Welcome Message from the Scientific Program Committee Chair

AMIA 2016 Annual Symposium is the 40th anniversary of the Symposium. On behalf of the 2016 Scientific Program Committee we want this year to be a homecoming that energizes our new and longtime members, welcomes attendees who haven’t visited the meeting in a few years; and attracts first time attendees to the incredible informatics community AMIA represents.

AMIA is multi-disciplinary and interprofessional. We have the best of all worlds when it comes to soliciting and presenting the very best in informatics science and practice. In the rapidly moving world of health and healthcare, informatics innovation is integral to progress. No meeting captures the breadth and depth of informatics better than the AMIA Annual Symposium.

What’s New?

Diversified the SPC leadership and named four AMIA 2016 Vice Chairs: Noemie Elhadad, PhD; Mark Frisse, MD, MS, MBA, FACMI; Andrea Hartzler, PhD; and Madhu Reddy, PhD, FACMI
Unified the foundations and applications tracks to support work that crosses those boundaries
Appointed additional expert leaders to the SPC to manage the review process for more than 1200+ expected submissions
Updated the keywords to reflect the wide range of submitted content
Added option of three keywords per submission to improve the match between the submission topic and the expertise of the reviewers

The Symposium Experience

Sharing scientific discovery and demonstrating best practice and innovation is at the core of the AMIA Symposium experience. But the most unforgettable part of the meeting is the people. Informatics is a specialized field and the Symposium gathers our community of colleagues, peers, mentors, students and leaders for networking and fellowship, collaboration and friendship, and discussion and debate.

Wanda Pratt, PhD, FACMI
University of Washington
Chair, 2016 Scientific Program Committee
2016 AMIA Board of Directors

Officers

Thomas H. Payne, MD, FACMI
University of Washington
Chair

Blackford Middleton, MD, MPH, MSc, FACMI
Apertiva, Inc., and Harvard TH Chan School of Public Health
Past Chair

Titus K. Schleyer, DMD, PhD, FACMI
Treasurer

Eneida A Mendonça, MD, PhD, FACMI, FAAP
University of Wisconsin – Madison
Secretary

Directors

Wendy W. Chapman, PhD, FACMI
University of Utah

Theresa Cullen, MD, MS
Veterans Health Administration

Patricia Dykes, DNSc, MA, RN, FACMI
Brigham and Women’s Hospital

Peter J. Embi, MD, MS, FACMI
The Ohio State University

Cynthia S. Gadd, PhD, FACMI
Vanderbilt University

Gretchen Purcell Jackson, MD, PhD
Vanderbilt University Medical Center

Curtis P. Langlotz, MD, PhD, FACMI, FSIIM
Stanford University

Wanda Pratt, PhD, FACMI
University of Washington

Neil Sarkar, PhD, FACMI
Brown University
Dean F. Sittig, PhD, FACMI, FHIMSS
University of Texas Health Sciences Center at Houston
2013 - 2015

Jessica Tenenbaum, PhD
Duke Translational Medicine Institute

Adam Wright, PhD
Brigham and Women’s Hospital/Harvard Medical School

Ex-Officio Board Members

Suzanne Bakken, RN, PhD, FACMI
American College of Medical Informatics President
Columbia University
2015 - 2016

John T. Finnell, MD
Academic Forum Executive Committee Chair
Regenstrief Institute/Indiana University School of Medicine

Douglas B. Fridsma, MD, PhD, FACP, FACMI
President and CEO, AMIA

Michael Weiner, DO
Industry Advisory Council Chair
IBM

Laura K. Wiley, PhD
Student Working Group Representative
UC Denver Medical Center
AMIA 2016 Scientific Program Committee

Chair
Wanda Pratt, PhD
University of Washington

Vice Chairs
Noemie Elhadad, PhD
Columbia University

Mark Frisse, MD
Vanderbilt University

Andrea Hartzler, PhD
Group Health Research Institute

Madhu Reddy, PhD
Northwestern University

Members
Joanna Abraham, PhD
University of Illinois

Samantha Adams, PhD
Tilburg University

Jessica Ancker, PhD
Weill Cornell Medical College

Uba Backonja, PhD, RN
University of Washington

Sameer Badlani, MD
University of Chicago

Olivier Bodenreider, MD
National Library of Medicine

Sarah Collins, RN, PhD
Partners Healthcare System/Brigham and Women's Hospital/Harvard Medical School

Dina Demner-Fushman, MD
National Library of Medicine

Jason Doctor, PhD
University of Southern California

David Dorr, MD
Oregon Health and Science University

Patricia Dykes, DNSc
Brigham and Women’s Hospital

Hamish S.F. Fraser, MBChB, MRCP, MSc
University of Leeds

Joydeep Ghosh, PhD
University of Texas Austin

David Hanauer, MD, MS
University of Michigan

Christopher Harle, PhD
Indiana University

Jina Huh, PhD
Michigan State University

Cathy Ivory, PhD
Vanderbilt University

Rebecca Crowley Jacobson, MD, MS
University of Pittsburgh

Bonnie Kaplan, PhD
Yale University

David Kaufman, PhD
Arizona State University

Abel Kho, MD
Northwestern University

Pedja Klasnja, PhD
University of Michigan

Paul Kleeberg, MD
Aldedade

Ross Koppel, PhD
University of Pennsylvania

Craig Kuziemsky, PhD
University of Ottawa

Brad Malin, PhD
Vanderbilt University

Benjamin Marlin
University of Massachusetts Amherst

Andrew Mellin, MD
McKesson

Genevieve Melton-Meaux, PhD
University of Minnesota

Casey Overby, PhD
University of Maryland School of Medicine

Adler Perotte, MD
Columbia University

Ari Pollack, MD
Seattle Children's Hospital/University of Washington

Guergana Savova, PhD
Children's Hospital Boston/Harvard Medical School

Katie Siek, PhD
Indiana University

David Sontag, PhD
New York University

Shane Stenner, MD
Vanderbilt University

Jimeng Sun, PhD
Georgia Institute of Technology

Tammy Toscos, PhD
Mirro Center for Research and Innovation

Tiffany Veinot, PhD
University of Michigan

Colin Walsh, MD, MA
Vanderbilt University

Chunhua Weng, PhD
Columbia University

Adam Wilcox, PhD
University of Washington

Lauren Wilcox, PhD
Georgia Institute of Technology

Meliha Yetisgen, PhD
University of Washington

Pierre Zweigenbaum, PhD

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publishers of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in recommended dose or in the contraindication for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
Obtaining a timeline of clinical events described in clinical narratives, even if only classified as historical or current, is very useful for caregivers. To automatically classify clinical events found in clinical notes as happening before, after, or overlapping with the clinical note creation time, we compared a selection of classification machine learning algorithms with a baseline. The highest accuracy measured reached 84.2%.

Introduction

Clinical narratives are rich source of information about the patient’s clinical history, progress and treatment plans marking major clinical events that occur over the course of longitudinal care. Oftentimes, it is crucial for caregivers to obtain a summarized overview of these clinical events, for example in the form of a visual timeline, to assist with making accurate care decisions. By classifying each clinical event mentioned in a clinical document with respect to the document creation time, we can obtain a high-level summarized timeline. These clinical events can be classified into one of four temporal relations to the document creation time: BEFORE (historical events that strictly ended before the document creation time), AFTER (future events that will start after the document creation time), OVERLAP (current events that hold true during the document creation time) and BEFORE/OVERLAP (events that started before the document creation time and continue to the present). Using automated natural language processing techniques combined with supervised machine learning, we evaluate the performance of a wide selection of algorithms and discuss the impact of features and parameters fine-tuning on the final classification accuracy.

Method

The THYME (Temporal Histories of Your Medical Events) corpus for colon cancer patients from Mayo clinic was used in this study. In the context of the 2015 Clinical TempEval competition, each clinical note in the corpus was manually annotated with clinical events and their temporal relations to the document creation time. The corpus was randomly divided into a training set (n=293) and a testing set (n=147). To automatically classify each clinical event temporal relation with the document creation time, we first processed each clinical note with cTAKES to extract lexical, morphological and syntactic features, as shown in Table 1. These features were augmented with additional event attributes (Polarity, Modality, Degree and Type) also provided in the reference standard. Features listed in Table 1 were then extracted for each word annotated as a clinical event in the reference standard, as well as for their surrounding context (local context window of 5 preceding and 5 following words, lemmas, parts of speech tags, and chunks). The Python scikit-learn machine learning toolkit was used with selected number of machine learning algorithms: linear support vector classifier (LinearSVC in scikit-learn), decision tree (DecisionTreeClassifier), random forest (RandomForestClassifier), stochastic gradient descent (SGDClassifier), and naïve Bayes (MultinomialNB). The CRF++ tool was utilized to build a sequence labeling model based on conditional random fields algorithm. All algorithms were trained on the training set and evaluated on the testing set. As baseline, we used the most frequent temporal relation category (i.e., OVERLAP) for all relations. The evaluation metric was accuracy (number of correctly classified instances divided by the total number of instances). Note that accuracy is equivalent to the F1-measure in this case, since all instances must be classified into one of four possible labels.

Results

When evaluated with the held-out testing set, accuracy ranged from 74.4% to 84.2% (Table 2). In general, algorithms performed significantly better when including features from their local context (e.g., SGDClassifier), but a few had a lower or no improvement in accuracy with these features (e.g., RandomForestClassifier). The support
vector machine (LinearSVC) cost of classification parameter $C$ is used to control the complexity of the model and its tendency to overfit (a higher value indicates more overfitting but less error on the training set). Using a grid search algorithm (GridSearchCV) to find the best $C$ value can have determinant effects on algorithm performance, as evidenced when setting $C=0.024$ for the LinearSVC algorithm; which increased accuracy from 81.8% to 84.2%. Similarly, performing grid search for the $\alpha$ parameter in a naïve Bayes (MultinomialNB) algorithm allowed for improved accuracy. The decision tree (DecisionTreeClassifier) algorithm did not benefit from local context features, and the random forest (RandomForestClassifier) performance was even penalized. The latter could be due to the random selection strategy of features that are used to train decision trees on sub-samples from the training data. The final classification is performed by averaging the output labels from the decisions trees in the forest. When poor features are randomly selected for some decision trees in the forest, they tend to affect the final classification decision. When using a feature selection limited to the top 10000 features, the random forest classification improves (indicated with * in Table 2), indicating that this algorithm is sensitive to the feature sets used for training. Note that a sequence labeling classification approach with CRF++ attained high accuracy of 83.3% consistent with previous results reported in a similar task\textsuperscript{3}. All classification algorithms allowed for higher accuracy than our baseline.

### Conclusion

This study showed the importance of local contextual features and algorithm parameters fine-tuning when classifying clinical event relations with the clinical document creation time. The highest accuracy was reached by a support vector machine (LinearSVC) algorithm with a grid search for the best $C$ parameter. This accuracy is higher than previously reported for this task\textsuperscript{4}. We found it useful to work with a machine learning framework like scikit-learn that offers a wide selection of classification algorithms. Future work might focus on utilizing these temporal relations to give a summarized view of a patient clinical events timeline.

### References

Introduction
US healthcare systems are rapidly implementing online patient portals linked to electronic health records (EHRs) in order to meet federal Meaningful Use certification criteria. Specifically, Stage 2 Meaningful Use tied financial incentives to portal access by requiring that 50% of patients be offered online access to their health information and 5% of patients use portal websites at least once. Lagging behind other healthcare systems in patient portal implementation, safety net institutions face particularly large obstacles to widespread adoption, including patient populations with limited health literacy and/or English literacy, limited proficiency with digital technology, concerns about breaches of privacy, and mental health and/or substance use conditions. This is the first study to our knowledge that has explored patient portal implementation at the organizational level among safety net healthcare systems striving to meet Meaningful Use measurement thresholds. Drawing on sociotechnical theories in which technology adoption is conceived as a situated, emergent process of organizational change rather than simply a technical matter, we investigated the strategies used to implement patient portals at clinics that successfully achieved Meaningful Use certification. Our goal was to better understand how Meaningful Use criteria, and the portal tool itself, shaped specific implementation activities and outcomes.

Methods
We used a rapid ethnography approach in order to glean insights about a range of contextual factors, practices, and experiences of administrators, clinicians and staff that were relevant to patient portal implementation and efforts to meet Meaningful Use targets. Between August and October 2015, we conducted 5 site visits with community health centers across California. All 5 sites were engaged in Meaningful Use Stage 2 reporting to increase patient registration and use of their newly launched online patient portal websites. We selected the health centers to represent Northern and Southern California, rural and suburban sites, and a range in size (single clinic to a 10+ clinic organization). Sites also represented both high and moderate success in reaching the two Meaningful Use patient-level benchmarks (i.e., 3 had already met the benchmarks and the other 2 were still working on their attestation process). For 4 of the sites, we conducted 1- to 1.5-day site visits that included in-depth interviews with leaders, informal focus groups with frontline staff, observations of clinic practices for patient portal sign-up, and review of marketing materials and clinic workflows. Unable to arrange a site visit at the 5th clinic, we instead conducted in-depth phone interviews with leaders and frontline staff. Interviews and focus groups were audio-recorded and professionally transcribed, and 3 team members wrote detailed fieldnotes. Data analysis followed the constant comparative method, in which themes were identified through repeated readings of the data and group discussions. Interpretations were further informed by sociotechnical theory’s insights about the interrelatedness of social and technical processes in technology adoption.

Results
All five clinics used an array of strategies to ensure that Meaningful Use thresholds were reached. We found that these efforts fell into three broad domains (see Table for additional findings by domain): 1. Aligning interests: health systems strove to ensure that Meaningful Use requirements were prioritized by stakeholder groups responsible for registering patients for portal use, particularly frontline staff. Implementation efforts focused on (a) promoting the portal to staff and clinicians as a strategy for improving patient care and clinic efficiency and (b) ensuring commitment to patient registration as the primary implementation goal. Patient outreach was often limited to basic information about the portal and assistance with the registration process. 2. Articulating existing clinical work with the demands of the tool: health systems mobilized considerable resources to transform existing clinic workflows in order to routinize portal sign-up and patient message routing. Customizing the portal to make it more usable for staff, clinicians and patients was constrained by the inflexibility of the EHR’s functionalities. 3. Defining success: overall the clinics in our study understood successful implementation to be based on (a) how well enrollment procedures and patient message routing were integrated into clinic work and (b) achievement of Meaningful Use targets. For the most part, success was not contingent on use of the portal by patients, or on the impacts of portal use...
on clinic operations and patient health outcomes. In short, clinic priorities were compatible with Meaningful Use mandates but included limited efforts to enhance the relevance and usability of the portal for patients. Sustained use of the portal by a large proportion of patients was a goal deferred to an unspecified future.

### Discussion

We found that safety net health systems engaged in a diverse array of strategies to ensure a good “fit” between Meaningful Use requirements, patient portal functionalities, and clinic work processes. To a large extent, implementation efforts resulted in the successful achievement of Meaningful Use goals and a belief among clinic staff that the patient portal is a means of improving patient care. However, adoption activities primarily served the goal of increasing patient registration rather than enhancing patients’ skills and motivation to use the portal, or ensuring that the tool is useful, relevant and beneficial to patients. Ultimately, Meaningful Use was achieved without addressing significant mismatches between EHR platforms and the priorities and circumstances of safety net patient populations. Future policies to promote patient engagement with EHRs should a) consider the demographics and needs of safety net populations into consideration; b) require strategies to increase patients’ computer literacy and access to internet-connected devices; c) include incentives for more meaningful outreach and collaboration with patients; and d) ensure that patient portal websites are available in languages other than English.

Deep Learning Recommendation of Treatment from Electronic Data

Melissa Aczon, Ph.D., David Ledbetter, Long Van Ho, Alec Gunny, Randall Wetzel, M.D.
Children’s Hospital Los Angeles, Los Angeles, CA

Introduction

Electronic health records (EHR) containing the medical and treatment histories of patients are collected in hospitals nationwide. Advanced information extraction techniques from the machine learning community increasingly have been applied to these data to provide insights and predictions that help physicians provide the best care to their patients.\textsuperscript{1, 2} In this work, we utilize a Recurrent Neural Network (RNN) to learn a model that can predict the effect of treatments on an individual patient’s vitals and probability of survival. The model enables a clinician to insert a therapy and assess whether the vital and mortality predictions are perturbed in a useful fashion. We use mortality prediction for two primary reasons:

- Mortality is a well-defined, short-term truth that lends itself to an objective assessment of a model’s ability to understand the different correlations amongst the many variables that define a patient.
- The more accurate this function is as a predictor for mortality response, then the more reliable it is as an objective function to optimize when making treatment recommendations.

A novel aspect of this approach is its ability to enable treatment recommendation without an explicit diagnostic step. No explicit clusters of similar patients are made to determine a diagnostic or prognostic significance. In effect, however, clustering of similar patients is implicitly accomplished during model training.

Methods

We leveraged EHR of more than 8,000 patients who were admitted to the Pediatric Intensive Care Unit (PICU) of Children’s Hospital Los Angeles (CHLA) over a period of more than ten years. The recorded data include irregular time series of patient vitals (e.g., heart rate), laboratory measurements (e.g., glucose levels), drugs given (e.g., epinephrine), and interventions (e.g., intubation). Each patient’s PICU encounter also has a well-defined outcome: she either lived or died at the end of her stay.

Figure 1 illustrates a high-level overview of our scheme, where the kernel is an RNN utilizing a Long Short-Term Memory (LSTM) architecture.\textsuperscript{3} Inputs to the network are patient vitals and treatments, while outputs are predictions for probability of survival and a subset of the vitals: heart rate, diastolic blood pressure, systolic blood pressure, respiratory rate, and pulse oximetry.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure1.png}
\caption{Overview of RNN framework applied to CHLA PICU Data}
\end{figure}

The RNN approach is inspired by our view of a patient’s trajectory as a continuous dynamical system that consists of many variables internal to the patient (vitals and labs, denoted by the vector $X_V$) interacting with administered treatments (drugs and interventions, denoted by the vector $X_T$): $d/dtX_V(t) = F[X_V(t), X_T(t)]$. Any finite difference scheme that approximates this continuous system takes on the form

$$X_V(t_{n+1}) = G[X_V(t_n), X_T(t_n), X_V(t_{n-1}), X_T(t_{n-1}), \ldots, X_V(t_{n-k}), X_T(t_{n-k})].$$

The RNN kernel is trained to learn the function $G$ which describes the evolution of patient state from internal and treatment history. In the above equation, $t_n$ denotes the current time, and $t_{n+1}$ is the desired time for a future prediction. The difference, $\Delta t_n = t_{n+1} - t_n$, is an input to the kernel at the current time, along with the associated patient physiologic and treatment data at that time: $[X_V(t_n), X_T(t_n)]$. This set-up is amenable to a real-time scenario where
a clinician would have the ability to insert alternative treatments and specify how far ahead into the future the model makes its predictions. To enable quantitative evaluations of the model’s vitals predictions, $\Delta t_n$ was chosen such that $t_n + \Delta t_n$ corresponds to a time at which recorded measurements are available. In the PICU database, $\Delta t_n$ ranges from minutes to several hours.

A single patient can have multiple encounters, where an encounter is defined as a contiguous time between a patient’s admission into and discharge from the PICU. This is an important point for validation because vitals and treatments can be more highly correlated between encounters of the same patient than one would expect between two distinct patients. When the database was partitioned into training and test sets, multiple encounters of a single patient were not allowed to be separated. This partitioning resulted in a training database with 5831 unique patients spanning 7679 encounters and a test database with 2520 unique patients spanning 3311 encounters.

**Results and Discussion**

The RNN’s model predictions were assessed using ROC AUC at clinically significant hours: [1, 3, 6, 12]. In other words, after observing the patient’s state for $n$ hours, the RNN would predict whether the patient survived or died at the end of their stay. Figure 2a illustrates the model’s performance in mortality predictions on the test set. As the observation window increases there is a corresponding increase in accuracy of the mortality predictions evident in the ROC AUC.

Vital predictions are made for the subsequent timestep which range from a minute to several hours into the future. The mean absolute error over the entire test set is 1.5%. For comparison, a simple forward fill, which can be regarded as a baseline, yields an error of 2.2%. The RNN model reduced the error by 30%. Figure 2b displays predictions for an individual patient (from the holdout set) who died in the PICU. In this particular case, a catastrophic deterioration, from which the patient never recovers, can be seen two days before death.

![ROC Curve](image)

Figure 2: (a) Mortality assessment via Receiver Operating Characteristic curves. (b) Example of vitals and mortality predictions through time for an individual patient.

**Summary**

We utilized recurrent neural networks to generate predictions for vitals and mortality. The RNN-based framework is amenable to real-time scenario simulation: it enables the effects of treatment decisions to be modeled prior to execution. The goal of this work is to build a clinical decision support tool that evaluates the impact of alternative treatments and displays to the clinician those treatments that have the highest probability of positive impact to the patient.

Using data assimilation to forecast post-meal glucose for patients with type 2 diabetes

David Albers1, PhD, Matthew Levine1, BA, Andrew Stuart2, PhD, George Hripcsak1, MD MS, and Lena Mamykina1, PhD

1Department Biomedical Informatics, Columbia University, New York, NY
2Department Computing and Mathematical Sciences, Caltech, Pasadena, CA

Introduction

Type 2 diabetes (T2D) is a disease with dire consequences if not treated to minimize its effects, is costly ($245 billion a year in 2012), and is prevalent, affecting over 8% of the US population [1]. Treatment of T2D relies primarily on self-management of nutrition, exercise, and medication and is highly dependent on the individual. While there exists general guidelines for healthy eating, each individual with diabetes must find their own way to translate these guidelines into daily meal choices [2]. This is usually accomplished through a lengthy, often complex and opaque, trial and error process in which individuals experiment with different foods and observe their impact on blood glucose levels. As is the case with many complex nonlinear processes, humans are not well suited to finding optimal solutions that are context-specific and personalized without machine-based support. The methodology we use here, data assimilation (DA) [3], is data-science technique used in a wide range of applications, e.g., weather forecasting or aerospace engineering. Data assimilation marries data with human knowledge encoded in mechanistic models, personalizes model parameters, and makes a real-time forecast based on the model and the data. In applications where data are sparse and the system is nonstationary, data assimilation overcomes data-quality problems by leveraging knowledge encoded in mechanistic models. DA, through the continuous personalization of mechanistic glucose/insulin models, computes nutrition and glucose-based post-meal glucose forecasts, creating a quantitative, real-time link between nutrition choice and blood glucose.

Methods

We prospectively collected at least 21 days of nutrition and blood glucose data from patients in a T2D intervention study. The data were collected using the Mealzer mobile application and constrained to realistic T2D outpatient data collecting: sparse finger prick glucose measurements before and after meals and pictures of meals whose nutrition content was estimated by trained nutritionists. We then selected two mechanistic endocrine models, a relatively simple ultradian model [4] and a complex meal model [5] with detailed modeling of metabolism. Both models can take blood glucose, insulin, and carbohydrates as input variables, have between 6 and 12 state variables including plasma glucose and insulin and have between 30 and 70 other physiologic parameters. We use several DAs to integrate data with models, including a dual unscented Kalman filter (UKF) [6], particle filters, and other inverse-problem Bayesian methods [3]. Using the patient data and the DA, we generate personalized, real-time nutrition-based post-meal glucose forecast for both models. To evaluate which model performed better, we use both mean squared error (MSE) of the model forecast compared to training set and improved with more accurate nutrition estimates, but forecasting a given post-meal glucose value was relatively insensitive to nutrition estimate accuracy. Finally, careful off-line parameter estimation yielded more accurate forecasts.

Results

Within 20-30 meals both models personalized and converged to the individual patients, and both models forecasted post-meal glucose well, cf. Fig. 1. The ultradian model minimized the MSE while the meal model minimized the KL divergence between kernel density estimate of the measured and forecasted glucose densities. The disagreement between these model evaluation metrics has a clinical implication: model evaluation metrics must be chosen to maximize accuracy relative to a clinical goal, such as resolving mean glucose. We also found the models to be sensitive to nutrition estimate: personalizing the model parameters required a consistent training set and improved with more accurate nutrition estimates, but forecasting a given post-meal glucose value was relatively insensitive to nutrition estimate accuracy. Finally, careful off-line parameter estimation yielded more accurate forecasts.

Conclusion

Data assimilation methods, even with limited training, can provide accurate, personalized, nutrition-based glucose forecasts in real time. While both models personalized to the individual, they provide different “optimal” knowledge; further research is needed to determine which knowledge type is more relevant to promote individual decision-making in diabetes. Given the number of mechanistic glucose models available [8], we must evaluate which model will be of greatest potential impact, subject to an evaluation metric chosen to yield the best self-care-based outcome. Model parameter estimation --- personalization and adaptation of the model --- is best done using consistently sourced and accurate nutrition information to put the DA into the right parameter region, but the real-time nutrition estimate used to forecast a post-meal glucose can have substantial error and remain accurate. Because of these conclusions, we are hopeful that DA can be used to personalize nutrition-based, post-meal glucose forecasts, allowing individuals with T2D to make informed nutrition choices based on real-time glucose forecasts.

Figure 1: The blood glucose measurements and the data assimilation based real-time continuous glucose and on-measurement blood glucose forecasts for days 1-5 and 20-25 for the ultradian model (top) and the meal model (bottom). As more measurements are accumulated, the data assimilator adjusts the parameters given the individual’s data allowing for more accurate forecasts as more measurements are accumulated as can be seen by comparing the left and right plots.
A Terminology Framework for Nursing Documentation Redesign

Deborah Ariosto, PhD, MSN, RN
Vanderbilt University Medical Center, Nashville, TN

Abstract

**Background:** In response to nurse staffing ratio changes, an initiative to decrease time spent documenting was launched. **Methodology:** Informaticists and clinical staff redesigned documentation using the Clinical Care Classification System\(^1\) for a problem based, modified charting by exception approach. **Results:** A 30% decrease in volume charted contributed to successful adoption and high nurse satisfaction. **Discussion:** Staff nurse involvement guided by a terminology framework reflective of professional practice model\(^2\) shaped a better product than either could alone.

Introduction

Nurses are the primary caregivers in inpatient settings. Studies report that much more time is spent documenting than delivering care\(^3\). In response to staffing ratio changes, at a large southeastern academic medical center, a team of clinicians and industrial engineers were deployed to observe and interview nursing staff to identify opportunities to save nursing staff time. Top priorities identified by staff nurses were unnecessary/redundant documentation, finding equipment, and better communication with the care team. In 2014, executive leadership endorsed the formation of cross enterprise clinical workgroups to address these priorities. This presentation focuses on the methodology applied to a highly successful documentation reduction initiative completed and rolled out in 2015 across both the adult and pediatric populations.

Methodology

Over fifty clinical staff from acute and critical care in both the adult and pediatric hospitals was challenged to standardize and simplify nursing documentation. Exclusions included Obstetrics, Neonates, and Psychiatry. A representative core group of nurses met weekly to shape a common documentation model using a terminology framework that reflected professional nursing practice endorsed by the American Nurses Association\(^1\).

The Clinical Care Classification System (CCC) was used to organize nursing care concepts and compress into 15 Care Categories to create a high level framework for nursing centric problems (e.g. acute pain, confusion, injury risk), interventions, and goal setting. SNOMED CT\(^4\) concept matching was used to standardize symptoms and intervention detail. Free text narrative statements captured the overall patient response to care and communication/event notes.

Other strategies included a modified charting by exception approach and elimination of most copy/paste functions. Assessments auto-populated the plan of care and easily visualized the daily progress toward problem resolution. Documentation focused diagnosing problems, implementing and evaluating patient response to the plan of care. Documentation that did not reflect this professional practice model or support high value decision support was discouraged.
Results

Several pre/post evaluation approaches were utilized. Timed classroom simulations by clinical staff showed on average, a 25 minute reduction in time spent documenting. Real-time documentation of nursing care on pilot units also showed on average, 25 fewer minutes spent documenting. In addition, the overall volume of data documented per patient per day decreased by 30% overall when comparing January 2015 (pre-implementation) to January 2016 (post-implementation). The graph below shows the relative changes in documentation by adult and pediatric populations.

Discussion

Staff has had an overwhelmingly positive response in that they have more time to spend with their patients and take needed breaks. Rounding during implementation reassured leaders of the value of their investment in staff time and resources and gave staff an opportunity to show their work and tell their stories. One poignant story shared was: “I can take my toddler off the ventilator and sit with him, and let him be a child again.”

Providing nurses with a nursing terminology framework that they could shape and own was key. While the informaticists knows the value of standards for data re-use, interoperability, decision support, and system stability, the clinician knows their own practice and unit needs. Working together, documentation re-design achieved both goals.

³National Institute for Occupational Safety and Health/CDC, Cincinnati, OH and Morgantown, WV
⁴Yale University, New Haven, CT, USA

Introduction
Although primary care providers are usually the first to see patients with medical issues such as asthma symptoms that may be caused by workplace exposures, they do not routinely ask patients about their work ¹⁻⁵. Occupational health physicians have developed evidence-based guidelines for helping to manage many such patients, but primary care providers are rarely aware of their existence⁶. Though computerized clinical decision support (CDS) holds potential for increasing awareness and providing guidance, it must be developed and implemented to fit the context and workflow of those who would benefit from having the information⁷.

This qualitative evaluation project was part of a larger project funded by the National Institute for Occupational Safety and Health (NIOSH) of the Centers for Disease Control and Prevention. The NIOSH project is designing, developing, and piloting CDS for the health of working patients in primary care outpatient settings. The first step in this project was the development of three knowledge resources (KRs) containing evidence-based information, decision logic, scenarios and examples of use. The KRs were prepared by three subject matter expert (SME) groups for three topics that are related to the health of patients who work and considered especially pertinent to a primary care practice. The three KRs focused on dealing with work environment factors that impact the management of a chronic disease (diabetes), guidance for return-to-work after lower back pain diagnosis not related to work, and diagnosis and management of work-related/work-exacerbated asthma.

The goal of this qualitative study is to identify the barriers and facilitators related to CDS for the clinical management of working patients in a variety of primary care settings, including assessment of the technical and organizational feasibility of implementing the CDS represented by each KR.

Methods
We used the Rapid Assessment Process (RAP), as previously described⁸, for studying five organizations, though we adapted it to include graphical elicitation interviews⁹ to evaluate the KRs. Institutional review boards (IRBs) at NIOSH and OHSU and each clinical site with an IRB approved or reviewed the study. Sites were selected for diversity in size, geography, organization, and electronic health record (EHR) product used. We selected subjects based on their roles. Data collection consisted of semi-structured and graphical elicitation interviews⁹ and observations in clinics. Broad areas for exploration included 1) present CDS, 2) clinic and individual workflow, 3) information already available to help manage care of working patients, such as the patient’s work information, 4) barriers and facilitators of CDS for the clinical management of working patients, and 5) evaluation of the three KRs. Both template and grounded hermeneutic methods were used for analyzing data¹⁰⁻¹¹.

Results
We conducted five site visits between July 21st and September 11th, 2015. We interviewed 41 clinicians not deeply involved in informatics, 23 individuals who were informaticians or information technology specialists, 15 managers or staff members, and four quality improvement specialists, for a total of 83 interviews. We spent 30 hours observing in ten clinics. Template analysis of data pertaining to the three KRs gathered during graphic elicitation interviews yielded valuable content and context-related information for developers and implementers. Figure 1 includes the themes and subthemes that emanated from the hermeneutic analysis, grouped as facilitators and barriers. The main themes are of equal importance for acceptance of the proposed CDS, while the subthemes vary in strength of importance and specific relevance to worker health CDS.
Figure 1. Facilitators and barriers to worker health CDS

Discussion and Conclusion
Using a qualitative approach which adapted RAP to evaluate three knowledge resources related to clinical management of working patients, we identified themes representing both barriers and facilitators that can be considered as the CDS is further developed and implemented. While some of these factors are similar to those discovered in prior CDS research, others, such as changing work patterns and roles and the sensitivities and complexities of work-related information, are novel and deserve further investigation.

Translating Hereditary and Familial Cancer Guidelines into Clinical Decision Support

Ayesha Aziz, PhD,1 Lance Pflieger,2 Bryce Carter,2 Joshua Schiffman, MD,2 Brandon M. Welch, MS, PhD1

1Medical University of South Carolina, Charleston, SC, 2University of Utah, Salt Lake City, UT

Abstract:
Family Health History (FHx) is one of the most important cancer risk factor. To develop effective evidence-based CDS tools for hereditary and familial cancer, there is a need to translate knowledge from cancer guidelines into computable CDS knowledgebase. We conducted a systematic analysis of available familial and hereditary cancer guidelines to identify gaps in published guidelines, and challenges in informatics standards and terminologies that would impede the ability to implement these guidelines as standard-based CDS.

Introduction
A family history (FHx) of cancer is a major contributor to one’s risk for cancer. For a clinician, a complete and accurate FHx helps to identify a patient’s cancer risk and initiate risk-reducing strategies at an earlier stage. A number of recognized medical and government bodies (e.g. U.S. Preventive Services Task Force, National Comprehensive Cancer Network, American Cancer Society) have published cancer care and prevention guidelines that incorporate family history of cancer. While collection of family health history from patients has traditionally been sub-optimal,1 current efforts in health IT are expanding the ability to collect a patient’s structured family health history. Notably, HL7 developed and published a pedigree model with the aim of representing FHx in a detailed format.2 Additionally, Meaningful Use Stage II guidelines include FHx as an optional menu set item for electronic health record certification.3 As a result, EHRs, researchers, and vendors are also developing informatics tools to improve the collection of a structured FHx.4 With a patient’s FHx information more readily available, the opportunity exists to translate established cancer guidelines related to family cancer into computable clinical decision support and implemented within FHx tools. While there have been previous efforts to implement family cancer guidelines in CDS, these efforts were built upon proprietary systems and limited to a single guideline and a single cancer use case (e.g. breast cancer).5,6 Moreover, these implementations lacked compliance with the current health IT standards and terminologies, and provided no mechanism of updating the CDS knowledgebase as improvements in the published guidelines became available. Therefore, given the opportunity to deploy cancer guidelines on new, state-of-the-art FHx collection approaches, we conducted a systematic analysis of cancer guidelines that could use FHx information. We sought to (1) assess the feasibility of converting currently available guidelines into standards-based CDS, (2) identify gaps in informatics standards and terminologies, and (3) highlight challenges within current guidelines that limit their ability to be implemented. To our knowledge, this is the first systematic analysis of hereditary and familial cancer guidelines that assess ability to be implemented in standards-based CDS.

Methods
We identified a set of 20 professional, advocacy, medical, and government organizations that publish guidelines for eight cancers with common heritable and familial risks. Using pre-specified search terms, we identified logical (IF.. THEN..) statements related to cancer in the family. Independent reviewers (AA and LP) who are specialized in Biomedical informatics and computerized clinical decision support conducted the review. For each statement, content analysis was conducted to determine if the statement could be represented using current Meaningful Use stage 2 FHx health IT standards, which include the full HL7v3 pedigree model, HL7v3 pedigree model limited (first degree relatives only), SNOMED full, SNOMED limited (first degree relatives only). We identified whether or not an existing statement can be recorded as structured data for each standard. Assessments of each standard were reported as either (1) explicit or derivable, (2) conditional to fuzzy terms in the guideline, (3) not explicit or derivable, (4) conditional to fuzzy terms and not explicit, or (5) uninformative statements. After each independent reviewer completed their initial analysis, assessments were compared. Disagreements in assignment were discussed and consensus was built by the reviewers with assistance from an additional reviewer/mediator (BW).
Results
We identified a total of 78 guidelines that included statements or recommendations meeting our inclusion criteria. A total of 589 statements were selected for analysis. Out of these statements, Breast, colorectal and ovarian cancer represented roughly half of the total number of statements studied. The analysis revealed that only about 60% of statements derived from the selected guidelines could be implemented using HL7 pedigree model and less than 50% could be implemented using current meaningful use stage 2 standards. The discrepancies between guidelines and standards result from (1) gaps in data model or terminologies, and/or (2) inadequate or poorly represented guidelines (e.g. inadequate or ambiguous definitions). A more detailed description of these discrepancies will be described during the podium presentation.

Discussion
This systematic analysis identified significant gaps that would impede the ability to implement these guidelines as standard-based CDS. Some of the issues could be resolved if the guidelines included more clear or explicit definitions. Other issues could be resolved if the data models or terminologies were improved. The guidelines could be improved if the developers explicitly defining terms such that they can be properly implemented. For example, in several guidelines the phrase ‘strong family history of {disease}’ was used with no clear definition as to which relatives are included or what qualifies as ‘strong’. This issue is not limited to cancer family history guidelines, rather is a common issue faced by CDS knowledge engineers.7 Gaps in implementation vary by the health IT standards used. The full HL7 pedigree model provides the most complete coverage, whereas the minimum requirements using SNOMED CT and first degree relatives as set forth by Meaningful Use Stage II, provides the least guideline coverage. Nevertheless, most guidelines could be implemented if definitions are created and/or data models and terminologies are extended. Therefore, results from this work can be used to inform guideline developing organizations and standards organizations. The systematic method for assessing cancer guidelines could be utilized for other clinical domains.

Evolution of an integrated Patient & Population Analytics Portal (iP3)

University of Illinois at Chicago, IL 60612

Abstract
Effective care coordination especially when managing complex populations requires partnerships of multidisciplinary teams, physicians, specialists, pharmacists, care organizations, payers and institutions. Another requirement for a successful model is to have effective data integration and analytics platform. In this presentation, we intend to share our experiences and evolution of an integrated patient analytics portal for management of The University of Illinois CHECK (Coordination of Healthcare for Complex Kids) project, which aims to create and test a “medical neighborhood” comprised of over 40 practices in Cook County. The program intends to target 6,000 children with complex conditions. We established a centralized data warehouse to accumulate and process clinical, claims, assessment, engagement and school data that provide systemic insights into the program and aid in meeting program’s aims while managing risks and overcoming significant people, process and technology related challenges. We present our methodology of mapping program goals to analytics goals that eventually led to creation of the portal iP3, an Integrated Patient & Population Analytics Portal that can be generalized for future healthcare research studies.

Introduction
CHECK (Coordination of Health Care for Complex Kids) is designed as a model that improves care for populations with specialized needs, with a focus on the specific priority area of high-cost pediatric and young adult populations. Specifically CHECK aims to: 1) to reduce both inpatient admissions and emergency room visits, 2) to reduce missed school days and, 3) to increase patient satisfaction, engagement that will eventually reduce healthcare costs. To accomplish these goals, UI Health partnered with multiple community primary health care providers, community mental health providers, community dental health providers and social services providers. Data from over 10 disparate sources needed to be collected and transformed at UIC’s centralized warehouse to a) Perform ETL on Medicaid Claims from multiple care organizations, Clinical EMR data from multiple provider organizations, Assessment data from RedCap and Third Party tools, Engagement Touches from Care Coordinators, Patient Communication logs and Public School data, b) Develop Risk/Eligibility Criteria to identify eligible patient cohorts, c) Track ongoing enrollment and disenrollment process, d) Facilitate data exchange to enable assessments performed by a third party, e) Monitor the financial impact of the program continuously in form of PMPM and Service Utilizations across targeted diseases and encounter types, f) Create integrated patient analytics portal for program leadership to facilitate monitoring and decision-making based on financial and clinical indices and g) Identify Bright Spots where CHECK is making the greatest impact.

Methodology
To meet program goals and design iP3, our informatics team worked closely with various stakeholders from executive management, community services management, clinical leadership, mental health and dental professionals, third party outreach & assessment centers and Centers for Medicare & Medicaid Services (CMS). Each stakeholder viewed the program and its aims through the prism of their domain that added complexity to defining metrics, informatics goals that will eventually lead to reports and visualizations for consumption by different audiences. We established systematic processes to engage multiple stakeholders to avoid duplication of efforts and bring everyone to a common platform. We mapped the program aims to measurable outcomes and identified the required data elements. From identifying data sources for required data elements to establishing ETL processes with numerous MCOs to developing coherent view of the patient across all MCOs, the whole process was executed by breaking down program’s functions into separate groups that eventually led to nominating functional owners of both Clinical and Informatics domains.

Result and Discussion
In this presentation, we glanced over our methodology to design an integrated Patient & Population Analytics Portal (iP3) that involved handling vast amount of heterogeneous disparate data. As of today, iP3
allows CHECK leadership to perform these activities in real-time - Identify potential cohort for the program based on one of many available Risk Stratification algorithm such as NYU ED & UCSD CDPS, create population profiles based on Medicaid Costs distributions such as PMPM (Per Member Per Month) and service utilization per 1000 across various primary diseases, time series analysis of engaged population costs. iP3 used geo-mapping techniques to visualize CHECK population across various stages of engagement, diseases, risk score across various zip codes within Chicago areas to identify potential disease concentration based on environmental factors of the neighborhood and to understand healthcare accessibility based on the potential distance between the patient and the care. Next logical step for iP3 would be doing predictive analytics to identify high-risk patients early on during the patient engagement stage and develop real-time mechanism for community health worker to get up to the minute information of unexpected hospitalizations directly from the hospital of their assigned patients. iP3 is at an exciting place where opportunities are limitless but to navigate substantial risks and challenges successfully we will continue improving our methodology and processes to materialize those opportunities.

Introduction

Background Extension for Community Health Care Outcomes (ECHO) Project is a novel and groundbreaking way of utilizing telemedicine technologies to deliver care and education to rural and underserved areas1. By definition, Project ECHO strives to reduce health care disparities between urban and rural regions by providing evidence-based and state-of-the-art medical education and mentoring to rural providers. Show-Me ECHO Project is a replication of the Project ECHO introduced by Dr. Sanjeev Arora in 2003 at the University of New Mexico2. The Show-Me ECHO project was initiated in November of 2014 with two pilots – autism and chronic pain management. Following the state appropriation of $1.5 million, four other ECHO projects started in July of 2015: endocrinology, dermatology, hepatitis C, and pediatric asthma. Show-Me ECHO is a partnership between an academic medical center – University of Missouri (MU), Missouri Primary Care Association (MPCA), and the State of Missouri, formed to address the lack of specialty care in rural Missouri.

Objective We sought to examine how the ECHO project can potentially influence changes in self-efficacy among primary care providers (PCPs). Provider self-efficacy may be linked to both provider and patient behavior change, patient compliance, and patient outcomes

Methods

Design This was a cross-sectional study of participating providers, which was a part of the Show-Me ECHO required program evaluation. It was a pre-post study that included the same participants, as the repeated cross-sectional surveys provide useful information regarding trends over a period of time3. Participating providers were asked to complete a 14-question self-efficacy survey prior to attending a Show-Me ENDO ECHO first block, and again after their participation. The survey was divided into three sections: 1) confidence in screening for diabetes, 2) confidence in medication and treatment for diabetes, and 3) confidence in patient education.

Setting Program evaluation took place at the University of Missouri from September 2015 – November 2015. The hub team of specialists was located at the University of Missouri, while participating providers at spoke sites were from different regions of the state (Picture 1).

Interventions Weekly 1.5 hour sessions were offered via telehealth to participating providers across the state. Each session was made up of two parts – a case presentation by a participating primary care provider, and a continuing medical education (CME) - approved didactic presentation. Case presentations were done in a de-identified format. The didactic portion of the fall 2015 sessions consisted of the initial “Introduction to ENDO ECHO” session, followed by three blocks: a) thyroid block, b) diabetes block 1, and c) diabetes block 2.

Main outcomes measurement Since the Show-Me ECHO project is in its infancy, at this stage of program evaluation we are not able to analyze provider and patient behavior changes and full impact of ENDO ECHO on Missouri communities. In partnership with the MU Office of Social and Economic Data Analysis (OSEDA), we will analyze the MO HealthNet (Missouri Medicaid) claims data: PCP prescription patterns, emergency department visit costs, diagnosis codes, patient geographic region, HEDIS codes, and outpatient visit costs. Self-efficacy surveys were collected and managed using the REDCap electronic data capture tool hosted by School of Medicine at MU4. Tableau was used to analyze the data5.
Results:
During the Fall 2015 ENDO ECHO block there was a total of 12 sessions with 12 CME-approved didactics. ENDO ECHO was attended by 34 unique attendees, of which 9 active case presenters presented 34 cases. Self-efficacy survey was completed by 44%. The small response rate may be attributed to the fact that participating providers did not receive personalized invitations to participate, and that there were no incentives provided for participation, which are known strategies used to increase rather low healthcare research responses. Overall, self-efficacy increased for all participants. However, in some individual cases it decreased for participating PCPs. The authors associate the decrease of self-efficacy with overestimating one’s knowledge prior to attending educational sessions and subsequently realizing gaps in knowledge. Figure 1 indicates participating PCPs’ reasons for attending ENDO ECHO sessions. The highest increase in overall self-efficacy was in initiating and prescribing insulin injections to patients (pre self-efficacy score was 68.40, post 85.00). The smallest overall increase was in advising self-monitoring of blood glucose (from 78.80 to 82.25). Individual participants indicated decrease in self-efficacy in identification of patients that need screening for diabetes (from 100 to 90), screening patients for neuropathy (from 74 to 56), and cardiac problems (from 70 to 50).

![Image](picture1.png)  
**Picture 1: ECHO ENDO Session**

![Image](figure1.png)  
**Figure 1: Reasons for joining ENDO ECHO**

Discussion:
ENDO ECHO uses disruptive innovation technologies to deliver specialty care and education to rural communities. Disruptive innovation technologies utilize existing technologies, in this instance telehealth, to enhance patient care, PCP’s education, and access to care with minimal or no additional cost⁶. Continuous program evaluation is necessary to ensure the success of the project. Provider self-efficacy surveys were instrumental in providing the specialty hub team with information necessary to create a successful didactic curriculum. In other words, topics with either increase or decrease in self-efficacy were reviewed and additional lectures on those topics were provided, as they were indication that more knowledge in those areas might be needed. MO HealthNet (Missouri Medicaid) claims data will be utilized to tailor the didactic sessions to the needs of the providers, but also to target recruitment of Missouri providers for ENDO ECHO and Show-me ECHO.

Little Impact of Highly Specific Alerts for Potassium-Increasing Drug-Drug Interactions — A Randomized Controlled Trial

Jürg Blaser, PhD1, Patrick E. Beeler, MD1, Markus Schneemann, MD2, Emmanuel Eschmann, MD1

1Research Centre for Medical Informatics, University Hospital, Zurich, Switzerland; 2Division of Internal Medicine, University Hospital, Zurich, Switzerland

Introduction

Drug-drug interaction (DDI) alerts are often overridden due to their low specificity. Approaches addressing this issue include (a) focusing on high-priority DDIs, (b) enhancing alerts by displaying critical laboratory data, (c) considering patient data in order to suppress unspecific alerts, (d) timing of alerts (i.e. when an adverse reaction becomes evident or when a DDI is insufficiently monitored, as opposed to systematic alerts at the point of medication order entry), and (e) removing alerts when the triggering conditions are no longer met. However, most DDI alerts focus on a selection of only a few of these approaches and clinical studies evaluating their impact revealed poor adherence and low appropriateness of overrides.

Therefore, we combined all approaches and applied the resulting concept to potassium (K⁺)-increasing DDIs, the most important high-priority DDI at our hospital. The purpose of the study was to determine the effect of this enhanced concept on both process parameters and clinical outcome.

Methods

The study was a cluster randomized controlled trial. All inpatient clinics of the University Hospital Zurich, a teaching hospital in Switzerland with 37,000 inpatient stays per year, were assigned to the intervention or control group. We used replacement randomization, controlling for the frequency of K⁺-increasing DDIs and insufficient K⁺ monitoring. The intervention period lasted one year, starting from 1/7/2014. Data collected during stays in intensive care units were excluded since electronic order entry is not provided in these units.

Both, at onset of and during K⁺-increasing DDIs, the physicians of the intervention group were (i) reminded to monitor the serum K⁺ (if current K⁺ unknown and no K⁺ level measurement ordered), (ii) alerted of the risk for hyperkalemia (most recent serum K⁺ ≥4.9mEq/l and <5.5mEq/l), and (iii) alerted of hyperkalemia (serum K⁺ ≥5.5mEq/l). Alerts and reminders were only displayed as long as the triggering conditions were met. The alerts displayed the prescribed K⁺-increasing drugs, the most recent serum K⁺ level, the glomerular filtration rate and included detailed advice. All reminders and alerts were non-interruptive. They were calculated and logged for all patients, but were only displayed in the electronic health records of the intervention group.

