatory mood assessment app, MoodTrek™, and available knowledge related to single nucleotide polymorphisms that impact metabolism of common anti-depressants. Patient reported data will be combined with genomic data in an EMR integrated dashboard that physicians will use during normal treatment planning. A three stage study design will assess the acceptability of the patient facing mobile intervention, workflow impact to physician users of the EMR dashboard, and clinically relevant patient outcomes.

Introduction & Background

Depression is a chronic mental illness that affect millions of patients around the world. Prevalence in U.S. has been measured at 4.1% for major depression and 9.1% for any depression [14]. Major depression accounts for 3.7% percent of the Disability-Adjusted Life Years (DALYs) in the U.S [15]. Current recommendations for treatment of depression is a combination of psychotherapy and antidepressants. Primary care physicians are on the front lines for treatment of depression, treating approximately one third to one half of adults and almost two thirds of older adults with major depression [16]. Patients are commonly assessed in regards to the symptoms of depression such as quality of sleep and sleep patterns, and other subjective measures including appetite, concentration, energy levels, and suicidal ideations. Patients self report how they have been doing in these areas since the last clinical encounter. This information is then used to modify treatment, such as changes in prescriptions and intensity of care.

Nearly three-fourths of adolescents (age 13-17) in the United States (US) have access to a smartphone and 92% report going online daily or more frequently [7]. The rise of smartphone health applications are aimed to improve the retrieval of information in clinical practice, two-way communication between patient and medical provider, provide patient resources and education, and connect to external devices (e.g. sensors, monitors, DME) to seamlessly feed and push information [6]. By enhancing the data capture outside of discrete times (e.g. office visits) we strive to decrease the prominent problem of recall bias in the accuracy or completeness of the recollections over time with adolescent patients with depression. This proposal aims to develop, enhance, and implement an ecosystem of tools to improve adolescent depression functioning through the capture of personalized, patient reported data to support patient-centered decision support.

Mental disorders are complex and effectiveness of drugs usually used to treat common mental illnesses such as depression may be linked to genotypes of the particular patient [11]. To better understand the effects that different variants and mutations have on mental illnesses and the way patients metabolize drugs for the same, various SNPs associated with Cytochrome P 450 (CYP450) metabolism could be tested. CYP450 genes affect how the body metabolizes selective serotonin reuptake inhibitors (SSRI) drugs as well as many other drugs. CYP450 genotyping (genetic testing) is being proposed as a means of guiding the use of SSRI drugs to improve the effectiveness of treatment for depression.
In addition to the traditionally viewed precision medicine technique of genomics, patient reported outcomes and patient generated data are important classes of data to be considered for precision medicine. Collection of patient reported data via mHealth tools in support of depression management have been well studied. In particular, recent research into the use of mHealth tools for ambulatory assessment in the mental health space have shown strong support for physical activity monitoring and single item mood score collection. A UK based study published in 2015 [1] found that a single question ambulatory assessment of depression using text messaging was found to be a valid measure of latent affective depression as validated against the PHQ-9 [10]. A similar study from 2015 [2] conducted in the US also showed a correlation between daily and one week average mood scores, and the standard PHQ-9 assessment scores. Another 2015 study [3] found that use of mobile phone sensor data could be used to classify patients with (PHQ-9 score > 5) and without (PHQ-9 score <= 5) depressive symptoms, with an accuracy of 86.5%.

In addition to strong support for correlating simple single score mood score to validated measures such as PHQ-9, other studies in the mental health space have found positive results with regards to usability and adherence. FOCUS [4], a smartphone based system, provided pre-scheduled and on-demand real-time/real-place illness management in schizophrenia. 33 patients with schizophrenia used the tool for one month. 90% of participants found the tool as highly acceptable and usable. Despite the short duration of the study, reduction in psychotic and depressive symptoms was noted in the study cohort. Another mobile intervention used in a 2014 study [5] was personal digital assistant to prompt engagement in self-management. Preliminary results showed adherence similar to that reported in non-psychiatric populations, with high participant satisfaction. Based on these studies, mHealth apps and devices seem feasible and acceptable in augmenting psychosocial interventions for severe mental illness.

When combined with genomic data of the patient such as presence of pathogenic variants or mutations, these applications can provide a valuable source of patient reported data that can be used to tailor treatment for individual patients.

**System Design**

**MoodTrek™**

MoodTrek™ ([http://www.mood-trek.com/](http://www.mood-trek.com/)) is designed to minimize the impact of the recency effect on the diagnosis and treatment of depression. Composed of two parts, MoodTrek™ is a patient-facing app and a provider-facing view within the Electronic Medical Record (EMR). The app allows patients to track their moods, activity, and sleep, as well as journal about their experience. This information can be automatically shared with a physician within the EMR. By integrating this patient generated data into the EMR, MoodTrek™ helps streamline the physician workflow by providing the care team with all of the benefits of a traditional mood chart plus a richer data set powered by the patient’s actual activity in real time. These integrated tools allow caregivers to accurately understand their patients experience with depression. Rather than relying on anecdotal conversations related to how an individual “feels”, they are able to see the flow of mood over time compared with activity and sleep levels.