The predefined primary endpoint for assessing the impact of the intervention was the frequency of prolonged K⁺-monitoring intervals during DDI-periods, defined as >72h-periods without K⁺-monitoring. Secondary endpoints of the study included the occurrences of hyperkalemia or deaths during DDIs and the median length of the K⁺-monitoring intervals during DDIs.

Wilcoxon rank sum tests, chi-square tests, and Fisher’s exact tests were used for statistics; p values of ≤0.05 were considered statistically significant.

Results

We analyzed data of 15,272 inpatients in the intervention group and of 18,981 in the control group, including a total of 922,121 drug orders resulting in 2,057 and 2,804 K⁺-increasing DDIs in the intervention and control group, respectively. In the intervention group 869 reminders to monitor K⁺ (1 per 3.2 K⁺-increasing DDIs), 356 alerts of the risk for hyperkalemia (1 per 7.9 DDIs), and 62 hyperkalemia alerts (1 per 45 DDIs) were displayed.

No benefit could be seen with respect to both clinical endpoints: Hyperkalemia occurred during 50 of 2,196 K⁺-increasing DDIs (2.28%) in the intervention group compared to 27 of 1,610 (1.68%) in the control group. The death rate observed in the intervention group was 1.17% (22/1,876) compared to 0.96% (14/1,465) in the control group. No patient died during or within 48 h of a hyperkalemia following a therapy with a K⁺-increasing DDI.
The primary endpoint analysis showed that the frequency of insufficiently monitored DDI-periods was not lower in the intervention group (451 of 9,686 periods >72h; 4.66%) compared to the control group (246 of 6140; 4.06%). In contrast, a statistically significant difference was observed for one secondary endpoint: The length of the K+-monitoring intervals during DDIs was slightly shorter in the intervention group (median 20.3 h) compared to the control group (22.1 h; p<0.001).

**Discussion**

We implemented a highly specific alert concept in order to improve patient safety during K+-increasing DDIs while minimizing the risk of overriding and alert fatigue. However, the randomized controlled trial showed no impact on poorly monitored DDIs and no reduction of hyperkalemia events or death rates. The modest reduction of the median length of the K+-monitoring intervals during DDIs bears little clinical significance.

Not much evidence has been gathered so far for documenting significant clinical benefit of decision support interventions warning for potentially harmful DDIs at the time of order entry. In our study, however, even a sophisticated clinical decision support effort was not successful to improve patient safety regarding the most critical high-priority DDI at our institution.
Linking patients with non-PHI data

Luca Bonomi¹, Xiaoqian Jiang¹
¹ University of California San Diego, La Jolla, CA 92093

Abstract

Patient linkage is important for medical data integration and analysis. Traditionally, this critical step is conducted using protected health information (PHI). We demonstrated that it is possible to link patients with non-PHI data. Our novel model for temporal pattern linkage offers an alternative solution when PHIs are not available and can also serve as a powerful complement to existing PHI-based solutions to break the ties (when limited PHIs lead to ambiguities).

1 Introduction

The medical information systems have undergone significant improvement making it possible to collect various kinds of healthcare data. However, the healthcare data are often fragmented, making the task of reconstructing patient information very challenging. In this work, we proposed a novel method for patients linkage to support Electronic Health Records (EHR) data integration from different sources. Our model takes advantage of the temporal pattern in patients’ non-PHI data (e.g. diagnoses) to link the patient’s complete diagnostic pathway across multiple institutions.

2 Related work

A first step toward the data integration of EHR records consists of extracting useful knowledge form the longitudinal patients data. The authors in⁴ proposed several data mining techniques to predict relationships across diseases. In the traditional database community, a variety works have been proposed to linkage temporal records. Typically, the similarity between two records is computed based on attribute value similarities. However, if entities evolve over time, attributes that subject to change become less reliable indicators for record matching. Thus a temporal model is often constructed to learn how entities evolve over time which determines the weight of each attribute in the matching step. However, these solutions are not very robust to noise and missing data making them not suitable in our setting.

3 Methodology

Our goal is to enable patients linkage using non-PHI data across EHR databases. However, these data (e.g. diagnoses, lab test results) change over time, may be subject to noise, and in general are very sparse, thus, classic record linkage solutions may not be effective. Therefore, we propose a novel technique for linking patients using the similarity between their longitudinal data. Specifically, we model the patients longitudinal data, in our case diagnoses, into sequence, named patients diagnostic pathways. In our approach, we assume that a set $T$, containing the complete diagnostic pathways for some known patients, is given in input. Then, we use this training set to learn the parameters of our similarity model which are used to link a set of new patients (i.e. test set). For each patient in the test set, we randomly divide his/her diagnostic pathway $Z = X \odot Y$ and create two datasets $X \in D_1$ and $Y \in D_2$. Our goal is to link these datasets and reconstruct the original patients diagnostic pathways.

Pathways Linkage Scoring. In linking the patient’s longitudinal data, we consider a linkage score for each candidate pathway $Z = X \odot Y$, where higher scores imply higher chances for $X$ and $Y$ to match. Hence, $Z$ represents the same patient’s data evolution. In determining the linkage score, we consider two components. First, we evaluate the similarity in terms of shared subsequences (i.e. patterns) of the pathway $Z$ with the single patient pathways in the training set $T$. In fact, if we observe common temporal patterns between $Z$ and the sequences in $T$, this gives us a good indication that the pathways $X$ and $Y$ refer to the same user. We call this component the temporal agreement score for the candidate pathway $Z$. Second, patient’s attribute values may change over time. For example, a patient may receive a set of diagnoses that might change due to the disease evolution. Therefore, we consider a temporal disagreement score which measures this variation within the sequence. To evaluate this disagreement, we introduce a function that combines both the temporal and set-based between the observations within the pathway $Z$. This measure
is motivated by the concept of temporal locality, that is, if a time point a diagnose is observed, then it is likely that the same diagnose is observed in the near future. Then, our final linkage score $lScore(X,Y)$, combines both the diagnostic pathways temporal agreement and disagreement.

4  Experiment and results

Data. We conduct our experiments on two real-world datasets: MIMIC-III, and UCSD. MIMIC-III is a de-identified dataset which comprises over 58,000 hospital admissions for 38,645 adults and 7,875 neonates. The data spans June 2001 - October 2012. UCSD dataset contains the patients admissions between January 2007 and December 2012 for a total of 41,730 patients in the hospital at UCSD. In our evaluations, we construct the diagnostic pathways of each patient using the information regarding the diagnoses and time recorded at hospital admission in each dataset. Since, we are interested in linking patient diagnostic pathways, we only keep the pathways that comprise at least two observations. As a result, we obtain 6,588 pathways and 18,850 pathways for MIMIC-III and UCSD respectively.

Evaluation Criteria. We perform 10-folds cross validation, where 9/10 of the data is used as a training set and 1/10 as a test case. For each patient in the test set, we randomly split his/her pathway across two databases $D_1$ and $D_2$. Then, for each patient partial pathway in $D_1$, our approach scores the pathways in $D_2$ using the linkage score and returns the top-$k$ pathways as a match. Different from the classic definition of True Positive and False Negative, we measure the accuracy of our solution as the ability of returning the real matching pathway in the top-$k$ results.

Table 1: Accuracy Results

<table>
<thead>
<tr>
<th>$k$</th>
<th>1</th>
<th>2</th>
<th>4</th>
<th>10</th>
<th>20</th>
<th>50</th>
</tr>
</thead>
<tbody>
<tr>
<td>MIMIC-III</td>
<td>50.5%</td>
<td>66.4%</td>
<td>76.2%</td>
<td>89.0%</td>
<td>96.8%</td>
<td>99.5%</td>
</tr>
<tr>
<td>UCSD</td>
<td>56.3%</td>
<td>68.0%</td>
<td>80.1%</td>
<td>90.8%</td>
<td>95.5%</td>
<td>99.7%</td>
</tr>
</tbody>
</table>

Results. The accuracy results are reported in Table 1. The accuracy in linking patients is as high as 99% for both MIMIC-III and UCSD. Even when the top-1 path is retrieved, our solution leads accuracy higher than 50% demonstrating the effectiveness of our linking approach.

5  Discussion and Future Work

One of the major benefit of this approach consists in using the diagnostic pathways to represent the patients temporal evolution and in computing their similarity. In our setting, the shared information is only related to the patients diagnoses. Therefore, the privacy implications are limited, thus, more institutions would be willing to share this non-PHI information to effectively link patients data. Furthermore, the non-PHI data available in real scenarios are not limited to diagnoses but could also include more heterogeneous information such as: medications and lab tests. Therefore, as future research direction, we aim to extend our linkage framework to include all the temporal non-PHI data to further improve the linkage accuracy.

The Effect of a Large-Scale Mobile Health Emergency Project: A Telehealth Enabled Informatics EMS Intervention

Tiffany Champagne-Langabeer, PhD1; Michael Gonzalez, MD2; Diaa Alqusairi, PhD2; Adria Jackson, PhD2; Jennifer Mikhail, MPH1; James R. Langabeer II, PhD1
1The University of Texas School of Biomedical Informatics, Houston, Texas; 2Houston Fire Department, Emergency Medical Services

Introduction

Mobile health (mHealth) technologies have evolved in many areas of healthcare, but have not been widely adopted by emergency medical service (EMS) agencies. With almost half of all emergency visits initiated with ambulance transport, it is essential that mobile technologies better enable clinical and transport decisions. Technologies—including telehealth, health information exchange, and clinic scheduling—offer potential solutions in an environment where paramedics and physicians are increasingly resource-constrained with patients presenting with non-urgent complaints. Telehealth, specifically, shows potential given its ability to augment clinician productivity over distance through audio and video communication models. Within EMS, there is significant opportunity for transformation, given the historically high levels of emergency department transports for low-level acuity problems, resulting in unnecessary ED visits and overcrowding. We hypothesize an alternative model of technology-based emergency prehospital care will be effective at reducing costs and unnecessary hospital emergency department visits. This study describes one large regional mHealth program at the Houston Fire Department (HFD), Emergency Medical Services.

Objective

The objective of this research was to develop a mobile health technological solution for a large, urban EMS system, and to document the comparative effectiveness relative to traditional EMS care for primary care related incidents. The study was guided by two research questions:

1. How can telehealth and other mHealth technologies be implemented in a prehospital EMS environment?
2. What effects (in terms of clinical and economic outcomes) will such innovations produce for the Houston healthcare delivery system?

Methods

A project team was assembled of academics, informaticists, physicians, vendors, and medics to conceive a plan for a mobile health technology demonstration project in Houston, Texas. Technology vendors and partners were assembled, including major wireless carriers, tablet hardware provider, patient care record (PCR) systems provider, the regional health information exchange, and affiliated safety net clinics. A solution was designed to support transportation and treatment of non-emergent patients by more appropriate levels of care (such as a clinic instead of an emergency department). A schema of all interoperable web and mobile technology solutions was developed, and included telehealth, access to the regional health information exchange, clinic scheduling, and online taxi transportation solutions.
To study the effect of this program, we used an observational case-control study design. The intervention group received mHealth-enabled care and the control group was treated and transported per standard protocol. Primary outcomes were utilization (the % of ambulance transport to local ED) and productivity (“back in service time”, measured as cycle time differential from EMS start to finish). We compared the effectiveness analysis of the outcomes in each groups, comparing differences using Mann Whitney U median tests for statistical differences.

Results

The project initiated in December 2014 and has treated more than 6,000 patients (n=6,103) through February 2016. We found a significant reduction in medically unnecessary transports to the ED, with a 76% relative decrease in ambulance transports for the mHealth intervention group (74% ambulance transport for control group vs 18% for the mHealth program). This affected the median time from the initial EMS notification to its ability to back in service in order to respond to another 911 call. The median total response time was approximately 39 minutes for the mobile health patients, while median response for the control group was 83 minutes. This 44-minute median reduction in total response time per incident was statistically significant (Mann Whitney $P$<.001). This equates to approximately 2.1x greater utilization per day for the EMS unit when compared with the standard EMS control group. The units were able to return to service significantly faster as a result of less frequent trips to the ED, ensuring they can respond to other more emergent incidents. Table 1 summarizes the outcome differences.

Table 1: Outcome Differences

<table>
<thead>

<td>Total Back in Service Time</td>
<td>83 (67) minutes</td>
<td>39 (34)</td>
<td>&lt;.001</td>
</tr>
</tbody>
</table>

Discussion

A large-scale mobile health emergency project—incorporating telehealth and other innovative technologies—is effective at reducing unnecessary ED visits and putting EMS units back in service 2.1x faster. Telehealth, coupled with other technologies such as electronic scheduling and health information exchange, can enable transformation of the traditional EMS-based healthcare model. These results suggest broader implementation in other regions.

Conclusion

Mobile health technology enables an effective, alternative model of providing prehospital emergency care.

Mining and Visualizing Sequential Patterns in the Electronic Health Record: A Case Study for Asthma With and Without Mental Disorders

Elizabeth S. Chen, PhD1, Genevieve B. Melton, MD, PhD3, Mark Howison, MS2, Erik Knoll, BA2, Ashley Lee, MS2, Indra Neil Sarkar, PhD, MLIS1

1Center for Biomedical Informatics and 2Data Science Practice, Brown University, Providence, RI; 3Department of Surgery and Institute for Health Informatics, University of Minnesota, Minneapolis, MN

Introduction

With the widespread adoption of electronic health record (EHR) systems, increased efforts are needed for adapting data mining techniques to transform EHR data into clinically actionable knowledge1. Association rule mining and sequential pattern mining are two such approaches that can be used to identify patterns in unordered and ordered sets of events, respectively2,3. In prior work, an open-source pipeline, incorporating the \texttt{arules} and \texttt{arulesViz} R packages, was developed to generate and visualize family history and substance use association rules from EHR data for pediatric asthma and adult epilepsy patients4,5. The goal of this study was to build upon this pipeline to identify sequential patterns using the \texttt{arulesSequences} R package, which has been previously used for predicting next prescribed medications6 and discovering comorbid neurodevelopmental disorders7. As a demonstration, a case study was performed for examining the development of comorbidities, including mental disorders, in patients with asthma.

Methods

A four-step process for data selection, data preprocessing and transformation, data mining, and interpretation was used8. First, ICD-9-CM diagnoses for adult asthma patients with at least two admissions were extracted from the Medical Information Mart for Intensive Care III (MIMIC-III; v1.3) database, which includes EHR data from Beth Israel Deaconess Medical Center from 2001 to 20129,10. Two datasets were generated that included diagnoses ordered by admission date for asthma patients with and without mental disorders. The 2015 Clinical Classifications Software (CCS) for ICD-9-CM that provides categorization schemes for diagnoses was leveraged to identify asthma and mental disorder diagnoses as well as to group all diagnoses into single- and multi-level categories11. The \texttt{arulesSequences} (v0.2-11) R package was used to generate sequences for both datasets at different levels of abstraction: (1) ICD-9-CM codes (e.g., 493.90 for “Asthma NOS”), (2) multi-level CCS categories (e.g., “Other asthma without status asthmaticus or exacerbation”), (3) single-level CCS categories (e.g., “Asthma”), and (4) ICD-9-CM chapters (e.g., “Diseases of Respiratory System”). To facilitate interpretation for this feasibility study, different filters were applied and visualizations of sequences were created (e.g., interactive Sankey and sunburst diagrams using the \texttt{googleVis} [v0.5.10] and \texttt{sunburstR} [v0.2.1] R packages). A preliminary comparison of sequences was performed to identify similarities and differences between asthma patients with and without mental disorders.

Results

The pipeline was implemented in R (v3.2.3) and PostgreSQL (v9.5.0). A total of 821 adult asthma patients, with 3.1±2.2 admissions and 14.5±7.1 unique diagnoses per admission, were identified in MIMIC-III. Sequences were generated at the four levels of abstraction for 539 (65.7%) asthma patients with mental disorders and 282 (34.3%) without. Figure 1 shows the proportion of common and unique sequences using single-level CCS categories for both datasets; an F-measure of 0.44 suggests differences in the progression of comorbidities in these subpopulations. Figure 2 depicts a visualization of a subset of unique sequences generated for asthma patients with mental disorders.

Discussion

The association between asthma and mental disorders (e.g., anxiety and mood disorders such as depression) has been long recognized12, but longitudinal studies are needed to ascertain temporal relationships of these conditions and contributions of social, behavioral, and familial risk factors over time13. This study is a first step towards an open-source framework for supporting such studies that may be generalizable to other conditions. Next steps include conducting formal evaluations of the generated sequences, incorporating algorithms to rank sequences and consider time intervals, examining the effect of different coding systems (e.g., ICD-9/10-CM and SNOMED-CT) and levels of abstraction (e.g., CCS for ICD-9/10-CM) on the number and quality of sequences, and applying the pipeline to EHR data (e.g., diagnoses, problem list, and social history) from different institutions and comparing sequences.
Figure 1. Number and Examples of Sequences (length a ≥ 2 and support ≥ 0.1) using Single-Level CCS Categories ([n%] = % of common and unique sequences; {A}{B} supp = Diagnosis A from an admission and Diagnosis B from a later admission with support value (i.e., proportion of patients) for respective datasets).

INTRODUCTION

The meaningful use era of electronic health records (EHR) presents learning health system opportunities to answer “grand challenges” in automatically learning clinical decision support (CDS) content. The current standard for distributing executable clinical expertise are human-authored order sets to reinforce best-practices. We previously developed a clinical order recommender system by automatically data-mining hospital EHR data. This approach aligns with established standards of care and is predictive of real physician behavior and patient outcomes, but its usability in a clinical decision workflow is unknown.

METHODS

As described previously, we extracted deidentified structured data for all inpatient hospitalizations from the 2009-2013 STRIDE clinical data warehouse. The data covers >74K patients with >11M instances of >27K items (medication, laboratory, imaging, and nursing orders, lab results and diagnosis codes). We built an order recommender based on this data, modeled on Amazon’s product algorithm using item co-occurrence statistics.

We built a simulated computerized physician order entry (CPOE) interface with open technologies including PostgreSQL, Python, Apache HTTP, and HTML/JavaScript. Our unique addition is an automated recommender (Figure 1), analogous to a “Customers Who Bought This Item Also Bought This…” function.

We developed clinical cases for common inpatient medical problems and initial trigger symptoms (with ICD9 code) of diabetic ketoacidosis (250.1), chest pain (786.5), neutropenic fever (288.0), and gastrointestinal bleed (578). Each case includes clinical notes to represent the patient’s history and physical exam. Lab values are only visible and change state if respective orders are entered (e.g., low hemoglobin reported only if a blood count is ordered). With each order entered, the recommendations update based on the accumulating patient information.

We recruited practicing physicians to use the interface to simulate admitting hospital patients. For the first case (diabetic ketoacidosis), the researcher guided participants through basic functions (data review and conventional order entry). For subsequent cases, the recommender function was activated. Participants completed a System Usability Survey (SUS) focusing on the dynamic recommender list. We organized qualitative observations and participant comments by thematic analysis.

RESULTS

Six board-certified Internal Medicine physicians participated in the simulated clinical order entry user-testing. All were local practicing physicians with 3-5 years of clinical experience, and thus familiar with the existing EHR order entry process. Their System Usability Survey (SUS) score median (IQR): 81 (76,90) translates to the 90.5th percentile (76.5,99.8) for usability relative to SUS normative evaluations. Table 1 includes major themes of comments and observations on the system. Table 2 includes design implications learned from initial issues.

DISCUSSION

We produced a clinical order entry interface and simulated cases that model changing patient states in response to user actions. This initial evaluation focuses on core usability, the commonly overlooked failure point for applied decision support, where as little as five participants identify the bulk of system usability problems. Physicians rated the integrated order recommender in the “excellent, grade A” category of usability and, more importantly, their qualitative comments and observations help to inform future system design.
### Category | Comment or Observation
---|---
Utility vs. Order Sets | • All participants used the pre-authored order set for the first example case (diabetic ketoacidosis)
|  | • No participant used case specific order sets once the recommender list was activated
Influence on Decisions | • “Recommender helps, but I’m deciding on my own. Reassuring though, that I am not alone.”
|  | • “I wouldn’t have ordered a CT scan, but I feel pressure to do so when it’s suggested.”
Trust of Suggestions | • “I know what to do, but I wish this safety net existed in real-life as I race between admissions.”
|  | • “I became comfortable with the recommendations until I realized a key antibiotic was missing.”
Interpretability of Scores | • “I like the prioritization of orders, not buried amongst useless ones.”
|  | • “The actual numbers don’t inform my decisions unless they are extreme.”

Table 1 – Participant comments and researcher observations on the recommender system.

All participants used the pre-authored diabetic ketoacidosis order set which is *required* in real-world settings to order an insulin drip. For subsequent cases, no participant used (and most were not even aware of) pre-authored scenario specific order sets from the hospital EHR. In contrast, every participant used multiple system recommended orders for all cases, suggesting a more seamless integration with their thought processes.

We observed no gross medical management errors of commission, though there were arguably errors of omission. Only one participant ordered prophylactic antibiotics (i.e., ceftriaxone) for a patient with a variceal GI bleed, which notably was *not* on the computer generated recommendation list. At the same time, most participants did not order filgrastim for neutropenia, despite it prominently featuring in the recommendation list. Multiple participants argued that they focus on acute stabilization and defer second order decisions until they can speak with a specialist. In fact, participants complained about seeing recommendations for procedures that only a specialty consultant would perform / order. These reinforce that a recommender system (and even conventional order sets) remain decision *aids* that a human decision maker still must consider in the context of their individual patient.

Table 2 – Apparent issues in initial recommender design with respective implications learned from simulation.

Overall, practicing clinicians were receptive to an automated recommender integrated into their order entry decision process. With confidence in the core usability of such a design concept not disrupting clinical workflow, further evaluation of such data-driven clinical decision support systems will determine whether they can actually improve the quality and efficiency of medical decision making in a closed-loop learning healthcare system.

Abstract

Objectives: To demonstrate a statistical survival analysis for identifying subpopulation at high risk for suicide using statewide hospitalization and suicide mortality data. Methods: Eight years of claims data (2005-2012) on hospitalizations due to intentional self-injury from the Office of the Connecticut Medical Examiner and the Connecticut Hospital Inpatient Discharge Database were combined with mortality data by suicide, to study the survival time of patients after their most recent hospital admissions due to unsuccessful suicide attempt. For each subject, his/her historical records were aggregated to the time of his/her most recent hospitalization that did not result in death. We consider a “follow-up” study of these subjects, starting from their most recent admission times that did not result in death until death due to suicide or until the end of the study at 12/31/2012. From suicide prevention perspective, this is exactly the cohort that is at high risk of suicide-related death and is exactly at the time that the prevention efforts can be readily applied. A cause-specific Cox’s proportional hazard model, coupled with regularized variable/interaction selection techniques, was used to build a parsimonious and interpretable model, to study the associations between the survival times and the potential predictors constructed from the hospitalization records. The out-of-sample predicted survival probabilities from the Cox model were used to identify high-risk groups from the study cohort. Results: Several important predictors and their interactions were identified to be associated with the survival time after most recent unsuccessful suicide attempt. The predicted individual survival probability is demonstrated to be a valid risk measure of suicidal death. High-risk group with several folds of increased risk was identified based on the out-of-sample predicted survival probabilities, and several insights were gained on the unique characteristics of the high-risk group. Policy Implications: Data capturing hospitalization for suicide attempts and suicide deaths can inform prevention activities by identifying high-risk subpopulation to which resources should be allocated.

Methods

Eight years of claims data (2005-2012) on hospitalizations due to intentional self-injury were combined with mortality data on death by suicide over the same period, to study the survival time of patients after their most recent hospital admissions due to unsuccessful suicide attempt.

Using historical hospitalization data from the Office of the Connecticut Medical Examiner and the Connecticut Hospital Inpatient Discharge Database, we identified all the suicide-related hospital admissions during an eight-year period from 2005 to 2012. A fabricated subject identifier was created to identify subjects with multiple admissions, by matching gender, age, ethnicity, birth date, and residential zip code (We remark that the exact identifier indicating multiple visits of the same subject was not available). For each subject, his/her historical admission records were aggregated to the time of his/her most recent admission time that did not result in death. The aggregated admission records include demographical variables (such as gender, age, ethnicity, etc), summary statistics of visit histories (such as number of suicide-related admissions, average length of stay in hospital, etc), and numerous indicator variables created from diagnostics codes, procedure codes and discharge status codes (ICD9). 164 subjects who died during their only hospital admission were removed from the study, and we also limited the study to subjects under 70 years old at their most recent admission times due to unsuccessful suicide attempt. This results in totally 15,246 unique subjects during the 2005-2012 periods. As such, we consider a "follow-up" study of these subjects who were admitted to hospitals due to suicide attempt, starting from their most recent admission times that did not result in death. From suicide prevention perspective, this is exactly the cohort that is at high risk of suicide-related death and is exactly at the time that the prevention efforts can be readily applied. We then used the CT Suicide Mortality Database to find out whether these subjects have died due to suicide until 12/31/2012. It can be viewed that the 15,246 subjects at risk were “followed” until death due to suicide or until the end of the follow-up study at 12/31/2012. (As the complete death records in CT were not available, we were unable to identify deaths due to other causes; nevertheless, the potential bias is controlled, as we have limited the study to subjects under 70 years old.). We conducted a statistical survival analysis to model the associations between the survival times and the potential predictors constructed from the admission records. Specifically, a cause-specific Cox’s proportional hazard model, coupled
with regularized variable/interaction selection techniques, was used to build a parsimonious and interpretable predictive model. The final model is selected based on cross validation. High-risk subgroup can then be identified based on estimated individual survival probabilities from the fitted model. To objectively access the predictive power of our approach in identifying high-risk subgroup, we repeatedly split the data to 80% training and 20% testing randomly; the survival model was fitted using the training data and then used to identify the high-risk group, defined as 5% of the patients in the testing data having the lowest predicted individual 5-year survival probabilities. The estimated 5-year survival probability of the high-risk group and that of all the patients in the test data were then calculated. This procedure was repeated 500 times. Results from this analysis indicate whether the identified highest risk cohort indeed have much higher risk of suicidal death than that of all attempters.

Results
Predictors included patient demographics, primary and secondary diagnosis codes (both ICD 9 and MS-DRG), and primary and secondary procedure codes. We considered all the main-effect and two-way interaction terms as candidate variables. Altogether 18 separate risk factors and combination of risks were identified. Our out-of-sample random splitting procedure showed that while the 5-year mortality rate among the entire previous attempters was 3.5%, the highest risk cohort identified by our predictive model, comprising 5% of all attempters, had a 5 year mortality rate of 14.3%. The identified 12 separate risk factors and combination of risks can indeed differentiate the high risk group from all patients hospitalized for a suicide attempt (Table below). White men and older patients were significantly more likely to be in the high risk group; those whose prior attempt involved hanging or suffocation were 5.6 times more likely to be in the high risk group. Several conditions and comorbidities related to the prior attempt were also predictive of being at high risk for suicide, including acute alcoholic intoxication (ICD 9 303), alcohol intoxication in the context of poisoning by sedatives and hypnotics (ICD 9 967), alcohol intoxication in the context of open wound of other and unspecified sites except limbs (ICD 9 879).

A Framework for Visual Tracking of Risk and its Drivers in Monitoring Patients Susceptible for Cardiorespiratory Instability

Lujie Chen, MS\textsuperscript{1,2}, Gilles Clermont, MD\textsuperscript{3}, Marilyn Hravnak, PhD\textsuperscript{4}, Michael R. Pinsky, MD\textsuperscript{3}, Artur Dubrawski, PhD\textsuperscript{2}

\textsuperscript{1}Heinz College and \textsuperscript{2}School of Computer Science, Carnegie Mellon University, and School of Medicine\textsuperscript{3} and School of Nursing\textsuperscript{4}, University of Pittsburgh, Pittsburgh, PA

Abstract

Monitoring cardiorespiratory instability (CRI) in hospitalized patients is challenging, primarily due to the heterogeneity of patterns of CRI risk escalation and the diversity of the involved risk drivers. We present a framework for producing interpretable visualizations of CRI risk estimates obtained from multiclass machine learning models. Our approach can be used as a tool for “aerial view” of patients’ risk characteristics as well as support online monitoring and real time tracking of CRI risk.

Introduction

Cardiorespiratory instability (CRI) denotes a physiologic decompensation event observed among hospitalized patients. Its early recognition and intervention can improve outcomes\cite{1}. However, detection and forecasting of CRI is a challenging task, primarily due to the heterogeneity of CRI risk escalation patterns\cite{2} and to the diversity of risk drivers\cite{3}. Existing bedside monitoring systems are capable of recording large amounts of fine-grained physiological data. In current practice, however, these data are rarely used to track and characterize patients’ risk trends in real-time. We propose a novel visualization framework to support tracking of CRI risk escalation patterns and risk drivers over time. It relies on assimilating large amounts of multi-parameter vital signs (VS) data using a multi-class classification model, and visualizes the resulting risk estimates for easy bedside interpretation.

Method

In our previous work\cite{2}, we described a method to characterize and phenotype patient’s CRI risk escalation patterns using Group Based Modeling. We further extended this work by developing a multi-class Random Forest classification model to track patient’s group status over time using the numeric features extracted from VS from recent past. The output of the model is a multi-dimensional vector whose components estimate the probability of the patients to follow a particular CRI risk escalation pattern, given their VS signals observed up to the current time. Here we also include an independent multi-class classification model to track the CRI risk drivers in six dimensions (high heart rate [HR], low HR, high respiratory rate [RR], low RR, low blood oxygen level [SpO\textsubscript{2}] and abnormal blood pressure [BP]), and the resulting multi-dimensional estimation vector can be interpreted similarly.

For each patient, we project the series of multi-dimensional estimated probability vectors onto 2-dimensional polygons, as shown in Figure 1. The vertices of each polygon represent unique categories in our classification models, while each projected data point corresponds to the tracked patient state at a certain point of time. The mapping between a multi-dimensional vector and the coordinates in the plot follows the formula:

\[
x^t = \sum_{i=1}^{k} x_{0i} P^t_i \quad y^t = \sum_{i=1}^{k} y_{0i} P^t_i
\]

Here, $P^t_i$ represents the probability that a patient’s state belongs to the $i^{th}$ category at time $t$ according to the model. Each pair $(x_{0i}, y_{0i})$ represents the coordinates of the vertex of the projection polygon corresponding to the $i^{th}$ category, whereas $(x^t, y^t)$ are the coordinates of the projected data point. We only map points with risk levels higher than a user-determined threshold based on the output of a binary classifier deciding whether a patient is at risk.

This approach permits us to map the model-based estimation of the patient’s current state in a multi-dimensional space into a point inside a 2-dimensional convex polygon for intuitive interpretation. For example, if the model estimates that a patient’s current state belongs to a particular category with high CRI likelihood, the corresponding data point will be rendered in proximity of the vertex representing that category. If, however, the estimation is split
between two distinct categories, then the data point will be located along the line connecting the corresponding category-specific vertices. It also follows that if the output of the model shows a high level of uncertainty about the category assignment, i.e. the estimated probability distribution is close to uniform, then the projection will be close to the center of the polygon. By varying temporal resolution of data to be visualized, we can modulate the presentation to visualize the dynamics of the patients’ CRI risk evolution over time between longer and shorter horizon perspectives.

**Results**

Figure 1 illustrates example visualizations obtained by tracking a specific patient’s CRI risk with respect to their risk escalation pattern and drivers. Figure 1(A) plots all tracked states during this patient’s entire length of stay whenever their estimated risk level exceeds a threshold of 0.5. The plot on the left summarizes the patient’s risk escalation patterns among three categories (“persistent high”, “early onset” and “late onset”), while the plot on the right traces the estimated risk drivers among the six categories. Contour lines depict density distribution of data. We can see that this patient’s most common risk escalation pattern was the “late onset” class with an occasional drift towards the “persistently high”. The primary risk drivers for this patient observed during their stay were low SpO₂ and high RR. Figure 1(B) illustrates the view when this tool is used for online monitoring in which only the last two hours of the patients estimated risk states are shown. Blue arrows illustrate the temporal sequences of the state transitions. Supplemental animation videos are available from this link: [http://lujiec.github.io/visual_tracking/](http://lujiec.github.io/visual_tracking/)

![Figure 1. Example visualization of (A) retrospective view of one patient’s CRI risk trajectory estimation and CRI risk drivers throughout their stay, and (B) trace of these estimates during the most recent 2 hours of their stay.](image)

**Conclusion**

We present a framework that can be used to obtain meaningful and interpretable summarization and visualization of the evolution of monitored hospitalized patients’ patterns of CRI risk escalation and the corresponding CRI risk drivers. Our framework can be used as a tool for either retrospective analysis conducted in order to profile and interpret the changes of a patients’ risk characteristics over longer intervals of time, or for real-time tracking to provide the clinical team with a fine-grained and communicative risk estimation information in order to devise CRI monitoring, mitigation, and remediation strategies tailored specifically to each patient.

Bulk Learning on EHR Data

Po-Hsiang Chiu, PhD\textsuperscript{a}, George Hripcsak, MD, MS\textsuperscript{a}
\textsuperscript{aDepartment of Biomedical Informatics, Columbia University, New York, NY}

Introduction

A central computational task in data-driven disease phenotyping is to use the variations of clinical concepts inferred from the electronic health records (EHR) to stratify phenotypic cohorts, each of which represents a clinical condition or a potential disease subtype that goes beyond historical disease definitions. Patients are essentially represented by clinical traits such as medication history and laboratory measurements. Phenotyping using statistical learning methods\textsuperscript{1} may seem to reach a higher level of automation when compared to the conventional rule-based approach; however, predictive analytics is not without its own challenges in the creation of training data since both the tasks of feature engineering and gold standard labeling require significant human intervention. To reduce the overhead of data annotation and achieve a higher level of automation, we adopt a hierarchical learning approach based on the ensemble learning paradigm\textsuperscript{2}, using infectious diseases as the domain of study, to construct abstract features that represent the shared clinical traits among the target infections. Statistical models such as logistic regression can then be built from within the abstract feature space of low dimensionality, thereby reducing the demand for labeled data.

Method

Bulk learning, as the name suggests, is a simultaneous training procedure for multiple clinical conditions. The key idea is to use diagnostic codes (e.g. ICD-9s) readily available in the codified EHR as surrogate labels, out of which we can train a hierarchical model with levels of feature abstraction that captures the common denominator of the target conditions, collectively referred to as the bulk learning set. Clinical evidence suggests that different infectious diseases share degrees of similarity in antibiotic prescriptions, various laboratory tests, among other clinical factors, all of which can potentially serve as high-level phenotypic measures for separating cohorts with different infections. Through the learned abstract features representing importance weightings of phenotypic measures of interest, the labeling of disease cases for the entire bulk learning set can be realized by training statistical models from within the abstract feature space. Since abstract feature space has a significantly lower dimension compared to the raw feature space spanned by patient attributes extracted from the EHR data, we postulate that a relatively small annotated dataset is only required for stratifying disease cohorts, which would otherwise have a substantially higher demand of labeled data considering the size of the raw feature set that can be used to model these phenotypic measures. An example three-tier hierarchical learning architecture based on stacked generalization\textsuperscript{3} is depicted in Figure 1: i) Base or level 0 consists of a set of classifiers, each of which is modeled to express a high-level phenotypic measure relevant to the target infections. Each measure is represented by the feature set extracted from Medical Entity Dictionary (MED) developed at NewYork-Presbyterian Hospital\textsuperscript{4}, a semantic network for medical concepts. ii) The level-1 tier is a meta-classifier that takes probabilistic scores from base classifiers and a set of indicators combined as the abstract feature set, where each indicator represents the absence or presence of data for the corresponding phenotypic measure (e.g. not all patients had intravenous chemistry tests during their clinical visits); up until this level, ICD-9 codes are used as surrogate labels. iii) The level-2 tier inherits the probabilistic output from level l coupled with the ICD-9 codes together as the abstract feature set while using annotated labels for model training.

Results and Discussion

In the experiment, we used the clinical data repository from Columbia University Medical Center and examined 100 clinically different infectious conditions. For simplicity, $\ell_2$-regularized logistic classifiers are used at both the base and the meta levels. In predicting the ICD-9 as surrogate labels, each base classifier has different predictive strength due to their varying degrees of clinical relevance. The phenotypic measure involving microbiology tests in general has the best predictive strength. The level-1 classifier consistently outperforms individual base classifiers, which can be explained by the diversity in predictions at the base level, a crucial condition for ensemble learning to work well. In the model evaluation with the gold standard, we annotated 83 clinical cases. Under this small annotation set, the ICD-9-modulated level-2 model reaches an AUC of 0.78. However, the model tends to result in false positives due to the inconsistent labeling between the ICD-9 and the gold standard; overcoming this performance shortage is an ongoing effort. Additionally, we experimented on alternative feature abstractions such as the ICD-9-modulated level-1 model, which combines the level-1 features with the ICD9; the performance tradeoff with its level-2 counterpart depends on the size of labeled data. Figure 2 illustrates the relative performance (in AUC) of the global
The level-1 model in reconstructing the ICD-9 labeling (through predictions), where the model was trained on the aggregated level-1 data across the bulk learning set (hence global to all diseases), followed by predicting individual diseases as the evaluation; the horizontal axis denotes the codified diseases. The empirical result indicates that the global level-1 model approximates the ICD-9 labeling well (with a grand mean AUC at 0.897), which is promising for using such hierarchical learning method for large-scale, high-throughput phenotyping in the near future.

**Figure 1.** Three-tier learning architecture with two levels of feature abstractions over 4 phenotypic models.

Patient Perspectives on Designing an Engaging Patient-Powered Research Network Patient Portal: Crohn’s and Colitis Foundation of America (CCFA) Partners
Arlene E. Chung, MD, MHA, MMCi,1-2 Maihan B. Vu, Dr.PH, MPH,1 Jessica Burris,3
Kelly Myers,3 Michael D. Kappelman, MD, MPH1-2
University of North Carolina at Chapel Hill,1 Carolina Health Informatics Program,2
Vanderbilt School of Medicine,3 Atomo, Inc.3

Background. Patient-powered research networks (PPRN) have the potential to improve health behaviors and outcomes, yet initiating and sustaining engagement is challenging. The overarching goal for CCFA’s PPRN is to promote both research participation and disease management. In order to build a PPRN patient portal that prioritizes the needs of its members who have inflammatory bowel diseases (IBD), we sought to better understand patients’ needs and preferences for what they feel to be essential components and features to facilitate and sustain engagement with the PPRN patient portal with particular focus on patient-generated health data (PGHD). As PPRNs are an emerging concept, little is known about patient’s preferences and information needs for PPRN patient portals and what features are considered the most important for self-management and engagement. This study identifies design principles for creating an engaging and impactful PPRN patient portal. We postulate that some of these principles could be useful for developing PPRN portals across other clinical conditions.

Methods. We conducted a two-phase qualitative study to elicit patient perspectives on what would make the PPRN patient portal engaging and useful for self-management and monitoring. In Phase 1, seven 90-minute focus groups involving 62 patients with IBD from two states were conducted with recruitment purposefully focused on including minority IBD patients. The focus group results informed the Phase 2 cognitive interviews, which included thirteen 60-minute phone interviews with patients from 11 states. Topics discussed in the group and individual sessions included barriers and facilitators to engagement with the PPRN and focused on the various aspects of PGHD and potential resources and tools to facilitate self-management within the PPRN’s patient portal. Individual interview participants were also shown mockups of PGHD displays including patient-reported outcome data. All focus groups and interviews were digitally recorded, transcribed verbatim, and analyzed in ATLAS.ti 7.5. From the combined data, thematic categories were derived and codes were grouped into emergent themes and relationships. We used these themes to determine design principles for the PPRN portal.

Results. Participants from the seven focus group discussions (n=62) were mostly middle-aged, female, and self-identified as White. 61% had Crohn’s disease and reported an average 21 years since diagnosis. Almost all focus group participants had a cell phone (mostly smartphones), Internet access on their cell phones, and had computers or tablets with Internet access. Individual interview participants (n=13) had an average age of 46 years with 93% being female and the majority identified as White. Approximately half of participants had Crohn’s disease and reported an average 16 years since diagnosis. All individual interview participants had a cell phone and computers or tablets with Internet access.

The four predominant themes that emerged through inductive coding techniques were: (1) The Impact of Knowing; (2) Participation Barriers and Challenges; (3) Engagement and Collaboration; and (4) Customizable Patient Portal Features and Functionalities. The design principles informed by each of the major themes are detailed in Table 1.

Discussion. Partnering with patients to inform the design principles for the development of CCFA Partners PPRN patient portal was critical for creating an engaging and impactful portal. Patient insights and perspectives on what features and functionalities are important for self-management and engaging in research provided invaluable information to inform the design of the PPRN portal.

Table 1: Design Principles for the CCFA Partners PPRN Patient Portal

<table>
<thead>
<tr>
<th>Themes</th>
<th>Issue</th>
<th>Design Principle</th>
</tr>
</thead>
</table>
| The Impact of Knowing           | Patients desire information about various treatment options & to learn the experience of others to help inform their own health and treatment decisions. Patients were motivated to participate because the knowledge gained in research studies would benefit both society and the individual patient (finding a cure, prevention for others, etc.) | Create a section on the portal to:  
• Provide resources and information about treatment options based on the current evidence base  
• Disseminate research findings from studies conducted with PPRN data in a format that patients can easily understand  
• Disseminate information on what studies are being currently conducted |
| Participation Barriers and Challenges | Patients are unsure about the credibility of IBD information online (both type and amount). Patients desire to be able to judge whether or not information is from a valid source. | Show data about what studies are being conducted using patient data and how their individual data is being used for each study conducted within the PPRN. Provide information and sources for any information posted on the portal, including conflicts of interest or industry relationships, so patients can determine the validity of the information. Provide a way for patients to choose who can use their PGHD & clearly state that patient data will never be sold. |
| Data security and protection was a concern. | PPRN portal is secure & privacy/security information should be visible and available on the PPRN portal website. |
| Engagement and Collaboration | Patients desire to know that someone from the PPRN is paying attention to them and interested in them as patients. | Provide daily check-in survey about overall health and IBD symptoms. Provide intermittent emails to update membership about new features and results from PPRN studies. |
| | Patients feel more likely to sustain engagement and participation if they feel invested in the PPRN’s products and outcomes. | Obtain continuous input from patient governance members and membership on what features and products are most impactful to them. Have an easy way for patients to submit feedback/suggestions. |
| | Personal invitations from their providers and some type of periodic check-ins for support and encouragement would facilitate engagement. | Create personalized invitations to join the PPRN from patient’s providers and provide a way for providers to support/encourage patients via messaging using the portal. |
| | Patients feel more likely to track with wearables/smartphone apps during flare-ups and when stressed, but also viewed continuous tracking as an opportunity to track how they were doing & how their body was doing. | Provide an easy mechanism to connect and disconnect various wearables/smartphone apps to track PGHD, which allows patients to pick which devices/apps are the most meaningful or helpful to them. |
| | Patients cited the need for a feedback loop for how their PGHD is being used for research. | Display how PGHD is being used and by whom, & provide patients with results from studies that use their PGHD. |
| Patient Portal Features and Functionalities with Focus on PGHD | Patients desire the ability to track trends (health status & IBD symptoms) over time. Patients specifically want the ability to pick what measures to compare and graph. Individual trends over time were more important than comparing to other patients. Participants desired both an overall & detailed view of their PGHD. | Provide a graphing feature that allows patients to select the measures & time frame to graph. Provide individual and comparative data displays for patient-reported outcomes data and wearable/app data. Provide an overall view of data trends over time but allow for click-to-expand on individual data points. |
| | Patients desire access to personal health information from electronic health records. | Using HL7, enable data exchange from patient portal/personal health record accounts. |
| | Patients desire to customize or change features to meet individual needs, especially for PGHD displays. | Provide patients an easy way to click and select features they wish to use within the MyMeasures section, which displays various types of PGHD and other health data. |
| | Patients felt that using a stoplight color scheme for PGHD displays was universally understood and helpful. | Display symptom and severity data in stoplight color scheme. |
| | Participants would like a dashboard of all their data and information in one place, and this dashboard should help communicate this information to their providers. | Create a dashboard using color-coding (stoplight colors) when possible to display wearables/app data, patient-reported outcomes, and disease activity. Allow for sharing of dashboards with providers. |

¹University of Nebraska Medical Center, Omaha, NE, ²University of Nebraska – Omaha, Omaha, NE

Introduction

The Personal Health Record (PHR) is intended to support patients’ access to data, clinical summaries, preventive care, educational materials, and medication reconciliation. It is one of the core requirements for Meaningful Use Stage 2. The PHR aims to improve medication adherence, self-management of disease, and the patient provider communication. Despite the potential benefits of PHRs, adoption has been poor, in part due to usability issues. We believe that by understanding the needs of users, the use and utility of the PHR will increase. A core hypothesis of this project is that desired PHR functionality will, in part, be determined by the age of the patient.

Methods

To determine how patients want their PHR to function, a qualitative study was conducted using the grounded theory approach. Following Investigative Review Board approval; patients were recruited to participate in a focus group to determine their thoughts about the PHR and how it fit into their care. Inclusion criteria for the study comprised of patients currently scheduled for clinic follow ups at the Cardiovascular Center at the University of Nebraska Medical Center, 19 years of age or older, and willing to give consent. The study was designed to recruit participants from a range of ages and economic diversity. Economic diversity was achieved by using zip code data from the 2010 census.

Focus groups consisting of 1-5 participants began July 2015 and sessions lasted approximately one hour. A moderator gave a scripted explanation of the study, and both audio and video recordings were obtained. The moderator asked participants questions concerning their use, if any, of the PHR, how they would like to use the PHR, and features they would like the PHR to provide. Our interdisciplinary team (2 physicians, 1 nurse and 3 informatics professionals) asked the participants relevant follow up questions, such as, questions concerning securing health information, questions related to communication with healthcare providers, device preference for accessing the PHR, and usefulness of the after visit summary (AVS). The audio and video files and transcripts of the recorded interviews were reviewed, and analyzed by two independent coders. The codebook was created using a thematic approach. Themes were revised until coders came to consensus and any disagreements between the two coders were settled by a third independent reviewer. Data analysis was carried out using NVivo©. We determined the frequency, intensity and convergence of the coded information. This study was funded in part by AHRQ grant: Optimizing the Electronic Health Record for Cardiology Care (R-01 HS022110-01A1).

Results

Focus groups including 39 individuals (19 males and 20 females) were conducted. Twenty-six participants were white, six Hispanic, five black, and two American Indian. Twenty-nine participants lived in an urban location and ten participants lived in a rural location. Twelve out of 39 participants resided in zip codes with low mean income. Responses were classified according to age groups: 19-39 (6 participants) referred to as young adults, 40-64 (8 participants) referred to as middle-aged, and >65 referred to as seniors (25 participants). Five out of six young adults were users of a PHR, three out of eight middle-aged participants were non-users of a PHR, and fourteen out of twenty-five seniors were users of a PHR.

Several common desired features of the PHR among the age groups were identified. These included the ability to not only access laboratory and test results, but displayed so they could see normal values and trends. In particular, they desired the physician’s interpretation. All age groups requested links to credible sources about their diseases. Most stated a desire to view their physician’s notes, or impressions, in lay terms. Participants within all age groups communicated electronically with their physician, either through their PHR or via e-mail. Most felt that it would be valuable to communicate with their provider before scheduled appointments in order to provide a list of questions and to provide their current medication list. Participants found the use of passwords cumbersome to remember and keep track of and were open to alternative authentication methods for accessing their PHR.

Several differences in the desired use of the PHR among age groups were identified. Young adults had interest in having access through the PHR to social groups with patients who shared similar diseases. When asked if
the after visit summary (AVS) was useful, young adults did not find the AVS very useful because the information found in the AVS was also available in the PHR and preferred to have access to an electronic version of the AVS. Young adults preferred to access their PHR through an app on their smart phones. Young adults also requested to be able to update information on the PHR, and to have the ability to communicate with providers through text, email, and through secure messaging within the PHR.

Reasons middle-aged participants (40-64) mentioned for not using a PHR includes: trust and security when using the Internet, being computer illiterate, not knowing if messages were received by their provider, and perceived frustrations with the functions of the PHR. Middle-aged participants did not mention access to social media as a priority. Preference for contacting provider was through phone call or email but no text messaging. Middle-aged participants, who were willing to use the PHR, preferred a PC or tablet to smartphones and larger font display. The paper-based AVS was more likely read by middle aged participants and stored for record keeping purposes.

Seniors (>65) also did not mention the need or use for social engagement with other patients. Most seniors found parts of the AVS useful but preferred paper copies. Seniors preferred communication with their providers through phone call, email, and in person. A unique feature requested by seniors is to give caregivers access to health information online. Seniors, who used the PHR, preferred a PC or tablet and also stated the need for improved accessibility in order to use the PHR, by the use of a larger font.

Discussion
Several critical desired features were identified in this study that could improve adoption of PHRs. Young adults high use of the PHR for convenience and preference for a smart phone over other modalities. A survey by Pew Research Center found that 85% of young adults (18-29) and 79% percent of adults (30-49) owned a smartphone. This could be why young adults in our study preferred accessing their PHR from their smartphone. Middle aged and seniors’ use of tablets could be because tablet technology is less intimidating, presenting a more simplified interface when accessing the Internet. A study by Jayroe and Wolfram found that older adults had an overall positive experience when using a tablet to complete search tasks. Seniors mentioned interest in having caregivers gaining access to their health information. The reason for this requested feature by seniors may be because of their dependence on caregivers for their health management.

This study is novel in its categorization of desired functionality of PHR by participants’ age groups. These results suggest that providing patients with an optimized PHR is not a ‘one size fits all’ endeavor. The results demonstrate that patients of different age have different PHR functionality requirements and preferences on how they would like information presented to them. These results could inform providers on the information patients seek and could improve the communication providers have with their patients during clinic visits. These results could also inform vendors of patient’s desired PHR functionality for the development of an improved PHR.

Conclusion
This study should inform the design and implementation the PHR to improve usefulness of PHRs and hence increase the use and satisfaction of the PHR. While this study included a diverse group of patient’s further study with a larger sample size is necessary to confirm these results. Future research should assess a PHR based on the results. Additionally, future research should include how caregivers are included in the communication between patient and provider and how caregivers may gain access to patients’ health information.

Variation in EHR Documentation across Primary Care Providers

Genna R. Cohen, BS ¹, Charles P. Friedman, PhD¹,²,³, Andrew Ryan, PhD¹, Julia Adler-Milstein, PhD¹,³

¹School of Public Health, ²Department of Learning Health Sciences, ³School of Information
University of Michigan, Ann Arbor, MI

Introduction: Substantial public and private funding has been invested to increase the adoption of electronic health records (EHRs) (1) because of an expectation that EHR use will lead to higher-quality, lower-cost care (2). EHRs do not, however, directly alter states of disease or health: their value depends on how they are used, and EHRs typically offer providers substantial flexibility in how to use them. This means that providers often have multiple choices for how to document the same type of information. When information is consistently documented in the EHR it is easier for clinicians to find and act on relevant details of the patient’s history. Consistently documented information also allows for tools that are designed to automatically extract information from the patient chart, such as clinical decision support functionality that alerts users to best practice management of medical conditions as well as reports to manage patient populations. However, variation in documentation likely undercuts these benefits.

Variation in EHR documentation is likely explained by a mix of “appropriate” and “inappropriate” factors. For example, variation within physicians across encounters is most likely to be appropriate since it should be primarily driven by patient characteristics. Variation is also likely to be mostly appropriate across offices within geographic regions, and across regions. The remaining variation, variation across providers within offices, is therefore the most likely to be inappropriate. Because providers of the same specialty in the same office see a similar mix of patients (3), this variation would reflect different preferences across providers and a lack of consensus about how best to document comparable information within an EHR (4). It is therefore critical to single out variation at this level. Data from a national, commercial EHR vendor are utilized to answer the following research questions:

(1) How much variation in EHR documentation occurs across PCPs for 15 categories of clinical documentation, and which categories reflect the greatest variation?

(2) For categories with the greatest variation, what proportion of variation in EHR documentation remains after accounting for variation across states, provider organizations (POs), and offices?

Results help inform ongoing efforts to optimize EHR use, and leverage these tools to support improvements in the quality, safety, and efficiency of healthcare delivery.

Methods: De-identified EHR log data from a web-based EHR vendor provide a record of granular clickstream data for all encounters during the month of June 2012 in ambulatory primary care offices. Data were grouped into 15 overarching clinical documentation categories, such as collecting vitals or updating or reviewing the problem list. Every element of EHR documentation is tied to a patient visit and a user ID. The data also capture nested relationships, linking users to their office, a parent PO, and state. The final analytic sample included 170,332 encounters led by 809 PCPs nested in 237 offices in 76 POs in 27 U.S. states.

For each encounter, 15 binary indicators capture activity within each clinical documentation category by anyone in the office. For each PCP, this yields a proportion of encounters with completed documentation (e.g., any activity) for each of the fifteen clinical documentation categories (i.e. fifteen outcome measures per PCP). Demographic data create a categorical variable for PCP primary care specialty type as well as PCP, office, PO and state identifiers.

To answer the first research question about variation across PCPs, the standard deviation of the proportion of encounters for which a given clinical documentation category is completed categorizes tasks according to their variation level (based on the standard deviation). Clinical documentation categories with a standard deviation above 25% were considered High Variation.

To answer the second research question a multi-level linear regression model for each of the “High Variation” clinical documentation categories calculates the proportion of variation that remains after accounting for variation explained by state, PO, and office. The outcome variable is the proportion of encounters for which a given clinical documentation category is completed for PCP i nested in office j nested in PO k nested in state l. The model includes a single fixed effect parameter that captures PCP specialty because there are likely differences in the distribution of patients treated by each type of PCP and therefore their EHR documentation. State- and PO-specific effects (random intercepts) are also included to capture variation in documentation occurring between units at each of these levels. This explained variation is expressed as a ratio to total variation for each level (state, PO, and office). The main variable of interest is the remaining variation across PCPs that is not explained by specialty, office, PO, or
state, also expressed as a ratio to total variation. Statistical significance in the ratio of unexplained variation is a signal of inappropriate variation because it reflects variation across providers in the same office. Bootstrapped standard errors were used because the theoretical distribution of the test statistic for this ratio is unknown.

Results: After analyzing the proportion of PCPs’ encounters in which each clinical documentation category was completed and the standard deviation across PCPs, five clinical documentation categories were considered High Variation: Updating the Patient’s Social History; Conducting a Review of Systems; Reviewing and Discussing Documents; Updating the Patient’s Problem List; and Assessing and Diagnosing the Patient. These tasks were completed in 32.5% - 66.3% of providers’ encounters on average, with high standard deviations of 28.5%-36.9%.

Multilevel models for the five High Variation clinical documentation categories reveal statistically significant variation across states for two clinical documentation categories: Reviewing and Discussing Documents (7.1% of variation explained, p<.05) and Updating the Patient’s Social History (4.0% of variation explained, p<.05). There was significant variation across POs for all but one clinical documentation category (8.3%-17.8% of variation explained, p<.01); the exception was Reviewing and Discussing Documents during the Visit (5.0% of variation explained, p=.21). There was statistically significant variation across practices for all but one clinical documentation category (13.5%-19.0% of variation explained, p<.01); the exception was Reviewing and Discussing Documents during the Visit (9.9% of variation explained, p=.08). Finally, the majority of variation for every clinical documentation category was the remaining, unexplained variation, not accounted for by variation across states, POs, or practices. Documentation of Social History had the least unexplained variation (62.2%, p<.001). The clinical documentation category with the most unexplained variation was documentation of Reviewing and Discussing Documents during the patient’s visit (78.1%, p<.001).

Discussion: Optimal EHR documentation requires pursuing a balance between the needed flexibility to accommodate differences across patients and a recognition that too much flexibility allows for inappropriate variation that compromises downstream uses of EHR data (5). The majority of variation in documentation in a national sample of PCPs exists across users in the same office, which is likely a signal of inappropriate variation. Indeed, the specific High Variation clinical documentation categories are those for which there are multiple places in the EHR to complete documentation. This creates opportunity for PCP preferences to result in variation. For example, a Review of Systems is often structured as a component of an admission note covering the patient’s organ systems. If the elicited information leads to the identification of a problem or diagnosis, that information could reasonably documented in the Problem List, as part of the Assessment & Diagnosis, or in all three categories. The observed, unexplained variation in completing these three clinical documentation categories may therefore be the result of different PCP preferences about the relative benefits of documenting in different sections of the EHR (4).

While the data do not allow for a definitive explanation of why certain clinical documentation categories are completed more variably than others, it provides direction for future research in this area. Specifically, additional analysis should explore variables at the provider- and office-level that may explain additional variation, such as the number and type of users participating in a given encounter by role (physician, nurse, etc). These types of variables would not necessarily reflect differences in patient needs, and would provide additional insight into the provider and staff work patterns that may contribute to variation. In the interim, EHR vendors and physician practices may want to consider developing clear guidelines and norms regarding High Variation clinical documentation categories to ensure that information which is entered in the EHR may be easily retrieved and used for high-value purposes.

Introduction
Care concerns experienced by hospitalized patients and their families are seldom reported in the absence of a safety event causing patient harm. A lack of reporting may stem from various influences, such as patients or families feeling uncomfortable in disclosing negative feedback to the clinical community or a lack of clear communication paths and coordination of follow-up. These influences combine to greatly limit our understanding of patient and family perspectives on safety threats and decrease our ability to intervene in real-time at a patient level. Moreover, analyzing patterns of safety concern data permits system-level recognition of targets for practice and process change. Engaged, activated patients experience fewer adverse events, have shorter lengths of stay, incur lower healthcare costs, and have a lower likelihood of pursuing malpractice litigation in the event of patient harm.[2–4] Data-driven mitigation of potential safety events and real-time analysis of trends based on patient data could transform hospitals into accountable, patient-centered learning health systems.[5] To better understand, mitigate, and track safety concerns from the patient and family perspective we developed and implemented MySafeCare, a web-based application that allows hospitalized patients and families to electronically submit and categorize safety concerns in real time with the option to remain anonymous. The user-centered design and evaluation process for MySafeCare has elucidated a number of important sociotechnical findings related to safety concerns from the patient and family perspective that have impacted our iterative design and implementation approaches. This podium presentation will describe: 1) the iterative user-centered development and implementation of MySafeCare, 2) quantitative analysis of submissions captured through MySafeCare, and 3) qualitative analysis of the unique perspectives of patients and families related to reporting safety threats identified and explored in this project.

Methods
We performed rapid iterative development and piloting of the MySafeCare tool, including the patient facing application (see Figure 1) and the administrator and clinician dashboard. System development included 7 steps: 1) stakeholder engagement, 2) iterative user-centered design, 3) extraction and prioritization of requirements, 4) wireframes and prototyping, 5) development, 6) testing, 7) version revisions based on testing and end-user feedback. The tool is deployed at the unit level to facilitate unit-based views of the clinical dashboard. Results reported here are for the initial 7 months of the pilot study. Data from all 15 months of pilot study (through fall 2016) will be included in the presentation. Version 1 was piloted for 3 weeks on a Vascular Surgery unit at Brigham and Women’s Hospital (BWH) during March and April 2015. Version 2 was implemented for a 6 month trial from May - October 2015 on the Medical Intensive Care Unit (MICU) and the Oncology Units (ONC) at BWH. Version 3 went live on MICU and ONC in February 2016 and will expand to medicine and surgical units later in 2016. We will present the counts and types of concerns reported from all versions and study units. Additionally, we will compare data submitted to MySafeCare to other safety data at our institution before and during the study period on our study units. These comparisons illustrate the novel information that MySafeCare captures. To better understand the unique perspectives of patients/families related to reporting safety threats we conducted interviews with patient and families and collected surveys on patient willingness to engage in their care and safety. These data are triangulated with the free text narrative of submitted safety concerns to define a conceptual model of the current state of patient and family safety reporting and to identify how data captured in MySafeCare can contribute to a learning health system.

Results
Based on our initial requirements gathering, the first prototype of MySafeCare was web-based so that patient/family users could “Bring Your Own Device” and did not require a log-in, allowing for patient/family users to remain anonymous (if desired) and to report a concern at anytime during their hospital stay. These features persisted as important to end-users throughout our testing and evaluation. Additional features include options for categorizing safety concerns, submitting a narrative of the concern, ranking the severity of the concern, remaining anonymous or self-identifying, and submitting concerns to a clinical dashboard that is viewable by the Nurse and Medical Director,
Patient Relations, or the patient’s care team. While disclose of identity could occur through details provided in the narrative, it is at the discretion of the patient/family to enter that information and that has not occurred to date.

Six concerns and 5 compliments have been submitted to MySafeCare: 5 from patients and 6 from family members. Among the concerns, 5 (83%) were submitted anonymously. Concern categories included care plan, communication, and infection. Per unit, this equated to 1 concern submitted every: 7 days on the Vascular Unit, 65 days on Oncology Unit, and 131 days on the MICU. In comparison, on average the Patient and Family Relations Department receives 1 complaint every: 33 days on Vascular Unit, 29 days on Oncology Unit, and 34 days on MICU. While counts are relatively low they were comparable to patient complaints received by Patient and Family Relations at our hospital during the same time period the prior year, and the content of concerns were useful and unique. Interestingly, a patient perceived harm related to intravenous infection control was in reality a best practice for changing intravenous line caps that the patient had not been educated about. The majority of patients/families interviewed were unaware of the administrative ‘chain of command’ of the hospital and paths for reporting a safety concern.

**Discussion**

MySafeCare application represents the next-generation of actionable measurement tools that provide a voice to, and data of, patient’s safety concerns. We know that patients have different comfort levels disclosing negative feedback to the clinical community – often referred to as “white coat syndrome”.[1] Hospitalized patients’ level of comfort in disclosing negative feedback poses a great challenge to the integrity and completeness of patient-reported safety data. MySafeCare successfully captured anonymous concerns and identified unique infection control concerns from the patient and family perspective. The notion that some patient and family concerns were due to a lack of knowledge of best practices for infection control illustrates the need to capture, track, and attend to the patient perspective to not only mitigate harms but mitigate the perception of harm when none has occurred. Patients and families lack of knowledge of the “chain of command” available for reporting safety concerns and the value of reporting concerns before they result in safety threats or harms illustrates a major gap in patient engagement strategies and the need for sociotechnical approaches to bridge this gap. We observed great variation in use of MySafeCare across clinical units. We are studying the trends and typical users on each unit (ie., family are typical users in ICU; Oncology patients often openly communicate concerns with Oncologist) to better understand if care unit, disease state, and prior experience with the health care system could impact comfort in safety reporting and the need for an anonymous, electronic reporting tool. We will report on lessons learned related to the effective implementation approaches and how these vary based on the patient population per unit. Finally, we will summarize our triangulated data of patients/families’ unique perspectives related to hospital safety.

Helping Patients with Breast Cancer Decide about Clinical Trials Participation

Prudence Dalrymple, PhD, MS¹, Lisl Zach, PhD,² Amy Leader, DrPH, MPH³, Laura Austin, MD³, Sarah Hegarty, MPhil⁴, Anna Quinn, MPH ³, Anett Petrich, RN³, Massimo Cristofanilli, MD,⁵ Russell Schilder, MD³, Ronald Myers, PhD³

¹College of Computing & Informatics, Drexel University, Philadelphia, PA; ²Informatics Insights, LLC, Philadelphia, PA; Department of Medical Oncology, Thomas Jefferson University, Philadelphia, PA; Division of Biostatistics, Thomas Jefferson University, Philadelphia, PA; ³Lurie Cancer Center, Northwestern University, Chicago, IL

Introduction
Treatment advances depend on clinical trials (CT), but numerous barriers to trial participation exist, including limited patient engagement in shared decision-making (SDM).¹ Previous studies have shown that decision aids (DAs) have a positive effect on the deliberative process of health decision-making.² We developed an online Decision Counseling Program (DCP)³ as an interactive DA to facilitate patient education and preference clarification. The qualitative research presented here is part of a larger study aimed at using the DCP to promote SDM between patients with breast cancer and their oncologists about CT participation.⁴ The goal of this sub-study was to elicit from patients their experience with the DCP. Findings provide insights and illustrate the challenges of implementing an interactive DA in clinical practice.

Method
Seven women who were newly diagnosed with breast cancer presented at an office visit for consultation with an oncologist about treatment. Immediately preceding the consultation, each woman met with a trained decision counselor, who obtained informed consent, administered a baseline knowledge survey, and used the DCP to review printed information on CTs and to complete a preference clarification exercise on CT participation. The online DCP generated a one-page summary form that displayed the patient’s preference for or against participating in a clinical trial; this summary form was given to the patient and placed in her medical chart for reference in an ensuing patient-oncologist clinical encounter. Six of the seven clinical encounters were successfully audio-recorded; one provider declined to be recorded. Approximately 30 days after the visit, structured interviews were conducted with the patients by phone and audio-recorded. These interviews ranged from 10 to 25 minutes in length (mean = 17:24 minutes; median = 15:22 minutes). Transcripts of the clinical encounters and the patient interviews were analyzed to identify key themes and patterns using open coding, which was pre-tested for intercoder reliability. This technique ensures that explanations developed from the data are verified repeatedly to protect against researcher bias.

Results
Seven women were enrolled in the sub-study. Participants ranged in age from 47 to 85 years; five women were white and two were nonwhite; two were married or living with a partner; and all had at least a high school education. Based on the results of the DCP, the derived preference of five out of seven women was to join a clinical trial; one patient had a neutral preference and the other preferred not to join a trial. One physician engaged in a short dialogue about the DCP
process itself, and another mentioned the study but didn’t refer to the materials; one nurse practitioner explained that education about clinical trials is “a good thing” even if no trial is available at the time. Although each participant was given a DCP summary form, analysis of the clinical encounter transcripts showed that the form was not mentioned in the encounters.

Analysis of the post-visit interview transcripts indicated that most participants did not recall the specific components of the DCP session, but did remember the educational materials and found them useful. They particularly noted that the materials improved their knowledge about CTs, especially that CTs normally do not include a “no-treatment” placebo control group. The women indicated that at the time of the DCP session, they felt “overwhelmed” because it was so soon after their diagnosis. This situation may explain why their recall of the session was incomplete. One woman who did recall the preference clarification exercise said “[I found it] helpful because I am sort of a visual person.”

Discussion
Our analysis of the transcripts from the clinical encounters and post-visit interviews are consistent with the findings of previous studies that patient knowledge increased from baseline to 30 days. However, it appears that completing the DCP session did not directly impact SDM about CT participation, perhaps because none of the participants was eligible for a clinical trial at the time of the sub-study encounter. However, the DCP may still be a valuable tool to prepare women who are eligible for a CT to engage in SDM, since it helps patients clarify their preferences and supports knowledge acquisition. It may also be the case that providing guidance to patients and training for physicians on how to use information generated by the DCP will be necessary to facilitate SDM about CTs.

Conclusion
Our results contribute to greater understanding of the complex challenges of integrating SDM into the clinical encounter. While several studies of the DCP have been published, this is the first time, to our knowledge, that the clinical encounter following the DCP session has been audio-recorded, thus affording insights into its impact on SDM reported in the patients’ own words.

Assessing the potential risk in drug prescriptions during pregnancy

Ferdinand Dhombres MD PhD, Vojtech Huser MD PhD, Laritza Rodriguez MD PhD, Olivier Bodenreider MD PhD
National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA

Introduction

Over eighty percent of pregnant women in the United States are prescribed at least one drug during pregnancy. The U.S. Food and Drug Administration (FDA) regulates the labeling of drug products and has established five risk categories for drug use during pregnancy. This classification was introduced in 1979. New FDA regulations (June 30, 2015) deeply revised the pregnancy and lactation labeling by eliminating these categories and replacing them with narrative summaries describing the risk of the drug and supporting evidence [1]. In a recent study on Medicaid data, 40% of pregnant women were dispensed at least one medication from categories D or X, for which there is positive evidence of human fetal risk [2]. In this work, our objective is to assess the potential risk in drug prescriptions during pregnancy, with respect to the new FDA standard. A secondary objective is to contrast risk assessment between the old FDA categories and the newly introduced narratives.

Materials and methods

**Acquiring reference risk categories.** As a proxy for the new FDA standard, we used the “pregnancy recommendations” from a reference textbook (Briggs, 10th ed. 2015) [3]. For each ingredient, it provides the level of risk (contraindicated, high risk, moderate risk, low risk, probably compatible and compatible with pregnancy), the source of evidence, if any (human or animal data), and other information as appropriate (trimester, dose and drug association restrictions). For the original FDA categories, we used an older version of the same textbook (Briggs, 8th ed. 2008), where each ingredient was associated with one of the 5 categories used at that time (A, B, C, D and X). When an ingredient was associated with more than one category (e.g., to account for risk variation based on dose, length of exposure, or associated comorbidities), we used the highest risk category. For vitamins, however, we took the lowest risk category, because prescriptions were generally within the Recommended Dietary Allowance (RDA).

**Acquiring and processing prescription data.** We analyzed patient-level, de-identified claims data of a privately insured population of 159.7M patients from 2003 to 2014 provided by the IMEDS Research Lab. We relied on procedure codes for delivery to identify pregnant women (13 CPT (Current Procedural Terminology v4) codes covering all vaginal deliveries and caesarean sections). We considered a period of 270 days prior to delivery or C-section for drugs dispensed during pregnancy. We used the RxNorm API to relate drugs from claims data to the reference. We derived the risk and supporting evidence associated with each drug, taking the highest risk in case of multi-ingredient drugs. We restricted our analysis to systemic drugs, because topical drugs generally pose a much lower risk. We counted prescriptions by category, using the new standard (level of risk and source of evidence) and the old FDA categories. We also contrasted the two standards. Two OB/GYNs (FD and LR) reviewed the top 50 of each category to ensure the reliability of the results.

Results

A total of 3,741,743 pregnant women were selected, to which 19,654,083 prescriptions were dispensed (15,815,624 for systemic drugs). The level of risk was defined using the classification extracted from Briggs (for the old and new risk categories) for 14,719,736 prescriptions (93%).

**New risk categories and supporting evidence.** Overall, 40.2% of the prescriptions were “compatible” with pregnancy and 1.2% were “probably compatible”. The prescriptions were contraindicated in 2.8%. There was a potential risk in 8,191,485 prescriptions (55.6%). For prescriptions for which the risk was quantified, the risk was low (37.6%), moderate (1.5%), and high (0.03%). For 60.8% of prescriptions, however, the risk was not quantified. Overall, evidence based on human data is available for 91.85% of all prescriptions. For “compatible” and “contraindicated” prescriptions (i.e., 43.0% of all prescriptions), the evidence was always based on human data, as defined in the Briggs recommendations. For prescriptions with a potential risk, the source of evidence was “human data” in 87.8%, “limited human data” in 10.7%, and “only animal data” in 1.49%. Only for a small fraction of the prescriptions with a potential risk (0.005%) was the evidence based on limited data, irrelevant animal data, or no data at all.
Comparison with the old FDA risk categories. (The definitions of the categories are adapted from Briggs 8th ed.)

- Almost all prescriptions originally categorized as A (i.e., controlled studies in women fail to demonstrate a risk to the fetus) are now listed as compatible with pregnancy.
- Similarly, all prescriptions originally categorized as X (i.e., with positive evidence of fetal risk that clearly outweighs any possible benefit) are now listed as contraindicated. Differences are generally due to trimester, dose and drug association restrictions.
- Prescriptions originally categorized as D (i.e., with positive evidence of fetal risk but benefits from use during pregnancy may be acceptable despite the risk) are now associated with a potential risk in 92.3% (low risk for 36.3%) and are contraindicated in 2.3%.
- Prescriptions originally categorized as C (i.e., either animal studies indicate a fetal risk, and there are no controlled studies in women, or no studies are available) are now listed as compatible with pregnancy in 46.6%, are associated with a potential risk in 51.2% (low risk for 29.1%) and are contraindicated in 0.5%.
- Finally, prescriptions originally categorized as B (i.e., either animal studies do not indicate fetal risk and there are no controlled studies in women, or animal studies have shown an adverse effect, but controlled studies in women failed to demonstrate a risk) are now listed as compatible or probably compatible with pregnancy in 41.2%, and are associated with a potential risk in 58.7% (low risk for 18.1%). None of these are contraindicated.

Discussion

Findings. This investigation demonstrates the feasibility of assessing the potential risk in drug prescriptions during pregnancy from a large claims dataset using RxNorm and the Briggs reference, with finer-grained recommendations compared to the old FDA categories, as well as stronger evidence. It had already been demonstrated that pregnant women are commonly prescribed drugs associated with fetal risk [2]. However, supporting evidence was not reported. Our results show that the proportion of prescriptions without reliable human data evidence was small (8.15%). Interestingly, in the Briggs reference, human data evidence is available for only a third of the ingredients associated with a potential risk. In contrast, in our cohort, there is human data evidence for 87.8% of the prescriptions for drugs with potential risk.

Limitations and future work. This preliminary investigation did not take into account recommendations for specific trimesters of pregnancy, which we will address in future work. This is of particular importance since risk may significantly differ over time. For example, *misoprostol*, an abortive drug, is contraindicated during pregnancy, but it is also widely used near term for labor induction [4]. Dose can impact the level of risk as well. For example, vitamin A is compatible with pregnancy under the Recommended Dietary Allowance (RDA), but contraindicated above the RDA. Several common drugs have a dose-related risk (e.g., *aspirin*, *fluconazole* and most vitamins), but the drug products commonly prescribed during pregnancy generally correspond to lower doses (e.g., *baby aspirin*, *multi-vitamin supplements*). However, for complex risk assessment (comorbidities, co-prescriptions, precise dose, duration of exposure), claims data may be insufficient.

Integrated Workflow Capture in an EHR Conversion: Standardizing on Best Practice Methods

Brad Doebbeling, MD, MSc1,2; Matthew Burton, MD3; David Kaufman, PhD1; Karl Poterack, MD4; Mac McCullough, PhD1; Adela Grando, PhD2,4; Rick Helmers, MD3; Tim Miksch, MBA5

Introduction:
Widespread implementation and meaningful use of health information technologies (HIT) has been hailed as a crucial step towards a learning health care system with safer, higher quality care. Implementation of the meaningful use policies has fostered major investment in electronic health records (EHRs). However, this rapid adoption has drawn attention to many challenges. EHRs are often insufficiently designed, tested, or integrated with clinical workflow in mind.1-4 In addition, the system transformation efforts involving EHR implementation nationally have often been costly with little or no documented improvement in interoperability, unless a conceptually-driven comprehensive transformation is planned.3,5 They have also been associated with various unintended-consequences- workarounds, adverse events, inefficiencies, and patient, provider and staff frustration.3-5

The productive use of HIT is determined by the extent to which it informs clinical decision-making and provides cognitive support for optimal clinical workflow. Little consensus exists around in-depth approaches for capturing clinical workflow prior to implementation of an EHR. Most organizations either do little to document the current state, or rely on private consulting groups or the EHR vendor to make these assessments. However, failure to do this important groundwork sets up the organization for potential failures in implementation, poor provider, staff and patient satisfaction, and inability to use these data for subsequent optimization and redesign efforts. HIT implementation or redesign that fails to consider workflow changes can lead to increased medical errors.3,7

Experts claim that the fit of HIT into clinical workflow is the most important basic necessity for safe, effective, and efficient HIT use; workflow can be assessed and described at many levels and dimensions that are often in conflict.5,7,9

Many capture, analysis, and representation approaches have been employed for evaluating complex clinical workflows.8,9 These fall into clusters of research that address, at best, a few dimensions of clinical work using theories, methods, and frameworks specific to a single discipline.10 Thus it is challenging to systematically describe work that involves highly complex, distributed, collaborative, continuously evolving, interruptive, cognitive/informational and physical elements.1,2

Methods:
The Mayo Clinic has invested significant resources to develop a rich electronic ecosystems for clinical information management. Much effort by IT professionals and providers has gone into eliciting and understanding the needs of clinicians and manifesting those needs as functionality and capabilities in numerous niche applications designed, implemented, and continuously evolved to facilitate workflow to enable high quality care. The Mayo Clinic is embarking on a large scale EHR implementation to replace multiple first generation EHRs. This undertaking has been named the Plummer Project in honor of Henry Plummer, MD, who drove Mayo’s transition in 1907 from clinic and physician records kept in ledger books to a patient-centered medical record. This project will involve migration from current, disparate EHR platforms (e.g., GE Centricity, Cerner) to a future state of a single, primary EHR (Epic Systems).

The convergence of a single, enterprise-wide EHR will enable if not necessitate the convergence of many operational processes across Mayo sites. This change will have a profound impact on the workflow of providers and staff, given the number and degree of niche, siloed applications in existence to meet the specific job duties of very specialized groups. Migration to a newly integrated EHR will be completed throughout the enterprise by 2018, giving an unusual and time-limited opportunity to document in-depth the current heterogeneous state before it is replaced. Documentation will not only serve an archival purpose but also provide invaluable “prior state” data that can be used to characterize existing pre-implementation processes in sufficient depth to reveal what has been lost in the conversion, as well as opportunities for further optimization, tool development and research and development. It will also serve as a basis to empirically assess the extent of workflow change, through process and outcome measures for both providers and patients. Additional benefits include informing data semantics for historical records and research initiatives that leverage longitudinal clinical data.

The ROOT project is both an acronym (Registry Of Operations and Tasks) and the name of Henry Plummer’s assistant Mabel Root, who played a major role in the transition to a patient-based medical record. This project begins in April 2016, to capture and archive existing HIT-mediated workflow with the current 3 EHRs (GE Centricity and 2 versions of Cerner) prior to conversion to another EHR (Epic) in all 4 of its health systems. It is a systematic effort to capture and curate a substantial portion of the current electronic ecosystem. Through the ROOT project, we will conduct a multi-method approach to reveal an in-depth understanding of work components (e.g., individuals, groups, contextual factors, information resources), as well as the interactive behavior and dependencies between the components that influence HIT-mediated performance. We will employ a comprehensive, multi-disciplinary, and multi-method Clinical Workflow Capture and Analysis methodological framework that draws on
numerous expert and evidence-based best practices and conceptualizes a more holistic and integrated view of clinical workflow consisting of interdependent, formal task structures and co-constructed, often informal task structures. The findings from various disparate, yet complementary approaches can be normalized through formal task-structures that explicitly define “who” does “what” (activities), “when”, “where”, and “how” (sub-activities) by employing “which resources or tools”, consuming, altering, or producing “what information”, and in “what relation” to other tasks or entities formally expressed in a Work Domain Ontology and visually depicted as Activity Network Diagrams. The informal task-structures are further elicited to express the actions of individual entities interacting dynamically in a complex activity system through mechanisms of coordination, awareness of co-workings, and qualitative descriptors that preserve the richness of findings from distinct methods.

A series of interrelated, interdisciplinary projects are planned for 1) capturing and archiving a massive multisite, multiprovider observational, interview and video dataset of EHR, clinical workflow, and contextual information; 2) discovering workflows from event logs generated by various information and communication systems; and 3) creating a repository of work data that serve as digital signatures, or patterns in an organization to understand common practices, deviations, and need for intervention and monitoring. A modified Delphi Panel of over 60 Mayo Clinic clinical experts involved in the Plummer project will further develop and rank a comprehensive list of clinical areas, providers and important workflows to be studied by the project. We will survey asynchronously clinical and operations leaders using the over 200 information systems that will be replaced and integrated by the Plummer project.

Results:
Mayo and ASU informaticists, clinicians and researchers have been partnering to define the methods and technologies needed to capture a sufficiently comprehensive snapshot of the current state. We will present results from the first six months, challenges and solutions to the barriers encountered.

Discussion:
The approach outlined here is important as a necessary step in preparation for the system transformation associated with an EHR implementation or conversion. We intend to use the ROOT project as a “reference implementation” of such tools, techniques, and methods to set the standard for future workflow analysis when implementing, optimizing, or enhancing HIT. The methodologies and tools applied to the ROOT project will be customized for use at Mayo and published as an established and authenticated standard for the organization. Without collecting and archiving such data prior to implementation, it will always be difficult to address questions of whether the patients, providers and processes are improved. Furthermore, such a strategy will help ensure the implementation is successful, that post-implementation optimization is well-informed, and that questions about functionality that may have been lost can be addressed. Starting with appropriate collection and curation of data, analyses may help to develop and disseminate software and analytic tools to streamline the process of modeling clinical workflow. We anticipate a program of R&D may hasten innovation, guide implementation of more efficient delivery systems, and help transform the health care system.

Delivering High Quality Birth Certificate Data from an EHR

Jeffrey Duncan, PhD¹, Catherine Staes, BSN, MPH, PhD²
¹Utah Department of Health, Salt Lake City, UT; ²University of Utah, Salt Lake City, UT

Introduction

Birth certificates are one of the core public health data sets and are used for public health surveillance, policy development, and research.¹ Birth certificate data are typically reported to state public health departments by hospitals using the 2003 US Standard Birth Certificate.² In practice, hospital birth clerks, typically employees in the Health Information Management or Medical Records departments are tasked with abstracting maternal and child information onto standard worksheets, then keying that information into a web-based Electronic Birth Registration System (EBRS) to report to public health. As healthcare facilities increasingly adopt electronic health record (EHR) technology, there is growing interest in automating the capture and reporting of birth certificate information. The National Center for Health Statistics (NCHS) has led efforts to develop and test methods for reporting birth certificate medical information from EHRs, resulting in a standard Integrating the Healthcare Enterprise (IHE) profile known as Birth and Fetal Death Reporting enhanced (BFDRe).³ BFDRe has been tested by EHR and EBRS vendors during interoperability showcases but has not yet been implemented operationally.

As the BFDRe standard matures and jurisdictions prepare for implementation, it is important to understand the quality, limitations, and transformations required to automate birth certificate reporting from an EHR. Our primary objective was to assess the accuracy of information extracted in the BFDRe CCD compared to that reported on birth certificates for select maternal and child data elements in order to ascertain readiness for automated birth reporting. An additional objective was to understand the strengths and limitations of automated birth reporting and to develop strategies to ensure birth certificate data quality. Table 1 shows the birth certificate data elements that were compared, organized by source of information.

Methods

Utah Department of Health (UDOH) worked with University of Utah Health Care (UUHC) to evaluate the quality of 12 selected birth certificate variables documented in its Epic EHR. In December 2015, UUHC implemented an interface with Epic’s Stork module to create HL7 CDA-standard Labor and Delivery Summary (LDS) documents for a sample of 60 recent births. The same information was collected at Sibley Memorial Hospital (SMH) in
Washington, D.C. and compared to birth information reported to the District of Columbia Department of Health (DCDOH). Information from the LDS was compared with: a) information previously reported on birth certificates, and b) a reference standard created by two birth certificate experts from UDOH and two from DCDOH who independently reviewed each of the 60 records in their respective jurisdictions and adjudicated differences.

**Results**
The availability and accuracy of information automatically extracted from the EHR varied widely depending on source of data and location. Table 2 shows preliminary results of comparisons between the Extract group and the EBRS group compared to the Reference Standard for both Utah and DC.

**Table 2. Preliminary finding showing the percent of records that differed in comparison to the reference standard, data element and by jurisdiction**

**Discussion**
The prenatal record is often noted as missing in operational records and when present, may be scanned into the hospital record which limits automated extraction of prenatal information. The availability of information in the EHR extract depends on where the information is documented in the EHR, and documentation practices vary by facility. Some items are not documented in the standard CCD.

**Conclusions**
Automated reporting of most of the birth certificate information is feasible using existing standards, provided that problems with the standard or facility documentation practices are addressed during implementation. In addition, ongoing assessment birth certificate information reported automatically is required to ensure quality is not sacrificed.

A Matching Algorithm between ClinicalTrials.gov and PubMed to Support the Monitoring of Gaps in Published Study Results

Adam G. Dunn, PhD¹, Florence T. Bourgeois, MD MPH²,³

¹Centre for Health Informatics, Macquarie University, Sydney, NSW, Australia;
²Computational Health Informatics Program, Boston Children’s Hospital, Boston, MA;
³Department of Pediatrics, Harvard Medical School, Boston, MA

Introduction

Clinical trial registries such as ClinicalTrials.gov provide detailed and structured information about clinical trials, including information on the study intervention and design and whether the study has been published. This information can be leveraged for a number of functions in monitoring research activities, such as identifying and monitoring gaps in the reporting of trial results or supporting automated searching and screening processes for systematic reviews. This type of automated surveillance requires consistent and comprehensive linking of trial entries in ClinicalTrials.gov to publications in PubMed. However, there is a substantial proportion of study records on ClinicalTrials.gov that is not indexed by PubMed and the links between the registry records and the publications are missing.¹,² This problem precludes systematic monitoring of trial result reporting and analyses of reporting bias.³,⁴ It also remains as a barrier to automating searching and screening in systematic reviews,⁵,⁶ for which current natural language processing methods applied to bibliographic databases appear to be reaching a performance limit.⁷

An automated tools to produce a comprehensive matching between ClinicalTrials.gov and PubMed may improve the integration of ClinicalTrials.gov with other sources of clinical trial information.⁸ Our aim was to evaluate an algorithm for matching published reports of clinical trials with their ClinicalTrials.gov study records.

Methods

Study Data: From 68,962 interventional studies on ClinicalTrials.gov, and the 330,500 PubMed records published between January 2007 and December 2016 with publication types matching clinical studies, we selected two datasets: one for training and validation, and a separate set for testing. The first included the 12,155 registry entries with exactly one matching PubMed article published after the trial completion date. The second was a random sample of 150 registry entries completed before January 2014, and with no linked PubMed articles. For this second set, we performed a manual search in PubMed to identify articles that report results following the standard approach, limited to PubMed.⁴

Design: We used MetaMap (2014AA with word sense disambiguation) to extract medical concepts from the titles, study descriptions, and conditions in the study records in ClinicalTrials.gov, and from the titles and abstracts of the articles in PubMed. We did not match investigator or author names in the prototype because this would have required a second type of matching to be able to include it in the cross-validation described below. The similarities between registry entries and articles were defined by summing weights (defined below) for shared medical concepts.

For each registry entry we produced a ranked list of articles with the aim of ranking the matching article as high as possible. To do this, we trained the medical concept weights such that concepts found to be useful for matching study records and articles would be assigned higher weights. Weights were initialized to their Jaccard index and then iteratively refined by assessing whether increases or decreases in the weight would improve the ranking for more trials than it would degrade. The schedule for selecting concepts for this assessment was based on the frequency of their occurrence, so that more common terms were updated more often in the training procedure.

In the first experiment, we trained the concepts weights using 12,155 registry entries and articles, with 80% used in cross-validation and 20% as a holdout. In the second experiment, concept weights from the first experiment were applied to 200 registry entries and 330,500 articles. As an example of how the tool could be used to measure unreported trials, we reported the time to publication on the testing set. The time to publication curve shows the proportion of trials that remain unreported at a given time and the follow-up period for trials with no known results.

Outcome measures: The rank distribution of the correct article matches within the set of candidates for each study record; the number of articles that need to be read (NNR) per study record to find matching articles. We defined the NNR metric to be comparable to metrics for the performance of automated searching and screening methods.⁷
Results

In the 20% holdout from the training and validation set, the median rank of the correct match was 1 (IQR 1-3). For 91% (2,217/2,431) of the study records, the correct article was in the top 10 candidates. In the manual check, we found matches in PubMed for 45% (90/200) of the randomly sampled registry entries. Using the algorithm, the median rank of the correct match was 42.5 (IQR 10-255), and 27% (24/90) of the correct articles were found in the top 10. Figure 1 illustrates the NNR per study record to identify a given proportion of matching articles.

Discussion

Methods for predicting links over a bipartite graph may be useful for reducing the number of PubMed articles that need to be checked to find articles reporting results of trials on ClinicalTrials.gov. A remaining practical limitation is the need to manually search a number of articles to achieve a pre-specified level of confidence. Planned improvements include the use of other metadata such as investigator names, as well as alternative representations of the registry entries and article abstracts that improve the document similarity measures.

Figure 1. Articles identified by NNR for the (a) training holdout (2,431 articles in 2,431) and (b) testing set (90/200) articles in 33,500); and (c) estimated time to publication among 200 trials without pre-existing matches in PubMed after reading 10 (0.003% of the total), 100 (0.03%), or 1000 (0.3%) of the ranked articles per registry entry.

Automated Identification and Predictive Tools to Help Identify High-risk Heart Failure Patients

R. Scott Evans\textsuperscript{1,2}, Jose Benuzillo\textsuperscript{2}, Benjamin D. Horne\textsuperscript{2}, James F. Lloyd\textsuperscript{1}, Alejandra Bradshaw\textsuperscript{2}, Deborah Budge\textsuperscript{2}, Kismet D. Lappé\textsuperscript{2}.

\textsuperscript{1}Medical Informatics, \textsuperscript{2}Cardiovascular Clinical Program

Intermountain Healthcare. Salt Lake City, UT

\textbf{Introduction:} Heart failure (HF) affects 2.4\% of adults in the US or nearly 6 million people. The HF cost burden was expected to reach $44.6 billion by 2015 (1) of which hospitalization represents 70\% of that cost (2). Moreover, as the prevalence of HF has increased, so has the incidence of hospital readmission and mortality (3) and HF is the leading cause for recurrent hospitalizations (4). The increasing prevalence of HF mandates a new approach to decision making and especially better communication that includes clinical decision support (CDS) to help identify high-risk HF patients as soon as possible (5). One method has been the use of predictive models to identify high-risk HF patients (6-15). However, those models are rarely used and little is known about their clinical use and their impact on patient care (6, 16). In 2010, the Intermountain Risk Score (IMRS) was published which predicted HF readmission and incident HF (17). In order to provide that information quickly to providers, a CDS application was developed to use natural language processing (NLP) to improve the identification of HF patients while another application based on the IMRS calculates their 30-day all-cause readmission risk and 30-day mortality risk. A new report is used by the Cardiovascular Clinical Program at Intermountain Healthcare each day which identifies the high risk HF inpatients that need to be closely followed using a multidisciplinary care process pathway (CPP). This presentation will report the development and use of these applications and the impact on patient care.

\textbf{Methods:} The NLP application was developed to read any type of dictated report in the electronic medical record (EMR) and use “key words/terms” along with diuretic use, B-type Natriuretic Peptide (BNP) level $> 200$ pg/mL, Ejection Fraction (EF) $\leq 40$ in the previous year, and ever been eligible to any of the Center of Medicare and Medicaid Services or Joint Commission HF core measures to identify patients with HF. The other application looks at each hospitalized HF patient each day and calculates their 30-day all-cause readmission and 30-day mortality risk scores. The risk scores were grouped and presented as low, moderate and high and based on gender. The information is then included in the Cardiovascular Clinical Program’s HF patient Identification and Risk Stratification Daily Report which was developed using Tableau Software and emailed to over 300 clinicians at 9:15am each morning. The report also includes other pertinent information to facilitate the clinicians’ work-up for each patient which comes from the Echocardiogram and laboratory data. The Cardiovascular Clinical Program initiated a new CPP for HF patients targeting those identified in the HF patient Identification and Risk Stratification Daily Report with the aim to improve the transition of HF patients from hospital to home care, decrease admissions to skilled nursing facilities and reduce 30-day readmission and 30-day mortality. A before-and-after study design was used to measure the use and impact of the new HF patient Identification and Risk Stratification Daily Report and CPP for HF patients. Patients treated using the new CPP from 02/03/2014 to 06/30/2014 were compared to patients receiving standard care at the same 354 bed hospital before the CPP from 10/01/2013 to 02/02/2014.

\textbf{Results:} The addition of NLP compared to just using ICD9 codes to help identify HF patients increased the sensitivity from 82.6\% to 95.3\% and specificity from 82.7\% to 97.5\% and a current positive predictive value of 97.45\%. The daily multidisciplinary cardiovascular planning meeting and CPP now based on the information in the HF patient Identification and Risk Stratification Report are able to identify HF patients sooner and the clinicians’ review of potential HF admissions takes only 10 vs. 40 minutes. From 02/02/2014 to 06/30/2014, 100 patients were treated using the new CPP compared to 75 patients during 10/01/2013 to 02/02/2014. The 30-day mortality rate was significantly lower (7\% vs.19\%, \(p=0.03\)) in the pathway group compared to the non-pathway group, the proportion of patients discharged to home health was significantly greater (34\% vs.19\%, \(p=0.02\)), and average length of stay was a half day less and the average hospital variable costs were $807.6 less, but not statistically significant (\(p=0.44\) and \(p=0.56\) respectively). However, there was no significant difference in the number of HF patients readmitted within 30-days in the study hospital which is the third lowest in the US for HF readmission.
Discussion: In order to improve the continuum of care for hospitalized HF patients, accurate and early identification during hospitalization is crucial. Manual identification of hospitalized HF patients is time consuming and challenged by inconsistent and poorly sensitive processes. We developed two new CDS applications and the HF patient Identification and Risk Stratification Daily report to facilitate the early identification and care of HF patients. This information is automatically provided to clinicians each day and allows them to prioritize their limited time based on the identified HF patients rather than spending time to identify them manually. Use of CDS coupled with a multidisciplinary CPP was found to be an effective method to improve HF patient identification and help to significantly reduce 30-day mortality and significantly increase patient discharges to home health rather than a skilled nursing facility. Both CDS applications and the CPP have been installed at the other Intermountain hospitals that treat HF patients and additional data and sustainability will be presented along with details of our NLP methods.

Automated De-Identification of Distributional Semantic Models

Gregory P. Finley, PhD1,2, Serguei V. S. Pakhomov, PhD1,3, Genevieve B. Melton, MD, PhD1,2

1Institute for Health Informatics, 2Department of Surgery, and 3College of Pharmacy
University of Minnesota, Minneapolis, MN

Introduction

Machine learning approaches to difficult problems in natural language processing (NLP) rely on abundant data for training. In the medical domain, unstructured text in electronic health record (EHR) systems provides an especially rich source of natural language data. However, EHR text contains protected health information with highly restricted access. The U.S. Health Insurance Portability and Accountability Act (HIPAA) specifies requirements for protecting confidentiality in EHR datasets used for non-clinical purposes by removing certain identifying strings, such as names and addresses.1 Performing this de-identification (de-ID) process manually, however, is prohibitively expensive for very large corpora.2 Automated methods have achieved some success,3–5 but healthcare institutions often remain hesitant to permit the release of automatically de-identified text.

We present an alternative approach: de-identifying a word co-occurrence table rather than raw text. Co-occurrence statistics lie at the heart of many distributional semantic models, which have numerous applications in biomedical NLP.6 By their nature, these models do not preserve the syntax of their source text, dramatically reducing the risk to confidentiality even before de-ID. If stripped of identifiers, these models could be safely shared with other researchers to improve outcomes in NLP and information retrieval.

The success of this approach depends upon meeting two objectives: the successful removal of identifiers from a model, and the preservation of that model’s NLP utility. We present experimental work addressing both concerns: we compare an automated de-ID strategy to manual expert de-ID of clinical notes in English, and we measure the effect of de-ID on the accuracy of an NLP tool for acronym disambiguation that relies on co-occurrence statistics.

Methods

We evaluate three variants of a simple string match de-ID algorithm: 1) any words not present in the inventory of non-proper nouns in the UMLS SPECIALIST Lexicon are removed; 2) words appearing anywhere in the names or addresses of all patients in the enterprise EHR system are removed; 3) both of the above. Numerals, months, and days of the week are removed in all conditions. Tokens are not stemmed. All string comparisons are case insensitive.

Note that many of these strings are not in themselves identifying but are rather fragments of identifiers—e.g., ‘street’, ‘from’—and that most fragments also have non-identifying uses that are far more common than their sensitive uses. With this in mind, we also test slightly relaxed variants of Condition 3 above in which the most frequently occurring words are kept in the model regardless of their status as potential identifier fragments.

To score coverage, we compare results of our de-ID method to manual expert de-ID of a corpus of clinical text (1.2 million words). Of 21,852 word types in the corpus, 3,109 can occur as identifier fragments. We measure the recall of our de-ID system over these 3,109. We also measure accuracy of an acronym disambiguation system following the automated de-ID of its co-occurrence table, scored against a manually annotated gold standard of 18,499 instances of 74 acronyms.

Results

Results in Conditions 1-3 are given in Table 1. Only Condition 3 achieves the comprehensive removal of identifiers; however, this strategy has a high false positive rate and leads to a major drop in NLP performance. (For reference, the non-de-identified acronym system achieves 90.7% accuracy.) Table 2 shows four variations of the relaxed Condition 3. Acronym accuracy increases dramatically from the unmodified Condition 3, trading with a slight impact on de-ID coverage. We found a good balance to be keeping the most common 2,000 words, which causes only a 1.3% drop in acronym model performance while still targeting nearly all potential identifiers.