MoodTrek™ is available on both iOS and Android platforms, and can connect with and integrate data from the Fitbit activity tracker. When using a Fitbit with the app the patient’s activity and sleep information can be captured accurately and completely with next to no action on their part. Through an invitation process initiated by the physician, patients can control which data are shared with the physician. The patient has full control over the type of data that can be shared, including sleep data, steps, mood, and journal entries. By using a SMART app interface[9], the MoodTrek™ data can appear alongside other clinical data within any physician’s EMR that supports the interface, thus providing a seamless workflow experience in using the data as part of normal clinical workflow.
Current sequencing methods range from running a genomic panel, which is focused on a specific set of genes, to whole-genome sequencing. Establishing the analytical validity of a sequencing diagnostic, however, is considerably more difficult for whole-exome or whole-genome approaches, in which the average depth of coverage is much lower than for targeted gene sequencing of a defined panel of genes. The establishment and maintenance of the analytical validity of a diagnostic test requires substantial effort. In a clinical laboratory, this entails initial and periodic testing on reference standards to demonstrate the reproducibility of the assay [12]. In contrast, panels targeting specific single nucleotide polymorphisms (SNPs) are in use and have a clinical track record. The cost of clinical-grade whole exome sequencing (WES) is high, whereas the cost of running a sample on one of such panels is relatively less expensive. As such, for treatment of mental illness, we will focus on usage of genomic information in SNP panels in order to better understanding how patients metabolize various drugs, including the most commonly prescribed ones. Panels will be run to test patients on variants involved in CYP metabolism. Designing panels to test for specific CYP gene variants that are involved in processing the drugs used in depression is also cost effective. The panels ideally would cover the spectrum of pediatric and adult clinical genetics in mental illnesses.

EMR Dashboard

By combining the MoodTrek™ data with genomic data from SNP panels in a single dashboard, physicians will have ready access to all necessary data to make a personalized treatment plan or adjust existing therapy. In a single view, physicians will be able to see mood scores over time, step counts, sleep amount and quality, journal entries and a journal word cloud, and SNP panel data (Supplement). The intention of the dashboard is to provide all relevant information necessary to make a clinical decision on the efficacy of pharmacologic treatment and other interventions. Because the dashboard is integrated into the EMR, other, more classical forms of clinical data are available through the normal means of chart review.

Study Design

A three stage study design is planned to optimally evaluate the 1) usability of the patient-facing MoodTrek™ application, 2) usability of the EMR provider dashboard, and 3) a clinical trial to measure outcomes of use of both the MoodTrek™ application and the EMR provider dashboard.

In the first stage of this proposed study design, we will evaluate the acceptance of a new patient-facing application, MoodTrek™, designed to minimize the recency effect of the diagnosis and treatment of patients with depression. To identify potential barriers, this stage aims to evaluate the usability, specifically perceived usefulness and perceived ease-of-use, of the patient-facing MoodTrek™ application. By adopting the empirically validated Technology Acceptance Model (TAM), we will understand the factors influencing how and when users will access the new application (Davis, 1989). This study will recruit ten potential users who are within the target demographic age (13-17) and who self-report current or past history of depression. Enrolled participants will be asked to complete a 33 item online questionnaire, modified from Gagnon (2012), following a one hour block of uninterrupted and self-promoted interaction with the MoodTrek™ application. The online questionnaire measures 8 dimensions including: perceived usefulness, perceived ease-of-use, attitude, compatibility, subjective norm, facilitators, habit, and intention [8]. Results from the questionnaire will be analyzed using descriptive statistics to determine the mean, standard deviation, and correlations between the 33 variables across the 8 dimensions (Suppl 1).

The second stage of the proposed study design surrounds usability testing of the EMR provider dashboard. The System Usability Scale (SUS) [13] scale will be used to test ease of use for clinicians when navigating the EMR-Genomic dashboard. The trial period will be 24 weeks, entailing dashboard use throughout by the clinician to treat and adjust treatment as necessary.

The third stage of study design consists of a randomized clinical trial. In order to assess the clinical efficacy of the MoodTrek™ app on outcomes that are important to patients and clinicians, a randomized trial will be conducted using a matched intervention group of patients who will use the MoodTrek™ app, and a control group who will not use the MoodTrek™ app. The primary clinical outcome measure will be the PHQ-9 [10]. In addition, patient reported outcome measurements will be collected using the PROMIS Emotional Distress-Depression – Short Form 4a measure (suppl 2). Secondary outcomes to be investigated will include the frequency of patient encounters and medication prescription stability.

The trial period will be 24 weeks, with the initial consenting clinic visit serving as the kickoff visit, and a scheduled visit at the end of the 24 week period. During this time, patients will be followed as normal, including
normal follow up clinic visits as necessary. Both study arms will be asked to submit the PROMIS Emotional Distress-Depression – Short Form 4a measure monthly through an emailed survey. The PHQ-9 will be collected at the beginning and end of the study period for each arm by the clinician. Retrospective data pulls will be used to determine frequency of clinic visits during the study period, and EMR sourced data on prescriptions will be used to measure the stability of pharmacologic interventions over time.