We systematically examined the 44 potential identifier fragments missed by the recommended de-ID strategy to determine if they pose any risk to confidentiality. In roughly half of all cases, the string was a personal name homographic with a common word (‘will’, e.g.); in most others, the string was part of a place name (‘new’ as in
‘New York’, e.g.). These misses likely pose minimal to no risk due to the nature of co-occurrence models: uses of as an identifier are impossible to separate from innocuous uses, and because these are exceptionally common words, counts of identifier tokens are dwarfed by counts of non-identifier tokens. Of all possible identifier fragments in the 2,000 most common words, fewer than 1% of their combined occurrences in the corpus were actually in identifiers.

Discussion

We show that it is possible to create semantic models from large corpora that are nearly completely stripped of potential identifiers yet still function quite well for NLP applications. Even extremely aggressive de-ID strategies can be applied without seriously compromising the utility of distributional models; using more sophisticated and less aggressive machine learning de-ID algorithms⁴ should lessen the impact on NLP performance further.

We recommend that these methods be employed to create sharable NLP resources, which would allow researchers and institutions without access to large clinical text corpora to benefit from NLP tools developed from data available to larger medical research institutions (e.g., CTSI, PCORnet). The increased availability of such resources would serve both to expand the research community in medical NLP and to enhance information extraction and retrieval outcomes for other informatics researchers.

Adoption of Nurse Facing Clinical Decision Support Following EHR Implementation

Denise Goldsmith, MPH, MS, RN\textsuperscript{1}, Karen Bavuso, MSN, RN\textsuperscript{2}, Charles Lagor, MD PhD CPHIMS\textsuperscript{2}, Sarah Collins, PhD, RN\textsuperscript{1,2,3}

Introduction

With the recent and rapid expansion of electronic health records in the acute hospitalization space nurses find themselves exposed to Clinical Decision Support (CDS) functionality that was previously unavailable to them. Such is the case within this Academic Medical Center (AMC) that recently implemented electronic nursing documentation, transitioning from paper. It was the objective of this study to evaluate the actions taken by nurses when presented with CDS interventions related to risk for falls, risk for skin breakdown and patient restraint use. These three domains were chosen for evaluation primarily because the CDS rules fire solely within nursing documentation and because accountability for the assessment, intervention and outcomes associated with these elements are all within the scope of nursing practice. Additionally, the elements of fall risk and skin integrity are contained within the National Database of Nursing Quality Indicators\textsuperscript{®} and appropriate management of restraint use is a standard of The Joint Commission. When presented with a CDS intervention in this electronic health record (EHR), nurses have the option to agree with and act on a CDS recommendation (accept), choose a reason for not taking the recommended action (override), or ignore it all together by not interacting with the alert and navigating out of the CDS window (ignore). The three CDS interventions we focused on are rule-based and driven off of nursing assessment documentation. Prior to CDS implementation each alert underwent a review of nursing and system workflow to determine the best time and place for the alert to fire. These CDS interventions are incorporated into the admission documentation process and are for the most part non-interruptive in that they do not require a nurse to take an action for the CDS in order to proceed with his/her documentation workflow. Minimal CDS education for nurses was included in the EHR implementation training. This podium presentation will provide an overview of all nurse-facing CDS interventions active at our institution and an in-depth evaluation of CDS interventions described above that target regulatory requirements using our most updated data sets and analyses.

Methods

CDS alert firing data for this evaluation was extracted from the EHR system used at this AMC. The data used in this analysis, extracted from a larger data set of all CDS data for the AMC, represents the alert firing activity and rates of ‘accept’, ‘override’ and ‘ignore’ for patients admitted as inpatients. Because the recommendations for these three CDS interventions were based on regulatory requirements we consider an ‘acceptance’ to be a compliant action, and an ‘override’ to be a non-compliant action, and an ‘ignore’ to be a non-compliant inaction. The three CDS interventions included in our analysis were non-interruptive alerts, presented as an interactive alert window, within the EHR admission assessment documentation screen. The CDS fired when specific assessment criteria were met (e.g., Morse Fall Scale and Braden Score above a specified threshold). The alert remained unresolved until it was either ‘accepted’ or ‘overridden’. For example, if the alert resulted in plan of care (POC) documentation (CDS recommendation was accepted), or if the nurse selected an override reason and did not complete POC documentation (CDS recommendation was overridden), the CDS would no longer be presented to the nurse. If an override reason was selected the alert was resolved for at least 24 hours or indefinitely depending on the reason selected.

Our current data set represents an eleven week time period beginning five months following EHR implementation and education of nursing staff regarding the use and value of CDS in their documentation workflow. We continuously update these data and will present our most updated data findings. For the three CDS interventions analyzed an ‘acceptance’ included the following possible actions: 1) following a link within the alert message that redirected the user to the patient’s POC or 2) placing an order as recommended by the alert. An override (“non-compliant” actions) included instances when the alert was acknowledged, commented on, or labeled insignificant by a nurse without following the link to the patient’s POC or placing an order as recommended.
After the data was extracted from the larger data set it was separated into discrete worksheets. A custom sort by Date, then Time, then Patient ID, then Follow-up action was performed. To prepare the data, we removed rows that were not a unique instance of a CDS intervention, such as “duplicate actions” that occurred for the same patient, the same nurse and the same CDS rule at the exact date and time. Once all duplicates had been removed we coded the actions as an “accepted” recommended action or an “overridden” recommended action. Each code was filtered by the type of follow-up action taken (e.g., linking to the patient’s Plan of Care (POC) or the placing of an order) to perform percent calculations.

**Results**

The three CDS interventions resulted in a total of 14,000 alerts fired over eleven weeks. Overall, nurses ignored the CDS alerts 91% to 95% of the time it was made available to them to act upon. Of the 5% to 9% of alerts that were not ignored, acceptance rates ranged from 20% to 52%. Our data indicates that overall, an alert was accepted (not ignored or overridden), only 4.6% (369/7976), 1.8% (37/2025), and 0.97% (39/3999) of the time. The Fall Risk CDS intervention which recommended that a POC problem be documented based on the patient’s Morse Fall score greater than 45 had an acceptance rate of (compliant with recommendation) 52% when the alert was not ignored. The Risk for Impaired Skin Integrity CDS, which recommended that a POC be documented, based on a patient’s Braden Score of 18 or less, had an acceptance rate (compliant with recommendation) of 32% when the alert was not ignored. The Restraint CDS recommended that a POC be documented based on the presence of an active restraint order. This CDS had an acceptance rate (compliant with recommendation) of 20% when the alert was not ignored (Table 1). The data also indicates variation in the rates of override actions among the three CDS interventions. When the Restraint alert was overridden, 23.5% of the time the nurse selected the override option indicating that the alert was ‘insignificant’. However, when the other CDS alerts were overridden, the ‘insignificant’ option was only selected 3.6% and 0.9% of the time for High Fall Risk and Risk for Impaired Skin Integrity, respectively.

**Discussion**

CDS is not intended to replace nursing judgment, but rather to provide a tool to assist them in making higher quality decisions while planning the care of their patients2. For patients that met the criteria for these regulatory-based CDS interventions we observed very high “ignore” rates. Even when the CDS was not ignored, the alert was overridden by the nurse most of the time. These results generate discussion and inquiry as to whether CDS for nurses that recommend POC interventions have value within their documentation workflow. We choose these CDS to be non interruptive to the workflow. This raises the question as to whether this was the right decision. Our analysis has limitations. We based our assessment of “accepted” versus “overridden” on a simple classification scheme of follow-up actions, which may not apply in every situation. We also do not know if the nurse acted upon the CDS recommendation from outside the CDS window. In this analysis we observed variations within the data that are useful to direct refinement and optimization efforts for nursing CDS as we learn how to better support nursing decision making and add value where it is most needed.

**Conclusion**

We have begun our monitoring and analysis of nursing CDS data and will continue to update our data sets and analysis. In our preliminary work we have observed interesting variation that can direct efforts for optimization and identification of CDS interventions that are not adding value to the nurses’ workflow and decision making. Further analysis needs to be directed at why nurses choose to either ignore or take the actions they do when presented with CDS intervention recommendations.

Implementing and designing a distributed regression analysis module within PopMedNet™ for a large scale distributed data network

Qoua L. Her, PharmD, MSc¹, Jessica M. Malenfant, MPH¹, Sarah Malek, MPPA¹, Yury Vilk, PhD¹, Elizabeth Cavagnaro, MPH¹, Lingling Li¹, ScD, Jeff Brown, PhD¹, Sengwee Toh, ScD¹
¹Harvard Pilgrim Health Care Institute, Boston, MA

Introduction: To obtain sufficient sample sizes and valid regression analyses, many clinical studies require pooling of individual-level data from multiple data sources.¹ Patient privacy and the protection of propriety information have limited this practice.² However, through distributed regression analysis (DRA), statisticians have demonstrated the ability to perform regression analysis with only de-identified intermediate statistics to obtain statistically equivalent regression parameters as pooled individual-level data analysis.³, ⁴ For logistic and Cox regression models, DRA involves iterations of each data source computing site-specific intermediate statistics and transferring the statistics to an analysis center, where the statistics are aggregated and used to update parameter estimates. These parameter estimates are sent back to the data source to further fine tune the intermediate statistics and re-estimate regression parameters. This iterative process continues until the model converges.

The inability to automate DRA iterations has limited its use in practice. DRA is highly desirable in the FDA’s Sentinel system, a distributed network that uses multiple electronic healthcare data sources to monitor the safety of medical products. Ensuring patient privacy is critical for data partner collaborations in Sentinel. PopMedNet™ (PMN), the open-source distributed data-sharing platform used by Sentinel, is being enhanced to facilitate the iterative DRA process and enable users to conduct secure DRA for continuous, binary, and survival outcomes. A major development goal was to limit modifications to data partners' existing hardware and software configurations. This presentation will describe the software designs, user interfaces, workflows, and challenges of building the DRA module in PMN.

Methods: An interdisciplinary team of Sentinel investigators including epidemiologists, computer scientists, programmers, biostatisticians, and informaticians is leading the development of the DRA module. Through an iterative process, the team analyzed PMN’s existing functionalities and mapped out software designs and workflows that would automate DRA. As part of the project, the team sent a short survey to data partners to (1) inventory current hardware configurations and software heterogeneity, and (2) assess each partner’s ability and willingness to allow DRA automation. DRA module’s results will be compared to the pooled individual-level data analysis. We will conduct evaluations in a simulated distributed environment and at select Sentinel data partner sites. If the DRA module is successful, it will produce results that are statistically equivalent to the pooled analysis.

Results: A privacy-preserving automated DRA module can be developed and implemented within the existing PMN environment. The proposed DRA will involve two steps: 1) assembling an analytical dataset and structuring data fields for DRA using Sentinel’s publically available Cohort Identification and Descriptive Analytics Tool, and 2) automating the DRA iterations between data partners and the Sentinel Operations Center (SOC) with PMN’s existing distributed querying capabilities and workflow.⁵ (Figure 1). The survey identified three general hardware configurations, the existence of SAS software heterogeneity, and mixed perspectives towards full automation, in which some data partners would like to review intermediate statistics prior to transmission to the SOC.

Discussion: DRA is feasible in Sentinel’s distributed data network and will leverage existing Sentinel and PMN infrastructure. Heterogeneous configurations across Sentinel data partners’ hardware configurations and willingness to automate the process pose some challenges. Thus, the study team will
consider a semi-automated design and workflow and conduct trainings to allow full-scale adoption. A functional DRA module will still require appropriate governance to facilitate real-world application. Successful implementation of a DRA module in PMN will likely lead to greater use of DRA in multi-center studies as PMN is open-source and the informatics platform is used by several other distributed data networks, including PCORnet, National Cancer Institute’s CRNnet, and the NIH Health Care Systems Research Collaboratory.

Implementing Pharmacogenomic Clinical Decision Support:  
Design and Prescriber Response in the eMERGE Network

Timothy M. Herr, MS 1; Josh F. Peterson, MD, MPH2; Luke V. Rasmussen, MS1; Pedro J. Caraballo, MD3;  
The eMERGE Network

1Northwestern University Feinberg School of Medicine, Chicago, IL; 2Vanderbilt University Medical Center,  
Nashville, TN; 3Mayo Clinic, Rochester MN

Introduction
Previous literature has established that pharmacogenomic (PGx) clinical decision support (CDS) may be an ideal  
implementation avenue for genomic medicine.(1) However, analyses of PGx CDS design and resulting outcomes in  
live clinical settings have been relatively limited in scope.  To better understand design approaches and prescriber  
response to PGx CDS, we evaluated implementations and alert data at seven different sites in the Electronic Medical  
Records and Genomics (eMERGE) Network.(2)

Methods
This study was conducted among seven large academic and research-oriented health care organizations.  The scope  
of the project was limited to alerts, providers, and patients that were part of the eMERGE-PGx Project.(3)  

To understand the PGx CDS design decisions made by each site in the eMERGE Network, we surveyed key  
representatives at each participating organization.  We developed survey questions via a series of informal  
interviews conducted with one representative at each site. We then assembled a formal questionnaire and distributed  
it by email for completion by the same representatives. Sixteen questions elicited differences in design objectives  
and constraints for each site’s implementation. Key topics included the drug-gene interactions (DGI) for which PGx  
alerts were implemented (and over what time period), where in the electronic health record (EHR) alerts fired, the  
source of alert recommendations, and available actions prescribers could perform in response to alerts.  

To understand how prescribers responded to PGx CDS alerts, we asked each site to provide evidence of provider  
response based on EHR log data. As the various eMERGE sites have widely different technical infrastructures,(4)  
we developed a standard data dictionary through a series of calls conducted by the eMERGE PGx Workgroup.  This  
allowed each site to report alert data in a consistent format for aggregate analysis.  Prescriber response was divided  
into two different actions – “alert response” (corresponding to the action taken on the actual alert in the EHR) and  
“clinical response” (corresponding to the relevant clinical action taken after viewing an alert).  Alert responses were  
standardized to “Accepted,” “Overridden,” and “Ignored.” Clinical responses were standardized to “Followed,”  
“Not Followed,” and “No Action.” Each site was responsible for defining these terms for its own data according to  
local practices. Other key data points collected included alert metadata (such as the drug and recommendation),  
alert time, and prescriber department and education level. Submitted data were analyzed both in total aggregate and  
broken down according to alert characteristics.  For consistency, preliminary data analysis was limited to active,  
post-test alerts only.

Results
All seven sites implemented some form of active alerting (interruptive alerts that fire during the prescribing  
workflow), while four implemented some form of passive alerting (non-interruptive alerts visible on a general  
recommendations screen, in-basket messages, etc.). Only two sites elected to implement pre-test alerting (alerts  
suggesting prescribers order a genetic test before prescribing a particular drug). Alerts varied widely on what  
genetic data were used as inputs – some simply looked for the existence of a genotype test result of any value, others  
looked for an actionable genotype, an actionable phenotype, or a combination of both. Alert recommendations were  
typically modeled after CPIC recommendations, though with some local modifications or review. Three sites  
implemented dynamic dose calculations for warfarin prescribing, while alerts for other drugs were typically static  
recommendations. The available alert actions varied widely from site to site and alert to alert.

Preliminary analysis included 294 active, post-test PGx alerts from six sites. The seventh site had zero alerts fire for  
the DGIs of interest, though they did report recording alerts for related medications not covered in this analysis.  
DGIs examined included codeine/oxycodone/hydrocodone/tramadol (CYP2D6), clopidogrel (CYP2C19),
simvastatin \((SLCO1B1)\), and warfarin \((CYP2C9, VKORC1)\). In terms of alert response, 183 (62%) alerts were accepted, 75 (26%) were overridden, 34 (12%) were ignored, and 2 (0.8%) had an undetermined action. In terms of clinical response, 124 (42%) alerts were followed, 126 (43%) were not followed, and 44 (17%) had no relevant action taken. There was moderate to high correlation between alert response and clinical response \((r=0.697)\).

Response rates varied by DGI. Only one DGI (codeine) had a majority of alerts followed (Table). All other DGIs had a majority of alerts that were not followed.

</tbody>
</table>

Discussion
These results demonstrate that there is currently little consensus for how to best design and implement PGx CDS alerts, even among sites within a collaborative consortium. Though our results show encouraging indicators that PGx CDS can be effective, a majority of alerts in these first generation systems were not followed or had no clinical follow-up. Taken together, these results indicate that there is significant room for further refinement of PGx CDS systems. Additional effectiveness studies are necessary to determine why response rates were generally low. Possibilities include low relevance of alerts, incorrect timing of alerts, or unclear communication of recommendations.

This study also demonstrates the complexity of understanding alert response. Actual alert responses vary greatly from simple accept/override/ignore conventions. Not all alerts have the same available actions, and some available actions are not fully represented by the accept/override/ignore paradigm. For instance, clicking a link to review educational materials could be seen as a successfully capitalized opportunity to educate a prescriber, even if they do not follow the recommendation in that particular instance. Additionally, there is some discrepancy between the action a prescriber took on an alert and the corresponding clinical action – there is not necessarily a 1-to-1 relationship between alert and clinical response. This is likely primarily due to the design of the alerts. For instance, an alert may simply have a “cancel” function, rather than an explicit “override” function. In this case, a simple analysis of alert logging data will not reveal whether the prescriber found the alert clinically irrelevant or simply ignored it entirely. Therefore, it is necessary to analyze clinical actions to fully understand alert response.

In conclusion, these seven systems are examples of first-generation PGx CDS in live clinical settings. While these systems show promise, early analysis indicates that there is significant room for improvement. These systems were largely developed based on expert opinion, so further systematic analysis and design could potentially lead to improved relevance, usefulness, and timeliness. Such changes would likely increase alert response rates and improve patient care. Follow-up research will focus on usability and usefulness analysis.

Interoperability and Electronic Availability of Outside Information among US Hospitals

Authors: A Jay Holmgren,1,2 Vaishali Patel, PhD,3 Dustin Charles, MPH,3 Julia Adler-Milstein, PhD1,2

1. University of Michigan, School of Information, Ann Arbor, MI. 2. University of Michigan, School of Public Health, Ann Arbor, MI. 3. Office of the National Coordinator for Health Information Technology, Washington DC.

Introduction

Interoperability is currently a top policy priority as well as the focus of substantial effort on behalf of provider organizations. (1) (2) While national levels of electronic health record adoption have been carefully tracked over time, it has been more difficult to assess interoperability capabilities of EHRs at the national level. The Office of the National Coordinator for Health IT (ONC) has conceptualized interoperability as including four core capabilities: the ability to find information from external organizations (i.e., query), the ability to send information to external organizations, and the ability to receive information from external organizations, and the ability to integrate information received into an electronic record system without special effort on behalf of users. (3) Together, these capabilities ensure that a range of key interoperability use cases can be supported, such as emergency care where finding information is essential and transitions of care where sending and receiving information is essential. In our study, we use national data on hospital interoperability to: (1) assess the extent to which hospitals are engaging in the four core domains of interoperability; (2) identify factors associated with such engagement; and (3) identify the extent to which engagement is associated with clinical data being electronically available from outside providers.

Methods

We used data from the American Hospital Association Annual Survey for 2014 – Information Technology supplement. Our sample included 3,307 hospitals from across the United States. We supplemented this data with information from the main AHA Annual Survey, as well as publically available CMS Meaningful Use Stage 2 Attestation data.

The primary outcome measures we were interested in were the proportion of hospitals engaging in the four core domains of interoperability (finding, sending, receiving, and integrating data), the factors that correlate with hospitals engaging in all four domains of interoperability, and the factors that are associated with reported electronic availability of clinical data from outside sources when needed. We performed a multi-variate logistic regression analysis in order to identify which hospital characteristics were associated with the outcome measures of performing all four interoperability functions and having clinical data available. We used weights to produce nationally-representative results.

Results

Only 21% of US hospitals engage in all four domains of interoperability. In our multi-variate analysis of the hospital characteristics, adoption of at least a basic EHR system (4) as well as participation in a Regional Health Information Exchange Organization (5) are both strongly
positively correlated with engaging in all four domains (Odds Ratios = 1.77 and 4.46, respectively. \( P < 0.001 \)) Hospitals who use primarily one EHR vendor in their organization are also more likely to engage in all domains of interoperability (Odds Ratio = 2.65; \( P < 0.001 \)) Other hospital characteristics associated with engagement in all four interoperability domains include medium-sized hospitals (100- 500 beds) (Odds Ratio = 1.70; \( P < 0.001 \)) privately owned for-profit hospitals (Odds Ratio = 1.92; \( P = 0.003 \)) and hospitals who participate in a Patient Centered Medical Home (6) (Odds Ratio = 1.73; \( P = 0.002 \))

We found that electronically finding, receiving, and integrating data were independently positively correlated with the electronic availability of clinical data from outside sources (Odds Ratios of 4.68, 2.25, and 2.20, for each domain respectively. \( P < 0.001 \)); however, electronically sending data was not significantly associated (\( P = 0.90 \)). Hospitals that engaged in all four interoperability domains were significantly more likely to report electronic availability of clinical data from outside sources (Odds Ratio = 1.81; \( P = 0.006 \))

Discussion
While less than a quarter of US hospitals engage in all four interoperability domains, our results suggest that doing so may be key to maximizing the extent to which clinical information from outside sources is electronically available when needed. Given that certain types of hospitals were more likely to have all capabilities in place, it suggests that not all hospitals are able to pursue comprehensive interoperability or see the value in doing so. The specific characteristics that we identified point to a combination of capability reasons (e.g., those with EHRs from a single vendor may find interoperability easier) and incentive-related factors (e.g., those engaging in PCMH models may see more value from interoperability). A targeted policy strategy that simultaneously makes interoperability easier to pursue and strengthens the incentives to do may help ensure that providers have electronic access to needed information across care delivery settings.

Introduction

Clinical notes are a vital part of the modern electronic health record (EHR). Progress notes often follow the SOAP (Subjective, Objective, Assessment and Plan) note format, established by Dr. Lawrence Weed in the 1960s as part of the Problem-Oriented Medical Record (POMR) framework (1). Clinicians report that, when reviewing a Progress note, the Assessment and Plan is the most important section that they often read first regardless of where this section appears in the note (2). Some have therefore suggested that the Assessment and Plan be located at the top of progress notes (2). Anecdotal evidence suggests that while some clinicians are writing progress notes with the Assessment and Plan section at the top, some continue to follow the SOAP format with the Assessment and Plan at the end, others use customized note templates, resulting in progress notes with variable sequences of sections. The purpose of this study was to determine whether the order in which sections appear in progress notes affects how clinicians’ review and synthesize patient cases.

Methods

This IRB-approved study was conducted at a large Midwestern Academic Health Center. A previously-described EHR system prototype (4) designed to look like CPRS/VistA was populated with four de-identified patient cases, each with nine progress notes (4). Cases were designed to represent realistic patients and to be of relatively similar difficulty. Each case contained progress notes that could be presented in one of four different section orders: SOAP (Subjective, Objective, Assessment and Plan), APSO (Assessment and Plan, Subjective, Objective), SAPO (Subjective, Assessment and Plan, Objective) and Mixed (the section orders were inconsistent across, with three notes of each of the above orders). A convenience sample of participants (n=23), internal medicine and surgery residents, was recruited for this study. Sample size was restricted by ability to recruit residents. Participants were seated at a desktop computer with the EHR opened to the notes section of the first patient case. Participants were asked to review the existing notes for that patient as they normally would and provide a verbal summary of the case. Upon completing the verbal summary, participants rated their perceived workload for the case using the NASA-TLX instrument (5). Participants repeated this process three more times, for a total of four patient cases. Participants were shown the cases in the same order. Each case had a different note order, with the note orders randomized across participants using a Latin squares design. At the end of the data collection session, participants completed an exit questionnaire that contained demographic questions as well as Likert-type questions in which participants self-reported their experience level with EHRs in general and with different specific commercial EHRs.

Results

Table 1 shows participant characteristics, including their perceived prior experience using two EHR systems in clinical practice. Most considered themselves “average” users of the EHRs. The results in Table 2 show that there was a borderline significant difference in time spent reading the notes (p=0.048) across the orders, with participants taking the shortest amount of time to read APSO ordered notes and the longest amount of time to read Mixed ordered notes. Post-hoc comparisons of all groups were preformed using a T-test and a Bonferroni adjustment for multiple comparisons. The difference in mean time spent reading was statistically significant between the APSO order and the Mixed order (p=.021). All other comparisons between mean reading times were not statistically significant. There was no significant difference in time spent on the verbal summaries (p=0.173) across the orders. There was no difference in average NASA-TLX perceived workload scores (0-50 scale) across the case orders (p = 0.650) (Table 3). Mean reading time was 10.0 minutes for surgery residents and 12.3 minutes for medicine residents. Mean
summarizing time was 1.6 minutes for surgery residents and 2.4 minutes for medicine residents. These differences were statistically significant for both reading time (p=.01) and summarizing time (p=.01).

Discussion
While participants perceived notes orders to be of equal workload, there was a significant difference in time spent reading the notes. Participants read the APSO ordered notes fastest; perhaps because they found the information they wanted more quickly. Participants read the Mixed Order notes slowest, suggesting that customized templates and the lack of an expected order for progress note sections may have negative consequences for note readers. The average reading time difference between APSO and Mixed Orders was two minutes which, scaled across many patients, is substantial. While there was no time difference for the verbal summaries, we did not examine whether the content and quality of those summaries differed in the current pilot study. Difference between medicine residents and surgery residents indicate that the two groups reviewed and summarized patient cases differently and future research should examine these differences further.

Abstract

Social Networking Analysis (SNA) is a discipline rooted in graph theory, sociology and anthropology allowing one to mathematically analyze the relationships between actors in a network in order to assess how the network functions and the various roles that actors play. We are exploring the use of SNA to more broadly define contextual factors that impact the success of LOOP, a cross-institutional social networking application centered on the patient. Audit-trail data from the intervention arm of an ongoing randomized controlled trial of LOOP, comprising messaging data from 12 collaborative teams, were used to show how SNA can be used to generate further hypotheses and refine qualitative analyses of social networking applications in general.

Introduction

Healthcare has been variously described as a complex adaptive system, a system that is non-deterministic and where conventional quantitative evaluations may fail to adequately provide the context required to understand, refine and generalize tools and solutions.1 A greater understanding of social networks is considered a window into the aggregate complexity of the system,2 and social networking analysis (SNA), an analytical discipline rooted in graph theory, sociology and anthropology that allows for rigorous understanding of those networks and the roles of actors within them,3 has been advocated by the Agency for Healthcare Research and Quality (AHRQ) as a way to understand the behavior of healthcare coordination networks specifically.4 Research on innovative collaborative teams across industries suggests that successful teams have high density of interaction and connectedness and low degrees of strict hierarchy and ‘core-periphery’ structures.5,6

LOOP is a social networking application with patients and caregivers as core members of distributed online teams seeking to improve collaboration and patient-centered outcomes;7 LOOP is currently in the midst of a pragmatic randomized controlled trial (RCT) in patients with advanced malignancy. Messaging in LOOP is open within a secure patient-oriented group; there is no private directed messaging. We applied SNA as an adjunct to the evaluation of LOOP in order to provide greater contextual understanding of the impact of LOOP on patients, caregivers and healthcare providers.

Methods

We used audit-trail data from 12 teams in the intervention arm of the LOOP RCT to quantify the level of engagement within teams. A directed tie between nodes (team members) X and Y is defined when any of the following occur: X marks a message as “attention to” Y, X replies to Y’s message, or X mentions Y in a message. SNA metrics (density, Krackhardt’s measures of hierarchy,8 and correlation with idealized core-periphery models) were calculated for the 12 teams using the UCINET software suite.9

Teams were ranked into quartiles in regards to their performance on each metric. The percentage of time a team was in the top quartile across metrics was correlated with a simpler metric of successful collaboration, the total number of messages sent within the team. If a straight count of messages sent in a team is an appropriate metric of collaboration, we would expect a strong correlation between this metric and the frequency with which a care team performs highly on the SNA metrics.

Results

Three teams (Teams 2, 3 and 11) had no activity. The graphical depictions (sociograms) and team compositions of the 9 teams with activity are shown in Figure 1. Of the teams with no activity, Team 2 was comprised of one patient and three physicians, Team 3 of one patient, one caregiver and two physicians and Team 11 of one patient and one physician.

LUB in the 9 teams with activity was universally 1.0, providing no useful information. One team, Team 8, was in the top quartile 100% of the time but was tied for 5th in terms of number of messages sent; another team, Team 1, sent the most messages but was in the top quartile on SNA metrics 0% of the time (Table 1). Overall, there was no correlation between the...
number of messages sent in a team and the percentage of time a team was found in the top quartile across the five metrics ($r = 0.30$). The sociograms of Teams 1 and 8 visually show the variation in collaboration across the two teams (Figure 1).

![Sociograms of Teams 1 and 8](image)

Figure 1. Sociograms of engagement in the 9 teams with activity. Team number in red. Node size proportional to outdegree. Green = patient/caregiver, Blue = physician, Purple = allied health provider, Orange = care coordinator, Grey = LOOP administrator.

Table 1. Number of messages sent and values for various SNA metrics across the 9 teams with activity. For each SNA metric (density, connectedness, hierarchy, efficiency and % in core), the values within the top quartile on that metric are highlighted in yellow. The final column shows the percentage of time a team’s SNA metrics were in the top quartile across the 5 metrics.

Conclusion

SNA can provide additional information beyond more simplistic metrics of collaboration, even in situations with relatively sparse data, and is a useful adjunct to the evaluation of social networking interventions. SNA uncovers teams that are strongly collaborative but who might be passed over as entirely average by a ‘messages sent’ metric (Team 8) as well as teams who, despite higher levels of messaging activity, seem to be collaborating poorly (Team 1). This provides the opportunity for enriched contextual understanding of tools through further targeted analysis of higher and lower performing teams.

Quantifying the Effect of Data Quality on the Correctness of an eMeasure

Introduction
The increasing secondary use of electronic health record (EHR) data to improve health outcomes is promising, but it depends on clinical information being of sufficiently high quality to support the secondary use.1 eMeasures, which are quality metrics derived from EHRs, are standardized performance measures that quantify how well patient care is meeting best practices. Correctly computing an eMeasure depends on how well the data are recorded in the EHR. Data may be adequate to document care but insufficient to support the computation of an eMeasure.2 Data may be missing, incorrect, out of range or inappropriate for the field. In these situations, the patient’s record may be excluded from the calculation of the eMeasure resulting in biased results as the eMeasure could not be applied to the entirety of the population it was intended to assess. Secondary uses of EHR data can be better trusted if the impact of the underlying data quality is assessed.3 An eMeasure was used in this research as an example secondary use, but the method described in this paper can be generalized to other secondary uses.

Recent work to define data quality concepts as an ontology improves the ability to discuss data quality issues and leads to an assessment method that allows data sets to be characterized along a number of data quality dimensions.4 Terms that are capitalized and in “CamelCase” refer to the specific aspects of data quality defined in that ontology. The purpose of this study was to quantify the impact of two data quality issues, data missingness (RepresentationCompleteness) and data conformance to a domain model (DomainConstraints), on the correctness of an eMeasure (CMS178). Data quality issues were artificially created by systematically degrading the underlying quality of sample EHR data using two methods: independent and correlated degradation. A linear model that describes the change in the correctness of the eMeasure was developed to quantify the impact of data quality issues for each domain concept (DomainConcept) on the eMeasure.

Methods
After IRB approval, a de-identified random sample of 72,127 patient encounters was obtained from a clinical data repository (CDR). The CMS178 eMeasure was used as an example secondary use to illustrate the assessment process. The definition of CMS178 is “Urinary catheter removed on Postoperative Day 1 (POD 1) or Postoperative Day 2 (POD 2) with day of surgery being day zero.”5 CMS178 is a ratio where the denominator includes all hospital patients (age 18 and older) that had surgery during the measurement period with a catheter in place postoperatively. The denominator exclusions are 1) patients who expired perioperatively, or 2) patients who had physician documentation of a reason for not removing the urinary catheter postoperatively, or 3) patients who had medications administered within 2 days of surgery that were diuretics, IV positive inotropic and vasopressor agents or paralytic agents. The numerator is the number of patients in the denominator whose urinary catheter was removed within 48 hours.

A data quality assessment process was previously developed to compute RepresentationCompleteness (data missingness) and DomainConstraints (how well data conform to the domain model).4 The current research extends that approach by quantifying the degree that data quality issues for each DomainConcept impact a task. This was accomplished by deliberately changing the underlying EHR data in a systematic way and observing how those changes affected the calculated value of the eMeasure. The unmodified sample CDR data was the baseline to compare against for correctness. A variable, missing events, was computed that quantifies the correctness of the CMS178 eMeasure after the data are modified. This variable represents the number of patients that had a catheter removed within 48 hours in the baseline data but after the data set was degraded, were subsequently not counted as satisfying the CMS178 criteria. These are events of interest that were missing due to the data quality issues. The full degradation process consists of iteratively applying the degradation method to the data for each of the DomainConcepts in the domain model. The task was performed (in this case, computing CMS178 and missing events) and RepresentationComplete and DomainConstraint were recomputed on the degraded data for every DomainConcept. These results, the CMS178 eMeasure, and missing events were recorded in an analysis database. Two approaches to degrading data were examined: 1) independent and 2) correlated.

To quantify the effect on the eMeasure of degrading each DomainConcept, linear regression modeling was utilized. A model was fit to missing events as the dependent variable, with the data quality results for
RepresentacionComplete and DomainConstraints for each DomainConcept as the predictor variables. Negative changes (degradation) to the data increase missing events and can be used to quantify what would happen if instead, data quality improved. If data in an EHR is of low quality (i.e. the degraded data) and a method existed to somehow improve it by correcting the data (assuming the incorrect data could be identified) then missing events would be reduced.

Results
The results of the linear model for RepresentationCompleteness showed that the birth date, admission type, medication start date, catheter duration and catheter rationale for continued use were significant and had an impact on missing events. The coefficients can be interpreted to quantify the magnitude of the impact on missing events for a 1 unit improvement in an aspect of data quality. The model showed that for every 1% reduction in RepresentationComplete data quality for admission type, there were approximately 1% more events missed and the eMeasure is further from its correct value. But a 1% reduction in data quality for catheter rationale for continued use only results in 0.11% cases being missed. Degrading the domain constraints yielded a different set of variables that were impactful compared to RepresentationComplete. For independent degradation, the DomainConcepts of death date, medication start date and medication end date were significant. But only medication end date had an appreciable impact. A 1% improvement in data quality for medication end date reduces the missed cases by 0.38%, but the other DomainConcepts only impact the missed events by less than 0.1%.

Discussion
The results of this study show that: 1) data quality issues for different variables impact the correctness of an eMeasure and the impact can be quantified and 2) the CMS178 eMeasure, as currently defined, depends on how data issues are handled, which may misrepresent how well an organization is meeting the best practice goal of removing catheters within 48 hours of surgery. Degrading each DomainConcept independently compared to degrading in a correlated manner produced approximately the same set of variables that were most impactful. Degrading the domain constraints had a smaller impact than missing data. This result is likely because the data is only altered to violate the constraints, it is not missing, so it can still be used for the computation of CMS178.

The second finding is that the CMS178 eMeasure may not adequately measure catheter removal within 48 hours of surgery. Decisions for how to handle data that are missing or that violate domain constraints can influence how well CMS178 measures catheterization best practices. As the data set is changed, one way to handle the data quality issues is to remove affected patient encounters from both the denominator and numerator. Even though missing events increase as the underlying data is degraded, CMS178 itself does not appreciably change because it is a proportion. Handling the affected patient encounters in a different way, however, could change CMS178, which highlights a potential problem with the definition of CMS178, and eMeasures in general. They should define explicit rules for handling missing and constraint violating variables and require data quality metrics be reported with the eMeasure.

One limitation of this research is that only two approaches to injecting errors into the data were explored but there may be other types of data quality issues that occur in practice. Also, the approach to data missingness does not take into account different kinds of missing data (i.e. missing due to omission). The usefulness of characterizing data quality using these methods enables healthcare organizations to prioritize data quality improvement efforts to focus on the areas that will have the most impact on correctness and assess whether the eMeasure values that are being reported should be trusted.

**Objective:** Identify comorbidities enriched in patients with the diagnosis of insomnia, by interrogating an electronic medical records (EMR) database.

**Materials and Methods:** We studied individuals with diagnosis codes or medication prescriptions for insomnia in a population of 314,292 patients from two urban tertiary-care hospitals between 1992 and 2010. We extracted structured EMR variables (e.g., demographics, billing codes, and medications) and unstructured variables related to insomnia or comorbidities from narrative notes. We developed a case-control methodology to match insomnia patients to non-insomnia controls, and calculated the enrichment of comorbidities specifically in insomnia patients. For each case with insomnia diagnosis codes, we applied 1:1 matching to identify a control (non-insomnia) patient with no insomnia diagnosis codes. Controls were matched for gender and age because all patients in our database had properly documented genders and dates of birth. Additional matching criteria included the total number of facts in the EMR associated with each case or control (including the number of laboratory measurements, prescriptions, diagnosis / procedure codes, and notes). Our rationale was that patients with similar numbers of medical facts are likely to utilize health-care resources equivalently. In addition to the absence of insomnia diagnosis codes, we achieved further confirmation by selecting controls only if no sleep medications were found in the patients’ medical profiles. Only patients 18 years of age or older were eligible to be selected as cases or controls. We calculated the case-to-control enrichment (i.e., insomnia-to-non-insomnia ratio) by dividing the ascertained values for insomnia cases by the corresponding values for non-insomnia controls in the 12 months prior to the first diagnosis code or medication prescription for insomnia. The case-to-control ratio was calculated for each comorbidity and reflected the enrichment level of the comorbidity in insomnia relative to non-insomnia controls. We compared categorical variables using the chi-square test. Differences in means of continuous variables were compared using the t-test or Wilcoxon rank sum test, as appropriate. All statistical tests were 2-sided tests with Bonferroni correction for multiple comparisons of 59 covariates. We also assessed clinical variables associated with insomnia by penalized logistic regression and we used the bootstrap procedure to calculate confidence intervals. We further separately examined enrichment of comorbidities in insomnia patients in the inpatient versus outpatient setting, to better understand the potentially different practice patterns.

**Results:** In patients with insomnia-related diagnosis codes or medications, concepts related to insomnia were highly enriched in narrative notes. We find highly significant enrichment of several comorbidities in insomnia patients, including all 10 of the conditions that contribute to patients with “multiple chronic conditions”. The top-ranked comorbidities by logistic regression were also highly ranked in our enrichment analysis. Narrative mentions of insomnia-related concepts were enriched in notes from outpatient but not inpatient encounters.

**Conclusion:** Our results highlight the importance of analyzing narrative notes to understand the scope of conditions such as insomnia that are challenging to study using structured variables alone. By systematically identifying common comorbidities that co-exist with insomnia, this report can clarify the medical impact of insomnia.

Introduction

Engagement of patients in research is critical to generating evidence that is relevant to their concerns and values. There is meager understanding of optimal engagement in early phases of research, such as the selection of relevant topics for person-centered outcomes research (PCOR). High-touch methods such as in-person focus groups and interviews are not easily scaled to larger populations, while high-tech methods such as online surveys and conference calls suffer from superficial interaction. This study addresses this gap by assessing deep, high-tech engagement with stakeholders of pSCANNER: Patient-centered SCAlable National Network for Effectiveness Research, a clinical data research network of 21 million patients.

Methods

We conducted a series of stakeholder panels for weight management/obesity (WMO), heart failure (HF), and Kawasaki disease (KD) to set PCOR priorities, using online software and a well-documented modified-Delphi method, a deliberative and iterative approach to attaining consensus with discussion and statistical feedback. The topics were rated using five criteria—informative decision making, collaboration, relevance, impact, innovation—applied to aspirational goals: i.e., to decrease the proportion of adults who are obese by 10% by 2020, to reduce unwarranted hospital readmissions for HF by 25% by 2020, and to reduce the percentage of new Kawasaki disease patients with permanent disability by one-quarter (from 7% to 5.25%) by 2020. Panelists were adults with overweight/obesity, HF, or Kawasaki disease (including parents for Kawasaki disease), clinicians and researchers recruited nationally via social media or pSCANNER clinical sites. Within condition, participants were randomized to either a single-stakeholder (patient or clinician) or mixed-stakeholder (patients, clinicians, and researchers) blinded panel. Only two panels were fielded for KD due to overlap among clinicians and researchers. Participation was online, asynchronous, and took four hours over four-weeks. Analysis included rank-ordered topics (based on mean score), determination of consensus (positive agreement) within panels on each criterion, and comparisons across panels.

Results

349 panelists participated in the project. Retention rate, the percent of panelists who participated in both round 1 and round 3 voting, was 67% for WMO, 68% for HF, and 97% for KD. (Table 1)

</table>
In WMO, the panels altogether achieved consensus on three of nine topics. HF panels did not achieve full consensus on any of the seven topics and KD panels achieved consensus on two of seven topics. (Table 2) The top research priorities in WMO and HF by rank (by ratings of criteria on a 1-9 scale) and overall mean score (averaged across all panels) were related to care coordination and lifestyle self-management while medications and surgery were ranked lowest. In contrast, the top priorities in KD were related to medications and diagnostic tests while the lowest were lifestyle related. In WMO, clinicians’ ratings differed significantly from patients and the mixed panel. HF patients differed from clinicians and the mixed panel. KD showed the least disagreement between patient and mixed panels.

Discussion and Conclusion

We demonstrated that structured, high-tech engagement of large numbers of patients and other stakeholders in prioritization using online tools can yield rich contributions for PCOR. In this first of its kind study of substantial-scale stakeholder engagement in PCOR prioritization, results differed by health condition and stakeholder group. We plan to conduct analysis of online discussions which may offer insights as to why. Our results raise further research questions on how to combine and balance the input of diverse groups, particularly patients and caregivers.

Developing a Harmonization Process between a Nursing Reference Terminology and a Classification System

Tae Youn Kim, PhD, RN1,2, Nicholas Hardiker, PhD, RN, FACMI2,3, Kay Jansen, DNP, PMHCNS-BC, RN2,4, Amy Coenen, PhD, RN, FAAN2,4

4University of Wisconsin-Milwaukee, Milwaukee, USA

Introduction

Health and nursing terminologies keep evolving to incorporate advances in science, changes in practice, and health policy. Harmonizing these terminologies is of importance to enhance the coverage of domain knowledge of interest and ensure interoperability of clinical data across multiple disciplines and settings. Of various efforts and initiatives established to cross-map diverse terminologies, harmonization of International Classification for Nursing Practice (ICNP®) and the Clinical Care Classification (CCC) is under way through a formal collaborative agreement between International Council of Nurses (ICN) and SabaCare, Inc.1 This collaborative work promotes bi-directional transformations of electronic health information and complements each system’s strength in the eHealth practice environment. The purpose of this study was to a) examine differences in structure and conceptual granularity between ICNP and CCC, and b) establish a harmonization process between a reference terminology system (i.e., ICNP®) and a classification system (i.e., CCC).3 It is expected that the outcome of this study will facilitate on-going collaborative efforts as both systems evolve.

Methods

Using ICNP nursing diagnoses (n=720) and intervention (n=735) concepts, this study involved a 3-step process of harmonizing ICNP and CCC: 1) identifying conceptual equivalency between ICNP and CCC, 2) determining conceptual similarity (i.e., ICNP concepts are narrower or broader in meanings) between ICNP and CCC, and 3) clustering unmapped ICNP concepts using the highest level concepts in CCC (i.e., 21 care components which provide a standardized framework for organizing nursing diagnoses and interventions). Conceptual equivalency was determined based on pre-existing equivalencies4 within the Unified Medical Language System (UMLS) maintained by the U.S. National Library Medicine5, followed by experts’ reviews of the candidate equivalencies. Of the ICNP concepts that were not mapped to CCC, conceptual similarity was sought manually by reviewing the formal computable definition of each ICNP concept modeled using Web Ontology Language (OWL) in Protégé environment2 and the definition of the remaining CCC concepts.3 When there was neither conceptual equivalency nor conceptual similarity between ICNP and CCC, the remaining ICNP concepts were manually clustered using 21 components (e.g., activity, medication, self-care) of the CCC framework. Any disagreements were further discussed with the ICN eHealth team and SabaCare until consensus was reached.

Results

Of 720 ICNP nursing diagnoses, the first step yielded 163 equivalencies (23%) between ICNP and CCC.6 In the second step, 328 ICNP diagnoses (46%) were identified as having conceptual similarity with CCC diagnoses – in all cases the meaning of the ICNP concept was narrower than that of the CCC statement. Lastly, the remaining 299 ICNP diagnoses were categorized into one or more of the 21 CCC care components. Table 1 presents example concepts selected from each step. In contrast, of 735 ICNP nursing interventions, 138 (19%) were exactly matched while the remaining 601 ICNP interventions were conceptually narrower or broader than CCC interventions.

**Discussion and Conclusion**

Our analysis of the two coding systems demonstrated structural differences between ICNP and CCC. ICNP is the largest compositional reference nursing terminology where each concept is defined formally using properties and associations with other concepts. This concept modeling process is necessary to prevent inconsistency and ambiguousness of an individual concept within the terminology system. An individual statement in CCC, however, represents a set of abstract concepts that collectively describe a nursing problem or action. For example, Medication Treatment in CCC is defined as ‘actions performed to administer/give drugs or remedies regardless of route,’ implying multiple activities (e.g., medication verification, medication administration and monitoring in ICNP) can be mapped to the CCC statement. While this structural and conceptual difference between ICNP and CCC was challenging to cross-map ICNP concepts and CCC statements, the 3-step harmonization process designed in this study has promoted to meet the goal of this project. Importantly, it became apparent that any attempt as universal one-to-one mappings between ICNP concepts and CCC statements will not reveal a complete solution for practical application. Rather the differences between the reference terminology (i.e., ICNP) and the classification system (i.e., CCC) encouraged the development of an alternative solution to mapping – the representation of ICNP concepts within the CCC conceptual framework. This harmonization work also demonstrated the versatility and flexibility of ICNP in complementing each system’s strength. Further study is needed to test the applicability of the 3-step process of harmonizing ICNP and other classification systems.

Comparison of Data Models used in Research Data Repositories for Electronic Phenotyping

Jeffrey G. Klann, PhD1,2,3; Vijay Raghavan, MS, MBA1; Michael Mendis, BS2; Douglas MacFadden, MS1; Sarah Weiler, PhD1; Kenneth Mandl, MD, MPH1,4; Shawn N. Murphy, MD, PhD1,2,3

Introduction

Research data repository systems and research networks are increasingly appearing, utilizing the vast quantity of information collected routinely by electronic health record systems. Each initiative requires data to be stored in a particular data model to support shared analytical tools. Several very different standard data models for clinical research are emerging. Each data model offers unique advantages and disadvantages in the storage, retrieval, and analysis of clinical data. Here we analyze three very popular but divergent approaches. Broadly, they differ most markedly in whether they focus on a single-table approach for storing data or a more traditional relational schema. The models include:

- **PCORnet Common Data Model (CDM).** The Patient Centered Outcomes Research Institute (PCORI)’s PCORnet is a rapidly developing collection of data research networks than presently span almost 80 clinical sites across the nation to perform large-scale comparative effectiveness research. [1] For pan-PCORnet queries, all networks support a common data model (CDM) developed by PCORnet’s Coordinating Center. This is derived from the Mini-Sentinel data model, which has increasing uptake in claims data analysis. [2]

- **Informatics for Integrating Biology and the Bedside (i2b2).** i2b2 is an open-source clinical data warehousing and analytics platform funded by the National Institutes of Health. [3] It is used at over 100 sites nationwide, including several PCORnet networks and the National Center for Advancing Translational Sciences (NCATS) Accrual to Clinical Trials (ACT) network. i2b2 uses a star-schema format, pioneered by General Mills in the 1970s and very popular in retail data warehouses. [4]

- **Observational Medical Outcomes Partnership (OMOP).** OMOP has been adopted by the Observational Health Data Sciences and Informatics (OHDSI) Consortium, a diverse, multi-stakeholder collaboration dedicated to providing robust analytical tools for research and quality improvement. [5] Because of its large community and an impressive suite of free analytical tools, the OMOP model is gaining traction in many research environments. Its data model is a hybrid of star schema and relational schema.