Calculating for 80% statistical power, and a 10% attrition rate, 682 patients will be enrolled in the study. Target patients will include 13-17 year old adolescents with a diagnosis of major depressive disorder. Patients will be recruited in clinic, where supplementary materials can be shared and consenting can be performed with patients and patients’ guardians.

Implementation

The MoodTrek™ app and EMR integration for the clinical trial will be implemented at University of Missouri Health Care (MUHC), in the primary care setting. MUHC uses the Cerner EMR system. The clinical integration of Mood Trek with the Cerner platform has already been developed and is available to install in the MUHC system. The MoodTrek™ app is available on the Google Play store and the Apple Store. Training on the use of the MoodTrek™ integrated EMR component will be provided to all primary care physicians through training outreach performed by members of the research staff. Training for users of the MoodTrek™ app will be minimal and will consist of flyers handed to the study subjects during the consenting and enrollment process.

Conclusion

Mobile interventions such as MoodTrek™ promise to bring personalized data into the hands of the clinician. Combined with genomnic sources of precision medicine, such as metabolic panels, the described system is expected to deliver better care. We expect to see this reflected in improvements in overall PHQ-9 scores and improved responses to the PROMIS Emotional Distress-Depression – Short Form 4a measure. Additionally, we expect that when clinicians leverage these sources of precision data, the stability of pharmacologic treatments will improve, with fewer changes per patient in dosing or drug. Also of importance, given the shortage of adolescent psychiatry services, is the expectation that patients will use fewer services when patients and physicians are connected to more precise and objective forms of data outside of the clinic.

PrecMed: A collaborative environment for precision medicine research and practice

Jianlin Shi MS, MD, Lance Pflieger
Biomedical Informatics Department, University of Utah, Salt Lake City, UT

Abstract

The goal of precision medicine is to transform healthcare by providing patient-specific care through the application of evidence-based practices gained from large and often heterogeneous health-related data. However, current evidence and practices can be statistically insufficient to infer proper precision healthcare guidelines, especially in respect to common genetic variants. Hence, it is important to incorporate and utilize data from an array of disciplines and institutions. PrecMed is a platform designed to foster collaborations, not only for data use and generation, but also for crowd-sourcing of ideas and application development with an emphasis on peer evaluation. PrecMed also supports distributed data analyses to aid with large cohort studies and provides real-time results aggregation, facilitating iterative application development. Furthermore, it provides an easily accessible place for disseminating precision medicine research information, results and applications.

Background

Personalized medicine aims to break from traditional population based medicine by providing individualized treatment tailored specifically to a single patient. It is defined commonly as “The right treatment, for the right person, at the right time” and in many circumstances should include the right cost. While personalized medicine is associated frequently with advances in genomics, personalized medicine also incorporates clinical, biological, environmental, social, economic and life style factors. Ideally, the collection and analyses of these personalized factors will lead to predictive analytics to identify a person’s risk for developing disease, guidelines for prevention and the precise course of treatment. Realistically, multiple barriers need to be addressed and overcome before such system is possible. These barriers include the need for a multi-discipline collaborative environment, the collection, integration and analysis of big data and the dissemination of information and tools.

As outlined by the Massachusetts Institute of Technology’s report Convergence: The Future of Health and the European Cooperation in Science and Technology Conference report on personalized medicine, the integration of expertise across multiple disciplines, such as life science, engineering, physics, math and computation science are critical to addressing health care challenges. The report highlights many areas of that will require a collaborative approach to further understanding, such as the need to improve knowledge surround brain function, infectious diseases and cancer. As an example, cancer treatment needs to evolve beyond chemotherapy and radiation. To do so, fundamentally new approaches need to be researched and developed comprising of advanced engineering techniques such as early detection techniques and nano-particle delivery systems as well as genetically guided treatment.

Another barrier to personalized medicine is need for collection, integration and analysis of big data sets. The use of massively parallel sequencing techniques coupled with increasing data collection of clinical, lifestyle and environmental data are all beneficial to the transition to personalized medicine. Regrettably, these data are often inaccessible to large cohort studies, leading to one-off studies that have insufficient power to validate disease risk associations. The lack of consensus, especially in the pathogenicity of genetic variants, has led to confusion and disagreement about the clinical importance of such associations. In an attempt to overcome this barrier, the National Institute of Health initiated the Precision Medicine Initiative, which will collect data from 1 million people across the US. Fostering collaborations with a multidisciplinary approach could allow these data to be continually used for cross-institutional retrospective studies, helping to incentivize updating and achieve a personalized medical system.

Finally, the need for clinician education and access to personalized tools must be addressed. Clinicians and other primary care workers will be instrumental in the transition to a personalized system. However, studies have shown a large gap in needs for a personalized education for front-line workers. In order to implement personalized tools in a clinical setting, it is imperative to help fill this educational gap through easily accessible information and
guidelines. Additionally, clinical decision support tools need to be developed to reduce the knowledge burden on clinicians. Again, this will require a multi-disciplinary and collaborative approach with many stakeholders.

To our knowledge, no system exists to easily facilitate collaboration to foster a precision health care environment, although many barriers exist (Appendix 1).

**PrecMed architecture**

To circumvent many complex privacy and security challenges in the collaborations mentioned above, PrecMed offers a platform to share apps instead of data. The PrecMed apps could be research oriented software, clinical decision supports applications, or patient side support solutions. The PrecMed platform consists of three components: the coordination server, the app store server and the PrecMed client server.

Figure 1 illustrates how the three components are organized and how a typical user would interact. The coordination server hosts the projects and serves as a central platform for coordination among different users during app development and evaluation phases. Compared with traditional research or the software development process, PrecMed offers an open collaboration in a crowdsourcing fashion—each phase can be accomplished by one or more separate projects that are conducted by self-organized groups. After an app is evaluated and approved by a government agency (e.g. FDA), the app can be published to the app store server. The app store server hosts all the approved apps so that any client users can deploy selected apps to their own local PrecMed client server. A PrecMed client server is set up by each healthcare organization or individual practitioner. The PrecMed client server provides a unified environment to host and run locally deployed apps. With user agreement, apps can potentially send aggregated results to the App store server. These results can be used to update mathematic models (e.g. a survival prediction model) and provide feedback on specific populations that may have been originally unavailable in development. Specific components and functions are listed in Table 1. An online interactive mockup can be assessed from https://invis.io/X67R6D6JP

**Innovation and significance**

This framework provides a fundamental change in how personalized medicine information and knowledge is shared by switching from a data sharing model to an application sharing model; potentially bringing a revolution to precision medicine research and practice. The significance is listed as following:

1. Privacy and security issues that have plagued data sharing are addressed by sharing application models and ideas instead of Personal Health Information. PrecMed allows apps to be run in a distributed manner, meaning individual
patient data will be processed without leaving its original site. After the data are processed, aggregated data results can then be returned to PrecMed. This mechanism not only improves the protection of personal health information but also provides application developers real-time feedback to update and improve their app.

2. Using PrecMed, studies can effortlessly reach sufficiently large sample size and be easily conducted across geographic locations. Since data are processed at each PrecMed site, de-identification is not necessary, potentially allowing data access and processing at scale. This is in contrast to many current research studies which, even with a sample size in thousands, is considered to be underpowered. Through collaboration and distributed processing, PrecMed allows for a larger magnitude of data, further pushing healthcare into the big data era.

3. Real-time learning is no longer a dream. Many current precision medicine studies describe prediction models using an array of data resources. Many of these prediction models are trained using a static dataset with few rounds of training. With high volumes of data accumulating every day, it is unreasonable to not utilize the data and update models over time. PrecMed inherently supports learning not only in real-time, but also in distributed manner with the scalability to include hundreds or even thousands of healthcare organizations.

4. PrecMed supports multi-disciplinary team work. Since not every researcher is able to access all the resources that needed to complete their research, PrecMed ask users to contribute what they have and in return offer them what they may be lacking. For instance, an informatician may have expertise in information processing and analyzing, but lacks access to healthcare data. This research can utilize a PrecMed to make an app with sample data and make it available on PrecMed. Other healthcare data holders can review this app and evaluate it on their own site, using their own data.

5. PrecMed offers a centralized location that offers a multitude of collaborative services including: crowd-sourcing idea generation, app development, shared IRB application support, idea and app evaluation, government agency approval and final market dissemination. This service creates a unique place where people can work together toward the goal of precision medicine. Appendix 3 contains multiple use-cases to showcase the PrecMed framework.

6. PrecMed incents users to engage in collaboration through a credit system. As illustrated above in Table 1, this credit system consists of two components: the reputation scores and the credit points.

7. Through reinforcing the PrecMed API (Application Programming Interface) and a set of standards (e.g. FHIR--Fast Healthcare Interoperability Resources standard), PrecMed hides the heterogenous underline IT systems that maintain the health related resources (e.g. personal health record, genetic data, social media data). It offers a unified environment for app development and execution. Thus, PrecMed apps have the outstanding “write once run everywhere” property, which largely maximizes the software production efficiency. As Java virtual machine sits above various operating systems to provide a unified programming environment, PrecMed sits with various health IT systems to provide a unified app developing and execution environment.

8. PrecMed makes app dissemination and deployment easier than ever before. One simple click by an authorized user will deploy the selected app onto the user’s local PrecMed environment. Utilizing user feedback, great apps will receive the attention they deserve and be disseminated quickly, while poorly developed apps will be marginalized.