Here we focus on the critically important process of electronic phenotyping. [6] In this framework, we provide an analysis of each approach and one practical example: The Scalable Collaborative Infrastructure for a Learning Health System (SCILHS, pronounced “skills”). SCILHS is a growing network of health centers across the United States, presently covering over 10 million patients at eleven sites. SCILHS is a Clinical Data Research Network (CDRN) in PCORnet, as well as an i2b2-based network with a similar architecture to ACT. Therefore, it supports both CDM and i2b2.

Methods

CDM. CDM is designed with a traditional relational-database structure. The current release (v3) contains fifteen tables, each corresponding to a clinical domain (e.g., diagnoses, vitals, procedures, etc). The tables are wide, with many columns including both table keys (patient identifier, encounter identifier, etc) and additional details about each data element (e.g., primary diagnosis flag). New releases of the data model have occurred when new clinical elements are supported in analysis – for example, recent releases have added new domains (e.g., lab values) and made changes in data representation (e.g., smoking status).

i2b2. i2b2’s data model is designed to be highly adaptable and able to easily ingest data from various source systems without data transformation. As such, it has adopted a “star schema,” with one large “fact” table containing individual atomic observations. This is a narrow table with many rows per patient encounter. Local implementations develop concept hierarchies (called “ontologies”) that provide a window into the imported data. Consequently the data model is only modified when core features are added to the platform. Import of new types of data elements can be done directly into the fact table, and the ontology can be modified to make these data accessible to researchers. Analytical tools and data networks require conformance to a standard ontology, but this can be updated easily as network data availability changes, and it does not require changes to sites’ underlying data or schemas.
**OMOP.** OMOP is a hybrid approach that also provides a fact table (like i2b2) and domain tables (in the vein of CDM). Its schema is significantly more complicated than either of the other approaches (specifying 39 tables). Unlike CDM, the domain tables are in many cases derived values for specific analytical purposes (e.g., drug_era and visit_cost), and, like i2b2, raw data can be stored in the fact table. Also similar to i2b2, OMOP provides metadata tables providing information on terminology and concept relationships. Unlike i2b2, however, this terminology is standardized and not modifiable at each site. This requires data to be transformed to standard terminologies upon import, but demanding such standardization does enable a broad analytics suite.

**Results**

**Comparison of Approaches**

Each data model has significant strengths and weaknesses. PCORnet CDM is a ready-to-use analytical data model that is easy for researchers to understand and write analytical tools against. However, it is limited to only the data domains defined in the schema, and because clinical data is so diverse and source systems change so frequently, it is not a likely choice for robust electronic phenotyping algorithms. i2b2, on the other hand, is very flexible and has the proven capability to flexibly import data from a variety of source systems, even as source systems change. This may explain its popularity in many large research hospitals. i2b2’s ontology system allows dynamic query design and execution on local data, and, with mapping to standard ontologies, common analytical tools can be written. However, the star-schema is not very intuitive for researchers designing analytics, and analysts frequently prefer data transformed into a traditional column-oriented format like CDM instead. OMOP provides both tables for a standard analytical model and a fact table for dynamic support of new data elements. This hybrid approach is very promising. However, it does lose out on some of i2b2’s flexibility - due to requiring terminology mapping at time of import. This limits integration of new data types (e.g., mHealth data) to improve phenotyping algorithms.

**The SCILHS Network**

The SCILHS network is live at 11 sites across the United States, presently covering over 10 million patients. The SCILHS workflow uses i2b2 as the primary data warehouse, due to its flexible data ingestion and querying capabilities. We developed a robust mapping methodology to allow sites to map to a standard ontology without modifying the underlying data, which our sites have implemented. [7] The SCILHS network supports live preparatory-to-research queries using an ontology-driven graphical query tool. SCILHS also offers data in PCORnet CDM format for easy-to-understand data exports and compatibility with the larger PCORnet, using a transformation program based on the ontology mappings. This approach could be adapted to OMOP, so SCILHS could also take advantage of OMOP’s powerful analytical tools.

**Discussion**

Each analytical data model is optimized for some use-case, and transforming between them might be the best overall solution. [7] PCORnet CDM is a straightforward model that is very approachable to researchers and analytics developers. OMOP offers some data flexibility while providing a very powerful and expanding suite of analytical tools. For flexibly supporting complex, adaptive phenotyping algorithms, we find that i2b2 is superior – in that it supports diverse source data and is dynamically adaptable to new data element types and concepts, even when they are not represented in a standard terminology. The SCILHS network has chosen to use i2b2 for its primary data repositories, providing exports in other formats (presently PCORnet CDM).

Superiority of Carboplatin-Based Doublet Chemotherapy Regimens to Cisplatin-Based Doublet Chemotherapy Regimens among a Cohort of Medicare Patients Aged 70 and Older with Stage IV Non-Small Cell Lung Cancer

Elizabeth Lamont, MD, MS,1,2,3,4 Nancy L Keating, MD, MPH2,4,5 Christopher Azzoli, MD1,2 and Mary Beth Landrum, PhD5

1 Massachusetts General Hospital Cancer Center; 2 Department of Medicine, Harvard Medical School; 3 Department of Bioinformatics, Harvard Medical School; 4 Section of General Internal Medicine, Brigham and Women’s Hospital; and 5 Department of Health Care Policy, Harvard Medical School, Boston, MA

Background: During the period of study, platin-based chemotherapy doublets were established through phase III trials to be clearly superior to single agent chemotherapy regimens. For this reason, platin-based doublet chemotherapy regimens became the standard guideline recommended firstline therapy for patients with stage IV NSC lung cancer. Among the platin drugs, some evidence suggests that cisplatin-based chemotherapy doublet regimens are more effective than the less toxic carboplatin-based doublet regimens for patients with advanced NSCLC, but their effectiveness among elderly cancer patients who are treated in usual care settings is not known. We sought to compare cisplatin-based chemotherapy doublet regimens to carboplatin-based chemotherapy regimens among usual care elderly patients to determine if the findings from clinical trials were also evident in this understudied large subgroup of all patients who are diagnosed with stage IV NSC lung cancer in the United States.

Methods: We identified 13,406 elderly Medicare patients who were (1) diagnosed with stage IV NSCLC between the years 1995-2007 in one of the Surveillance, Epidemiology, and End Results (SEER) regions and (2) started treatment as an ambulatory patient with either a cisplatin-based or a carboplatin-based doublet chemotherapy regimen in the subsequent six months. Using propensity score weighting, we balanced the two treatment cohorts with respect to observable attributes. Table 1 shows our samples before and after propensity score weighting. We then estimated our key end points survival and post-treatment hospital-based health care use as a proxy for treatment-related toxicity.

Findings: Overall, patients treated with cisplatin-based doublets lived two weeks longer on average than patients treated with carboplatin-based doublets (i.e., 7.4 months vs. 7.0 months, p=0.05). For patients ≥70 years of age, first-line therapy with cisplatin-based doublet chemotherapy regimens was associated with increased post-treatment morbidity and no survival advantage compared to carboplatin-based doublet therapies.

Interpretations: Our results show that overall there was a clinically small survival advantage of marginal statistical significance for elderly Medicare patients with NSCLC who are treated with cisplatin-based doublet chemotherapy regimens compared to patients treated with carboplatin-based doublet chemotherapy regimens. However, the overall survival benefit appears to have been due to a larger survival advantage among the large subset of patients aged 66 through 69 years who lived approximately three and one half weeks longer than similarly aged patients treated with carboplatin-based doublet regimens (p < 0.01). There was no apparent cisplatin-associated survival advantage among patients 70 years and older. These findings are apparent in Figure 1. Among this latter group of patients, there were clinically and statistically meaningful differences in morbidity associated with cisplatin-based therapy. Patients who were treated with cisplatin-based doublet chemotherapy regimens were observed to use more (1) hospital-based health care and (2) more intensive hospital-based care following the beginning of chemotherapy than patients who were treated with carboplatin-based doublets.

These results advance clinical medicine in several ways. First and most importantly, we fill an existing void by providing “real world” estimates of morbidity and mortality outcomes in elderly Medicare patients with NSCLC according to cisplatin-based vs. carboplatin-based doublet therapy and according to tumor histology and patient age. These results may be immediately useful to oncologists and their older patients
as they discuss treatment options by providing more representative estimates of morbidity and mortality of two first-line treatment options. These real world estimates are of critical importance given that the average survival following both forms of doublet therapies (i.e., 7.0 months for carboplatin-based doublets to 7·4 months for cisplatin-based doublets) were approximately six weeks shorter than those reported in existing data like meta-analyses of clinical trials (i.e., 8·4 to 9·1 months respectively). Further, the small (< 2 weeks) and marginally significant survival advantage associated with cisplatin-based regimens in the larger cohort was clearly driven by the youngest patients, those 66-69 years of age who experienced a larger (> three week) survival advantage which was statistically significant. For those 70 years of age and older, there was no survival advantage, but clearly greater morbidity as represented by greater subsequent use and intensity of hospital-based health care. This suggests that carboplatin-based doublets are superior to cisplatin-based doublets for such patients through of minimization of treatment-related morbidity.

Figure 1. Forest Plot Comparing Relative Hazard of Death of Carboplatin- vs. Cisplatin-Based Doublets in Elderly Medicare Patients with Advanced NSCLC by Patient Age (N=13,406)

Legend: In this forest plot, unity (1.0) represents equality in patient survival between carboplatin-based vs. cisplatin-based doublet therapy among elderly Medicare patients with metastatic NSCLC. Deviation rightward represents superior survival associated with cisplatin-based doublet therapies and deviation leftward represents superior survival associated with carboplatin-based doublet therapies. NSCLC=non-small cell lung cancer
A Regional Cardiovascular Data Registry Linking Hospitals and Ambulances

James R. Langabeer II, PhD; Safa Fathiamini, MD MS; Tiffany Champagne-Langabeer, PhD; Jenny Mikhail, MPH; Wendy Segrest, MS; Raymond Fowler, MD, FACEP

1 The University of Texas Health Science Center, Houston, TX; 2 American Heart Association, Denver, CO; 3 The University of Texas Southwestern Medical Center, Dallas, TX

Introduction

Analyzing and reducing ‘total ischemic time’ is critical for improving the care and survival of acute myocardial infarction (MI, heart attack) patients as well as for clinical researchers focused on improving cardiovascular outcomes. Yet, an electronic health records system (EHR) maintains only part of the data, once patients arrive at their doors, and out-of-hospital data are generally unavailable. Physicians and hospitals must continually look for ways to reduce time delays in door-to-balloon (D2B) and system onset to arterial reperfusion (SOAR); and key to this is understanding the longitudinal record of care for cardiovascular patients prior to arrival. This study describes one unique longitudinal data registry developed for a regional myocardial infarction quality improvement project sponsored by the American Heart Association, specifically to share and link patient time and treatment data between 25 emergency medical services (EMS) agencies and 15 hospitals in Dallas Texas (AHA Caruth Initiative).

Objective

The objective of this study was to create an integrated, automated cardiovascular care data registry for one of the largest geographical regions in the country (Dallas Texas; the 9th largest city in the US). Dozens of commercial EHRs were in use by the participating 15 hospitals, and nearly 20 different custom patient care record (PCR) systems by the 25 EMS agencies, creating disparate data sources and formats that were impossible to assemble and analyze for clinical informatics purposes of measuring total ischemic time and identifying areas for improvement. Analyzing longitudinal patient-level data is difficult given that both sets of providers use different systems and codes to identify their patients, and in the absence of a master patient index (MPI), matching patient records across those systems is far from straightforward. Figure 1 shows the conceptual longitudinal linkage between the data sources.

Figure 1: Linking Ambulance and Hospital Records Reduces Treatment Times

Methods

De-identified data for MI patients who underwent primary percutaneous coronary intervention (PCI) in Dallas County, Texas were extracted in extensible markup language (XML) and shared securely by independent EMS agencies and hospitals monthly to the University of Texas Health Science Center researchers. A Microsoft SQL Server database was created with tables to store demographic, intervention, outcome, and time data. Automated scripts were developed to first scan the data for specific quality concerns (such as appropriate dates and values) and
then insert the data by source (hospital or agency) into the database. A probabilistic algorithm was written to help identify and match EMS to hospital records for each patient. Since the two data sets did not share a common patient identifier, the patient matching algorithm was based primarily on: a) approximate date and time of myocardial infarction; b) patient zip code; c) patient date of birth; d) hospital destination; and e) gender. After matching, an exception report alerted the system administrator of unmatched records for human review. Automated statistical analyses and reports were generated on a monthly and quarterly basis for all stakeholders in the region.

**Figure 2: Cardiovascular Registry Schema**

![Cardiovascular Registry Schema](image)

### Results

This cardiovascular care registry was developed to support analytical investigation of patient and provider level longitudinal time-based outcomes, which otherwise did not exist. We linked approximately 90% of all pre-hospital records against hospital records. After implementation of the registry, a new performance metric was created (termed Symptom Onset to Arterial Reperfusion), which allowed cardiologists, nurses, EMS agencies and others to manage key time-to-treat performance outcomes between ambulances and hospitals. The quarterly results were used for quality improvement processes. Teams were assembled to review findings, identify opportunities, and recommend changes to processes that might impact treatment times. Several key changes were made, such as allowing paramedics to remotely activate the catheterization lab from the ambulance. Challenges faced included financial, technology, data privacy, and organizational. The program resulted in a significant reduction in two key cardiovascular outcomes, door-to-balloon and total ischemic time, both between 10-15% improvements over a two year period. ²

### Discussion

Time is critical in emergency cardiovascular care. Registries which store longitudinal data on times and treatments allow quality improvement programs to identify collaborative strategies for reducing both pre- and in- hospital treatment delays. This study confirms that when EMS and hospital information is longitudinally shared, clinical informatics can produce useful analyses and help drive improvements in outcomes.

An Automatic, Multi-Algorithm Approach to Classify Ventilator Waveforms

Monica Lieng¹, Brooks Kuhn, MD¹, Greg Rehm¹, Edward Guo¹, Jean-Pierre Delplanque, PhD¹, Nick Anderson, PhD¹, Jason Adams, MD, MS¹
¹University of California, Davis

Introduction

Mechanical ventilation (MV) is a life-saving intervention for critically ill patients. Approximately 30% of patients in Intensive Care Unit (ICU) environments receive MV¹. Due to variety in underlying disease and rapid changes in patients’ physiological states, events where breath delivery is inadequate for patient demand are common. These events, known as patient-ventilator asynchronies (PVA), have been correlated with structural injury to the lung², increased sedative use², prolonged MV duration³,⁴ and, in one observational study, increased mortality⁵.

Quantitative analysis of PVA for research and improvement of patient care has historically been hindered by low data sampling intervals and manual paper-based recording methods. Several previous studies have demonstrated the feasibility of algorithmically detecting PVAs using a computerized system⁵,⁶. Most of these studies have looked at only one sub-type of PVA, with only one study reporting on the detection of more than two subtypes.⁵ Furthermore, these studies have been limited to brief sampling intervals, small sample sizes, use of un-validated proprietary software, and lack of the ability to filter out common clinical artifacts.

Misclassification of PVA events may occur due to morphologic similarities between common clinical artifacts (e.g. cough, endotracheal tube suctioning) and individual PVA subtypes. For example, patients receiving endotracheal tube suctioning for mucous removal may generate waveforms that share morphologic features with double triggering asynchrony. In a single-event algorithmic approach, such artifacts may be mistaken for clinically significant asynchronies which may in turn over-represent the prevalence of true PVA events or result in alert fatigue if applied in a clinical decision support application. To address these issues, we describe an integrated multi-event algorithm approach for simultaneously detecting a variety of PVA subtypes in clinically-derived ventilator waveform data based on a heuristic evaluation framework derived from the clinical rules used for the detection of PVA by bedside clinicians.

Methods

Continuous flow and pressure waveforms were acquired from both healthy volunteers and ICU patients on Puritan Bennett 840 mechanical ventilators using an unobtrusive wireless peripheral device. Classification algorithm development used a combination of simulation-based and clinically-derived waveforms. Waveforms were visualized using a novel visualization platform powered by Flask and Dygraphs and algorithm performance was compared to gold standard reference data sets produced from two-physician consensus annotations. All algorithms were implemented in Python 2.7. Clinical metadata were extracted from raw waveform data to facilitate PVA detection. These included common calculations such as expiratory and inspiratory tidal volume, respiratory rate and peak inspiratory pressure. Similar to previous work⁵,⁶, we estimated tidal volume by integrating the area under the inspiratory and expiratory flow-time curves. Expert physicians defined the heuristic rules by which common PVA subtypes and clinical artifacts are classified. These rules were translated into pseudocode and then subtype-specific algorithms in Python. Additional heuristic algorithms were created to parse the “raw” output of the individual classification algorithms in order to distinguish between PVA subtypes and common artifacts. For example, if a given breath is classified as both a suction event and a double trigger asynchrony, our integrated multi-algorithm approach favors the suction event and removes the detection of the double trigger to prevent the misclassification of a PVA-like artifact as a true PVA event. We then compared the sensitivity, specificity and positive predictive value (PPV) of our individual PVA subtype classification algorithms to that of our integrated multi-event algorithms.

Results

Data were collected from 17 patients and clinicians sampled 15 minute regions with high PVA and artifact density. The pooled data contained 5075 breaths, where 1179 were pathologic (double trigger or breath stacking) and 182 were artifacts (multiple trigger, cough, ventilator disconnect or suction). Overall, algorithm performance appears to have improved for both double trigger and breath stacking (Table 1). Notably, PPV for the double trigger and breath stacking improved from 66.7% to 91.1% and 92.4.7% to 95.2%, respectively. For example, patient 7 had improvements in accuracy, specificity and PPV for double trigger asynchronies. In the single-event algorithm, 33 false-positive double triggers were detected where only 28 true positives existed, representing more than a 2-fold overestimation of the prevalence of double trigger events when using the single-event classification algorithm. After implementing the multi-event algorithm, the number of false positive double trigger events reduced to 2.
**Discussion**

Our results suggest that implementing a multiple-event detection algorithm improves PVA sub-algorithm specificity without substantially compromising sensitivity. In particular, the double trigger sub-algorithm saw improved performance with the integration of clinical artifact filtering sub-algorithms. While preliminary, our findings highlight the need for clinical artifact detection and filtering approaches for the analysis of streaming waveform data. We have shown that single-event detection can result in a substantial over-estimation of the true prevalence of clinically meaningful events when artifacts are not detected and removed from analysis. In addition to the effects that artifact detection and removal may have on the study of PVA in the ICU, multi-event detection algorithms stand to improve the efficacy of clinical decision support (CDS) analytics by reducing alert fatigue and potentially improving the prognostic performance of CDS systems to identify those patients truly at risk of adverse outcomes. Furthermore, reducing the false positive rate could decrease potentially unnecessary and harmful changes in ventilator settings that may lead to additional patient distress.

Our study is limited by the relatively small sample size of our derivation cohort and relatively low PVA and artifact event rates despite manually enriching for high event rate regions of interest (ROI). While our manual ROI selection process may have introduced bias into algorithm performance, manual ROI selection was felt necessary given large numbers of normal breaths and the absence of validated available waveform analysis software with which to select ROIs. For proof of concept, we focused on a limited subset of PVA and artifact types and it is possible that multi-event algorithm performance may change when additional PVA and artifact sub-algorithms are added in the future.

This approach demonstrates the ability of a multi-algorithm framework to analyze large volume streaming waveform data acquired from mechanically ventilated ICU patients. Future work will focus on analysis of multi-event algorithm performance in a separate validation cohort, use of our analytics to study the relationship between PVA and clinical outcomes, and development of a CDS system using our multi-event algorithm to deliver actionable near real time information to critical care care providers to improve the management of patients with acute respiratory failure.

Technology, Incentives, or Both?
Factors Related to Level of Hospital Health Information Exchange

Sunny C. Lin, M.S. 1, Jordan Everson, M.P.P. 1, and Julia Adler-Milstein, Ph.D. 1,2
1School of Public Health, 2School of Information
University of Michigan, Ann Arbor, MI

Introduction
A key component of Stage 2 meaningful use (MU) is using EHRs to share information to improve care coordination. Hospitals must generate a summary of care record (SCR) and transmit it for at least 50% of care transitions, with 10% transmitted electronically. The electronic transmission threshold was set low because of concern that hospitals may not have the capabilities to engage in high levels of HIE. However, hospitals with HIE capabilities may still limit exchange volume given concerns that HIE may put them at a competitive disadvantage. We therefore sought to determine the extent to which the level of electronic SCR transmission was related to hospital capabilities, incentives, or both.

Methods
We combine Stage 2 MU attestation data with AHA Annual and IT Supplement survey data. Capability factors included whether the hospital had a basic or comprehensive EHR, potential trading partners (percent of hospitals in the market that attested to Stage 2 MU), and active participation in a Health Information Organization. We chose incentive factors based on theories from resource dependency and institutional theory, which suggest that hospitals may share more information if they are dependent on partners in the communities (e.g. participation in capitated or shared risk programs, or members of a hospital system or network), but may share less information if they are struggling to maintain demand for their services or have an organizational emphasis on revenue generation (e.g. hospitals in more competitive markets, hospitals with less market share, or for-profit hospitals). (1) Hospitals may also see a benefit in exchanging more information to maintain legitimacy if their mission is to serve the community (e.g. non-profit hospitals). (2) We used multivariate OLS regression with state fixed effects to analyze the relationship between capability and incentive measures and the percent of care transitions with an SCR transmitted electronically. To assess whether factors were uniquely related to the level of electronic transmission, we repeated the analysis using percent of transitions where an SCR was sent in any mode and percent of SCRs sent electronically. Controls include: hospital size, teaching status, percent Medicare and Medicaid days, geographic location, hospital beds in county, and hospital-ambulatory integration. Hospitals included in the analyses were all non-federal, general acute-care hospitals in the United States that attested to Stage 2 Meaningful Use as of April 2016 and responded to 2014 AHA IT Supplement survey (N=1778).

Results
Full regression results are presented in Table 1. For-profit ownership, compared to government, was associated with a 9.570 decrease in percent of discharges with an electronic SCR (p<0.001). Market share and competition were not significant. System membership was associated with a 4.123 increase in percent of discharges with an electronic SCR (p<0.001). However, network membership did not have a statistically significant relationship with percent of discharges with an electronic SCR. Compared to less than basic EHR, having a comprehensive or basic EHR were associated with a 4.370 increase in percent of discharges with an electronic SCR (p=0.002). The other two capability variables were not significant. Of these statistically significant factors, only for-profit ownership was also associated with any-mode SCR transmission; however, for profit ownership was associated with a 12.008 increase in the percent of discharges with any SCR (p<0.001). This suggests that for-profit ownership is associated with higher SCR transmissions overall, but lower electronic SCR transmissions specifically.

Discussion
This is one of the first national studies to examine a precise measure of the level of HIE, instead of simply HIE capabilities. We sought to understand what factors influence the level of exchange after the capability to exchange data is already determined. We found that the percent of care transitions with an electronically transmitted SCR was related to two incentive-related factors (ownership and system membership) and one capability measure (having a more advanced EHR). While our hypothesis suggests that this is because hospitals with emphasis on revenue generation and those with greater dependence on community partners may be incentivized to share less or more information, respectively, further research into the mechanisms behind this finding is warranted. Our study suggests that capability factors as well as incentive factors may
be influencing the extent to which hospitals are engaging in HIE. Achieving high thresholds of exchange in the future will therefore require addressing both domains.

Designing a Tablet Tool for Complex Patients to Prioritize Discussion Topics during In-Person Primary Care Visits
Courtney Lyles, PhD, Neetu Chawla, PhD, Christine Kowalski, MPH, Deanna McQuillan, MA, Andrea Altschuler, PhD, Elizabeth Bayliss, MD, MSPH, Michele Heisler, MD, MPH, & Richard Grant, MD, MPH

Introduction: Complex patients (i.e., those with several concurrent chronic diseases) experience higher healthcare costs and poorer health outcomes, partly driven by limited amounts of time to discuss all of their health issues with their doctors. User-friendly technology may improve communication between complex patients and their primary care providers by helping prioritize health concerns during brief in-person visits. We employed user-centered design using in-depth qualitative methods to create a tablet tool to assist complex patients with setting discussion topic priorities at upcoming visits – as this population that is comprised of mostly older adults is not often the focus of technology design. We outline here the main findings from this qualitative work, as well as the specific design implications that emerged.

Methods: We conducted semi-structured interviews with 40 patients and their 17 primary care providers across three sites: Kaiser Permanente Northern California (n=12 patients and 5 providers), Kaiser Permanente Colorado (n=13 patients and 8 providers), and University of Michigan, Ann Arbor (n=15 patients and 4 providers). All patients had 2 or more chronic conditions. In-depth interviews across sites lasted approximately 45 minutes. We then conducted three 60-minute iterative focus group sessions (all at KPNC using the same recruitment criteria, n=12 with repeat attendance by most patients) to iterate a paper-based prototype of the tablet tool with screenshots of the application and scripts of the audio clips. All interview and focus groups discussions were audiorecorded and transcribed for analysis. For the interview analysis, three coders (one at each site) collectively determined the primary discussion topics, and then each of these coders pulled all relevant transcript excerpts related to those topics. For the focus group analysis, we reviewed all design/content modification recommendations that emerged from the group design sessions. We organized recommendations into themes and sub-topics and linked these exemplary quotes to the major changes during our design process.

Results: The mean age of participants in the baseline interviews was 65-73 years old across the sites; 58% of participants were women. Focus group participants were primarily women (71%), with an average age of 71. Key themes across all qualitative work included: 1) streamlining the tablet tool design (including for those with lower technology proficiency), 2) improving tool content, and 3) recommending appropriate patient subgroups for the final tool (specific findings are in Tables 1-3). A total of 25% of patients in the baseline interviews explicitly stated that they were not interested in using this tool during their upcoming visits, for technology proficiency or lack of fit to their ongoing care processes (e.g., already made lists for providers).

These qualitative findings informed the following major design decisions: 1) making the tablet tool accessible for patients who lacked technical proficiency by reducing the quantity and complexity of text presentation (e.g., adding 3 <30-second audio clips explaining/coaching how to use the tool and removing all scrolling and extra text from each screen), and 2) ensuring specific content choices based on patients’ and providers’ personal experiences (such as the ability to raise private or sensitive concerns), and 3) targeting new patients for using the tool in future work since they were seen to have the most communication needs. Our final tool had text at the 6th grade reading level, used 6 screens total with sufficient space for free text entry.

**Conclusions:** Applying user-centered design methods, we substantially modified our initial design concept based on robust input from patients and physicians. The final tool was simpler to use while also providing richer choices and more engaging layouts. Rigorously documenting this adaptation process is a critical step of health informatics research in order to generalize knowledge about how the user-centered design process works in real-world scenarios, especially for older adults with multiple chronic conditions who are often left out of technology design processes. In future work, we see the potential to use even more patient data from the EHR and other sources to personalize the information within the tablet tool even further.
POE: A Pathology Extraction Tool for Finding Attribute-Value Pairs in Glioma Pathology Reports.

Veronica E. Lynn, BA¹, Niranjan Balasubramanian, PhD¹, Tahsin Kurc, PhD¹, Joel Saltz, MD, PhD¹, Rebecca Jacobson, MD, MS²,
¹Stony Brook University, Stony Brook, NY; ²University of Pittsburgh, Pittsburgh, PA

Introduction
Histopathologic features, identified by direct examination of neoplasms, play a critical role in cancer diagnosis. Diagnostic classifications, such as the WHO classification for glial neoplasms, provide guidance on the sub-classification and grading of cancer. For example, a high degree of cellularity and necrosis is associated with higher grade and worse outcomes in glial tumors. New integrative approaches that combine information from histologic, imaging and genomic features have the potential to advance methodologies for cancer classification[1] and will likely necessitate development of new classification schemes. These approaches will require scalable extraction of semantically rich features, potentially in very large datasets.

At present descriptions of histopathologic features are available in free text surgical pathology reports, and natural language processing is needed to extract them. In this case study, we develop and evaluate a pathology extraction tool, POE, which builds on the TIES framework[2], for Glioma pathology reports. Many existing NLP tools [2,3,4] identify medically relevant entities drawn from medical terminologies; TIES in particular provides a carefully hand-crafted set of cancer-specific entities. Tools such as TIES provide additional markup including negative observations and findings which have diagnostic value. In addition to these valuable annotations, we also need entity-attribute relationships to capture salient morphologic features, and the grading of observations, which has critical diagnostic value. For example, we may want to know whether cellularity was high or low to assess whether the specimen is a low or high-grade glioma. While it is relatively easy to find modifiers, determining which entity they modify is difficult. The terse nature of the reports means there are often many possible candidates, making this a hard task. To address these challenges, POE uses i) a feature classifier to identify relevant histopathologic features, and ii) a feature grade extractor that uses a syntactic dependency parser to locate the modifiers for each feature mention and map it to a grade value.

Method
On its own, TIES processes documents to identify entities and annotates their text spans with their concept name, concept code, and negation information. POE extends this by using the entity annotations to identify specific morphological features and link them with modifiers, which are then mapped to a grade value. This process is explained in more detail in Figure 1. In total, POE can extract 12 features, chosen due to being commonly considered when making a diagnosis, which can be assigned values based on severity (absent, present, mild, mild to moderate, moderate, moderate to high, or high) or shape (round, round to oval, or oval). Some examples are given in Figure 1.

Results
We evaluated POE using 473 pathology reports (250 glioblastoma, 223 low-grade glioma) collected from the Cancer Genome Atlas (TCGA). For these reports, the final diagnosis is given but the feature values must be extracted from the text. We therefore manually annotated 213 of these reports (132 glioblastoma, 81 low-grade glioma) to obtain the feature values.
POE’s feature identification classifier was evaluated through cross validation on the manually annotated set. It was able to determine if a feature was mentioned within a report with an F1 of 87.2. We also evaluated POE’s extractor for its ability to assign values for each feature. Across all possible values, POE obtained an accuracy of 52.2% at assigning the correct grade, a nine percent improvement (statistically significant) over a nearest-modifier heuristic. The drop in accuracy reflects the difficulty of assigning a grade compared with identifying feature mentions. Grade assignment typically requires a deeper semantic understanding of the text, necessitating a more sophisticated approach.

We demonstrate the utility of POE’s extracted features by using them to train a random-forest classifier to predict glioma type. The classifier is evaluated through cross validation using the full 473 reports, all of which have been automatically annotated using POE. We achieve an accuracy of 76.3% (80.4% glioblastoma, 71.7% low-grade glioma), compared to a random chance baseline of 52.9%.

Discussion

Our preliminary evaluations show that POE’s extensions to TIES can effectively extract relevant histopathologic features from glioma pathology reports. The evaluations also show that the extracted histopathologic features have some diagnostic value, motivating investigations into their utility for assessing new classification schemes. Effective extraction of histopathologic features from free-text reports is a precursor to determining how these features relate to each other, to image-based features and with outcomes. It will be a critical component in developing robust, integrative approaches for evaluating new classification schemes and designing effective therapies. Our next steps include (i) addressing extraction issues which stem from stylistic variations and the terse nature of the reports, and (ii) scaling the feature identification for other types of cancers. To promote further investigations in the community, we have released a dockerized version of POE (https://hub.docker.com/r/sbubmi/pathomics_morphex) that can produce a list of histopathologic feature-value pairs from pathology reports.

Development of an Oncology Subset of SNOMED CT Based on Patient Notes

Sina Madani, MD, PhD1; Jerry Henderson, MD1; Kin Wah Fung, MD, MS, MA2
1The University of Texas MD Anderson Cancer Center, Houston, TX
2National Library of Medicine, Bethesda, MD

Abstract

MD Anderson Cancer Center (MDA) is one of the world’s largest institutions involved exclusively in cancer care, research, and prevention. More than 120,000 clinical transcribed documents are added to the MDA EMR system on a monthly basis. We used natural language processing methods to generate a subset of SNOMED CT concepts that are frequently documented as cancer diagnoses in patient notes.

Introduction

SNOMED CT is gaining momentum as an international clinical terminology as the membership of the International Health Terminology Standards Development Organization (IHTSDO) tripled from its inception in 2007 to 28 countries. In the U.S., SNOMED CT is the designated terminology for the problem list and procedures according to the Meaningful Use of the electronic health record incentive program, as well as for transmission of data to cancer registries. Similar to the Clinical Observations Recording and Encoding (CORE) Problem List Subset of SNOMED CT, a list of commonly used SNOMED CT concepts in oncology will save effort in mapping local terms to SNOMED CT, reduce variability in data capture and enhance data interoperability. We describe our experience in the creation of an oncology subset based on natural language processing (NLP) of patient data in a large cancer treatment center.

Methods

We retrospectively analyzed the content of more than 15 million clinical narratives entered in MD Anderson Cancer Center legacy EMR system using MetaMap NLP framework to extract active clinical problem and cancer-related concepts at the patient level. After careful examinations of various note types and consulting with subject matter experts, we decided to target the last ten instances of the targeted clinical notes for all patients inside our EMR repositories. The targeted note types included Discharge Summary, Emergency, History & Physical, Consultation, Primary Medical Evaluation, Progress, and Clinical notes. We defined a “Problem” or “Cancer Disease” as something that required a plan for “diagnosis” and/or “management”. Therefore, from the selected note types mentioned above, all section headers related to the Assessment & Plan and Diagnosis sections, including subsections such as “Cancer Diagnosis”, together with their contents were extracted and analyzed by MetaMap v2014. We empirically set the threshold of MetaMap output to a score of 580. We restricted the UMLS targets to the “Disorders” semantic group, which included the semantic type “Neoplastic Process” for cancer-related concepts. We have also developed a post-processing module that prevented particular trigger strings within the narratives being mapped incorrectly to UMLS concepts, specifically, when the target concept was represented in an abbreviated format (like “gist” for Gastrointestinal Stromal Tumor). Such functionality has since been added to the latest version of MetaMap (v2016). One Extensible Markup Language (XML) file was generated for each patient note and serialized into a relational database. Phrases that MetaMap failed to map were stored separately for review. We applied the CORE Problem List subset (v2015) as an initial filter for removing unwanted and/or irrelevant concepts from the MetaMap output. Two trained physicians reviewed all concepts that were not represented in the SNOMED CORE subset and identified the ones that were relevant to cancer diagnosis. We calculated concept usage index by the occurrence of a cancer concept in a patient’s problem list by the total number of recorded cancer across all patients. To evaluate our NLP pipeline, we manually reviewed the output in two random patient samples (one for
general problems and the other for cancer diagnoses) to calculate the standard NLP performance metrics (precision, recall, F-measure).

**Results**

Based on the selection criteria mentioned in the method section, 554,801 unique patient records associated with 2,998,322 notes and 3,404,575 section headers were processed in the MetaMap pipeline. We identified 563 synonyms for the two categories of the target section headers. The performance metrics of the section header identification algorithm calculated as 97%, 99%, and 98% for precision, recall, and F-measure respectively. More than 3.7 million instances of cancer concepts corresponding to 2,698 unique concepts were extracted (Table 1).

**Table 1.** Top 5 cancer concepts and their usage index by instance, note, and patient frequencies.

NLP performance evaluation for the general problem list concepts (Disorders semantic group) on twenty randomly selected patients showed 94%, 90%, and 92% for recall, precision, and F-Measure respectively. We also evaluated performance metrics for only Neoplastic Process semantic type on a separate group of twenty randomly selected patients and calculated 100%, 83%, and 90% (recall, precision, and F-Measure). Nine cancer diagnosis discovered by MetaMap in this group (like Carcinosarcoma vs. Ovarian Carcinosarcoma) were considered as “too general” by the evaluating subject matter experts.

**Discussion**

We showed that it is feasible to use MetaMap to extract cancer-related SNOMED CT concepts from narrative patient notes. The oncology subset will be made available for download through NLM’s website by any user with a SNOMED CT license. While the subset is not meant to be exhaustive, it can be used as a starter set as it is expected to cover the majority of SNOMED CT concept needed in most cancer treatment institutions. During the creation of the subset, we encountered some concepts that had considerable usage but were not in SNOMED CT. We would review the unmapped concepts for validity and submit them to IHTSDO as suggested additions to SNOMED CT. Furthermore, we plan to use NLP outputs for a gap analysis between a vendor’s terminology and the internally identified cancer synonyms from MDA corpora for the enrichment of the existing provider friendly terminology incorporated within Epic system.

Protein Biomarker Discovery and Ranking for Early Detection of Necrotizing Enterocolitis in Neonates

Subramani Mani MBBS PhD\textsuperscript{1}, Daniel Cannon MS\textsuperscript{1}, Karri Ballard PhD\textsuperscript{2}, Robin Ohls MD\textsuperscript{1}

\textsuperscript{1}University of New Mexico Health Sciences Center, Albuquerque, NM, 87131

Necrotizing enterocolitis (NEC) is a serious inflammatory condition of newborns and infants with high mortality and morbidity and affects premature infants disproportionately. Small circulating blood volume in premature and low birth infants at higher risk of NEC and the need to minimize blood draw calls for the development of novel approaches for early detection of NEC. Developing informatics methods for protein biomarker discovery and ranking to facilitate early detection and intervention in NEC is a definitive clinical need as currently there is no specific diagnostic test that is available to clinicians in a neonatal intensive care setting. Predictive biomarkers are needed for early detection and to formulate treatment strategies for improved outcomes. Using a sample of 118 infants (24 cases and 94 controls) we identified the top 15 predictive protein biomarkers for NEC and ranked them.

Introduction and background: The recent publication titled “Improving Diagnosis in Healthcare” from the National Academies of Sciences, Engineering, and Medicine drives home the message that the delivery of healthcare has a significant blind spot, that is, diagnostic errors—inaccurate or delayed diagnoses [1]. Unfortunately this holds particularly true in the domain of necrotizing enterocolitis of neonates.

Necrotizing enterocolitis is a serious problem in neonatal intensive care units, particularly in extremely low birth weight (ELBW) infants. It affects 10\% of infants born <29 weeks gestational age [2, 3]. Nearly one half of NEC cases die, and many develop sepsis [4, 5]. Immaturity is clearly a causal factor [2], but clinical factors alone do not predict risk of NEC. About half of NEC cases occur 7 to 21 days of life, but timing of onset varies across neonatal intensive care units [2]. Predictive biomarkers are needed for early detection and to guide treatment strategies. Despite the frequency with which life-threatening NEC is encountered in the new born intensive care unit (NBICU), a rapid, sensitive, and specific diagnostic test remains elusive. Blood cultures are frequently negative, despite clinical symptoms that reflect significant inflammatory response, circulatory collapse, neutropenia, and thrombocytopenia. The identification of novel biomarkers that can provide a quantitative risk of development of NEC before the onset of symptoms will facilitate earlier intervention and improved outcomes [2].

Study objective: Our primary objective was to build predictive models and identify a set of ranked protein biomarkers for rapidly and reliably detecting necrotizing enterocolitis in infants.

Methods: We enrolled 118 eligible VLBW infants (gestational age \leq 32 weeks, birth-weight \leq 1500 grams, postnatal age \geq 120 hours) over a five year period from 2007 to 2012. Based on current best practice at NBICU, we assigned gold-standard diagnostic labels to the infants retrospectively using all available information. We categorized 24 infants as cases (NEC) as they satisfied Bell’s criteria for stage II and above [6] and the remaining 94 as controls. The Bell’s staging system for NEC is based on historical, clinical and radiographic criteria with stage I labelled as suspect and stages II and III considered definite and advanced NEC respectively. We used serum samples collected from each infant over a 21-day period to perform a focused proteomic assay of 90 potential biomarkers suspected to play a role in infection and inflammation. The quantitative proteomic assay was performed by Myriad RBM using a customized implementation of the Lumines xMAP technology, a microsphere-based multiplexed immunoassay platform. Using stratified 10-fold cross-validation, we evaluated a variety of machine learning methodologies including Random Forest, C4.5, ADT, logistic regression, and Naïve Bayes. Using Random Forest variable importance modeling we also ranked the predictive proteomic biomarkers. First we did this context free using only the proteins as potential predictors for modeling. Subsequently we also included the available clinical and lab parameters such as blood glucose, temperature, pulse rate, respiratory rate and repeated our predictive modeling experiments. The study protocol was approved by IRB and written, informed parental consent was obtained.

Results: Random Forest and logistic regression were the best two performing algorithms. Random Forest had the overall best performance with an Area under the curve (AUC) of 0.826, sensitivity of 0.817, specificity of 0.676, positive predictive value (PPV) of 0.391 and negative predictive value (NPV) of 0.935. See Table 1. Random Forest variable importance ranking identified 15 informative biomarkers which are shown in Table 2. Addition of the clinical parameters improved the predictive performance of Random Forest resulting in an AUC of 0.845.

Discussion and Conclusion: We have proposed an informatics approach based on machine learning to identify and rank the most predictive protein biomarkers for early detection and possible intervention in Necrotizing enterocolitis. The specific biomarkers TNFR2, IL-6 and IL-10 are known to be associated with inflammation and
infection. However, these are not routinely used in clinical practice. The role of other predictive biomarkers we identified have not been clearly established in NEC based on published studies. Endothelin-1 is a potent vasoconstrictor peptide which has been implicated in cardiovascular disease but plausibly can play a role in the pathogenesis of NEC due to its vasoconstrictive and pro-inflammatory actions. While additional validation is necessary before contemplating clinical use, our results suggest the potential utility of a proteomics-based diagnostic tool for early detection of NEC in preterm infants.

Acknowledgments: We thank the Thrasher foundation and the CTSC for funding support for the study.

Quantitative Neurocognitive Phenotype of ICU Survivors: A Multimodal Data Modelling Project

David M Maslove, MD, MS, FRCPC1, Michael Wood, BA2, Stephen H. Scott, PhD2, J Gordon Boyd, MD, PhD, FRCPC1,2

1Department of Critical Care Medicine, Queen’s University, Kingston, Ontario, Canada
2Center for Neuroscience Studies, Queen’s University, Kingston, Ontario, Canada

INTRODUCTION - The last two decades have seen a significant increase in the number of patients that are surviving critical illness and injury, leading to a heightened recognition of post-intensive care syndrome (PICS). This syndrome, characterized by long term, persistent neurocognitive and neuropsychiatric dysfunction, has recently become the focus of a growing number of research programs. Important constructs remain vaguely defined, thereby undermining the precision with which predictors and outcomes can be characterized for further rigorous study. These include concepts related to the Intensive Care Unit (ICU) stay, such as delirium, as well as those related to recovery, such as good functional outcome.

Current tools to characterize these deficits include screening surveys, subjective rating scales, and neuropsychiatric tests, which tend to be cumbersome, costly, and time-consuming. At the same time, novel monitoring systems and diagnostics are increasingly capable of providing precise, objective, and granular assessments of cerebral performance and neurocognitive function, suggesting opportunities for informatics-based methods to support rigorous studies in this area. In addition to large quantities of clinical and physiologic data routinely collected in the ICU, additional modalities can provide useful data for developing and testing hypotheses in neurocritical care. One example of such a system is near-infrared spectroscopy (NIRS), which is increasingly used as a non-invasive measure of tissue oxygenation, including cerebral oxygenation.

Newer technologies allow for data-enabled monitoring and evaluation beyond the ICU, following a patient’s discharge from hospital. Functional outcomes can be more precisely quantified using a novel robotics tool (KINARM), which generates rich, quantitative metrics of upper limb motion in humans. The KINARM has been used to identify subtle neurocognitive deficits in patients after stroke, that are not detectable by routine clinical assessments. Importantly, the deficits identified correlated with quality of life after stroke. More recently, the KINARM device has been used to quantify the neurocognitive phenotype in other settings, including patients with traumatic brain injury. The KINARM battery of tests consists of 8 tasks, which together assess a variety of sensory, motor, visuospatial, and executive functions that are integral to the description of post-ICU functional status. Within each task, 6-12 performance metrics (e.g. limb speed, reaction time, accuracy) are measured. Therefore, for each patient, up to 100 performance metrics may be available. Properly analyzed, the data generated by these tools will provide a precise, quantitative neurocognitive phenotype of the ICU survivor, and identify clinical conditions in the ICU that may increase the risk of PICS.

METHODS - The Cerebral Oxygenation and Neurological Outcomes FOLLowing CriticAl Illness (CONFOCAL) research program (NCT02344043) aims to define the acute and chronic neurological complications of critical illness using highly granular data. A multimodal dataset is generated for each patient enrolled in the CONFOCAL study.

Figure 1 - Time series of high-frequency heart rate (red) and brain tissue oxygenation (BtO2, blue) signals from a critically ill patient in the intensive care unit, spanning more than 18 hours. The area shaded in grey shows a period during which concordance between heart rate and BtO2 was evident, suggesting loss of cerebral autoregulation.
merging physiologically and temporally disparate but complementary signals. Data collection begins in the ICU, where we use NIRS to measure brain tissue oxygenation (BtO₂) in critically ill patients. Delirium assessments are done using the Confusion Assessment Method for ICU (CAM-ICU), a validated screening tool for detecting delirium in critically ill patients. At 3 and 12 months following ICU discharge, we use the KINARM to assess neurocognitive function, supplemented by the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS®) evaluation.

We developed informatics tools to explore relationships between BtO₂ data, telemetry, pulse oximetry, and other physiologic data collected by the bedside ICU monitor. We merged high-frequency vital signs and BtO₂ data (Figure 1) using automated Python and R scripts, and identified correlations between physiologic parameters in the ICU, and the presence of delirium. We also used unsupervised machine learning algorithms to determine the optimal number of neurocognitive phenotypes based on raw, normalized data from the KINARM and RBANS assessments, and centroid-based clustering methods to assign patients to individual clusters. We then used clinical parameters from the ICU stay, including BtO₂ values, to classify patients into one of the outcome clusters identified, using decision trees. We determined the classification performance of the model using a leave-one-out cross-validation approach.

RESULTS - As of March, 2016, nearly half of the target enrolment of 150 patients has accrued, with 3 month outcome data available on a smaller subset of these. Early analyses have revealed important relationships between physiologic parameters that have not previously been described. Patients experiencing delirium during their ICU stay were found to have lower BtO₂ values than those who remain neurologically intact. Patients with delirium also exhibited a linear relationship between BtO₂ and hemoglobin (r=0.485, p < 0.05) which was not present in patients without delirium, suggesting a role for impaired cerebral autoregulation and oxygen delivery in the pathophysiology of delirium. Hierarchical clustering of outcome data from the first 18 patients is shown in Figure 2. The raw outcomes data partitioned into 3 clusters. The decision tree model based on clinical features at the time of ICU admission was able to classify patients into outcomes clusters with an overall accuracy of 78%.

DISCUSSION - We developed a multimodal data collection and analysis platform that merges physiologic and neurocognitive information to identify quantitative phenotypes of ICU survivorship. Future directions will involve completing enrolment of the CONFOCAL clinical trial, and further developing data analysis pipelines with a focus on time series analysis, unsupervised learning for hypothesis generation, risk factor identification, as well as more nuanced and precise gradations of functional status. These tools will support research in the area of post-ICU syndrome, an increasingly recognized clinical entity with significant morbidity and socioeconomic impact.

Patient use of electronic prescription refill and secure messaging, and its association with undetectable HIV viral load

Abstract

Electronic personal health records may help patients engage in their own health care. We analyzed medical record data from 3374 veterans with HIV. There was a statistically significant positive association between use of electronic prescription refill and a change from detectable to undetectable HIV viral load status between 2009 and 2012, with OR=1.36 (95% CI 1.11-1.66). Use of a personal health record may result in greater control of HIV.

Introduction

Electronic Personal Health Records (PHRs) help patients engage in management of their own health care.¹² With such systems, patients go online to request prescription refills, view laboratory results, or communicate with their providers via electronic secure messaging. The Department of Veterans Affairs (VA) PHR, known as My HealtheVet (MHV), was introduced in 2003 and has more than 3.5 million users. Veterans with HIV register for MHV at higher rates than veterans with other chronic conditions. However, it has not yet been established that use of MHV improves self-management or clinical outcomes for veterans with HIV. The present study investigates whether there are associations between use of MHV, and specifically its prescription refill (Rx Refill) and secure messaging (SM) functions, and HIV viral load in US veterans. Viral load measures how well HIV medications are working for a person infected with HIV, with the goal being a viral load so low that it is considered undetectable.³

Methods

We conducted a retrospective cohort study, analyzing medical record data from a cohort of 3374 veterans with HIV who received VA care between 2009 and 2012. Multivariable analyses accounted for facility level clustering and examined whether the dichotomous outcome of viral load status (detectable or undetectable) was associated with use of either Rx Refill or SM. Analyses controlled for age, gender, marital status, race/ethnicity, urban/rural residence, economic need, and comorbidities.
Results

There was a statistically significant positive association between use of Rx Refill and a change from detectable to undetectable HIV viral load status between 2009 and 2012, with OR=1.36 (95% CI 1.11-1.66). There was a similar association between SM use and change in viral load status with OR=1.28 (95% CI 0.89-1.85), but without achieving statistical significance. Analyses did not demonstrate a dose-response of Rx Refill or SM use on the achievement of undetectable viral load.

Conclusions

These findings suggest that use of a PHR among US veterans with HIV may result in greater control of this chronic illness, as measured by undetectable viral load. Exactly how this happens is unclear, but it is possible that PHR features may help increase patient-provider communication or patient motivation to self-manage one’s health. Alternatively PHRs may contribute to improved medication adherence by reducing gaps in patient supply of HIV medications on hand. This study’s limitations include the lack of experimental design, and unmeasured confounders such as health literacy and computer literacy. Due to these limitations it is possible that PHR use does not improve health processes or health measures such as viral load, but rather is a marker for high levels of engagement in one’s health. Additional analyses, and if possible including experimental designs, are needed to better understand the mechanism by which PHR use may (or may not) be contributing to health care processes and outcomes.

Feature Portability in Cross-domain Clinical Coreference

Timothy A. Miller, PhD1, Dmitriy Dligach, PhD1, Chen Lin1, Steven Bethard, Phd2, Guergana K. Savova, PhD1

1Boston Children’s Hospital and Harvard Medical School, Boston, MA; 2University of Alabama-Birmingham, Birmingham, AL

Introduction

Clinical coreference resolution is the task of grouping together multiple entity mentions in a text that correspond to the same real word entity. This has been a task of interest in natural language processing for decades, but has proven difficult and is still considered unsolved. Even to the extent that coreference systems can be built for clinical text, and score on par with systems in the general domain, there is some concern that these trained models are overfit to the domain of the training data. In this work we focus on the overfitting problem, and take advantage of new gold standard coreference datasets to explore the extent to which systems trained on one corpus can apply to another. We focus especially on mention-specific features, looking at the relative portability of word identity features, part of speech tag features, and dependency-tree-based features.

Methods

Datasets: We use two clinical datasets containing gold standard coreference annotations. The first is THYME (Temporal History of Your Medical Events), a temporally-annotated corpus that also contains coreference annotations on a subset of notes1. We use the THYME training data as our supervised training source, containing 273 colon cancer notes, including clinical notes and pathology notes that are intended to cover the disease course from initial visit to diagnosis to treatment. The second corpus we use is from the cancer deep phenotyping project (DeepPhe)2, which focuses on extracting detailed descriptions of cancer phenotypes from a range of different cancer types. From this corpus we use a preliminary version of the training data, containing 48 breast cancer notes, including radiology, discharge summaries, progress notes, and others. This corpus is not yet publicly available.

Methods: Coreference resolution is typically modeled as a supervised machine learning problem. One of the most common and successful approaches is the pairwise entity paradigm3, where the classifier is trained to decide whether pairs of mentions refer to the same entity. The outcomes from this classifier are then passed to a second phase where any inconsistent labels must be reconciled. We focus on a newer paradigm, the mention synchronous approach4, in which coreference chains are built incrementally, and newly encountered mentions are compared against existing chains in the document. This is part of a broader research agenda to track clinical events across notes, and so we model the known information about an event (e.g., tumor size, location) as it is mentioned and potentially use this information to resolve the notoriously difficult cross-document coreferent mentions. Evaluation in coreference resolution is performed using several different metrics (MUC, B^3, and CEAF), each with strengths and weaknesses, and recent work has used a combined score that averages the three (CoNLL – Computational Natural Language Learning5). We use the official CoNLL scoring tool, version 8.01.6

One difficult aspect of clinical coreference resolution is that clinical notes can be quite long and contain many entities. Since making every possible comparison is computationally prohibitive, we use a number of heuristics to limit the number of comparisons. First, we attempt to link a mention to any cluster that has a mention in the last five sentences. Next, we attempt to link to any cluster with an element that is part of a section header. We also allow a possible link to any cluster with more than one element. Finally, we allow linking to any cluster where a mention has the same headword as the current mention.

Our system uses a variety of standard features – adapting strong features from our previous pairwise system7 as well as newer features that look at the likelihood of a mention being a singleton8, the selectional preferences of different UMLS (Unified Medical Language System) semantic types, and that take advantage of the fact that the antecedent is a cluster instead of a single mention. Our system uses a linear support vector machine (Liblinear) to do classification.

In this work we examine the value of token features for coreference, since these features are very strong in other relation extraction tasks. Our experiments on THYME development set found that performance without token features was 56.8 (CoNLL), while with word token features it was 58.4. Given the difficult task, on a system we had
spent quite a bit of time developing, this was a surprisingly large gain. But with the specificity of our training domain, we had some concern that features focused on word identity would not generalize. We thus explore the potential gains possible with different representations of token-level features, with the explicit aim of evaluating on a new corpus which we had not seen. We looked at several configurations: Baseline (no token features) Word (word identity in three words preceding each mention, inside each mention, and three words following each mention), POS (part of speech tags using the same context as word features), and DEP (combinations of the mention head word and POS tag with its dependency tree parent head word and POS tag).

We hypothesize that while word features have a positive effect when trained and evaluated on THYME, they would have no effect or harmful effect in the new domain. We expect POS features to generalize better, and we expect dependency features to be better yet, since they rely on syntactic context, which is less reliant on local variation.

### Discussion

First, we should note that cross-domain performance is probably not as bad as it appears, because the two corpora differ in representation of de-identified names, which are quite common, and our system is tuned for THYME. THYME de-identification creates more realistic-looking names, so on real data we would thus expect the system to perform reasonably well on names. Our results (see table above) show that word features were indeed not valuable at porting to a new domain, and seem to hurt performance. We were surprised, however, to see that the same is true for POS features and DEP features. While DEP features combine Word and POS features with syntactic context, they too proved to be a drain on cross-corpus performance. These results could be taken two ways; first, they could be used to suggest that token identity features should be omitted for more robust coreference resolution. Alternatively, these results could be used to suggest that new methods that allow systems to incorporate target-domain lexicon into the feature representation would improve coreference system portability.

Applying Active Learning to Clinical Abbreviation Disambiguation in Real Time

Sungrim Moon, Ph.D.\(^1\), Yukun Chen Ph.D.\(^3\), Jingqi Wang M.S.\(^1\), Joshua C. Denny M.D., M.S.\(^4,5\), S. Trent Rosenbloom M.D., MPH\(^4,5\), Ky Nguyen R.N., B.S.N.\(^1\), Toluulola Dawodu R.N., B.S.N.\(^2\), Hua Xu Ph.D.\(^1,3\)

\(^1\)School of Biomedical Informatics, \(^2\)School of Nursing, The University of Texas Health Science Center at Houston, Houston, TX, USA; \(^3\)Pieces Technologies Inc, Dallas, TX, USA; \(^4\)Department of Biomedical Informatics, \(^5\)Department of Medicine, Vanderbilt University, Nashville, TN, USA

**Objective:** This study aims to assess the effectiveness of active learning\(^4\) in a real-time annotation process for building machine learning based classifiers for clinical abbreviation disambiguation. Previous studies\(^1\) have shown that active learning could achieve significant reduction in the size of annotated data and annotation time primarily in the simulation mode to achieve desired model quality. However, very few studies have also considered the actual annotation cost in active learning in a real-time setting, especially in the clinical domain. In this study, we used an existing active learning annotation interface, DUALIST\(^5\), to build real-time clinical abbreviation disambiguation. We designed a user study with both physicians and nurses as annotators to investigate the efficiency of active learning on the two types of experts.

**Methods:** In the current study, we built classifiers for six ambiguous clinical abbreviations: CA, CC, DM, LAD, PE, and RA. Two physicians and two nurses were asked to annotate sentences containing ambiguous clinical abbreviations, via either active learning or passive learning (random sampling) in a fixed time period of five minutes. DUALIST implements an uncertainty-based querying algorithm integrated with multinomial Naïve Bayes as the classifier for active learning. We evaluated the performance of the classifiers from active learning or passive learning using an independently annotated dataset of ambiguous abbreviations. We then generated learning curves, which plots the accuracies of the models vs. annotation time, as well as the area under the learning curve (ALC), which represents a global score of the learning process for each annotator, disambiguation task and sampling algorithm. We also report the annotation speed (the number of sentences annotated per minute) and the annotation difficulty (the ratio of sentences annotated as unsure and errors over the total annotated sentences).

**Results:** Overall, active learning outperformed passive learning in terms of the final accuracy on the test set. Table 1 shows results from all twelve experiments for the physicians and nine out of twelve for the nurses; the average final accuracies were 0.87 and 0.85 in the active learning and passive learning modes, respectively. A comparison of the effectiveness between physicians and nurses shows that ALC scores from active learning for physicians were higher (3.2% improvement on average from active learning to passive learning) than nurses (1.7% deterioration on average). Table 2 shows that annotations in active learning experiments had higher annotation difficulty (6.8% and 15.5% for physicians and nurses, respectively) than passive learning (1.1% for both groups in annotation difficulty). In other words, annotators had higher errors and uncertainty to annotate senses in active learning. Furthermore, active learning had lower annotation speed than passive learning. Also, physicians annotated more sentences in relatively short times as compared to nurses. Figure 1 presents the learning curves for the abbreviation, RA, for one physician (P1) and one nurse (N2). To achieve an accuracy of 0.95, active learning decreased annotation time by 77% (3.8 reduced minutes) and annotated sample size by 87% (101 reduced samples) than passive learning. In fact, passive learning could not reach 0.95 accuracy in five minutes for the same task. Figure 1 also shows that physician annotated 41 more sentences with higher accuracy (0.07) than nurse as well.

**Discussion:** Active learning showed higher performance of both final accuracies and ALC scores than passive learning for the real-time clinical abbreviation disambiguation tasks. We also found that active learning could be more beneficial to advanced clinical experts because physicians annotated more informative cases with lower error rate and higher speed than nurses. Despite the relative simplicity of this study, it presented the applicability of the active learning to build real-time WSD classifiers in the clinical domain.

Towards Phenotyping Stroke: Leveraging Electronic Health Record Data to Identify Stroke Cases in a Large-scale Epidemiological Study

Yizhao Ni¹, Charles Moomaw², Kathleen Alwell², Dawn Kleindorfer², Daniel Woo², Opeola Adeoye², Matthew Flaherty², Simona Ferioli³, Jason Mackey³, Felipe De Los Rios La Rosa², Sharyl Martini³, Pooja Khatri², Brett M. Kissela²

¹Cincinnati Children’s Hospital Medical Center, ²University of Cincinnati, Cincinnati, OH ³Indiana University, Indianapolis, IN, ⁴Michael E. DeBakey VA Medical Center, Houston, TX

Introduction

Administrative epidemiological studies typically use International Classification of Diseases (ICD) codes or death certificate data to identify stroke cases. However, they are limited by positive predictive values (PPVs) ranging from 6% to 97% across study designs and stroke types. A paucity of studies utilizes physician chart review of electronic health record (EHR) data to confirm cases and has greater accuracy, but these studies are costly and labor intensive. The large volume of false positives has hindered the re-use of collected samples for research requiring high statistical power, such as the Electronic Medical Records and Genomics (eMERGE) studies, which use patient cohorts of high purity to identify genome-wide associations. To minimize loss of statistical power, we investigated machine learning methods to identify high-precise stroke cohorts based on a broad array of EHR data. Our objective was to develop a machine learning-based approach that identifies stroke cases with high predictive performance.

Data and Method

We utilized stroke events collected in the Greater Cincinnati/Northern Kentucky Stroke Study, which is a large-scale, population-based epidemiological study that measures temporal trends in stroke incidence rates in a population of 1.3 million. The study identified hospitalization events with stroke-related diagnoses (primary/secondary ICD9 codes 430-438) from 17 regional hospitals in 2005 and 2010. Detailed information from patients’ EHRs was abstracted for each potential event by trained research nurses. The abstracts contained 281 structured variables categorized into 16 sets, which are presented in Table 1. Each abstract was reviewed by at least one stroke physician to determine if the event was a stroke case and, if so, the stroke subtype. The study personnel reviewed a total of 8131 potential events, of which 6987 samples were adjudicated to be stroke cases.

The event labels adjudicated by the physicians served as the gold standard to train and evaluate the predictive models. The baseline algorithm used ICD9 codes (430-431, 434-436) that identified stroke cohorts with high precision. We then compared the baseline with four machine learning classifiers: logistic regression (LR), support vector machines with polynomial (SVM-P) and radial basis function (SVM-R) kernels, random forest (RF), and three-layer artificial neural network (ANN) with L2-norm regularization. We chose these classifiers to allow for the possibility of linear and non-linear relationships between the variables and event labels. A nested ten-fold cross-validation was used to optimize model parameters and compare model performances. The model parameters (i.e., regularization parameters for LR, SVM-P, SVM-R and ANN; degree parameter for SVM-P; γ parameter for SVM-R; and number of trees for RF) were optimized using grid search parameterization. A core set of variables (DEMO, VI, ICD9, SS and CT/MRI) was selected based on the physicians’ expert knowledge. The nominal variables (e.g. ICD9 codes) were converted to binary features, whereas the numerical variables (e.g. blood pressure) were discretized into bins before converting to binary features. Macro-average PPV, sensitivity (SENS), negative predictive value (NPV), specificity (SPC) and the area under the ROC curve (AUC) were calculated to assess model performance. To explore all variable sets and validate their contributions, we also used the best first search strategy to incrementally add the variables into a LR model and assessed the corresponding performance.

Results and Discussion

The performances of the predictive models are presented in Table 2. Compared with the baseline, all machine learning algorithms yielded significantly better AUCs (p<1.0E-10 under paired t-test). The RF achieved the best AUC (89.51%), and its improvements over the other models were statistically significant. Figure 1 shows the false discovery rate (1-PPV)-sensitivity curves achieved by the models. We observed that the ICD9-coded predictor could not achieve an acceptable PPV (95%) to support studies requiring high precision such as the eMERGE studies. On the contrary, the RF could provide approximately 90% of the true cases for these studies under an acceptable PPV of 95% (dotted line, Fig. 1). Figure 2 shows the AUC curve when incrementally adding the variable sets using best first search. The top predictive variables included signs and symptoms, CT/MRI findings, ICD9 codes, interventions, demographics, visit information, and ED assessments. The core set designated by expert knowledge covered most of the predictive variables and its performance (85.90%) was close to the best AUC ever achieved (85.95%, Fig. 2).
The developed models identified stroke cases with high precision and adequate sensitivity, allowing high statistical power for retrospective stroke research without labor-intensive clinician review. The predictive variables identified in the study could be used to assist physician chart review and to develop generalizable stroke phenotype algorithms.

Evaluation of Whether Radiology Decision Support Embedded in the Order Entry Function of an Electronic Medical Record System Improves Appropriateness of Cross-Sectional Imaging Orders

Ted E. Palen, PhD, MD, MSPH1 and Susan Shetterly, MS2
1Institute for Health Research, Colorado Permanente Medical Group, Denver, Colorado
2Institute for Health Research, Denver, Colorado

Abstract
Possibly 30% of diagnostic imaging may be unnecessary or inappropriate. We evaluated whether the use of radiology decision support improved the appropriateness of radiology orders. The proportion of appropriate orders during baseline was 78.6% compared to 80.6% after the appropriateness alerts were turned on ($p < 0.06$). Among primary care physicians the adjusted rate of appropriate imaging orders was 77.8% at baseline and 81.0% after the alert was “on” ($p = 0.005$).

Introduction
The use of diagnostic imaging has rapidly increased over the last two decades.1-3 Studies indicate that perhaps 26% to 30% of diagnostic imaging procedures may be either unnecessary or inappropriate.1,4 Not only does increased use of medical imaging lead to increases in health care expenditures it also leads to patients being exposed to increasing amounts of ionizing radiation.2,4 Investigating appropriateness of medical practice is a logical extension of the empiric research which has revealed substantial variation in the type and intensity of health services, including medical imaging services.4 The American College of Radiology (ACR) has developed Appropriateness Criteria (AC) for imaging studies based on clinical indications.5 The ACR AC ratings range from 1 (least) to 9 (most) appropriate study for a clinical indication. It also displays the relative level of radiation exposure for specific imaging studies. In an attempt to address the rising rate of imaging and the concomitant rise in unnecessary or inappropriate imaging studies, radiology decision support tools are being incorporated into electronic medical records (EMR) which provides clinicians with evidence-based decision support at the time of ordering imaging studies. In comments submitted by Dr. Fridsma (President of AMIA) and Dr. Payne (AMIA Board Chair) to the Centers for Medicare & Medicaid Services (CMS), they stated that AMIA believes CMS has an unprecedented opportunity to learn which components of these legacy programs [payment systems] will effectively support our healthcare system in moving toward the triple aim and recommended that CMS engage medical informatics expertise more broadly to understand how technology should be leveraged to improve care experience, expense and efficacy.5 Conference participants attending this presentation will be presented with results regarding the use of radiology ordering decision support at the point-of-care. Studies like this will help inform the objectives of both AMIA and CMS in understanding how to incorporate technology into care processes.

Objective
Our goal was to evaluate whether the use of radiology decision support embedded in an EMR point-of-care ordering system will improve the appropriateness orders for cross-sectional radiology studies.

Study Site
The study site was an integrated health care delivery system. It serves a patient population of over 600,000 members. The health plan employs over 6,000 staff and the medical group consists of over 1,000 physicians. The system deployed a commercial EMR in 2004. The study involved a step-wedge, cluster design, preceded by a “run-in” period. Twenty-four ambulatory clinic locations were randomly divided into four clusters. Radiology decision support software using the ACR AC criteria was interfaced with the ambulatory electronic medical record order entry system. During the “run-in” period, users were required to enter either a coded and or free-text clinical indication at the time of ordering an imaging study. However, during this period the decision support software did not display the AC rating for the imaging study ordered, although the software calculated and stored the rating. After a six week “run-in” period the ACR AC rating alert was activated for users in cluster one clinics who had selected one or more coded clinical indication when ordering cross-sectional imaging (CT or MRI) studies. At 2-4 week intervals the ACR AC rating alert was activated for users in cluster two, three, and four clinics. If the AC rating is in the poor or not indicated range (ACR score 1-6) the software suggests a more appropriate imaging study. The ordering clinician can then either
precede with the original order (indicating an over-ride reason), choose the suggested imaging study, or cancel the order completely.

Results

After close of the study period we analyzed the data using generalized linear mixed models with a logit link (e.g. logistic regression) where the AC rating was treated as a binary outcome variable (AC rating 1-6 inappropriate and 7-9 appropriate). After excluding records that did not have an AC rating, the final sample included 18,121 (58.9%) of orders. The orders were made by 941 different clinicians (71.8% MD, 13.8% PA, 7.6% NP, 6.0% DO, and 0.9% OD, DPM, or DC). The patient median age was 56.7 (SE 16.3) and 56.8% female. During the period when the alert was “off” the adjusted rate of order appropriateness (AC rating of 7-9) was 78.6% compared to 80.6% after the AC rating alert was “on” (p = of 0.06). Among primary care physicians the adjusted rate of appropriate imaging orders was 77.8% at baseline and 81.0% after the alert was “on” (p = 0.005).

Discussion

Even though we saw an overall increase in the proportion of appropriate imaging studies it was not statically significant. However, we are uncertain whether this increase maybe clinically significant. That is, we do not know if more appropriate ordering improved clinical outcomes or decreased the need for additional imaging studies. We were surprised at the high proportion of appropriate imaging studies at baseline (“run-in” period). This may indicate a computer Hawthorne effect, that is, perhaps just requiring clinicians to enter a coded clinical indication may influence their clinical decision making. Or, it could indicate that baseline ordering behavior is highly evidence-based due to other factors. These questions all deserve additional investigation.

Conclusion

We used decision support software embedded into the order entry system of an electronic medical record system. The software displayed the ACR AC rating for the appropriateness of the cross-sectional imaging study ordered based on the indication selected by the clinician. The proportion of appropriate imaging studies ordered for specific clinical indications increased. The overall rate increase was not statistically significant. However, for the sub-analysis of primary care physicians only, we did see a statistically significant increase in the rate of appropriate ordering.

Detailed Clinical Models for Nursing Actions

Hyeoun-Ae Park, PhD1, Joo Yun Lee, MS1
1Seoul National University, Seoul, Republic of Korea

Abstract
The aims of this study were to develop and evaluate detailed clinical models for nursing actions in perinatal care. We extracted entities (dyads of action and target concepts) of nursing actions, attributes and possible values needed to describe either action or target concepts in more detail by analyzing nursing documentations, reviewing the literature, and interviewing nurse experts. In total, 233 models were developed with 34 action, 212 target, 211 attributes, and 534 value concepts.

Introduction
The potential benefits of electronic health records (EHRs) include improvements in patient safety and quality of care, reduced medical errors, reduced cost and improved ability to conduct research and population health1. However, these benefits depend on the semantic interoperability of data to be shared and exchanged.

One way to ensure semantic interoperability is to have an agreed clinical data structure2. Agreed data structures may be referred to under many different names, such as detailed clinical models (DCMs), clinical element models, care information models, clinical content models, clinical templates, archetypes, clinical fragments, and more3. A DCM is a relatively small, standalone information model designed to express a clinical concept in a standardized and reusable manner. A DCM consists of an entity-attribute-value (EAV) triplet where an entity is a core or focus concept of a datum, an attribute is a qualifier that represents the entity in more detail, and a value set is a uniquely identifiable set of valid values describing instances of an attribute.

While the importance of developing DCMs for nursing has been addressed by many nurse informaticists4, there are only a few reports on this topic in nursing literature. To the best of our knowledge, these efforts mainly focused on the nursing problems and/or nursing diagnoses5,6. The aims of this study were to develop and evaluate detailed clinical models for nursing actions and or interventions in perinatal care.

Methods
First, we extracted action and target concepts which are the core concepts of nursing action, attributes and possible values sets needed to describe either action or target concepts in more detail by analyzing narrative nursing action statements, and reviewing related literature. For this, we analyzed 27,596 narrative statements used to describe nursing services, actions and/or interventions in electronic nursing records of 63 women who were hospitalized to give a birth from March 1 to April 30, 2012 at a tertiary teaching hospital in Korea. We also analyzed 795 unique narrative nursing activity statements in 26 NIC nursing interventions relevant to perinatal care based on SCOG guideline. In addition, we reviewed text books on perinatal care, AWHONN'S perinatal nursing and ISO's Conceptual framework for patient findings and problems in terminologies to identify additional action and target concepts, attributes and possible value sets.

Second, DCMs were modeled by creating dyads of action and target concepts as entities and linking these entities with possible attributes with value sets and optionalities.

Third, DCMs were validated by eight nurse experts on the reusability, non-ambiguity, relevancy, exclusiveness, completeness, and consistency using 4-point rating scale (from 1 = strongly disagreed to 4 = strongly agreed). The coverage of the DCMs was evaluated by mapping concepts extracted from 1,092 narrative statements used to describe nursing services, actions and/or interventions of 5 women who were hospitalized to give a birth from May 1 to 51, 2012 at a the same tertiary teaching hospital to the EAV triplet concepts.

Results
In total, 233 DCMs were identified from analysis of narrative nursing action statements from nursing documentation, and literature review. Three more attributes and 7 more value sets were added after consulting the nurse experts. These 233 DCMs consists of 233 entities (dyads of 34 action and 212 target concepts) with 214 attributes, and 541 value sets. There were 1 to 33 target concepts linked to one action concept with an average 6.7 target concepts. There were 1 to 3 action concepts linked to one target concepts. Action concepts such as ‘applying’, ‘assessing’ and ‘inquiring’ has the most number of targets with 33. Target concept linked with the most number of action concepts was ‘blood product’. Each entity linked to 1 to 9 attributes with ‘administering
intravenous infusion’ with the most number of attributes. Table 1 presents the ‘teaching breastfeeding’ DCM as an example.

</tr>
</tbody>
</table>

* SC : Character String with Code / REAL : Real Number

Rating scores for reusability, non-ambiguity, relevancy, exclusiveness, completeness, and consistency were 0.91, 0.96, 0.87, 0.96, 0.80, 0.96 and 0.84 respectively. Based on the experts’ evaluation, we deleted 5 entities, and 6 attributes; we added 7 entities, 23 attributes and 6 value sets; and we revised 3 entities, 1 attribute and 2 value sets.

For coverage evaluation, 192 unique statements extracted from 1092 narrative nursing action statements were mapped to DCMs. As presented in Figure 1, 174 statements were fully mapped, 7 partially mapped and 11 not mapped. Eleven not mapped statements need new action-target dyads. Six out of seven partially mapped statements need new attributes and remaining one needs new value.

**Figure 1. Mapping narrative nursing statements to detailed clinical models components**

**Conclusion**

DCMs developed in this study will be used to generate nursing narratives using natural language generation technology. Narratives generated from the DCM will guide a structured and standardized data entry and ensure semantic interoperability of data to be shared and exchanged.

A probabilistic model for learning relationships between diagnosis codes and clinical free text

Adler Perotte, MD, MA1, Noémie Elhadad, PhD1
1Department of Biomedical Informatics, Columbia University, New York, NY

Introduction
In this work, we aim to develop a probabilistic model that simultaneously models the hierarchical nature of a diagnosis code vocabulary and captures the relationships between diagnosis codes—including non-billing codes—and clinical free text. We focus on diagnosis codes from the International Classification of Diseases, Ninth Edition (ICD-9). Effective representations of these relationships can enable several applications including (i) the ability to highlight terms of interest in documents associated with a given diagnosis code; (ii) the ability to search for billing codes associated with a given free-text query; and (iii) the ability to search for documents of interest based on billing or non-billing diagnosis codes.

Several models and systems have been developed that leverage natural language processing (NLP) to process clinical documents, such as discharge summaries, and assign billing codes associated with that episode.1,2,3 In contrast, our goal with this is to create a flexible representation of the relationships between terms and diagnosis codes that can serve as the foundation for many applications including billing code assignment.

Our approach is based on a novel probabilistic model called the Hierarchically Identified Latent Dirichlet Algorithm (HILDA) and builds on prior work in statistical NLP to model diagnosis codes and document text simultaneously while respecting the hierarchical constraints of the ICD taxonomy. As we will demonstrate, the parameters of this model are interpretable and useful.

Methods
HILDA is a model for bag-of-word data with multiple hierarchical labels. This model is an extension of Latent Dirichlet Allocation4 (LDA) and closely related to Labelled LDA and Hierarchically Supervised LDA.3 This work differs by creating a one-to-one relationship between diagnosis codes and topics while also respecting the hierarchy of the vocabulary. In particular, the observation of a leaf diagnosis code implies the observation of ancestor diagnosis codes. Of note for this work, unobserved diagnosis codes that are not the ancestor of an observed code are considered negative.

Model Description
Let \( \mathbf{w}_d = \{ \mathbf{w}_{1,d}, \ldots, \mathbf{w}_{N_d,d} \} \) be the set of \( N_d \) terms in document \( d \).
Let \( y_{r,d} \) be the root of the ICD-9 hierarchy for document, \( d \), and \( y_{a,d} \) represent the children of the root where \( a = \{1, 2, \ldots, A\} \) and \( A \) is the total number of direct children of the root. Each subscript for the set of variables associated with the ICD-9 hierarchy represent a level. Therefore, codes that are 6 levels deep will have 6 subscripts indicating the branch at each level in addition to the subscript representing the document, \( d \). Let \( z_{n,d} \) represent the topic/diagnosis code assignment for a given term, \( \theta_d \) represent the distribution over topics/diagnosis codes for the document, and \( \phi_c \) represent the distribution over terms associated with each topic/diagnosis code.

A collapsed Gibbs sampler was developed to perform inference in this model, integrating out \( \theta_d \) and \( \phi_c \). This model was trained on a corpus from the MIMIC-II database of 20533 clinical documents (discharge summaries) and associated ICD-9 codes. There was an average of 9.24 codes and 606.27 words per document.

Results
Although predictive performance was not the primary goal of this work, HILDA predicts diagnosis codes in a held-out set with an F1-score of 37.7%. This is competitive with other discriminative classifiers, including a hierarchical
SVM. Related work predicts using random vector representations. In that work, at least one diagnosis code was in the top 10 predictions in 20% of cases whereas we observe a performance of 48%. However, this may not be the most informative performance metric and the corpus studied in that work is not very comparable to MIMIC-II.

</tr>
</tbody>
</table>

Discussion

We presented a novel probabilistic model, HILDA, for jointly modeling clinical texts and diagnosis codes. This model generates term based representations of diagnosis codes and, in particular, develops interpretable representations for non-billing ICD-9 codes that never actually appear in the training data; i.e., even though these codes had no associated documents, the model is able to assign them interpretable distributions over terms (Table 1). Note that a query for “shock” returns comorbidities of shock such as respiratory failure and liver injury. Lastly, this model can also be used bi-directionally, identifying the most relevant diagnosis codes for a given query term. (Table 2) Thus, the model can be useful as a component in systems that perform tasks such as hypothesis generation, search, document and patient summarization, as well as automated clinical document labeling.

Information Blocking: How common is it and what policy strategies can combat it?

Eric Pfeifer, BA, School of Information and School of Public Health, University of Michigan, Ann Arbor, MI

Julia Adler-Milstein, PhD, School of Information and School of Public Health, University of Michigan, Ann Arbor, MI

Introduction: Congress has expressed concern about “information blocking” - the practice of knowingly interfering with the electronic exchange of patient health information – as a serious impediment to realizing value from EHRs and related HITECH investments. (1) However, there is little empirical evidence on who is engaging in information blocking, the specific forms it takes, and what policy solutions might effectively counter it. We therefore undertook a national survey of leaders of Health Information Exchange efforts (HIEs) to collect the first systematic data on information blocking.

Methods: Between October and December 2015, we conducted a nationwide, close ended survey of those currently leading state and community HIE efforts, typically CEOs, who would be most likely to observe information blocking if it were occurring. Respondents were those who participate in our annual census of HIE efforts. (2) The survey asked about several dimensions of information blocking (using the ONC definition of information blocking) separately for the two stakeholders currently suspected of information blocking: EHR vendors and hospitals/health systems. We created descriptive statistics to capture (1) the frequency of engaging in information blocking, (2) the specific forms it takes and degree of associated harm in terms of interfering with needed information sharing, and (3) the viability of policy solutions to counter it. The survey was initially piloted with three HIE leaders and was refined based on the feedback from these individuals.

Results: We received 60 responses (57% response rate). 50% of respondents reported that EHR vendors routinely engage in information blocking, and 25% of respondents reported that hospitals/health systems routinely do so. (Figure 1) The most common form of information blocking among vendors was deploying products with limited interoperability (49% indicated that vendors did so routinely, with an additional 31% reporting sometimes, Table 1) and this was also perceived as the most harmful form of information blocking (90% indicated very or moderately harmful). For hospitals/health systems, the most common form of information blocking was coercing providers to adopt a particular EHR or HIE technology (28% routinely and 24% sometimes, Table 1), but the most harmful form was using HIPAA as a barrier to HIE when it is not (83%). The forms that information blocking manifests itself from hospitals/health systems appears to be influenced by a fear of losing a competitive edge as a result of data sharing. To address vendor information blocking, the top policy action was tougher demonstrations of interoperability for certification (90% deemed very or moderately effective) and for hospital/health systems it was stronger CMS incentives to engage in HIE (92% deemed very or moderately effective).

Discussion: Based on the experiences of those leading HIE efforts, information blocking is widespread, though more common among vendors than providers. This is a key limitation of our study, we are only measuring the perception of whether information blocking is occurring. When information blocking occurs, it is widely perceived as harmful to needed information sharing. Viable policy remedies exist and the most popular would rely on existing mechanisms: EHR certification requirements and CMS incentives. Though there has been substantial discussion about information blocking since Congress raised it as an issue, it has been difficult to take action given that the evidence is anecdotal. Our study offers the first national data on the extent of information blocking as well as more detailed information on its forms, degree of harm, and viability of policy strategies to counter it. The federal government is in a position to take action and could do so without new legislation.

Patient-provided Data Improves Race and Ethnicity Data Quality in Electronic Health Records

Fernanda Polubriaginof MD, MA1, Hojjat Salmasian MD, MPH, PhD2, Andrea Wells Shapiro MHA2, Jennifer Prey MPhil, MS1, George Hripcsak MD, MS1, Adler Perotte MD1, Nicholas P. Tatonetti PhD1, David K. Vawdrey PhD2,1

1Department of Biomedical Informatics at Columbia University, New York, NY;
2NewYork-Presbyterian Hospital, New York, NY

Introduction

Race and ethnicity are commonly used for estimating disease risk and for assessing health disparities, and these characteristics are frequently reported in observational studies that rely on Electronic Health Record (EHR) data. In the United States, the Meaningful Use financial incentive program includes the requirement that EHRs collect patients’ race and ethnicity in a structured fashion.1 Previous research on the quality of race and ethnicity data recorded in EHRs was conducted with small groups of selected patients.2,3 We undertook a study to evaluate data quality of race and ethnicity in EHRs, and to understand the impact of allowing patients to directly provide or curate their information.

Methods

We conducted a retrospective analysis of race and ethnicity data recorded for patients that had at least one visit at NewYork-Presbyterian Hospital/Columbia University Medical Center from January 1, 2014 to December 31, 2015. The institution collected race and ethnicity data using a two-question format, with one field recording the patient’s race (American Indian or Alaska Native, Asian, Black or African American, Native Hawaiian or Other Pacific Islander, White, Unknown, Other, or Declined to Answer), and the second field capturing the patient’s ethnicity (Hispanic or Latino, Not Hispanic or Latino, Declined to Answer, Unknown). We calculated descriptive statistics on the frequency of race-and-ethnicity pairs. Patients classified as “Unknown”, “Other” or “Declined to Answer” were considered to have clinically uninformative data; we combined these categories into a larger category designated as “Unidentified”. Completeness was assessed based on the percentage of pairs with race and ethnicity not as “Unidentified” in the database. Furthermore, we analyzed the changes for race and ethnicity reported for the same patient over multiple visits, using HL7 logs from the EHR.

We assumed patient-reported data to be the reference standard for race and ethnicity data collection. In order to assess differences between patient-reported race and ethnicity information and the EHR data, we analyzed two sources of patient-reported data: 1) the HCAHPS (Hospital Consumer Assessment of Healthcare Providers and Systems) Survey, which collected demographic information from patients in the form of a document sent via U.S. Mail after discharge, and 2) data from a randomized controlled trial where patients admitted through the hospital’s emergency department reviewed and corrected their race and ethnicity information (obtained via the EHR) using a custom patient portal application on a tablet computer.

Results

We found 352,486 unique patients who had at least one visit during our two-year study period. As shown in Table 1, 58.9% of patients did not have race or ethnicity identified in the EHR. There were 254,458 modifications made to race or ethnicity fields in the EHR for 153,535 unique patients. Modifications in the race or ethnicity could improve completeness (i.e., a change from ‘uninformative’ to a specific race or ethnicity category) but this was not always the case (Table 2). In fact, 30.5% of the modifications to the race field were changing “Other” to “Unknown”. Similarly, 29.7% of changes made to ethnicity converted “Hispanic” to “Unknown”.

During the study period, 28,658 unique patients responded to the HCAHPS survey, and 19,414 (67.74%) provided race and/or ethnicity information that was discordant with data recorded in the EHR. In the randomized trial that assessed patient-reported demographic data entered at the time of hospital admission, 65 patients were recruited. Of those, 35 (53.85%) made changes to their race and/or ethnicity (30 patients edited both, four patients edited ethnicity only, and one patient edited race only). Analysis of all of the “Uninformative” categories for race and ethnicity demonstrated that the majority of patients were willing to provide their information. Among the randomized trial study patients, 32 had “Uninformative” race information and 42 had “Uninformative” ethnicity documented in the

Our findings suggest that patient-facing tools that allow patients to provide this information before, question format (i.e., collecting race and ethnicity data collection as separate fields) that is now widely used, as well as the clarity of the difference between “race” and “ethnicity” for patients. Interestingly, our Hispanic patients did not seem to consider themselves to belong to any of the OMB-defined race categories as the majority identified their race as “Other” and often entered “Hispanic,” the majority did not consider their race to be available in the list of options; 10 patients recorded or retained their race as “Other,” and two as “Unknown.”

Discussion

The U.S. Meaningful Use of EHRs financial incentive program requires participating healthcare providers to record patients’ race and ethnicity in a structured fashion. Categories for collecting race and ethnicity are based on current standards published by the Office of Management and Budget (OMB) in 1997. When analyzing race and ethnicity data in the EHR, we observed that a significant percentage of patients had a documented race and ethnicity that was not clinically informative. Analysis of changes in race and ethnicity data over time showed that the most frequent changes were from uninformative concepts to different uninformative concepts (e.g., from ‘Other’ to ‘Unknown’). We also observed that changes were made not only when uninformative concepts were detected, but also from more informative to less informative concepts (e.g., from ‘White Hispanic’ to unknown race, unknown ethnicity). This phenomenon speaks to the challenges faced by registration personnel, particularly in care delivery settings with racially and ethnically diverse populations.

One way to improve the quality and completeness of patient demographics in electronic health records is to allow patients to review and request updates to their own information. This could be accomplished in many ways, but one useful method may be through patient portals. When comparing ethnicity data before and after patient review in the Emergency Department, we observed that patients were willing to review their information and make changes when needed. The majority of the patients with uninformative race and ethnicity in the EHR changed these values to more meaningful concepts. Interestingly, our Hispanic patients did not seem to consider themselves to belong to any of the OMB-defined race categories as the majority identified their race as ‘Other’ and often entered “Hispanic”, “Latino” or their country of origin in a free-text field. This behavior raises questions about the efficacy of the two-question format (i.e., collecting race and ethnicity data collection as separate fields) that is now widely used, as well as the clarity of the difference between “race” and “ethnicity” for patients.

The appropriate collection of race and ethnicity information is key to recognizing disparities that affect minority populations. Further, this information can be used to perform disease risk assessment both for individuals and populations. Our findings suggest that patient-facing tools that allow patients to provide this information before, during, or after their healthcare encounters could markedly improve data quality.

Validating the Occupational Data for Health Model: An Analysis of Occupational Information in Reports, Standards, Surveys, and Measures

Sripriya Rajamani, MBBS, PhD, MPH1, 3, Elizabeth S. Chen, PhD2, Ranyah Aldekhyyel, MS3, 5, Yan Wang, PhD3, Genevieve B. Melton, MD, PhD3, 4
1Public Health Informatics Program, 3Inst for Health Informatics, 4Dept of Surgery, Univ of Minnesota, Minneapolis, MN; 2Ctr for Biomedical Informatics, Brown Univ, Providence, RI; 5Medical Education Dept, College of Medicine, King Saud Univ, Riyadh, SA

Introduction
Recognizing the importance of social factors in influencing health status and outcomes, recent reports have advocated for their incorporation in electronic health record (EHR) systems. The National Academy of Medicine (NAM; formerly Institute of Medicine) 2011 report1 titled “Incorporating Occupational Information in Electronic Health Records” highlighted the need for robust representation of occupational information in EHRs. Work initiated by the National Institute for Occupational Safety and Health (NIOSH), a leader in promotion of occupational health and strong supporter for incorporation of occupational information in EHRs, has resulted in an ODH (Occupational Data for Health) data model2. Subsequent statements by reputed sources3-5 as well as landmark reports by NAM in 2014 on social and behavioral domains and measures in EHRs6,7, further emphasize the importance of capturing occupation-related information. NIOSH has also supported demonstration projects around occupational data. The study objective was to collect occupational health items from resources ranging from recommendations, standards, public health reports, public health surveys, and research measures in order to validate the ODH model.

Methods
Five key source types (reports and recommendations, standards and specifications, public health reports, public health surveys, and research measures) comprising 20 resources were identified by review of relevant reports and literature searches (e.g., using “occupation” and “representation” as search terms) to create a master list of items (e.g., elements or questions/responses) on representation of occupational information. This list was used as a guideline to evaluate the ODH model by NIOSH which comprises of six categories: Occupational History, Usual Occupation and Industry, Employment Status, Work Schedule, Occupational Injury, and Occupational Exposure. The methodology consisted of four main components: (1) create a comprehensive list of items from representative sources; (2) develop guidelines to map items to the ODH model; (3) map items to ODH categories and elements; and (4) ascertain coverage and identify areas for enhancement. Guidelines for mapping were developed by study authors with expertise in biomedical standards, informatics, and clinical and public health practice. Two of the experts (SR and RA) mapped 10% of items calculating inter-rater reliability (Cohen’s kappa = 0.94 and proportion agreement = 0.99) and also mapped all items, which were then reviewed and analyzed by the study authors.

Results
Twenty resources (Table 1) including 247 items were identified for inclusion in the master list for representation of occupational information and 100% mapped to the ODH model. Occupational History was the most common category across the resources (65%), followed by Employment Status (55%), and Usual Occupation and Industry (45%). Certain elements contained clinical interpretations (e.g., Work-relatedness) and some were derived data elements (e.g., duration of Occupation and Industry). The need for more granularity in the Occupational Injury and Occupational Exposure categories was identified. Some of the survey questions captured temporality for recent past (e.g., last week) and compensation for work (e.g., wages). The ODH model includes Employer Location that may be different from actual worksite for exposure data. Value sets for Employment Status were varied across the resources.

Discussion
Our study findings illustrate the robustness of the ODH model for representation of occupational information that may ultimately contribute to supporting clinical care decisions. The results also highlight the multitude of associated concepts and complexity of their representation. The ODH model is in draft stages (under review) and likely to have expanded elements (e.g., for Occupational Exposure) when released. Definitions of the occupational categories and elements, codes for their representation, and guidance for certain categories (e.g., Employment Status) are critical for uniformity in use. With the growing adoption of EHRs and the possibility of future EHR certification criteria for occupational information, it is essential for reputed entities like NIOSH to continue their advocacy.

Information Needs of Physicians, Care Coordinators, and Families to Support Care Coordination of Children with Special Health Care Needs (CSHCN)

Pallavi Ranade-Kharkar, PhDC,1,2 Charlene Weir, PhD, RN2,3, Chuck Norlin, MD2,4, Sarah A. Collins, RN, PhD5, Lou Ann Scarton, PhDC, Gina B. Baker, RN, MSN1, Damian Borbolla, MD, MS2, Vanina Taliercio, MD, MS2, Guillerme Del Fiol, MD, PhD2

Introduction
Children with special health care needs (CSHCN) are “those who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally.”1 CSHCN comprise an estimated 15.6% (11 million) of the pediatric population in the US, and their healthcare costs 3 times that of other children1. Caring for CSHCN is highly complex and often involves multiple medical and non-medical providers working independently and using disparate information systems. As a result, finding the information needed to support the care of CSHCN can be daunting. Timely access to information can support care coordination for CSHCN, avoiding care delays, duplicated efforts, diminished quality and frustration, and bring substantial value. Previous studies on care coordination for complex patients identified care process activities. In this study we aimed to elicit the kinds of information needs and associated goals that are raised by physicians, care coordinators, and family members while coordinating the care for CSHCN. Ultimately, our findings can be used to inform the design of informatics tools to support and improve care coordination for CSHCN.

Methods
We conducted interviews according to the Critical Decision Method (CDM); triangulating information from physicians, care coordinators, and family members (University of Utah IRB# 00075524). Interviewees were recruited from practices in a pediatric Patient-Centered Medical Home Demonstration project in Utah and represented different healthcare institutions. We interviewed 8 physicians, 7 families and 4 care coordinators; total interview time was over 17 hours. Following the CDM technique, interviewees were asked to recall a recent episode of care for CSHCN that they perceived to be challenging from the information-seeking perspective. The interview script prompted for goals (why), content (what and from whom), mode (how), barriers, and strategies used to meet the information needs. We systematically analyzed the interview transcripts using a content analysis method.3 Interviews were first unitized based on closely related sentences forming a meaning unit. From each unit, two researchers independently extracted one or more information needs in the form of questions, based on a code book. These questions were then converted to generic questions (e.g.,“What are the child's seizure patterns?”) and iteratively classified into information need goals. Throughout the process, disagreements were resolved through consensus among the researchers.

Results
On average, each interview identified 80 information needs. Our analysis categorized them into six information need goals: 1) situation understanding, 2) care networking, 3) planning, 4) tracking/monitoring, 5) navigating the health care system, and 6) learning (Table 1). Physicians and care coordinators described the need to develop situation understanding about the patient through accessing extensive healthcare records from various settings. For families, this goal related to understanding the assessments and goals of clinicians throughout the care process. Interviewees described care networks for CSHCN that go much beyond the healthcare system and include schools, community services, extended families and friends. Physicians coordinated care within the primary, specialty and the extended care network. Families reported frustrations due to inadequate feedback from their child’s care network. Physicians described planning for potential life-threatening emergencies. Families spoke of vigilantly planning episodes of care with the goals of optimizing resource utilization and trying to maintain a sense of normalcy in their child’s life. Physicians monitored test results and trends of assessments, care coordinators tracked episodes of care and completion of tasks. Families spent significant time and effort tracking symptoms, diet and response to medications. Parents spoke of having to navigate complex and time-sensitive processes for procuring needed services and resources with no single source of information. Care coordinators greatly assisted parents by taking care of paperwork-intensive processes to ensure coverage of care and regulatory requirements. Families had a significant
need for learning about symptoms, side-effects, and alternative treatments. Interviewees reported that meeting these information needs typically required considerable effort and involved various individuals and multiple information systems. Quite often, families had the burden of serving as the coordinators of their child’s health care, seeking and conveying information among members of their care network.

Discussion
To our knowledge, this is the first study to provide an in-depth assessment of information needs and associated goals in the care of CSHCN. We found that caring for these children generates a large number of information needs that require substantial effort from families, physicians, and care coordinators. These information needs present significant opportunities to improve care through multifaceted informatics solutions (e.g. a HIPAA-compliant social network application for care networking), integrated with multiple systems via health information exchange (HIE).

Introduction

Genomic laboratory tests have been an established tool for the diagnosis and treatment of certain conditions. With more recent advances in sequencing technology and in our understanding of the human genome, these tests have offered new options for patient care. Historically, the results of these tests have been returned as narrative text reports that are then incorporated into the patient’s medical record. They may be stored in locations that do not facilitate future retrieval, and in formats that are not computable for use in clinical decision support (CDS).

Multiple approaches have been put forth, each with strengths and limitations¹, to enable the flow of genomic information from the lab to the clinician. To date, there exist several examples of genomic medicine programs that have integrated genomic lab results with the electronic health record (EHR)²⁻⁵; however, these do not represent all possible implementation paths. Following the design principle that genetic and genomic data require special handling (similar to picture archiving and communication systems [PACS] for radiology images) and are best suited for storage in an ancillary system rather than the core EHR, we designed and implemented the Ancillary Genomics System (AGS) as part of the electronic Medical Records and Genomics Pharmacogenomics (eMERGE PGx) project⁶.

Methods

As part of eMERGE PGx, Northwestern University selected three drug-gene variant interactions (DGIs) of interest for which samples would be analyzed and returned in a primary care setting (clopidogrel: CYP2C19; warfarin: CYP2C9 and VKORC1; simvastatin: SLCOB1). Two external CLIA laboratories processed samples from 750 consented subjects. The Northwestern IRB reviewed and approved the study.

Although focused on a PGx use case, we designed the AGS to receive and process lab results for different levels of genotyping (e.g. from SNP panels to sequencing). Furthermore, the AGS was designed to house the original data from the CLIA lab, to process it using a set of approved rules, and to create a derived interpretation (or a “computed observation”) that would then be transmitted to the EHR as a discrete result. The intent of this design is to streamline the development of CDS alerts and rules. As knowledge or clinical recommendations change over time, the system design will allow existing data to be reprocessed, and updated results transmitted to the EHR.

Figure. The Ancillary Genomics System, including sub-components and interactions with external systems.