**Implementation plan**

PrecMed will be implemented through an iterative and incremental development model. In this model, there is an ongoing iterative development circle, which consists of requirement analyses, design, coding, testing and examination. Throughout all phases, a user-centered design principle will be followed in order to encourage participation from all stake-holders including clinical practitioners, clinical researchers, healthcare managers, IRB board members, healthcare government agents, informatics researchers and health IT professionals among others. The architecture of PrecMed will be designed as a platform structure which enables loose coupling between functional components. Development will start with essential components through the incremental modeling process, new and improved functionality will be generated based on continuously gather user requirements and feedback.
Evaluation plan

The evaluation will also be iterative and require multiple phases. For the design phase, evaluation will be conducted through a mockup usability study and/or experts’ walkthrough. In the coding and test phases, evaluation will be conducted through test cases for individual requirements such as those regarding security, validity, reliability, and efficiency. In the examination phase, a test environment will be used. Groups of user’s, including all stakeholders and potential users, will be recruited and asked to use the PrecMed system for a two-month period to evaluate the currently implemented tasks. Users’ satisfaction, engagement, usage barriers, system flaws, and system stability will be studied and evaluated. Hacking competitions will be organized periodically to test the security of PrecMed throughout the iterative development circles, allowing potential security risks to be identified and fixed.

Dissemination plan

Initially, PrecMed will be initiated and developed through a few leading healthcare organizations and published as an open-source platform. Using an open-source platform will allow for more organizations and individual researchers to join during the implementation. Later on, a non-profit organization will be founded to help maintain and disseminate PrecMed. This organization will take charge of PrecMed’s development, evaluation, upgrading, fund rising, project incubating, partner coordination and any other necessary tasks. Books, online tutorials and guidelines will be developed to help new users to get involved. Workshops, seminars, webinars, conferences and hackathons will be organized periodically to increase the PrecMed’s community influence.

Discussion

For precision medicine applications, few alternative solutions are available or feasible. Some public datasets provide structured individual level data (e.g., genotypes and phenotypes), such as dbGaP. These datasets do not include detailed clinical data such as clinical notes. The data structure is fixed and hard to be extended. Some public datasets share structured research results. For instance, ClinVar shares the relationships between human variations and phenotypes. Given current sample size and research scope limitations, many arguable conclusions exist, which overburden the data inclusion decision. The planned NIH initiative for 1 million people data may overcome the disadvantages above; however, concerns are still expressed about data size. Additionally, due to significant costs, data created from previous cohort studies are unlikely to be updated frequently to accommodate new data, procedures, treatments, and tests. Moreover, some data subtlety might be lost during de-identification.

PrecMed overcomes all these weaknesses through sharing applications and ideas, not data. Additionally, it supports real-time data analyses, which is rarely available in the other solutions. One limitation of the PrecMed solution is the possibility of no real data during the app development stage. This shortcoming can be mitigated by using a small amount of de-identified sample data, and following iterative development and evaluation circles.

Leveraging High Patient Information Density: Chronic Disease Monitoring with the Precision Patient Ledger

Vincent Caruso, MS, Geoffrey Schau, MS, Kristen Stevens, Matthew Sundling, PhD
Department of Medical Informatics & Clinical Epidemiology, Oregon Health & Science University, Portland, Oregon

Abstract

Patients undergoing routine monitoring of chronic symptoms are often limited to infrequent interactions with their primary care providers that take place exclusively in the clinical setting. Sparse patient-provider interactions force clinicians to make impactful decisions with equally sparse data. We propose a convenient, easy-to-use digital tool that allows clinicians to prescribe relevant and desirable clinical assessments to be self-reported by patients in the convenience of their own home. By relieving the patient from having to physically visit the clinic to collect meaningful data, we can allow more frequent assessments of patient health. We have developed an example use case of our concept with the Department of Rheumatology at Oregon Health & Science University. The preliminary implementation of our design delivers an assessment of RAPID3, a simple and clinically validated questionnaire approved by the American College of Rheumatology that serves as prognostic assessment for patients living with rheumatoid arthritis. An interactive prototype of our design is accessible at http://precisionpatient.info/.

Introduction

Problem Definition. Presently, patient-provider interactions are typically limited to scheduled clinic visits. As a result, providers are often forced to make major medical decisions based on data collected only during infrequent interactions. Such sparse data may provide an incomplete or even inaccurate description of a patient’s long-term well-being. This issue is compounded for patients who experience difficulty in scheduling, traveling to, or getting time off work to attend their scheduled clinic visit. These challenges implicitly limit the quantity of essential data used by providers to formulate long-term assessments of patient health and develop optimal treatment planning.

A related problem exists for patients who experience chronic yet stable conditions. Inconvenient or difficult circumstances for travel to and from a clinic may yield limited new data to indicate a change in the patient’s condition. The over-treatment of these patients results in inefficiencies by unnecessarily over-scheduling the clinic with visits of marginal value. A tool that allows a patient to regularly conduct a guided self-assessment of one or more chronic conditions and communicate their assessment results remotely to their care provider or electronic health record (EHR) would address both of these related challenges. The opportunity to better personalize treatment plans for chronic disease requires accurate and complete data to describe a patient’s long-term health.

Promoting Home-Based Care through Digitized Self-Assessment. At Oregon Health and Science University (OHSU), the Department of Rheumatology regularly incorporates patient self-assessment a prognostic tool for rheumatoid arthritis patients called RAPID3. The RAPID3 questionnaire asks patients to grade 10 everyday functional activities, such as getting out of bed and lifting a glass to their mouth, on a scale of difficulty, and also asks them to assess pain and global status. Self-reported functional assessments such as RAPID3 have been shown to be the most significant quantitative clinical predictor of premature mortality in rheumatoid arthritis patients when compared to radiographs or laboratory tests

The AMIA Challenge. Our team chose to develop a platform that allows providers to quickly access and interpret long-term trends of their patients’ health, regardless of whether the patient has visited the clinic. We propose a simple, easy-to-use app, which we call the “Precision Patient Ledger,” designed to remotely collect patient-reported health data from clinically-validated health assessment questionnaires including RAPID3. If the long-term trend of a given condition appears stable, then the value of these data could support the decision to decrease the frequency of clinic visits and thus save the patient time and money while reducing the burden on the clinic. Similarly, for patients experiencing a flare-up of their rheumatoid arthritis at the time of their scheduled visit, a provider may access the historical trend leading up to the present event to better determine whether the current case is an acute flare or a chronic indication of worsening prognosis.
Solution Design and Development

*Design Process.* As our AMIA design challenge solution began without clear stakeholders, our initial task centered on identifying a critical need in precision medicine. Each team member proposed a number of clinical problems conducive to data-driven design solutions. In addition to our chosen design solution using electronic self-reporting for chronic diseases management, we also considered (1) an interactive database to allow oncologists and cancer patients to share information on compassionate drug use, (2) an app to assist community oncologists better predict the development of neutropenic fever in at-risk patients, and (3) an app that suggests FDA-approved drugs for repurposing, specifically when patient tumor genomic profiling identifies alterations in the same cancer pathway that an approved drug targets. We ultimately decided to pursue our chosen design solution after conducting a series of stakeholder interviews with clinicians in rheumatology, general internal medicine, medical oncology, and radiation oncology (see Acknowledgements).

This initial exercise laid the foundation for the software design process best suited to the particular strengths of our team members and the constraints of the challenge at hand. Due to the relatively short timeline, we employed many of the principles of Agile Development Methods as described by Ian Sommerville. This approach to software development is based on iterative and concurrent specification, design, implementation, and testing. Importantly, design documentation is minimized to allow greater focus on delivery of a system that is simple and comprehensible on its own (i.e. clear structure, code, and comments). It also utilizes the principle of “people not process,” whereby the skills of the team members are exploited and each person is left to develop their own ways of working in between weekly meetings without prescriptive procedures. Some additional crucial advantages are accelerated delivery of the highest priority functionality to the user with reduced development effort, early user engagement with prototypes to ensure commitment to the system, and focused validation from stakeholders based on the most important system functionality. The prototype of our current design solution is the fourth iteration in this process, reflecting a progression from initial user interface design, static prototype, functional prototype, and finally our user-validated submission.

*Solution Description.* Our proposed solution is a platform that enables patients to regularly self-report data and allows providers to periodically visualize the aggregated longitudinal data. This is comprised of two components. On the patient side, a mobile app permits simple and convenient self-reporting of a prescribed assessment from home or anywhere the patient has access to a smartphone or computer, between visits to the clinic. Only data that has been validated for clinical utility will be collected, maximizing its potential impact. This data is then uploaded to an access-restricted database such as an existing EHR. The second component is an EHR-integrated app that produces a visualization of the longitudinal patient data for the provider, facilitating quick and intuitive review.

The mobile app will fulfill a number of requirements generated in discussions and feedback from clinicians. In our rheumatology prototype, the question and answer format is taken directly from the standard RAPID3 questionnaire app so as to remain faithful to the clinically validated assessment. The app must be simple enough for a wide range of users, especially those who are not computer literate. Our prototype employs a linear design that guides the user from start to finish through a session with the assessment, with easy-to-navigate labeled buttons. Buttons and text on a smartphone are as large as possible to minimize difficulty for patients with rheumatoid arthritis or poor eyesight. Furthermore, while a number of assessments will be possible with the app, to avoid confusion, only those pertinent to a given user will be presented. In order to promote patient self-reporting, the mobile app will include an optional reminder feature, which will prompt patients to complete assessments at appropriate intervals and at a time they deem most convenient. In addition, the app may ultimately include a visualization for the patient of collected data, a potential incentive for those who are motivated by observing their own progress over time. Finally, the app will incorporate its own layer of security, requiring a PIN or login for each use. This will prevent unauthorized data entry by family members who may also have access to the patient’s smartphone or computer.

The other key component for effective use of patient-generated data is a visualization tool for providers (Figure 1). This will be integrated with the EHR as an app, allowing seamless integration into existing clinical workflows. The visualization tool will have an intuitive display, consisting of data points connected by lines plotted against time. This takes advantage of a familiar and easy-to-interpret format for longitudinal data, making patterns and trends immediately apparent to the human eye. The time scale will be adjustable, allowing the user to zoom in or out depending on the desired time frame. In addition, the plot will be minimally annotated with critical patient care events, such as medication changes and missed doses, recent hospitalizations and surgeries. Such annotation serves two important functions: it can alert a provider to potential issues or conflicts with other concurrent treatments; and
it could allow potential inference of the effect of treatments on the patient’s condition based on associated trends in the data.