Results

An overview of the AGS design is shown in the Figure. It consists of various sub-components interacting with a central data store. The Data Import module is a collection of data adapters developed for the specific format provided by each CLIA lab for this study. Each adapter takes an import file and extracts the discrete results for storage in a relational database. The Data Analysis component includes a separate interpretation engine for each
Each engine first normalizes the results depending on the original format of the lab result (e.g., star variant, SNP genotype). For example, a homozygous star variant represented as just “*2” would be normalized to [‘*2, *2’]. This allows for more streamlined and consistent processing of results. The analysis module then uses these normalized results along with a set of lookup tables to create computed observations representing the corresponding PGx phenotype (e.g., “clopidogrel poor metabolizer”). In addition to a discrete representation of the phenotype, the system generates an interpretation report describing the corresponding finding and its implications.

Additionally, we developed a web client to allow study staff to review the computed observations and associated interpretation, and to flag unusual results not conforming to the standard interpretation. The system was initially developed to allow two phases of approval – the first to verify and approve the result, and the second to release approved results to the EHR. Study staff can control when and how results were returned, with an option to automatically release to the EHR upon approval. Upon release, the Results Export component transmitted the computed observation and report to the EHR. Within our configuration, each observation was returned as a lab result using a standard HL7 v2 message, although any HL7 v2 message could be generated.

Following withdrawals during the course of the study, in total 746 patients had each of their 3 DGI results returned to the EHR (2238 results in total).

Discussion

Although other approaches to integrating genomic results within the EHR have been successful, we highlight here the following benefits of the AGS solution presented above: (1) A dedicated AGS for storing lab results reduced the complexity of reviewing genomic results for most clinicians. This AGS design allowed us to centralize review on the computed observation, and then link to supporting genomic results. (2) The upfront use of computed observations reduced the burden on the EHR CDS engine by not requiring a large number of decision tree paths to be explored each time a patient’s record was viewed. While only 746 patients were included in this study, we anticipate this approach to scale in the future to incorporate more patients, more DGIs, and more complex results. (3) The use of computed observations allowed the CDS rules to be more streamlined (requiring fewer Boolean combinations and decision paths). This reduced burden on clinical analysts during the CDS setup, and required no intervention from clinical analysts during the study as new variant combinations were presented. (4) The modular and independent computation of observations easily permits re-interpretation and delivery of new result “interpretation” in the event knowledge about the variant changes.

Conclusion

Following the principles applied to the specialized handling of radiology images in PACS, we have designed and successfully implemented an Ancillary Genomics System at our institution for returning PGx results to patients in the EHR. The use of an AGS may benefit other institutions wishing to manage discrete genomic results returned from external laboratories.

Technologies to Support Care Coordination for Medication Safety

Alissa L. Russ, PhD1-4, Cherie L. Luckhurst, PhD,1,2 Rachel A. Dismore, MA,1,2 Karen J. Arthur, PharmD,2 Amanda P. Ifeachor, PharmD,2 Peter A. Glassman, MBBS, MSc,5 Michael Weiner, MD, MPH1-3
1Center for Health Information and Communication, Department of Veterans Affairs (VA), Health Services Research and Development Service, 2Richard L. Roudebush VA Medical Center, and 3Regenstrief Institute, Inc., Indianapolis, IN; 4College of Pharmacy, Purdue University, West Lafayette, IN; 5VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA.

Introduction
Care coordination, the intentional organization of patient care activities between two or more individuals,1 is essential for medication safety. Limited research, however, has been conducted on care coordination as it applies to medication safety incidents. A recent, systematic review indicates a need for research on these topics.2 Our objective was to identify factors that make it difficult for healthcare professionals to coordinate care when resolving medication safety incidents. We also conducted a human factors analysis to identify approaches that could ease or improve coordination around such incidents.

Methods
As part of a larger study, physicians and pharmacists from a major Veterans Affairs Medical Center submitted cases, via a study tool, where they identified and addressed a medication safety incident. We completed cognitive task analysis interviews for 60 cases total across 3 categories: 1) adverse drug reaction; 2) drug-drug interaction; and 3) drug-disease interaction involving renal function. Cases were eligible for inclusion in the analysis if participants coordinated with any other individuals to resolve the incident, yielding 47 eligible cases. We stratified eligible cases by the three categories above, and by participants’ professional role (i.e., physician or pharmacist), to ensure even sampling. Since qualitative data saturation is typically achieved within a smaller sample size, 24 cases were randomly selected from the eligible cases for analysis, with plans to analyze additional cases, if needed, to reach adequate saturation. We performed an inductive, qualitative analysis without predetermined themes,3, 4 to identify factors that hindered healthcare professionals’ coordination of care. The analysis team (human factors expert, pharmacist, sociologist, and research assistant) identified emergent themes and discussed any coding discrepancies until reaching consensus.5

Results
We analyzed 24 cases (from 12 physicians, 12 pharmacists) with 8 cases from each category, above. No new themes emerged after the first 12 cases, indicating adequate data saturation. Overarching themes are outlined in Table 1. Results from the first theme suggest that healthcare systems should facilitate real-time communication for some types of coordination. Other results suggest five potential technology-related solutions to enhance coordination: 1) technologies to facilitate more directed, medication-related communication among healthcare professionals; 2) prescribing guidelines and drug compendia that are integrated into computerized provider order entry (CPOE) systems; 3) a semi-automated CPOE design that allows healthcare professionals to enter safety criteria for individual medication orders, so that if these criteria are met (e.g., a lab test exceeding a designated threshold), the prescriber and pharmacy would be automatically notified and, if pre-requested, the medication would be automatically discontinued; 4) documentation mechanisms, tied to specific medication orders, that state the medication’s indication and can be easily viewed by the patient’s other providers; 5) documentation mechanisms, tied to specific medication orders, that explain safety-related changes to individual orders, are easily viewable by the patient’s other healthcare providers, and that persist in the EHR long-term.

Conclusions
To our knowledge, this is the first study to systematically analyze care coordination activities that occurred in actual medication safety incidents. Results reveal factors that impede healthcare professionals’ ability to coordinate care for medications. Recommendations from this research are hypotheses that would need further evaluation. Results are expected to inform healthcare system design changes, some of which may be technology-based, to aid care coordination activities; findings may ultimately be used to enhance medication safety for patients.

Introduction: Mobile applications or ‘apps’ intended to help people manage their health and chronic conditions are widespread and gaining in popularity. (1) However, little is known about their acceptability and usability for low-income, racially/ethnically diverse populations who experience a disproportionate burden of chronic disease and its complications. (2, 3) The objective of this study was to investigate the usability of existing mobile health applications (“apps”) for diabetes, depression, and caregiving, in order to facilitate development and tailoring of patient-facing apps for diverse populations.

Methods: Usability testing was conducted with participants only on condition concordant apps, with caregivers (n=9) tested on caregiver apps, participants with depression (n=10) tested on depression apps, and participants with type 2 diabetes (n=10) tested on diabetes apps. There were a total of 11 of the most popular health apps (4 diabetes apps, 4 depression apps, and 3 caregiver apps) on both iPad and Android tablets. Apps were selected by a panel of experts as the most optimal for supporting self-management and were selected based on high ratings in the Android and Apple app stores. Participants were given condition-specific tasks, such as entering a blood glucose value into a diabetes app. The task completion coding scheme was developed a priori using adapted usability metrics from prior studies. (4, 5) We identified the proportion of tasks that were completed independently; and the degree of completion, categorized as: a) successful/straight-forward, b) successful/prolonged, c) partial, unsuccessful/prolonged, and d) gave up. (4, 5)

Results: Participants were recruited from an urban safety net hospital. We did not ask participants about income level, but it is understood that patients at this urban safety net hospital are low income. (6, 7) The participants were diverse: 58% African American, 27% White, 8% Asian, 8% Latino. The majority of participants were over 50 years old, with over half 56 and older. The majority of participants had limited health literacy and over half had at least some interest in using the internet to manage their health. In addition the vast majority had experience using a computer. Participants completed 79/185 (43%) of tasks across 11 apps without assistance. Participants performed better on data entry tasks compared to data retrieval tasks (Figure 1). Three themes emerged from participant comments: lack of confidence with technology, frustration with design features and navigation, and interest in having technology to support their self-management (Table 1). Specific design features that participants found frustrating were button placement and data entry locations as well as difficulty of navigating through multiple screens.

Discussion: App developers should employ participatory design strategies in order to have an impact on chronic conditions like diabetes and depression which disproportionately affect vulnerable populations. While patients express interest in using technologies for self-management, current tools are not consistently usable for diverse patients.

Templates for Ordering Specialty Care Consultations Lack Minimalism and Error Prevention: Results of a Heuristic Evaluation

April W. Savoy, PhD1,2,3, Himalaya Patel, PhD1,2, Mindy Flanagan, PhD2, Alissa L. Russ, PhD1,3,4, Michael Weiner, MD, MPH1,2,3

1Center for Health Information and Communication, Department of Veterans Affairs, Veterans Health Administration, Health Services Research and Development Service CIN 13-416, Richard L. Roudebush VA Medical Center, 2Indiana University, 3Regenstrief Institute, Inc., Indianapolis, IN; 4Purdue University, West Lafayette, IN

Introduction
Through electronic health record systems (EHRs), primary care providers (PCPs) frequently order consultations, also called consults, to refer patients to specialty clinics for evaluation or management. In the EHR used by the Veterans Health Administration (VHA), to facilitate consult ordering, specialty clinics have added templates for data entry in the consult order form. These templates extend the EHR’s user interface and organize the data saved in the order form. Some templates also communicate specialists’ requirements (e.g., pre-visit diagnostic testing) and may offer clinical guidance for both common and uncommon cases.

However, because each specialty clinic at each VHA facility maintains its own requirements and guidance—as may also occur among EHR users of multi-facility institutions outside the VA—consult templates lack standardization in structure and content. As a result, these templates vary in their efficiency and effectiveness, both within and among facilities. Incomplete or misdirected consult orders are frequently cancelled or discontinued without an appointment for the patient, creating delays in the delivery of care. The objective of this study is to identify usability problems in consult templates to guide design changes that will improve the efficiency and safety of care.

Methods
To identify the prevalence, variety, and potential severity of usability problems in VHA consult templates, a sample of templates was collected for heuristic evaluation, a method for assessing usability through expert evaluations of user interfaces (the templates, in this case). Templates were selected in a two-stage process. The first stage focused on templates identified directly by PCPs as either particularly easy or particularly difficult to use. The second stage focused on orders that were created but not executed (i.e., either cancelled or discontinued). The templates came from three geographically diverse VHA facilities. As part of a larger project to identify barriers and facilitators in the consultation process, the research team conducted 30-minute semi-structured interviews of primary care clinicians from December 2014 to February 2015 and from November 2015 to February 2016, at two of the facilities. From these interviews we marked explicit references to specialty clinics, yielding 11 corresponding templates. Data for the second stage covered consults from 2014 across all three facilities in six specialty clinics: cardiology, mental health, oncology, ophthalmology, orthopedics, and rheumatology. Because clinics often supplied multiple templates to accommodate specific clinical conditions, we excluded templates for routine procedures, inter-facility orders, out-of-network (non-VA) orders, and infrequent orders (less than 300). From those remaining, we selected the templates with the lowest completion rate (i.e., the highest combined cancellation and discontinuation rate). This stage yielded 18 templates with completion rates between 39% and 81%. Overall, of 28 templates selected, 26 were unique.

These templates were evaluated against 19 usability heuristics. Eighteen heuristics were from domain-independent lists published separately by Nielsen and Shneiderman. A nineteenth heuristic, meet users’ information needs, was created to address the difficulty of communication between clinicians. The evaluators were four researchers with backgrounds in social psychology, human factors engineering, or human–computer interaction. Evaluators viewed screenshots of each template and recorded each observed violation on a row of a spreadsheet. For each violation, evaluators recorded the most applicable usability heuristic, a description of the problem, applicable usability goal (efficiency, effectiveness, safety, learnability, memorability, and utility), and the estimated severity of the violation (integer, 0 to 4, with 4 indicating the most severe). Two evaluators reviewed each template for overlapping findings. Within a given template, findings overlapped if their descriptions identified the same basic problem—whether found multiple times by multiple evaluators, multiple times by one evaluator, or one time by multiple evaluators. Each group of overlapping findings was recoded into a single finding. For that recoded finding, the heuristic, dimension, and severity were determined by the group’s mode.
Results
According to the heuristic evaluation, the examined consult templates are needlessly complex. Recurring causes of heuristic violations included inconsistent organization, missing or misplaced instructions, instructions causing work outside the order form, and selections or actions with unclear outcomes.

The evaluators found 201 violations with an average of 7 violations per template. Of the 19 available heuristics, 14 were violated at least once. Five heuristics held most major and total violations (Table 1). An example of a major violation of recognition rather than recall was the requested reentry of data from elsewhere in the patient’s record. An example of a major violation of meet users’ information needs was a missing field for entering the reason for consultation. Of the six usability goals, five had potential negative impacts based on the heuristic violations. Efficiency and safety had the greatest potential impact based on major and total violations (Table 2).

Supplemental analysis indicated alignment among PCPs and evaluators regarding template quality. Evaluators’ comments echoed PCPs’ preference for templates with short length, clear guidelines, and linked order sets. A notable point of caution was the evaluators’ assumption of shared jargon between PCPs and specialty care providers. PCP comments indicated that unfamiliar terms were used in templates, which caused confusion.

Discussion
Although heuristic evaluations do not generate solutions to usability problems, they identify problems and describe the nature of violations to provide guidance for design changes. Our results indicate key principles for new template designs: concisely communicate specialty clinics’ requirements, limit context switches to other parts of the EHR with auto-population, and support PCPs’ need to communicate information outside the provided structured input fields. Concise communication of specialty requirements supports PCPs’ preferences for shorter templates and clear guidelines that would aid in increasing effectiveness of consult requests via templates. Limiting context switches would increase PCPs’ efficiency related to consult requests by eliminating excessive, redundant navigation to duplicate information in templates. Lastly, the inclusion of free-text fields enables PCPs to communicate additional information that is pertinent to the consult request, enhancing PCP-specialist communication and consult coordination. By addressing usability issues in the first step of the consult process, we expect a decrease in the number of consult requests that are discontinued or cancelled—problems that cause delays in care. Future work includes the evaluation of commercial templates to assess the applicability of the design principles to non-VA templates.

A Method for Enhancing the Portability of Electronic Phenotyping Algorithms: An eMERGE Pilot Study

Ning Shang, PhD, Chunhua Weng, PhD, George Hripcsak, MD, MS
Department of Biomedical Informatics, Columbia University, New York, NY, USA

Abstract
This work proposes a method to facilitate eMERGE phenotypes’ implementation that is portable across heterogeneous data environments. Parameterized and modularized queries facilitate the portability by parameterizing terminology and data schema and separating them from the query logic. Common data elements are identified to satisfy core algorithm requirements. Altogether, this research provides insight for developing a common data model for electronic phenotyping.

Introduction
Electronic phenotyping uses data from Electronic Health Records (EHRs) to provide computational definitions of phenotypes, which can then be used for genome-wide association studies or clinical study cohort identification. Existing approaches to develop electronic phenotypes often involve a complex and iterative process and rely on inputs from domain experts as well as data scientists. Algorithms developed for phenotype detection then have to be adapted to the specific local data environments at a particular institution. The implemented algorithms are not easily portable because different institutions may use different data models and different terminologies. An ongoing eMERGE pilot project aims to develop novel strategies for reusable and sharable computational algorithm implementations dealing with different source data models, terminologies and algorithm logics. Our main strategy is to separate the source data environment from algorithm logic. The logical separation has been explored before by the Arden Syntax to share task-specific knowledge implementations across institutions.

Methods
Nineteen eMERGE phenotypes (e.g. atopic dermatitis, ADHD, Asthma, Extreme Obesity, Height, Diabetes/HTN associated CKD, Type 2 Diabetes Mellitus, Dementia, Early Childhood Obesity) that mainly use structured EHR data were implemented as parameterized and modularized queries (implemented query codes are available at https://phekb.org/). The source data are the Columbia University Clinical Data Warehouse in the OMOP Common Data Model (CDM) v4. The parameterization aspect of our query approach deals with different terminologies and source data schemas by using parameter placeholders for codes and schema element names and then injecting corresponding terminology codes or schema/table/field names at execution time. The Modularization aspect is to build complex queries from simple query building blocks, separating concerns in different blocks. The modular query only interacts with the source data model in the first block and constructs a temporary entity–attribute–value (EAV) storage table to store the algorithm required data elements from the source data. Subsequent query building blocks use temporary tables to implement query logic and to store intermediate results.

Results
The temporary EAV table, constructed in the initial query block, includes person id, event date, event concept id, event type, event numerical and string value. Event type refers to a specific data element that is required in the algorithm, for example asthma diagnosis. The key data elements from source databases required for implementing the 19 phenotyping algorithms are analyzed (Table 1). We also specify in which tables in the OMOP4 CDM these key data elements occur. For illustration purposes, an asthma pseudo-algorithm query is depicted in Figure 1.

The logic query blocks implement all required logic in the eMERGE case/control algorithms: e.g., including or excluding specific data elements, calculating counts of eligible data element, checking if patient enrollment status in a series of years is continuous, generating a patient-specific index date from one or more data elements, calculating percentage of qualified data elements, or calculating summary statistics of a data element (e.g. median of height). All logic blocks can retrieve any data element with or without specific time range or relative temporal constraints.

Discussion
Rasmussen et al have explored a modular software approach employing the analytic framework KNIME to share implementations. Different from that, we combine data extraction and algorithmic analysis into a singular query...
based approach. The parameterized and modularized query can isolate core algorithm logic from the source data model. Local terminology coding and database schemata are encapsulated in the parameters. So site-dependent codes can be injected when executing the shared query codes. Consequently, the parameterized and modularized query is sharable and reusable. The pilot project implementations use source data in OMOP4 CDM, but it can also be adapted for other data models by only revising the first block. In addition, separating the query logic from the source data model improves the comprehensibility and reviewability of the query logic. Putting all algorithm related logic into blocks of query code can be challenging and sometimes complicated. For example, finding a patient with continuous enrollment and the median of some measurement. In this pilot project, we only implemented algorithms that require structured data. As a next step, we are exploring the applicability of portable algorithm implementations for phenotypes that use data from unstructured sources.

Joint Modeling of Survival Events through Multi-task Learning Framework

Zhaonan Sun, PhD\textsuperscript{1}, Xu Liu\textsuperscript{2}, Ping Zhang, PhD\textsuperscript{1}, Jianying Hu, PhD\textsuperscript{1}, Juan Wisnivesky\textsuperscript{3}, MD, DrPH, Fei Wang, PhD\textsuperscript{2}

\textsuperscript{1}IBM T.J. Watson Research Center, Yorktown Heights, NY; \textsuperscript{2}University of Connecticut, Storrs, CT; \textsuperscript{3}Division of General Internal Medicine and Pulmonary Critical Care, Department of Medicine, Mount Sinai School of Medicine, New York, NY

Introduction

Survival analysis, refers to a set of models for analyzing data where the outcome is the time until the occurrence of an event of interest. The event can be death, onset of a disease, or any other events under well-defined circumstances. Over the past few decades, survival analysis has gained wide and successful applications in medical, bioinformatics, epidemiology, and reliability studies. Cox Regression \cite{1} is by far the most extensively used survival model in the application of biomedical research. Classic Cox Regression models one event at a time. In practice, there could exist multiple associated events which are all of interest. Jointly modeling multiple events has the potential to improve modeling performance and gain more insights into the association between the targeting events. The Multi-Task Learning (MTL) approach, which jointly modeling multiple related targets, has recently drawn the attention of many researchers. In this study, we propose a novel approach that incorporates Cox regression into a MTL framework that is able to jointly modeling multiple associated events.

Methods

We used the data from The Cancer Genome Atlas (TCGA) datasets. Specifically, we collected the survival data and the micro RNA (miRNA) expression data for four types of cancer, which are breast cancer, colon cancer, kidney cancer, and lung cancer. Expression level data from 269 miRNAs are available for all four data sets. We used these commonly available miRNAs in this study. The survival of each individual type of cancer is regarded as an event of interest. The sample size (number of patients) for the four data sets are 105, 92, 122, and 106, respectively. Note that the proposed method allows data for different events to be generated from different sets of patients. For each data set, we performed the proportional hazard test, and none of the 269 miRNAs violates the proportional hazard assumption. The rationale for the proposed method is that different types of cancers may share some common mechanisms or genetic factors. The shared mechanisms or genetic factors are regarded as the association between events. If each event is modeled individually, which is referred to as the Single-Task Learning (STL) approach in this study, the association between events are totally ignored. In our proposed method, we intend to utilize the association between events. Let $k$ denote the number of targeting events in a study. In this study, $k$ equals four. In the proposed MTL approach, Cox regression is used as the base model for each individual event. Each base Cox regression model has a coefficient vector, denoted as $\beta_i$ for $i = 1, \ldots, k$, and each element in $\beta_i$ reflect the impact of a genetic factor (i.e. miRNA expression level) on the $i$-th event. If two events share the same genetic factor, the coefficients of the same miRNA in the two base Cox models are likely to be similar. Based on this assumption, the proposed method imposes a hierarchical model on $\beta_i$’s. We used $\Omega$ denotes the hyper-parameter in the imposed hierarchical model. In this study, $\Omega$ is generated from the human disease network \cite{2}. We further impose L-1 regularizer on $\beta_i$’s to enforce sparse solutions. The above mentioned components were finally formed into a convex optimization problem, and estimates of $\beta_i$’s can be obtained by solving the optimization problem. Figure 1 depicts the comparison between STL approach and the proposed MTL approach. The left panel illustrate the STL approach. In this study, we use Cox regression as the STL method, i.e. each event is modeled by Cox regression individually. The right panel in Figure 1 illustrates the structure of the MTL approach.

Results

In this study, we intend to demonstrate the advantage of jointly modeling multiple associated events by comparing the results from STL and MTL approaches. We use the concordance index (C-index) as the comparison criterion. For MTL, we use 5-fold cross validation to select the parameter for L-1 regularizer and to obtain the C-indices. For STL, 5-fold cross validation is used to obtain C-indices for each targeting event. Average C-index from the 5-fold cross validation is used for comparison. The results are summarized in Table 1. The MTL approach outperformed STL approach. The results demonstrated the advantage of taking the event association into consideration.
We further examined the structure of learned $\beta_i$’s. Remind that we impose sparsity assumption on $\beta_i$’s. If the j-th element in $\beta_i$ is non-zero, the j-th feature can be regarded as having certain effect on the i-th event. If the j-th has non-zero coefficient in at least two types of cancers, it can be regarded as a shared factor. On average, 23.5% of $\beta_i$’s are non-zero. We cross checked the shared factors with the miR Cancer database (http://mir cancer.ecu.edu/browse.jsp), many shared factors can be found to be relate to more than one type of cancer. For example, hsa-mir-1 has been reported to be related to breast cancer, kidney cancer, and lung cancer, hsa-mir-143 has been reported to be related to breast cancer, colon cancer, and lung cancer. Due to limited space, we will not report the full list in this article. Further investigation will be reported in our future study.

Towards a Formal Account of the Dynamics of Knowledge and Context in Surgical Rooms for the Practice of Surgical Safety CheckLists

Xing Tan, PhD\textsuperscript{1}, Xiangdong An, PhD\textsuperscript{1}, Nicholas Pairaudeau, MD\textsuperscript{2}, Jimmy Huang, PhD\textsuperscript{1}

\textsuperscript{1}York University, Toronto, ON, Canada; \textsuperscript{2}North York General Hospital & Department of Obstetrics and Gynaecology, University of Toronto, Toronto, ON, Canada

**Introduction**

For the purpose of reducing rates of surgical complication and death in hospitals and other medical settings, World Health Organization (WHO) Patient Safety has introduced and has been actively promoting worldwide implementation and usage of its Surgical Safety CheckLists (SSCL)\textsuperscript{1,2}. SSCL compile essential surgical safety objectives and steps into items to be checked by clinicians at work. There are strong evidences to support that, appropriate use of SSCL and adherence to it would lead to significance in reinforcement of accepted surgical safety practices, and in improvement of communication among operating team members\textsuperscript{3,4}. Nevertheless, further improvement and reliable use of SSCL require its formal integration with the pervasive computing systems in today's surgery rooms. In helping clinicians to share contextual knowledge with each other and in enabling context-aware and automated reasoning, the roles of ontologies and action theories are important for integration: An ontology would provide a formal specification of concepts related to SSCL, including people, places, medical instruments, operations events, and etc.; An action theory would offer a computerized mechanism to keep track of the change of operative context, thus provide a formal and on-site scrutinization on the appropriateness of application of steps enlisted in SSCL.

**Methods**

The methodology makes use of two foundational technologies in knowledge representation and reasoning\textsuperscript{5}: ontologies, referring in particular to a controlled vocabulary for SSCL; and action theories, for keeping track of relevant and critical changes of situations and context upon application of actions in surgery rooms. More precisely, we develop an ontology FOSS (Formal Ontology for Surgical Safety) and an action theory ACSS (Action Theory for Surgical Safety) in this research, supporting accurate implementation and pervasive usage of SSCL.

**Ontology**

An ontology\textsuperscript{6,7} comprises of syntactically structured and semantically rigorous descriptions of entities, attributes of entities, and relationships between entities in the domain of interest. When knowledge is represented ontologically, inferences of implication and consequence in the domain can be performed through computer-facilitated reasoning. Description Logics (DL) are logical systems that are widely used in ontological modeling, for manipulating compound predicates such as "A circulating nurse who is assigned as a Checklist coordinator in all operating teams at this hospital". DLs provide a logical foundation for OWL\textsuperscript{8}, a Web Ontology Language as standardised by the World Wide Web Consortium (W3C). OWL ontologies are often developed via Protege\textsuperscript{9}, a GUI-based integrated environment for ontology development.

Design of the ontology FOSS requires that it is competent enough to capture the following categories of surgical room knowledge: (subsumption) objects in the domain such as personnel and equipments are grouped into classes. One class could be subsumed by the other (e.g., the concept Anaesthetist is subsumed by the concept OperationTeamMember). (composition) One class comprises several others (e.g., OperationTeam comprises Surgeon, Anaesthetist, Nurse, Technician, and Other). (role) Tasks are specified as roles. The individuals who perform these tasks are defined as composite concepts (e.g., A ChecklistCoordinator, who in his role performing the task :checkItem, must be either a Nurse or a Surgeon). (membership) An individual/instance is a member of a class. (e.g., nancy is a Nurse).

**Action Theory**

Action theories in formal languages such as Event Calculus\textsuperscript{10} and Situation Calculus\textsuperscript{11,12}, are logic formalisms for representation of actions and reasoning on their effects in dynamical systems. This research uses Situation Calculus. There are two main ingredients in any Situation Calculus-based action theory: 1) Fluent conditions, whose actual values can be updated from applications of relevant actions. 2) Actions, applications of which will bring effects in term of changes of values of certain conditions (i.e., context) in a system. At first, there is an initial situation called S0. Starting from S0, as the system evolves over sequences of actions, the current situation of the system is unfolded into its future situations.
The action theory ATSS should include: A collection of fluent conditions (e.g., marked(X), indicating whether X is marked, where X is a variable and it can be instantiated into a particular site; Or counted(X), indicating whether X is counted and X can be instantiated into particular facilities, instruments, equipments, or items such as sponges and needles). A collection of actions (e.g., mark(X), an action to mark X; and count(X), an action to count X). **Precondition Axioms**, which are formal specifications on the applicability of actions (e.g., before the action inciseSkin, it is required that the site need to marked, marked(site) is true). **Effect Axioms**, which define the effect of actions (e.g., after the application of mark(site1), marked(site1) is set to true).

**Results**

This research presents FOSS and ATSS. Key concepts in FOSS include Place, Agent (human beings, hardware agents or software ones) and Role. **OperatingSuite** is defined as a compound place that comprises of **OperatingRoom, WashRoom, changeRoom, RestRoom, PreparationRoom, Storage, Office, RecoveryRoom, Corridor, and Other. OperatingRoom** hosts **Operation**, which is a sub-class of **Process**. All agents have properties. In the same time, agents can be associated with certain roles.

Our basic thesis is, applicability of actions depends on the context where actions are to be executed, meanwhile, applications of actions change the actual settings of the current context. In ATSS, applicability and effects are captured by Precondition Axioms and Effect Axioms. Each action type in ATSS is assigned one Precondition Axiom and one Effect Axiom. From these basic, atomic actions (ones that cannot be further decomposed), we can define iteratively compositied, more complex actions, till eventually we define the complex action check, which consists sequentially three sub-actions: **signIn, timeOut, signOut**. Any instantiation of the action check indicates one particular realization of the operative procedure that meets accepted safety requirements.

**Discussion**

Context information is critical to the effective use of SSCL in surgical rooms. A formal account (in terms of ontologies and action theories) of knowledge and context information enables integration of SSCL into their computational environments in surgery rooms. In this research, FOSS an OWL ontology to capture the knowledge in surgery rooms for the practice of SSCL is developed. Different from other recent efforts and approaches, we provide axiomatization of dynamics of context, through developing an action theory ATSS, in the formal language of Situation Calculus. We would also consider using upper level ontologies for building up FOSS. We will post our ontologies on [http://www.yorku.ca/adersim/xtan/ontologies](http://www.yorku.ca/adersim/xtan/ontologies)

Activated Working Baby Boomers Personal Health Information Management Needs and Expectations: An Exploratory Study

Donghua Tao, PhD, MA, MS1, Deborah E. Seale, PhD1, Cynthia M. LeRouge, PhD2
Jennifer Ohs, PhD1, Helen W. Lach, PhD1, Keri Jupka, MPH1, Ricardo Wray, PhD, MS1
1 Saint Louis University, Saint Louis, MO
2 University of Washington, Seattle, WA

Introduction

Baby boomers (adults born between the years of 1946 and 1964) make up the largest segment of the population in many countries, including the United States (about 26%)1. While they have increasing medical needs and thus demand more health care resources when they reach retirement age and beyond, they appear to understand the need to be proactive in order to achieve long-term health and successful aging. As a “sandwich generation”, baby boomers tend to have competing demands of work and family care, and they tend to be caring for both children and aging parents. Baby boomers, with more education and higher level jobs, and being witnesses and early users of communication and information technologies, are likely to want to take responsibility for managing their health and participate in health-related decision making (i.e., activated working baby boomers). To effectively take on these responsibilities, baby boomers need to efficiently manage and use their personal health information (PHI) (e.g., lab results, doctor contacts, medication lists, health insurance information, and information searched online, etc.)2. As a result, the need for better tools to support PHI management will increase substantially. This study investigated activated working baby boomers’ PHI management needs and expectations through focus groups.

Methods

Focus group interviews were used for the data collection with the IRB approval. Working baby boomers who were born between 1946-1964, full-time or part-time employed, and self-identified in a screening survey as being active in managing their health were the study participants. A two-step purposive sampling technique was used. First, a metropolitan non-profit business coalition was contacted to identify the organizations who agreed to facilitate in recruiting their employees for the study. Second, an email with a link to a brief screening and demographic survey was sent to the employees of those identified organizations. Eligible employees were those who answered positive in their response to 4 out of 5 following screening questions: 1) want to be actively involved in decision-making about my health; 2) see a healthcare provider for a routine checkup annually; 3) regularly look for health information to understand or manage my health; 4) use a computer, tablet or smart phone on a weekly basis; and 5) are interested in using technology to manage my health. Of 210 employees who completed the survey, 155 (73%) met eligibility criteria and received the focus group invitations, and 57 attended with age between 51 to 69 years old (mean = 57), primarily married white female, had at least a college degree with the income of at least $75,000 a year.

Six focus groups were conducted after work, at the work site, with dinner and a small monetary incentive provided. Each session was about 90 minutes long and audio-recorded. An experienced moderator who was not part of the research team led the discussions using a standard interview guide. Participants chose pseudonyms to ensure that no personal identifiers were recorded. The Gagnon and Chartier Citizen-Patient 3.0 Profile3 was used as a conceptual framework to develop focus group questions and guide transcripts coding: 1) search appropriate and secured medical information about his case and improve his “health literacy”; and 2) use consumer self-management health technology in a secured manner to manage his health. Focus group transcripts were coded with Dedoose, qualitative software. Transcripts were coded independently by three teams with two members in each team using theoretical thematic analysis4. Each team met to discuss discrepancies and came to agreement on coding.

Results

Three significant themes emerged related to activated working baby boomers PHI management behaviors, needs and expectations to better understand and manage their health. Working baby boomers are: 1) active searchers and users of health information on the Internet; 2) aware of the variability in online health information quality; 3) are challenged to access, organize and share PHI of their own and their family members.

Working baby boomers are Internet savvy
As activated healthcare consumers, working baby boomers in this study have the willingness and ability to search and use appropriate and trusted health information. Acting as their own “agent”, they want to be able to search, choose, and use health information to: 1) understand conditions, treatment and care; 2) compare perspectives and options concerning conditions, treatments and care in order to make health-related decisions, such as whether or not to have surgery, choose doctors, etc.; and 3) prevent onset or worsening of a condition, as well as maintain their overall health. Internet (e.g. Google) seems to be a default place for them to search for information about health, although health care providers, relatives and friends, and even unknown individuals from social media sites are also the sources for obtaining health information.

**Awareness of the variability in online health information quality**

Working baby boomers in this study are cognizant of information overload and the importance of the accuracy of medical information. They intend to and also have the ability to sift through online health information and identify trusted information to manage their health. They search health information from known reliable information resources, such as Mayo Clinic. They also make effort to verify specific health information by comparing multiple resources, including professional websites, for the same health-related topics or issues. However, they found it difficult to handle conflicting information and felt “a challenge and a risk in going to the Internet”. They wish there was “a way for the Internet to be a more reliable source of medical information” that “could be like librarians who have access to... who could tell you about landscape or tell you about any of other things that you may be unaware of...” There seems to be a gap between baby boomers’ willingness and the ability to appraise and apply health information to their situations and the availability and/or awareness of reliable information resources.

**Challenge of organizing and sharing personal health information**

Working baby boomers in this study found it challenging to organize and share their PHI. They repeatedly expressed the need to “set up my own health file” and keep their own health notes, test results and medication lists, etc., in order to track their health history and monitor changes in their health and medical conditions over time. However, their PHI was fragmented and scattered in multiple locations, repositories, devices or applications in both paper and electronic format. Many of them said they had difficulty in capturing, remembering and understanding what the doctor said and did during a visit. They had trouble knowing “how it’s spelled” and “you feel silly asking.” They expect doctors can “teach the patients how to set up their own personal health files” so “they’ve got a track record.”

This issue is especially a challenge for working baby boomers as a “sandwich generation”. Patient portal or Personal Health Record (PHR) systems seem to serve as a central place to store PHI. However, working baby boomers do not have control on what information they can access and input in most patient portals or PHR systems available today. Moreover, none of systems hold all PHI for the same patient across different health care systems.

Fragmented PHI creates difficulties in sharing PHI between providers and working baby boomers. They want to share their information with doctors of their choice, and “with the emergency room doctor that’s not in the network” and “link (their PHI) to specialists outside that group”. In order to do that, baby boomers kept separate lists in their wallets, retyped or printed out or copied down information from their portal to fill out physician’s forms. Participants wanted a consumer health technology that would allow them to share their PHI with whomever they want. They suggested having a chip or a thumb drive for updating and transferring PHI with health care team; or an app for the smart phone that can “sync the data that I have on my smart phone to their system” and vice versa.

**Discussion**

Activated working baby boomers care about their health and also want to be heavily involved in their health-related decision making and problem solving. Health information and knowledge empower them to take responsibility for managing their health and user-centered designed technology can help them successfully take on these responsibilities. A tool that can provide evaluated online health information and an app or a system that allows activated working baby boomers to obtain and share relevant PHI with whoever they want are two possible technology solutions for meeting the critical needs of working baby boomers in accessing reliable health information and effectively organizing and sharing their PHI.

Evaluating content coverage of a dental diagnostic terminology

H. Taylor, MPH, LDH¹, Z. Siddiqui, BDS, MS¹, K. Frazier, BS¹, T. Thyvalikakath, DMD, MDS, PhD¹,²
1- Indiana University School of Dentistry, Indianapolis, IN
2- Center for Biomedical Informatics, Regenstrief Institute, Indianapolis, IN

Introduction:

Dental diagnostic terminologies can be helpful in facilitating health information exchange, evaluating clinical outcomes, dental disease prognosis, evidence of appropriateness of care, identifying best practices, and improving diagnostic skills of students and clinical research¹. However, unlike medicine, there is no commonly accepted diagnostic terminology in dentistry². Currently, two dental diagnostic terminologies are available for use by clinicians and educators – Systematized Nomenclature of Dentistry (SNODENT) and Dental Diagnostic System (DDS). Both SNODENT and DDS Codes are not widely used in dental practices³; however a few dental schools have implemented the use of either SNODENT or DDS Codes into their clinical training sessions with dental students. Little data exists on the strengths, weaknesses, and usefulness of SNODENT, particularly from the perspective of education of faculty and students. This particular study reports on evaluating the content coverage of SNODENT within the Electronic Dental Record (EDR) used at the Indiana University School of Dentistry (IUSD).

Methods:

This study was approved by the Indiana University Institutional Review Board (Study #: 1503902699) and conducted at the IUSD. A convenience sample of 20 participants consisting of faculty, third-year dental students (DS 3), and fourth-year dental students (DS 4) of IUSD participated in the study. Participants were requested to evaluate a hypothetical dental case and asked to “think aloud” and document on paper their diagnosis for specific dental conditions as they reviewed the study patient’s medical history, dental findings, photographs, and radiographs. This hypothetical patient had clinical findings commonly encountered at the IUSD clinics. Participants were then asked to work within the treatment planning module of the Electronic Dental Record (EDR) (axiUm, Exan corporation, Vancouver, BC, Canada), and select the best SNODENT diagnostic code(s) that represented their written diagnosis. Subsequently, participants determined if the selected code(s) matched their written diagnosis “completely”, “partially”, or “not at all”. At the end of the study session, each participant completed a questionnaire based on their experience using SNODENT. The questionnaire had four questions on a four point Likert scale that ranged from strongly agree to strongly disagree (See Table 1).

Participants’ interaction with the EDR was recorded using screen and voice capture software (Camtasia®). Two investigators independently compared the participants' written diagnosis and the diagnosis code they selected in SNODENT to determine the match between the two diagnosis. Participants were classified into specific groups (DS 3, DS 4, and faculty). Sensitivity testing was performed to detect changes between participants’ written diagnosis and SNODENT code(s) selection. Chi-square test was performed to detect any significant difference among the groups. Participants' satisfaction with SNODENT was summarized using descriptive statistics. Cochran's-Mantel-Haenszel (CMH) test was performed to assess any consistent difference in participants' satisfaction among the three groups. The software IBM SPSS Statistics Version 23 (SPSS, Inc., Chicago, IL, USA) was used to perform the statistical analysis. Both Chi-square test and CMH test was performed at 95% confidence interval and 5% significance level. We analyzed participants' response to questionnaire using descriptive statistics.

Results:

The 20 participants selected a total of 251 SNODENT codes to diagnose the dental conditions of the hypothetical dental patient. The DS 3 and DS 4 students demonstrated high match between their written diagnosis and the SNODENT diagnosis they selected with sensitivity levels of 74.6% and 74.3% respectively. We observed a low match (sensitivity: 43.9%) between faculty participants’ written diagnosis and the SNODENT codes they selected. Most faculty participants wrote down treatment for the dental conditions instead of the diagnosis. The average sensitivity for the three groups was 64.5%. The three groups were significantly different in the match between their written diagnosis and the selected SNODENT codes, especially between the DS 3 students and the faculty
(p<0.0001) and the DS 4 students and the faculty (p<0.003). However no statistically significant difference was observed between DS 3 and DS 4 students (p 0.97). Participants noted that the following searches found no codes to match their diagnosis: Interproximal primary caries; generalized mild chronic periodontitis; Pulp Polyp; Gross caries; Poor oral hygiene; Non-restorable tooth; and Plaque-induced gingival diseases. The participants were satisfied with 62% of their selection of the SNODENT terminologies, partially satisfied with 33% and dissatisfied with 5% of the SNODENT terminologies. No significant differences (p 0.258) were observed among the three groups’ satisfaction with their SNODENT selections. As shown in Table 1, 19 out of the 20 participants strongly or mildly agreed that the SNODENT terminology worked well with entering appropriate diagnosis and will add value to patient care and treatment planning. Fifteen participants agreed that it is easy to understand and navigate through the SNODENT system and 12 participants agreed it is easy to implement use of SNODENT in routine patient care.

Table 1: Participants’ response to questionnaire related to SNODENT diagnostic terminology

<td>6 (30%)</td>
<td>6 (30%)</td>
<td>6 (30%)</td>
<td>2 (10%)</td>
</tr>
</tbody>
</table>

Discussion:

Dental students selected SNODENT codes that represented their written diagnosis at higher sensitivity levels than the faculty (DS 3: 74.6%; DS 4: 74.3%; Faculty: 43.9%). Interestingly, when study investigators analyzed faculty’s original written diagnosis for certain teeth, faculty wrote down treatment for these teeth as opposed to diagnosis. Faculty’s tendency to consider a patient case in the constructs of dental treatment rather than diagnosis is noteworthy and common in seasoned dental clinicians. This fact lends explanation to the low sensitivity levels of faculty’s selection of SNODENT codes compared to their written diagnosis.

The majority of SNODENT codes selected by all participants were sufficient in representing their original written diagnosis for selected teeth. However, a number of participants felt “frustrated” at their inability to locate a code that best represented their original diagnosis. The participants’ overall agreement that SNODENT enables appropriate diagnosis entry and adds value to patient care indicates the potential of diagnostic terminologies to improve patient care. However mixed responses to the ease of use and implementation of this terminology in daily practice shows there is a learning curve with the system and like any system in clinical practices, it will take some time to be commonly accepted by clinicians.

Conclusion:

Education on dental diagnosis is needed for dental students and faculty, especially faculty who are trained to think in terms of treatment for each patient as they work through a case. Coding term additions to the SNODENT coding terminology could improve satisfaction levels of dental practitioners’ use of the SNODENT system.

Convening Utah’s Healthcare Interests – A Statewide Care Coordination Infrastructure

Sidney N. Thornton, PhD1,2, Shan He, PhD1, Iona Thraen, PhD2,3, Matt Hoffman, MD4, Darren K. Mann1, Wu Xu, PhD2,3

1 Intermountain Healthcare, Salt Lake City, UT; 2 University of Utah, Salt Lake City, UT; 3 Utah Department of Health, Salt Lake City, UT; 4 Utah Health Information Network, Salt Lake City, UT

Introduction

Care of patients is dispersed across diverse health care professionals from different organizations1,2. Lack of timely information transfer among these providers can lead to medication errors, duplicative tests, and lack of follow-up care3. To enhance coordinated care, a community care team and supporting infrastructure need to be built beyond enterprise-wide care integration efforts and point-to-point connections. As the adoption of Electronic Health Record (EHR) systems in U.S. increases and interoperability among disparate systems enhances, the time is opportune to promote an infrastructure for care coordination among health professionals along the care continuum. The objectives of this project were to a) build a statewide infrastructure for care coordination across healthcare, public health systems and consumers, b) demonstrate automated care coordination workflows, and c) report our experiences and lessons learned including technical and non-technical strategies, opportunities and barriers.

Methods

In pursuit of a statewide solution for care coordination, stakeholders in the Utah healthcare industry including the Utah Health Information Network (UHIN) that governs the state-designated clinical Health Information Exchange—the cHIE, public and private healthcare providers (e.g., University of Utah Healthcare, Intermountain Healthcare, Revere Health, etc.), HealthInsight—a quality improvement organization, and Utah Department of Health (UDOH) convened in the form of governance, service, technical and legal committees to work together on solving emerging needs for coordinated care across the community. Instead of building expensive and independent organizational solutions, a statewide care coordination infrastructure leveraging existing resources was conceived as the most pragmatic approach.

First, as prioritized by the resource investment by the participating stakeholders, five cross-system care coordination use cases were selected for analysis to determine the core components of the care coordination infrastructure: 1) Newborn care bundle; 2) Discharge to skilled nursing facility (SNF); 3) Collaboration between the Utah Poison Control Center and emergency departments on poison exposure cases; 4) Physician Orders for Life Sustaining Treatment form and care summary access by Emergency Medical Services; and 5) Physical and behavioral health integration. Each use case represents a real-world scenario where multiple healthcare professionals across different systems are involved in a patient’s care. The data flow analysis showed that major care coordination components (e.g., message sending and receiving, event listeners, patient record linkage, community-based care team identification, workflow management, patient alert/notification, etc.) are common functionalities across use cases. The information transfer flow and connection requirement for each use case was analyzed in detail. One such example is the newborn use case, where the care continuum spans across prenatal care by an obstetrician, newborn care and first blood spot specimen collection at the birthing facility, newborn screening test at the state laboratory, newborn hearing screening by an audiologist, well-child visit and second blood spot specimen collection at a pediatrics clinic, public health follow-up programs for newborns with abnormal screening results, genetic consultation and specialty care. Regulatory record submissions related to newborns such as vital records are also required by UDOH. The length of the time span and the number of stakeholders involved in a newborn’s care make it impossible for any single system to support a smooth, connected care experience.

Second, existing local resources and interoperability capacities were evaluated to assess which modules can be integrated into the new care coordination infrastructure. Existing data resources include organizational and statewide master patient indices, organizational provider directories, clinical data repositories at the cHIE, billing records, all payers claim database, and public health vital records. Existing system and connection resources include certified EHR adoption and patient portals provided by major healthcare providers, and standard connections in operation among major participants.
Finally, results from the use case analysis and resource evaluation were consolidated into the care coordination infrastructure. Three use cases were implemented as pilot projects to evaluate and refine the infrastructure design.

**Results**

The Utah care coordination infrastructure leverages existing central repositories and HIE capabilities in the community in order to achieve automated information transfer across healthcare, public health systems as well as patients and caregivers. The key components of the care coordination infrastructure are illustrated in Figure 1.

![Figure 1 Utah Statewide Care Coordination Infrastructure](image)

The Care Coordination Broker (CCB) is the central logic engine that determines what information needs to be sent to whom upon what event and through which mechanism. The business process modeling standard—Business Process Management Notation (BPMN) is used as the underlying framework in the pilot implementation. It provides a scalable infrastructure to support new use cases in the future. The identity services and patient-provider relationship manager that maintains the community care team for an individual patient are the foundational services invoked by the CCB. Patient notification may be a critical piece for some coordinated care workflows through patient portals and patient-registered devices. The audit service will provide data for future evaluation on the impact of the automated care coordination workflows. The newborn care bundle, poison case management, and advanced discharge planning for SNF transfer are pilot implementations that demonstrate the feasibility of using pre-existing community resources. As more care coordination scenarios emerge and transaction volumes increase, the statewide infrastructure shows promise of efficiency and economy.

**Conclusion**

The collaborative demonstrated an innovative approach to facilitating care coordination by implementing automated information transfer rules on a business process management platform. Existing health information infrastructure in Utah is re-organized and leveraged to support the statewide care coordination services. It is critical to convene major stakeholders and promote collaborative partnership across the community. Creating a statewide care coordination infrastructure to manage patients across the care continuum is essential to achieving optimal health outcome, reducing costs, and enhancing the patient care experience.

Abstract

Providers are increasingly overriding drug-allergy alerts in electronic health records with average override rate of about one in ten alerts. We present a set of conceptual and practical recommendations to develop a new generation of drug-allergy alert systems. Recommendations were generated by a multidisciplinary group of experts from medicine, pharmacology, nursing, quality and safety, and clinical informatics.

Introduction

Drug allergy alerts are one of the key features of computerized provider order entry (CPOE) in electronic health record systems. These alerts can protect patients and providers from administration of medications that could result in an adverse reaction by comparing ingredients and cross reactivity between prescribed medications and medications on the patient’s allergy list. In practice, these alerts as currently used in most systems have serious limitations with over 90% of these alerts are being overridden.1–6 Observations from the last 15 years show override rates increasing from 50% in the mid 1990s1 to almost 90% in 2015.2,3 Many current alerts are inconsequential and almost never result in an adverse reaction.4,5 It is estimated that providers need to review more than 123 unnecessary alerts to prevent one adverse drug event.4 This presents a substantial problem with drug allergy alert systems that demands redesign. While most of the overrides may simply indicate low value alerts that are not providing useful decision support to providers, many alerts are overridden in situations that are not safe, for example, when patients have a history of severe or immune-mediated reactions. Though surprising, alert override rates for anaphylaxis or angioedema are often greater than 75%.2–6

Methods

New approaches to allergy alerting are critically needed. During 2015, we assembled a multidisciplinary group of experts from internal medicine, allergy/immunology, emergency medicine, pharmacology, pharmacy, nursing, quality and safety, and clinical informatics to identify new methods for drug allergy alerting systems. The group produced a set of conceptual and practical recommendations to develop a new generation of drug-allergy alert systems.