Almost all clinicians surveyed did not want automatic notifications when patients complete self-assessments, regardless of the resulting score, as this would impose an undue burden on their time and could also create liability concerns. Accordingly, patient data will be readily available to their provider (or a medical assistant) on an “as-requested” basis, typically during the patient visit or just prior. This brings up the importance of educating patients at the time that self-reported data collection is prescribed. Such training could be carried out by a clinic coordinator, nurse or medical assistant who assigns a PIN, demonstrates the app, and advises the patient that their provider is not regularly monitoring their data between appointments. In this way, the app itself will also emphasize patient-provider shared responsibility, suggesting that patients contact their provider directly in the event of a flare-up of their disease.

Alternative Solutions and Comparison

The current standard practice at OHSU and other clinics that have adopted regular RAPID3 assessments is to have patients complete a pencil-and-paper assessment upon arrival at the clinic. This means that patients’ disease status is reported and collected according to appointment frequency, which typically may only be once every few months. While this data is valuable and has been shown to be clinically useful, it leaves significant gaps in the record of disease progression/regression, and in the worst case such sparse reporting may actually misrepresent a patient’s disease. Currently, RAPID3 assessments are recorded in the EHR, but there is no tool for visualization of aggregate data. Instead, scores are tabulated in flowsheets, which give a less intuitive impression of patterns and trends. Furthermore, “between-visit” self-reporting has been shown not only to improve patient satisfaction with their healthcare, but also improve clinical outcomes. One notable case from medical oncology shows a significant difference in 1-year survival between patients using a computerized self-reporting system for symptoms while undergoing chemotherapy treatment compared to usual care.

We found some examples of existing mobile healthcare apps designed to track chronic disease symptoms. One of these is the Orchestra app, developed by the Collaborative Chronic Care Network housed at the Cincinnati Children’s Hospital Medical Center. This app, designed for young patients with irritable bowel syndrome, is similar to our proposal in concept and purpose, but provides tracking of a much wider range of data, including various symptoms, behaviors such as sleep and diet, and journals. It also incorporates messaging and lab chart review features. While such rich data would likely be very useful for personalizing treatment of chronic disease, it also presents drawbacks to widespread adoption. Such a level of self-reporting would only be met by highly motivated patients, while the time required for meaningful review of such diverse personal data would likely overwhelm most already-busy care providers. Furthermore, the complexity of the app would exclude its use by patients with low
computer literacy. Actual use of Orchestra appears quite low, as evidenced by its “100 Downloads” status in the Google Play Store.

Another chronic symptom-tracking tool that launched this Spring as a pilot program is the myHand app by eTreatMD. This app is designed for patients with osteoarthritis. It uses a smartphone camera to measure joint abnormalities and tracks pain and other symptoms. Unlike our proposed platform, it does not claim to track clinically validated metrics, nor does it appear to be intended for integration with the EHR. Rather, myHand appears to be focused on symptom tracking and management by patients themselves, with the possibility of informal sharing of this information with a doctor.

Implementation and Dissemination

The specific design of the Precision Patient Ledger as a secure mobile application focused on three key principles: 1) accessibility, 2) robust communication, and 3) integration with an EHR system. We pursued a design that leveraged existing, and well-established technology components to expedite implementation, and to ensure compatibility with existing EHR platforms and mobile devices. Additionally, we made overarching design decisions to comply with HIPAA requirements in both the mobile health app, and in the communication pipeline of patient data to the EHR.

Accessibility. A critical aspect of success for any mobile healthcare application is accessibility. We focused on creating a patient facing web-based application (or web app), designed to be compatible with a range of mobile browsers, leveraging the pervasiveness of smartphones and tablets. In addition to standard good user interface design practices, we decided on a number of key design elements important to make our app usable by a wide range of people, including patients with limited manual dexterity, color blindness, or poor eyesight. Our goal was to create a simple, intuitive, and consistent application compatible with many mobile devices. The interface was designed to adhere to the original language of the clinically validated tools, to help limit patient confusion and maintain the consistency and validity of the data entry.

We iterated through a series of interface designs, making improvements to the design based on specific feedback on usability, layout of functional elements (e.g. buttons, slider-bar selectors, etc.), color-scheme choice, and adhering to good UI design best practices. The interface design drafts started with 1) a hand-drawn storyboard, converted to 2) a PowerPoint slide show illustrating key application screen shots, then transferred into 3) a dummy interface using an online prototyping service to create a high-fidelity iPhone app mockup, and then implemented as 4) a functional online web-app (http://precisionpatient.info), compatible with most mobile web browsers. Our final prototype was coded using HTML5-compatible mobile-ready HTML, formatted for both desktop and mobile devices using CSS. The interface widgets (buttons, etc.) used the off-the-shelf JavaScript library components found in the jQuery library (v2.2.4). User credentials validation, data validation, and on-device storage was coded using PHP.

Robust Communication. Mobile healthcare applications that communicate over the internet need to be able to compensate for intermittent network access, while maintaining security of patient data, and compliance with HIPAA requirements. Our application required a few basic network functions, including verification of patient identity, secure communication across an insecure network (i.e. Internet), and deposition of mobile app data into EHR records. We decided to compensate for intermittent network access by creating a secure local database to cache application data until network access is reestablished. To meet our other communication requirements, we used the Fast Healthcare Interoperability Resources (FHIR), which is an emerging standard for exchanging medical information electronically. FHIR has a number of interoperability and communication components that are designed to address our application’s secure communication needs. Moreover, it is a software layer that is independent of any particular EHR system, and can be configured to communicate with any common EHR system typically found in a clinical environment. This gives our mobile app the added benefit of general EHR compatibility, and ensures, technologically speaking, that it could be widely used by the medical community.

Integration with an EHR system. A key design decision for the Precision Patient Ledger was to have direct integration of patient data with their electronic health record. This would provide the clinician with on-demand access of the mobile app data through the EHR software interface via an EHR integrated app.

Evaluation

As part of our agile development methods software design process, we have already initiated the first iteration of evaluation of our design solution. We presented our working prototype for faculty review at the OHSU/VA Rheumatology Grand Rounds on June 1, 2016. Here we elicited both oral and written feedback in the form of a
group discussion and short questionnaire. Much of the oral and free-form written feedback has been incorporated into our design solution as described previously. In response to a directed question on usability, Figure 2 demonstrates that 7 out of 10 rheumatologists would use our app (or something similar) in their clinical practice, and 9 out of 10 were open to the idea so long as an education component was included for older patients and those patients with lower computer literacy. Future evaluation will include patient usability feedback targeting the rheumatoid arthritis population.

**Figure 2.** OHSU Rheumatology faculty responses to the question: “Would you use this app (or something similar) in your clinical practice? Please choose Yes/Maybe/No.”

![Graph showing responses](#)

**Conclusion**

Ubiquitous digital devices afford more frequent, self-administered, and clinically impactful assessment of patient health. Incorporating higher-frequency data collection methods without over-burdening either the patient or provider could significantly impact the quality of decisions made within the clinic towards chronic symptom management. Empowering patients with easy-to-use tools for self-monitoring of their own symptoms may lead to a reduction in unnecessary clinic visitation, improve the quality of information needed to accurately monitor patient symptoms, and increase patient involvement with their own data-driven health.

Obesity Tracker Application: Mobile Health for Obesity in Children

Nattapon Thanintorn, MS¹, Pericles S. Giannaris, MS², Poungkamon Krisanabud, MS³
¹Department of Pathology and Anatomical Sciences, ²Informatics Institute, ³Sinclair School of Nursing
University of Missouri, Columbia, MO

Background
In the United States, the estimated one third of or 12.7 million children and adolescents are obese.² In addition to genetics, behaviors, and environments, adult of household’s education level and low-level income are associated with development of childhood obesity.³ Children are vulnerable and lack an understanding for their healthcare and food consumption provided by parents. It is common that children are diagnosed with obesity at later stage of life. Obese children have increased risks to develop comorbidities, such as cardiovascular disease, hypertension, prediabetes, and musculoskeletal problems.⁴, ⁵, ⁶ Obese children are more likely to be obese adults with lifelong comorbidities. For obesity, it is difficult for clinicians to diagnose if newborns will become overweight or obese due to personalized molecular mechanisms as well as other uncontrollable risk factors.

To reduce and prevent childhood obesity development and comorbidities, integration of mobile technology, advanced technology in clinical systems, and evidence-based guidelines has been introduced to shed some light on better tracking for children growth and more effective communications between healthcare providers and patients. The use of health mobile applications on smartphone contribute to increased physical activity for adults.⁷ Utilizing mobile technology to promote healthcare for obese children and family is promising because cell phones or tablets become one of the necessities in their lives. According to Pew Research Center, in 2013 estimated 37% of children aged between 12 to 17 years have a smartphone. Mobile health application development for children and adolescents to promote interaction between clinicians and patients, healthy behaviors and awareness of their health may contribute to substantially decreased childhood obesity.

However, WHO Anthro, one of the existing tools, is a good example of why we need to provide a solution for the AMIA specific challenge 2016. The tool is designed for healthcare specialists and lacks a communication space for interaction between healthcare providers and patients. The results and visualizations are not intuitive and easily understood by children or adolescents.

Proposed Solutions
In response to the AMIA specific challenge, we propose a mobile application, Obesity Track Application (OTA), that provides i) seamless interaction between providers and children with tendency of obesity development, ii) prediction of obesity development at birth using evidence-based guidelines and electronic health records (EHRs), and iii) visualizations on child’s growth and obesity development progress. The rationale for the proposal is that once children or adolescents understand risk factors and patient-specific explanatory growth chart that narratively depicts level of obesity and comorbidities, resulting in innovative approaches to promote healthier behaviors and prevent obesity development.

For providers, this application will allow them to log in on mobile devices to keep track on patient’s obesity development, receive automatic alerts when body-mass-index z-score substantially exceeds the standard BMI, and provide recommendations to patients. For patients, this application will allow them to engage interaction with clinicians through contact module and visualize their growth chart. In short, this application can facilitate shared patient-provider shared decision making in precision medicine setting and enable monitoring of growth chart and obesity development overtime using mobile technology and EHRs, and provide more self-explanatory displays for child patients.
Design Process