Results

Patient engagement in the allergy reconciliation process is a key to creation and maintenance of meaningful allergy lists. In many cases, allergy is never removed from the patient’s list once it is recorded. At the same time, even when patients have a medication allergy, it may not appear on the list. Strategies to engage patients in reviewing their
allergy information and reconciling allergies with their provider should be further tested and implemented. For example, patients should be able to update their allergy information in personal health portals, which should prompt the clinician to review the information with them on their next encounter.

Improved allergy documentation and characterization of allergic information to improve alert accuracy. It is crucial for allergy information to accurately characterize and distinguish adverse drug reactions as side effects, toxicities, intolerance, idiosyncrasy, or allergies. Clinicians recording these events may not know the distinctions and computerized clinical decision support could assist in these determinations. A more detailed specification of the patient’s allergy at the time of entry or reconciliation will ensure that alerts are triggered when they matter most, and avoid unnecessary alerts on mild intolerances or previously-tolerated medications.

Alerting mechanism: Allergy alerting systems should consider reaction severity and other contextual information (e.g., the type of match between the allergen and prescribed medication, reaction occurrence probabilities, information on whether this alert was fired or overridden in the past, etc.) into consideration when presenting alerts to clinicians. Fuzzy and disorganized alerting approaches produce noisy alerts that are not clinically meaningful. One potential solution that is common in drug-drug interaction alerts is alert tiering. Based on adverse drug reaction severity, or the likelihood of an immune-mediated reactions, such as immediate, IgE-mediated allergic reaction that on repeat exposure could lead to severe outcomes, drug allergy alerts can be classified as either informative (providers will still see the alert information but would not need to take an action to override the alert) or interruptive (providers will be required to provide a reason for override or cancel the prescription).

Continuous alert monitoring and improvement: organizations should track their allergy alerting and override rates over time. This will help identify changes in alerting patterns and turn-off alerts that are disruptive.

Discussion

We believe that these recommendations can advance and improve the current state of allergy alerting. Patient safety will improve if providers are not being barraged with inconsequential alerts, making them more likely to adhere to warnings that represent a serious concern.

Novel Approaches to Medication Teaching for Complex Medication Regimens

Demetra Tsapepas, PharmD1,2, Hojjat Salsamian, MD MPH PhD1,2, Sumit Mohan MD, MPH1,2, Jennifer Prey, MPhil MS2, Andrea Wells-Shapiro CPXP1, David K Vawdrey, PhD1,2

1NewYork-Presbyterian Hospital, New York, NY; 2Columbia University, New York, NY

Introduction

Mobile applications can enhance healthcare providers’ ability to deliver tailored interactive patient education at the bedside, but the use of such applications is not well understood, particularly in specialized populations.1,3 Solid organ transplant recipients, for instance, have complex medication therapy regimens requiring extensive personalized education. We evaluated the impact of a digital education program delivered through a mobile application on transplant patients’ awareness of their medication regimen and associated side effects.

Methods

This single-center retrospective study of adult kidney or pancreas allograft recipients transplanted from January 2015 to June 2016 analyzed the results of a survey distributed among patients who were educated through a novel teaching approach using tablet computers. Using interactive content on the tablet computer, hospitalized patients engaged in their own learning about their immunosuppressive regimen; reviewed the name, indication, dose, side effects, interactions, and special considerations for each of medication. Concise, stimulating video clips about each medicine were designed to appeal to a broad patient audience including those with limited healthcare literacy. Video clips were two to eight minutes in duration and consisted of images, text, and voice-over (see Figure). To reinforce key concepts and identify knowledge gaps, the application contained assessment questions followed by feedback that included explanations of the correct answers. Each patient answered 19 assessment questions, 14 focused on the medication indication and important information and five questions focused on side effects. Patients were encouraged to spend as much time as they needed to complete the module. A tailored in-person follow-up session was also conducted by a pharmacist to reinforce content and address knowledge gaps.

Results

Survey respondents included 183 patients who used the virtual teaching tool. Patients were ethnically diverse, ranged in age from 21–75 years, and 25% had an undergraduate degree or some college education. Ninety percent of patients were educated on our standard dual-maintenance immunosuppressive regimen and three opportunistic infection prophylaxis agents. While the majority of patients (90%) were able to identify the correct answers for questions related to drug indication, dosing, and special rules, many (62%) had difficulty recalling information about side effects (see Figure). The majority of patients (90%) favorably ranked this digital education program.

Conclusion

Utilizing virtual teaching via mobile applications may improve the efficient healthcare delivery by providing consistent, quality patient education interventions. In order to succeed, patient centered care initiatives need to empower patients to actively participate in their care. To our knowledge, this is one of the first and largest studies to demonstrate the efficacy of structured education program for transplant patients with complex medication regimens.

Diagnostic Journeys of Patients Evaluated for Lyme Disease and Given Extended Antibiotic Therapy

Yi-Ju Tseng, PhD1,2, Alfred DeMaria Jr MD3, Donald A. Goldmann MD4,5, Kenneth D. Mandl, MD, MPH1,6,7

1 Computational Health Informatics Program, Boston Children’s Hospital, MA, USA; 2 Department of Information Management, Chang-Gung University, Taiwan; 3 Bureau of Infectious Disease and Laboratory Sciences, Massachusetts Department of Public Health, MA, USA; 4 Institute for Healthcare Improvement, MA, USA; 5 Division of Infectious Diseases, Boston Children's Hospital, MA, USA; 6 Department of Pediatrics, Harvard Medical School, MA, USA; 7 Department of Biomedical Informatics, Harvard Medical School, MA, USA

Introduction
Lyne disease (LD) is most straightforwardly diagnosed when erythema migrans (EM) is observed, there is a history of possible exposure to ticks, or a serologic test is confirmatory. However, the diagnosis can be far from straightforward, particularly if the initial diagnosis isn’t made because EM doesn’t develop or isn’t noticed, the patient is unaware of tick exposure or bite, or the presentation is atypical. LD can be treated effectively with 2-4 weeks of antibiotics. If untreated, LD may lead to neurologic and rheumatic manifestations weeks to months later. Even after standard treatment, about 10-20% of patients with LD report nonspecific persistent symptoms, may result in a diagnosis of post-treatment LD syndrome, especially when the diagnosis is delayed or the treatment is inadequate. We sought to map diagnostic journeys taken by patients diagnosed with LD, hypothesizing that those ultimately receiving extended antibiotics may be clinically distinct.

Methods
We performed a population-based retrospective cohort study using insurance claims from a nationwide, private health insurance plan in the US from 2010-2012, for patients residing in the 14 states with a high-prevalence of LD—Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia and Wisconsin. The Boston Children’s Hospital Institutional Review Board approved the study, granting a waiver of consent.

We use a published LD claims data-based case definition including LD diagnosis code, serologic test, and antibiotic therapy for LD. Patients evaluated for LD and given standard antibiotic therapy (PLDSA) are defined as those receiving 2 to 5 weeks of antibiotics. Patients evaluated for LD and given extended antibiotic therapy (PLDEA) are defined as receiving ≥5 weeks. To enrich the cohort for patients beginning their diagnostic journeys, we included beneficiaries enrolled in the plan for at least 180 days before an LD diagnosis and who received the first LD diagnosis in 2011 or 2012.

We assessed the association between PLDEA and diagnoses grouped into clinically meaningful diagnostic categories using the Agency for Healthcare Research and Quality Clinical Classifications Software (CCS). Each category is defined as a binary variable, based on the presence or absence of at least one ICD-9 code from the appropriate category occurring during defined 30 day time periods between 1 and 180 before a patient’s first LD diagnosis. The presence of a diagnosis within the diagnostic categories among PLDEA was compared with the risk in PLDSA using logistic regression, adjusted by age and gender, and expressed as odds ratios (ORs). All analyses were performed using R software. All statistical tests were two-sided.

Results
A total of 7,928,693 insured individuals resided in the 14 states with a high-prevalence of LD. Of these, 3,207 (40.45 per 100,000 insured) and 600 (7.57) individuals met the case definitions for PLDSA and PLDEA, respectively. Compared with PLDSA, PLDEA cases were more likely to be female (62.1% vs. 48.5%, P<0.001) and older (42.5 vs. 40.7, P<0.05). Figure 1 maps out the temporal, claims associated diagnostic journeys of PLDEA compared with PLDSA in the six months leading up to the first diagnosis of LD. From 151-180 days before the first LD diagnosis, the risk for claims associated with back problems (OR, 2.1; 95% CI, 1.4-2.9; P < .001) and other connective tissue
disease (1.6; 1.1-2.3; P < .01) were elevated among PLDEA. From 61-90 days before, claims associated with malaise and fatigue (1.7; 1.1-2.6; P < .05), other nervous system disorders (2.0; 1.3-3.1; P < .01), and non-traumatic joint disorders (1.4; 1.0-2.0; P < .05) are more likely among PLDEA. From 1-30 days before, the risks of mental illness (1.6; 1.1-2.0; P < .01) and headache (1.5; 1.1-2.0; P < .05) associated claims are higher. In contrast, the only low risk claims associated diagnostic category in PLDEA is skin and subcutaneous disorders (0.6; 0.5-0.9; P < .01) occurring up to 30 days before the first LD diagnosis in the study period.

![Figure 1](https://www.hcup-us.ahrq.gov/toolssoftware/ccs/ccs.jsp) Claims associated diagnostic journeys. The colors in blocks indicate the odds of diagnostic categories in PLDEA compared with PLDSA, for statistically significant (P<0.05) relationships. The numbers on the color blocks indicate the percentage of PLDEA patients assigned the diagnostic category.

**Discussion**

PLDEA have distinct signatures with evidence of common progressions through alternate diagnoses and recognition of various co-morbidities. They had a higher risk than PLDSA for claims associated nonspecific signs and symptoms consistent with LD including fatigue, headache, joint pain and connective tissue diseases before their first LD diagnosis during the study period. Skin and subcutaneous tissue diagnoses are in the only category more likely to be found among PLDEA. Given the distinct character of the EM rash and the effectiveness of prompt treatment, this is not surprising. Early identification of these individuals based on patterns of diagnosis could reduce the time to diagnosis and yield cost savings associated with misdiagnosis or delayed diagnosis.

The Role of Culture and Personality in Health Information Communication with Social Network Members

Rupa S. Valdez, PhD1, Thomas M. Guterbock, PhD1, Kara Fitzgibbon, MS1, Ishan C. Williams, PhD1, Hannah K. Menefee, MPH2, Claire A. Wellbeloved-Stone, MPH1
1University of Virginia, Charlottesville, VA; 2Virginia Tech, Blacksburg, VA

Introduction
Consumer health IT solutions are proliferating as support mechanisms for patients who must increasingly take on self-management responsibilities. One aspect of self-management that has received limited attention from consumer health IT designers, but has been documented as burdensome for patients1, is the communication of health information to social network members (i.e., family, friends, acquaintances). These individuals are often engaged in supporting patients with the emotional, instrumental, and spiritual aspects of living with a chronic condition2,3. We sought to understand patient needs for consumer health IT by assessing patients’ existing health information communication (HIC) practices on social media. Specifically, we sought to determine the ways in which individuals with type 2 diabetes communicate health information with members of their social network on Facebook, the largest social media platform4. In this presentation, we report on how aspects of personality and culture were associated with different approaches to HIC with Facebook social networks (communication with Facebook networks both on and off Facebook). Such a study informs design and implementation of culturally informed consumer health IT solutions.

Methods
Our study consisted of three phases: 1) qualitative interviews and survey development (based on qualitative findings), 2) survey piloting and revision, and 3) large-scale sample survey. Eligible participants for all phases were 18 or older, used Facebook, had a diagnosis of type 2 diabetes, and were citizens or residents of the United States. **Phase one:** Twenty-five individuals recruited on Facebook5 participated in phase one. Phase one participants were interviewed about their HIC practices on and off Facebook as well as factors they believed shaped these practices. Relevant to the analysis reported in this abstract, participants were asked about cultural values influencing their approach to HIC. When queried about other factors beyond those explicitly raised by interviewers, participants mentioned the role of personality. To translate these findings into a survey, we conducted a qualitative content analysis of the cultural values mentioned by participants and designed a survey item reflective of these findings. To account for personality, we added the Big Five Personality Test6 to the survey. **Phase two:** Thirteen individuals recruited on Facebook participated in phase two. Phase two participants completed a draft survey based upon phase one results and participated in focus groups, during which they were asked to explain their interpretation of each survey question and discuss ways of altering the wording and organization to limit misinterpretation. **Phase three:** Seven hundred individuals recruited through a commercial survey access panel participated in phase three. Phase three participants completed a finalized version of the online survey, which contained between 75 and 80 questions (depending on version received) and took an average of 22.5 minutes to complete. Relevant to the analysis reported in this abstract, an exploratory factor analysis (EFA) on normalized survey findings (N=650) related to cultural values (Principal Component Analysis as an extraction method and Oblimin with Kaiser Normalization as a rotation method) was conducted to reduce the 29 themes generated by the qualitative content analysis into four factors. Based on an earlier analysis of phase three survey questions about HIC practices, we identified seven approaches to communicating health information with Facebook social networks (Table 1)7. We compared the cultural factors and personality traits reported by survey participants in each profile using one way ANOVA with post-hoc pairwise comparison and Tukey’s HSD method to test for significant differences between profiles (alpha=0.05). The University of Virginia’s Social and Behavioral Sciences IRB approved this study.

Results
The gender of phase one participants was approximately evenly divided and the gender of phase three participants was unequally distributed with approximately two-thirds of participants identifying as female. The majority of participants in both phases were 30-64 years of age, with about 20% above of the age of 65. In both phases, racial minorities
comprised approximately 40% of the sample. Ethnic minorities comprised 12% of phase one participants and 21% of phase three participants. The results of the exploratory factor analysis of cultural values indicate four underlying factors, which we conceptualized as 1) virtue, 2) comfort, 3) culture, and 4) religion and spirituality (see Table 2). Statistically significant differences among a subset of profiles (α = .05) were demonstrated across all four cultural factors and three of five personality characteristics (see Table 3). Statistically significant differences are indicated by a superscript. For example, there is a statistically significant difference between FC-H and MC-L on the personality characteristic “agreeableness.”

Discussion and Conclusion

This study demonstrates that there are statistically significant differences in the cultural values and personality traits associated with each HIC profile. These differences can help designers create distinct personas as a foundation for generating consumer health IT solutions that can be tailored to different types of individuals. For example, individuals identifying as OC-H who have strong identification with the “comfort” factor, indicate value placed on travel and regional location. This suggests potential design features such as enabling them to connect with others living in their geographical area and to those with similar health conditions when they are away from home. Moreover, at a general level, this study supports the idea that culturally informed consumer health IT need not only be responsive to culture as defined by race and ethnicity, but also as defined by cultural values that are patient-centered, in the sense that they are generated directly from patients. Future research should continue with an iterative design process with each of these groups to determine how consumer health IT solutions either diverge or converge based upon these distinct personality characteristics and cultural values.

The Discriminative Power of Non-Specific Laboratory Results
Jacob P. VanHouten, MS¹, Christopher J. Fonnesbeck, PhD¹,
Michael E. Matheny, MD, MS, MPH¹, Thomas A. Lasko, MD, PhD¹
¹Vanderbilt University Medical Center, Nashville, Tennessee, USA

Introduction
Physicians generally use all available data when making diagnosis and treatment decisions, but computational approaches to
phenotype identification often limit themselves to a small number of highly-specific, expert-engineered variables when
defining the phenotype of interest. While this approach does provide computational savings, it also limits the sensitivity and
specificity of the phenotype identification.

In this work we distinguish between local and distributed information for an outcome of interest. For example, local
information for diabetes could be an elevated glucose result, the use of metformin, or an ICD code 250, because they are
highly specific for and directly related to the disease. On the other hand, distributed information is non-specific information
distributed throughout the record that is nevertheless related to the presence of the disease, and in aggregate may indicate its
presence or absence. While much research has used local information for phenotype identification¹,², comparatively little has
explored the use of diffuse information³,⁴.

In this work, we estimate the discriminative power of information distributed among non-specific laboratory test results by
applying a standard classification algorithm several different problems. For each problem we also explored the effect of
complexity of data representation, recognizing that greater representation complexity can come at a higher cost in
computational resources and investigator effort.

Materials and Methods
We trained models for eleven different classification problems that had accurate, easily accessible reference standard labels
(Table 1). We selected patient demographic and surgical procedures to represent targets of various degrees In addition, we
trained two models on what we expected to be very difficult conditional problems: did the patient have a kidney transplant,
given that they did receive a kidney or liver transplant, and did the patient have a hip replacement, given that they did receive
a hip or knee replacement?

We used data from Vanderbilt’s Synthetic Derivative, a deidentified mirror of our electronic medical record. We selected the
top 150 most commonly performed laboratory tests, of which we excluded six because they were not laboratory
measurements (dose, patient location, etc.). We limited our study population to the most recent eight years, required that
records have results for at least 10 of the top 144 labs, at least one test for which there were three or more recordings, and no
missing data for sex or race. This left us with a final study population of 357954 records for training and testing.

To evaluate the tradeoffs between prediction accuracy and complexity of computation and data, we tried eight increasingly
complex data representations for each patient record:
1. Binary (whether the test was ever ordered),
2. Counts (the number of orders made for the test),
3. Counts per year for each of the eight years,
4. Cumulative counts by year,
5. Mean (of all results in the eight year span),
6. Quintiles (of all results in the eight year span),
7. Continuous smooth interpolations of result trajectories, and
8. Combination of order counts and result means.

For classifying patients by sex, we performed the analysis with and without prostate specific antigen, which was the only sex-
deterministic test in the suite of labs used.

We selected random forest as our classifier, because typically performs well, even for unbalanced problems; it scales well, it
can learn predictive non-linear combinations of variables, and it can estimate variable importance. We optimized the forest’s
parameters for each task and each representation.

Results
Of the data representations considered, the binary representation performed the worst and the combination of counts and
means performed the best, but means or counts alone were usually close to the best (Figure 1). The easiest problem turned
out to be the detection of kidney transplant, the hardest was distinguishing hip vs. knee replacement. The classifiers using the
continuous smooth interpolations of results could not be run on the entire data set due to memory limits, but analysis using a
subset of data found no improvement over the means representation (data not shown).
The most important variables were not always the same among representations within a specific task. For example, while the presence of a test for thyroid stimulating hormone or urine squamous epithelia was highly discriminative of sex in the binary representation, the actual results of creatinine, hemoglobin and MCHC were the most predictive in the means representation.

Conclusion

We were able to identify patients with specific low-noise findings using only non-specific laboratory tests as input features for random forest classifiers with generally high accuracy. This performance does not require much work to achieve, as models built using lower complexity representations often performed as well as more complex ones. Using result means alone is an efficient way to encode test results. Surprisingly, the timing of orders appears to be less important than whether the orders were placed at all. The extension of order counts to counts binned by year and to year-over-year cumulative counts only performed as well as total counts, not better. This result may be due to the nature of the random forest and how variables are selected for inclusion in each tree. If the sum count of orders is the most information-dense representation, then a random forest classifier would need to select many individual variables from a representation of counts binned by year to encode the same data.

We found that different representations cause the classifier to focus on different variables. It is clinically intuitive that important variables in one representation within a task are not the same as the important variables for a different representation. One possible explanation is that binary and count representations may reflect differences in clinical practice, while laboratory values capture signals related to biological differences between patients with and without the finding of interest. Developing a knowledge repository of these features for generalizable use has great utility.

While we used only random forest classifiers, we expect that our results may extend to other classification algorithms, at least those that are as effective as random forests in extracting complex nonlinear relationships between input variables. Our results suggest that summary measures such as overall means and order counts may be generally efficient data representations that balance performance and cost for common medical classification tasks.

Information Extraction from Italian medical reports: first steps towards clinical timelines development

Natalia Viani, MS¹, Valentina Tibollo, MS², Carlo Napolitano, MD², Silvia G. Priori, MD, PhD²³, Riccardo Bellazzi, PhD¹, Cristina Larizza, PhD¹, Lucia Sacchi, PhD¹

Introduction

Clinical reports include a great amount of valuable information in the form of unstructured text. The need to extract such information to improve medical decisions is well-known. Given that many diseases require continuous monitoring over time, identifying clinically relevant events and eliciting temporal relations among them is crucial. In the field of clinical Natural Language Processing (NLP), many works have been published dealing with unstructured English texts. However, the extent of the related research for other languages is smaller. In addition to the challenges specific to clinical NLP, other language-dependent issues have to be considered. In the case of Italian, the lack of freely available annotated medical corpora, the limited coverage of available dictionaries, and the lack of medical-specific taggers, make it hard to develop techniques to analyze unstructured medical texts. To overcome this problem, several strategies have been proposed. A considerable amount of work for the automatic analysis of both English and non-English texts relies on rule-based approaches. The definition of rules can be enhanced by using domain ontologies, containing information on the main clinical events and their attributes.

In this work we present a rule-based, ontology-driven approach to extract clinical data from unstructured Italian texts. The proposed approach represents a first step towards developing an NLP pipeline that extracts both clinical and temporal information from a set of medical reports, with the final aim of building clinical timelines.

Part of our NLP pipeline has been validated on a set of medical reports provided by the Molecular Cardiology Laboratories of the Fondazione S. Maugeri hospital in Pavia, Italy. Medical reports belong to patients with inherited or acquired heart diseases (e.g. long QT and Brugada syndrome), and cover a time span of 5 years. Many of the data included in reports are currently manually stored in the TRIAD repository (http://triad.fsm.it/triadweb), a database for clinical and genetic variations in the field of inherited arrhythmogenic diseases. It includes data on diagnoses, genetic mutations, cardiac events, performed tests, prescribed treatments and device implants.

Methods

In clinical reports, it is frequent to find occurrences of clinical events that are related to a set of attributes, which characterize the event itself. In the field of Cardiology, for example, ECG test represents an event, while heart rate and rhythm represent some of its related attributes. To explicitly represent this feature, we have defined an ontology, structured into Event and Attribute classes. Attributes can have a numeric (heart rate) or a categorical (rhythm) value. All concepts in the ontology are associated to a specific regular expression, which allows searching for their occurrence in free-form texts.

The NLP pipeline that we implemented is based on Apache UIMA and uses TextPro for standard pre-processing. Negation detection is performed by adapting an implementation of the NegEx algorithm to Italian. Clinical information extraction (IE) is performed in two steps. First, we identify mentions of clinically relevant events, such as diseases, tests and prescriptions. These events are extracted by relying on two external Italian dictionaries: the ICD9-CM, and the FederFarma dictionary for drugs. Each identified event is then linked to its attributes through the developed ontology. Specifically, the ontology modeled in Protegé-OWL is automatically translated into a configuration file used by a specific UIMA Annotator. There are three main reasons why we opted for an ontology-driven approach. First, every time a concept has to be added or modified, a simple ontology update is needed. Moreover, if the analysis of a new set of documents was needed, it would be only necessary to enrich the ontology with new domain-related information. Finally, to analyze a set of documents written in another language, it would be sufficient to modify all the regular expressions.

Given the lack of annotations in the analyzed corpus, to perform the evaluation of the proposed approach, we compared the output of our pipeline to the data stored in the TRIAD database for 4430 reports.
Results

The ontology developed in this work contains 11 events and 60 attributes. To define relevant attributes, the information stored in the TRIAD system was considered. To evaluate our pipeline, we considered a subset of events that are frequently included in Cardiology reports: main diagnoses, drug prescriptions and three diagnostic tests (ECG, Holter ECG and Effort Stress tests). For each report, we compared the values extracted by our pipeline to the corresponding values stored in the TRIAD system. For each extracted event, only those attributes for which an entry was detected in the TRIAD system were considered. Annotations were marked as correct if both the attribute name and its value matched those included in TRIAD. If the attribute extracted by the pipeline was stored with a different value, the annotation was considered not correct. The results obtained in this preliminary evaluation are shown in Table 1. Dealing with drugs was not trivial: while reports often contain separate information on drug names, forms and unit dosages, the TRIAD repository stores only drug names and daily doses. For this reason, the evaluation of extracted prescriptions was performed both on drug names only and on drug names with associated dosages (results marked with * in Table 1).

</tr>
</tbody>
</table>

Discussion

Diagnoses are identified with an accuracy of 88.5%. As regards tests, while the annotation of ECG and Holter tests shows good performances (94.7% and 88.5%, respectively), accuracy drops when considering Effort Stress tests, probably because the results of such tests are described by physicians with articulated sentences. As expected, the evaluation performed only on drug names led to a higher accuracy than the one considering both names and dosages.

The IE procedure that we developed shows promising results. That said, improvements are still needed. First, we plan to extend look-up dictionaries by computing n-grams that denote expressions frequently used in reports. Moreover, improvements on negation detection and misspelled words are needed. By improving the pipeline steps, it would ultimately be possible to build a well-performing system that automatically inserts data into the TRIAD system, saving a lot of manual work and improving data quality. Furthermore, the annotations produced by the system could be eventually used to create a pseudo-gold standard corpus, enabling further research.

Evaluation of SMART-on-FHIR I2b2 cell using PCORNET data model

Kavishwar B. Wagholikar, MBBS PhD 1,2, Rahul Jain, MPH CPHIMS, 3,5
Eliel Oliveira, MBS MS, 3,5 Joshua Mandel, MD 1,4, Jeffery Klann, PhD 1,2, Prasad Patil, MS, 5,6 Kenneth D. Mandl, MD MPH 1,4, Shawn N. Murphy, MD PhD 1,2, Thomas Carton, PhD3,5
1 Massachusetts General Hospital, Boston, MA; 2 Harvard Medical School, Boston, MA; 3 Louisiana Public Health Institute, LA; 4 Children's Hospital Boston, Boston, MA; 5 Research Action for Health Network, LA; 6 Persistent Systems, India;

Introduction

Informatics for Integrating Biology and the Bedside (i2b2) is an open source clinical data analytics platform originally sponsored by the National Institutes of Health. (1) It is used at over 100 sites nationally for querying patient data to address clinical questions. I2b2 has been adapted to build multi-institutional networks, and is a central component in the infrastructure for many institutions that have Patient-Centered Outcomes Research Institute (PCORI) awards.

Fast Health Interoperability Resources (FHIR) is a new standard for exchanging healthcare information electronically. It is based on emerging industry approaches, and builds on the lessons from previous healthcare standards. Several projects are underway through standards organizations to facilitate adoption of FHIR including the Argonaut Project, Data Access Framework (DAF) and Clinical Information Modeling Initiative (CIMI).

I2b2 has a SMART-on-FHIR i2b2 cell (SOFI), which serves data from an i2b2 instance in the FHIR format. SOFI provides an alternative, but secure way to retrieve data on per patient basis using OAuth2-SMART specification. (2)

Our objective in the current work is to evaluate SOFI on data in format used by PCORI sites. The goal is to reduce barriers for sharing tools across the PCORI’s patient powered research networks (PPRNs). Our work can significantly reduce the efforts at the PPRNs to develop a platform for running SMART apps, which will facilitate sharing of the apps across the network.

Methods

We imported patient data in CDM format into i2b2 using an i2b2 plugin (3), and adapted the SMART-on-FHIR i2b2 cell (SOFI) to query i2b2 using PCORI ontology. (4) SOFI cell provides demographics, laboratory results and diagnoses for each patient in FHIR format. The deployment was performed at two locations Partners Healthcare (PHC) in Boston, MA and the REACHnet Data Center (RDC) in New Orleans, LA.

For evaluating this infrastructure, we assessed the accuracy and completeness of the FHIR output from SOFI, by performing manual inspections, and by running the FHIR validator available with the specification. We performed spot inspection of 30 instances of FHIR resources (Labs, Diagnosis and Demographics) for random patients at both the locations. We verified the dates, codes and code expansions during the spot inspections, by comparing the FHIR output with the i2b2 data. Additionally, at RDC we traced the data-points into the imported CDM. To evaluate compliance of the SOFI with the SMART OAuth2.0 specification, we developed and executed a dashboard SMART app on both the installations. Finally, we measured the average time required for the platform to respond to request for FHIR resources. (Figure 2)

Results and Future work

The SOFI platform could be installed at both the sites: PHC and RDC. SOFI installation script could be readily run on a CentOS instance at Partners, but needed few modifications for running on Ubuntu instance at RDC’s Openstack node. At PHC we had previously created an i2b2 instance. At RDC’s we created a fresh i2b2 instance by importing CDMs for 300 patients.

The official FHIR validator ran successfully on randomly selected resources at both the sites, and the manual inspections revealed that the FHIR resources were valid and contained accurate data. The SMART app executed successfully at both the sites, demonstrating the security of the installations. SOFI requires an of average 5 seconds for responding to non-cached calls and 0.5 second for cached calls.

We plan to expand the range of FHIR resources served by SOFI on i2b2 instances derived from PCORNET-CDMs.
Furthermore, we are testing portability of apps from SMART gallery across the SOFI installations in PHC and RDN.

Figure 1. Pipeline for installing and evaluating the SMART on FHIR i2b2 cell (SOFI). SOFI provides an installation script that is tailored to virtual machine platform at Amazon. This script automatically pulls the SOFI source code from Github and installs the servlet container, database and webservice on a fresh instance. The pipeline to import data from the CDM format, into i2b2 instance and to install SOFI is available at [http://community.i2b2.org/wiki/display/FCC/FHIR+Connection+Cell](http://community.i2b2.org/wiki/display/FCC/FHIR+Connection+Cell)

![Diagram](image)

Response time in seconds

<table>
<thead>
<tr>
<th>Calls per second</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
<tr>
<td>0</td>
</tr>
</tbody>
</table>

Figure 2. Summarizes the time needed for SOFI to respond to FHIR queries from clients, when the calls are not cached. This incudes the timed needed to retrieve data from the i2b2 instance and translate it into FHIR format. The figure shows that the response times for non-cached calls, plateau at the rate of one call every 5 seconds, for the current server configuration of two cores of 3.3 Ghz with 4 GB RAM (t2.medium amazon ec2 instance). Increasing the configuration (core and RAM) of the server can potentially improve the non-cached response time. For calls that are previously cached the response time averages to 500 milli-seconds.

Introduction

In 2011, the American Board of Internal Medicine introduced the Choosing Wisely initiative. Based on empiric research, this initiative delineated healthcare services that should be avoided unless certain “red flag” criteria are present.¹ For example, Choosing Wisely recommends “avoiding imaging for patients with low back pain without ‘red flags’ like cancer or trauma”.² Choosing Wisely has become a widely adopted standard for measuring and promoting healthcare quality. However, Choosing Wisely metrics are currently encoded using International Classification of Diseases (ICD), version 9 codes.³ On October 1, 2015, the Center for Medicare and Medicaid Services CMS) transitioned to the tenth version ICD (ICD10) for billing claims.⁴ Diagnostic coding in ICD10 allows increased code granularity, but resulted in a larger number of available codes. To support transitioning to this larger code set, CMS commissioned the General Equivalence Mappings (GEMs) from ICD9 to ICD10 and Reimbursement mappings from ICD10 to ICD9. Many medical centers also created “one-to-one only” mappings to reflect local billing practices. To date, there are no ICD10 based versions of Choosing Wisely metrics. The purpose of this study is to estimate differences in prevalence assessment for a number of Choosing Wisely Metrics using all available mappings between ICD9 and ICD10.

Methods

This study was conducted using data from the Vanderbilt University Medical Center (VUMC) Research Derivative, a curated mirror of the clinical data warehouse designed to support research. ICD-encoded claims on all adult patients over age 65 at VUMC were collected in two time periods: period A) October 1, 2014 – February 15, 2015, corresponding to when ICD9 was in use; and period B) October 1, 2015 – February 15, 2016, corresponding to when the ICD10 was in use.

This study used Choosing Wisely criteria for: avoiding unnecessary imaging for low back pain; avoiding unnecessary imaging for benign prostatic hyperplasia (BPH); avoiding use of feeding tubes in patients with dementia. All codes from patients in period A were compared against Choosing Wisely ICD9 criteria directly. Codes from period B were mapped to ICD10 codes via the following 4 methods: 1) mapping Choosing Wisely codes to ICD10 using GEMs; 2) mapping Choosing Wisely codes to ICD10 using institutional 1:1 maps; 3) backwards mapping patient codes to ICD9 using reimbursement maps; and, 4) backwards mapping patient codes to ICD9 using institutional 1:1 maps. We calculated numbers of patients having an ICD encoding red flag symptoms among all patients having the underlying clinical condition for each Choosing Wisely metric studied. Cost estimates were based on assumptions in Colla et al.²

Results

In period A, there were 951,187 total ICD9 claims coded on 66,825 individuals. In period B, there were 1,185,198 ICD10 total claims coded on 63,395 individuals. Prevalence of

red flag symptoms varied most using GEMs to map Choosing Wisely codes to ICD10 (i.e., method #1 above). For back pain and BPH imaging, methods 2-4 were closest in estimates to baseline. For feeding tube use, baseline prevalence and cost was 1.2% and $181,658 respectively in Period A. In Period B, estimates ranged from 0.3% prevalence and $66,509 in waste for methods #2-4 up to 1.9% prevalence and $412,106 in possible waste using method #1.

Discussion
This study evaluated how different approaches to converting Choosing Wisely criteria for identifying red flag symptoms from the ICD9-encoded criteria to ICD10. Using Reimbursement Maps (i.e., method #3) led to most similar rates of patients being identified as having red flags compared to baseline, and is likely to be the most generalizable given their public availability. Results also indicate that the method of reconciling metrics based in ICD9 to claims coded in ICD10 may influence estimates of prevalence and cost for Choosing Wisely. This phenomenon was illustrated most by feeding tubes in dementia patients – a relatively infrequent but high cost service if it is implemented against the recommendations of Choosing Wisely.

Strengths of this work include a large dataset of real-world clinical claims and procedure data. Many of the mapping tables used in this work are readily available. Limitations of this study include a lack of a true gold standard in the ICD10 era. There are potential temporal patterns or confounders in clinical operations and workflow as the Choosing Wisely has become well known throughout the country. We are not aware of specific efforts at VUMC that should undermine the expectation that the four mapping methods would yield similar prevalence estimates in the ICD10 era.

Further research in this domain is required. Our analyses should be replicated using data from other centers where billing practices may vary. We speculate that simple mappings of ICD10 codes back to ICD9 or Choosing Wisely ICD9 Criteria to ICD10 is unlikely to achieve parity with what has been established in the era of ICD9. Achieving a highly discriminative algorithm may require a curated gold standard dataset created by professional coders from real-world clinical data.

Discovering representational differences between pathway knowledge bases for pathway resource merging
Lucy L. Wang, John H. Gennari, Neil F. Abernethy
Department of Biomedical Informatics and Medical Education
University of Washington, Seattle, WA

Introduction
Biological pathways are powerful tools for analyzing complex biological and pathological processes. There are a large number of pathway knowledge bases, specializing in the biology of different species, functions, and diseases. The contents of these databases are both unique and complementary. In order to perform analyses and draw conclusions over the full breadth of knowledge biologists have generated, we benefit from combining material from multiple pathway databases. Many resources have already begun this process, both by providing resources ostensibly in the same standard (e.g. PathwayCommons), and by allowing for queries and visualization over multiple knowledge bases (e.g. ConsensusPathDB, hiPathDB). However, resource integration remains difficult due to issues of resource quality and differences in knowledge representational choices between resources.

In order to successfully align the contents of these pathway knowledge bases, we must understand how their structure differs and provide a way to translate content between them. Some prior work has been done in describing semantic differences between reaction representations. However, semantics are not the only issue. Several classes of differences exist between pathway resources in entity annotation, entity existence, reaction semantics, and reaction and entity granularity. In this abstract, we focus on distinguishing these variations in content and, more specifically, on detecting inconsistencies in annotation between two popular human pathway resources: HumanCyc and Reactome.

Methods
In the first part of this work, we define a typology of pathway resource differences and provide criteria for identifying differences across five resources: HumanCyc, KEGG, PANTHER pathways, Reactome, and WikiPathways. The following examples use content extracted from HumanCyc (v19.5) and Reactome (v55) in BioPAX format.

Figure 1 illustrates several classes of representational differences in a reaction of the glycolysis pathway, the conversion of phosphoenolpyruvate to pyruvate. The reacting species ADP, phosphoenolpyruvate, ATP, and pyruvate are annotated with cross-referenced ChEBI identifiers, none of which match between the two resources, showing an inconsistency in entity annotation. For example, ATP is annotated as ChEBI:30616 in HumanCyc and ChEBI:15422 in Reactome. HumanCyc also provides one additional participant in this reaction, the H+ ion, an example of a disagreement in entity existence. Next, differences in reaction semantics are seen between the two resources in the representation of reaction direction. In HumanCyc, the entities in green are labeled with BioPAX property “right,” the entities in red are labeled “left,” and the entire reaction as having direction “right-to-left.” In Reactome, the reactants are labeled “left” and the products “right,” with the reaction proceeding “left-to-right.” Lastly, a difference in entity granularity is seen in the catalyzing enzyme pyruvate kinase. Where HumanCyc annotates to two instances of the protein, PKLR and PKM, and their UniProt identifiers, Reactome chooses to represent the enzyme as a complex, the pyruvate kinase tetramer.

Figure 1. A reaction (phosphoenolpyruvate + ADP → pyruvate + ATP) as represented in HumanCyc and Reactome. Cross-referenced identifiers for entities are given above or below their display names. Entities labeled BioPAX “left” are shown in red and those labeled BioPAX “right” are shown in green.
Table 1. Raw counts of proteins and small molecules in HumanCyc and human Reactome, and the corresponding frequency of UniProt/ChEBI annotations for each.

<table>
<thead>
<tr>
<th>Resource</th>
<th>Proteins Subset of proteins w/ UniProt ID (%)</th>
<th>Small molecules Subset of small molecules w/ ChEBI ID (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>HumanCyc</td>
<td>3009 (91.0%)</td>
<td>2467 (65.1%)</td>
</tr>
<tr>
<td>Reactome</td>
<td>19473 (87.0%)</td>
<td>3267 (88.5%)</td>
</tr>
</tbody>
</table>

The second part of this work focuses solely on mismatches of entity annotation. Annotation features (names and identifiers) are the most obvious way of matching entities between resources, so detecting these mismatches are important to performing resource alignment. Entities with the same string name in HumanCyc and Reactome but no shared identifiers are flagged as having potential mismatches in annotation. Samples of these potential inconsistencies are then evaluated to determine whether a true disagreement has occurred and to propose explanations for differences.

Results

The number of unique proteins and small molecules in HumanCyc and human Reactome are given in Table 1. The majority of proteins and molecules in these two resources are annotated with UniProt or ChEBI IDs. String names and identifiers were used to identify potential matches for entities with identifiers. For proteins, we found identifier matches between 2023 HumanCyc entities and 2885 Reactome entities. Of the remaining proteins, we found 208 pairs of complete case-insensitive string name matches between HumanCyc and Reactome that did not share any UniProt identifiers. For small molecules, we found identifier matches between 387 HumanCyc entities and 701 Reactome entities. Of those small molecules that did not have identifier matches, 1869 pairs of string name matches between the two resources were found, indicating potential identifier annotation mismatches.

Upon inspection of these annotation inconsistencies, we found several explanations for mismatches. For proteins, annotation with UniProt secondary accession numbers explained some of these differences. Secondary accession identifiers redirect to primary identifiers, and refer to synonymous entities, e.g., UniProt:Q96NC3 redirects to UniProt:Q6NXT4 (Zinc Transporter 6). For small molecules, the vast majority of ChEBI identifier mismatches result from annotation with conjugate acid/base pairs from ChEBI. In Figure 1, all four reaction participants show annotation to conjugate pairs in ChEBI, i.e., ChEBI:32816 (pyruvic acid) is a conjugate acid of ChEBI:15361 (pyruvate) and so on. The ChEBI identifiers can also point to tautomers, e.g., ChEBI:16828 (L-tryptophan) and ChEBI:57912 (L-tryptophan zwitterion); or groups instead of specific entities, e.g., “glyoxylic acid” references ChEBI:16891 (glyoxylic acid) and ChEBI:35179 (2-oxo monocarboxylic acid), and the former is an instance of the latter, which refers to a group of molecules.

Using string names to identify potential matches has its limitations. Some proteins in the two resources, for example, may have the same name but refer to different entities, e.g., ELK1 is an abbreviation for an ETS domain-containing protein or an Ether-a-go-go-like potassium channel. Therefore, although two proteins match on string name between the resources, there is a valid reason why they refer to different entities.

Discussion

Identifying and resolving differences between biological pathway resources is challenging. However, it is a necessary prerequisite to faithfully interpreting, integrating, and using the content of multiple resources. We described a typology of differences between pathway resources, and then quantified and explained annotation mismatches between Reactome and HumanCyc. Exploring entities that matched on string names but not identifiers offered some insight into why some of these annotation mismatches may occur. Our results suggest that computational tools can be built to aid alignment of these differences in representation. Through alignment and integration, we can better leverage our knowledge of biological pathways, and build next-generation tools for pathway analysis and drug targeting.

Introduction

Big data analytics is emerging as a critical way to address precision medicine, personalized health care, and research. Interprofessional assessments and interventions represent unique perspectives for health promotion and illness prevention, responses to diseases, self-care, population health, family and community health, and behavioral and social determinants of health. This data is frequently captured in a document type called flowsheets; however, interprofessional data is seldom integrated into clinical data repositories in a useful way that supports secondary use, such as research. Flowsheets are templated documentation forms similar to spreadsheets and include: the names of the observations are located in the first column and documentation by date and time in subsequent columns. In some electronic health records (EHRs), a screen view of flowsheet data is called a template which can be unit or discipline specific; contain groups of related assessments and interventions; and individual items (flowsheet measures) for actual documentation of care. There are beginning efforts to model flowsheet data for comparison across settings; however, there are numerous challenges to making flowsheet data useful for research. Challenges include the large volume of data which can slow the extract, transfer, and load process; duplication of semantically comparable flowsheet measures; institutions’ preferences and customizations; software upgrades; and, the lack of standard coding for the types of data captured. Thus, one post-implementation solution is to create information models that include concepts about a specific topic e.g. pain, and organize concepts in a hierarchical manner. These information models then can be used to map semantically comparable flowsheet measures to concepts and subsequently link the concepts to standardized terminologies. The purpose of this study was to derive information models from flowsheet data using a data-driven information modeling process.

Methods

An iterative data-driven consensus based method was used to create information models that hierarchically organize concepts about a specific topic and map flowsheet observations to the concepts. This method is similar to that used by Harris et al. when creating a pressure ulcer model from six EHRs. After IRB approval, a random sample of 199,665 de-identified encounters representing 66,660 patients who received care in a Midwest health system between October 20, 2010 and December 27, 2013 was transferred to a secure data shelter. The flowsheet data represents 34% of all of the observations in the clinical data repository (CDR).

Data in an EHR is designed from a clinician’s viewpoint and needs to be modeled differently for secondary use, such as research. Actual de-identified patient flowsheet data documented in the EHR were analyzed. Two master files were created in Excel to demonstrate both the documentation context and counts of unique flowsheet measures distributed across the entire EHR regardless of the context where documentation occurred. The data were extracted from a CDR to create these master files. The documentation context included the names and unique identification (ID) numbers for templates, groups of similar observations, and the flowsheet measures. The file of just the unique flowsheet measures included names and IDs aggregated across the EHR along with their value type (i.e. date, numeric, choice list, etc.), the responses documented, and the frequency of use.

Multiple steps were used to create the information models: identifying topics and related concepts, searching master files for relevant flowsheet measures, and creating a new Excel file linking flowsheet measures to flowsheet measures to Concepts and organizing the Concepts into Classes (groups of observations). Selection of topics was based on five quality measures prioritized by one of the health system research partners, documentation for five high volume physiologic systems, and four behavioral health national priorities. Relevant concepts were identified from knowledge sources, clinical expertise, and discovery when searching the flowsheet data. A manual process was used
to search the master files for flowsheet measure representing concepts and concept synonyms; flowsheet measures were copied and pasted into a new Excel file linking the measures to the information model Concepts. The Concepts and linked flowsheet measures subsequently were organized logically into Classes in the information model. This process is similar to that used for creating a pressure ulcer information model in the Federal Health Information Model (www.fhims.org/press_ ulcer.html). A second investigator reviewed the findings for each information model by affirming the mapping of flowsheet measures to Concepts and in addition, searched for any flowsheet measures that may have been missed. Results were presented to the entire team during weekly conference calls to obtain consensus on the information models and mappings. After all models were created, they were further reviewed by two of the investigators (BW & SS) and any changes were presented to the research team for consensus.

Results

There were 14 information models created and validated by the research team using a consensus process. These models include the following topics: Cardiovascular System; Gastrointestinal System; Genitourinary System (including CAUTI); Neurumusculoskeletal System; Peripheral Neurovascular System (including VTE); Respiratory System; Pressure Ulcers; Pain; Falls (Safety); Vital Signs, Height/ Weight; Aggression and Interpersonal Violence; Psychiatric Mental Status Exam; Suicide and Self Harm; and Substance Abuse. An example of one information model for Genitourinary System (including CAUTI) is shown in Figure 1.

Conclusion

In this study an iterative data-driven process was used to develop and validate 14 information models. While the 14 models were developed using consistent rules, there is no overarching information model that links between the models. The next steps include validation of the information models by six additional large organizations to increase the generalizability. Subsequently LOINC and SNOMED-CT will be used to link the observations to national terminologies. These information models build on work by Harris and colleagues and extends the LOINC coding of assessments captured in flowsheet data initiated by Matney and Settergren’s workgroup, which is part of the Nursing Knowledge Big Data Science Conference.

Introduction

Electronic health records (EHRs) offer to streamline referral processes by facilitating information exchange between referring and consulting providers, allowing them to document and communicate findings. In practice, poor coordination and communication gaps continue to challenge EHRs’ effectiveness, resulting in delays in care. In the U.S. Department of Veterans Affairs (VA) health system, among a sample of referrals in 2013, consultants evaluated Veterans within 90 days in only 28 (19%) of 150 referrals reviewed. The objective of this study was to identify barriers and facilitators to effective referrals and consultations between primary and specialty care clinics, and to suggest how EHRs can make this process more efficient.

Methods

Our interdisciplinary study team included experts in human factors, informatics and clinical medicine. Eight individuals conducted semi-structured interviews and ethnographic observations of referrers, consultants and other key roles involved in managing referrals from primary to specialty care at two large, geographically dispersed VA medical centers serving urban and rural patients. We sampled participants by inviting clinicians, nurses, triage teams, and support staff involved in the consultation process to participate. We recruited in-person and via email from primary care and six subspecialties selected to obtain a balance of high-volume medical and surgical services (Table). Four researchers analyzed interview data using inductive qualitative methods, synthesized emergent themes related to barriers and facilitators, created a codebook, and resolved coding discrepancies by consensus. They also reviewed observation field notes to create vignettes and workflow diagrams of the consultation process, providing context for interpreting interview data. VA Central Institutional Review Board approved this research.

Results

We conducted 61 interviews and 38 observations with 53 primary care and 46 specialty care clinicians, nurses and support staff (Table). Participants identified barriers and facilitators of EHR-based communication, additional modes of information exchange, and factors outside the EHR that influence the quality of the referral process. EHR-based request forms are customized by each specialty service. Referrers and consultants cited common frustrations with the ability of the forms to facilitate communication about a referral. Referrers noted great variability in quality of forms. Some forms “ask a bazillion questions” while others “will tell you what the prerequisites are and some of them won’t.” Forms that facilitated referrals were “brief,” asked for “just the most basic information,” and allowed users to enter text in form fields. Consultants, however, noted receiving incomplete referrals, including forms that did not specify a clear medical question. If a referral was incomplete or should be handled by another service, a consultant may deny the request through the EHR. Referrers, however, complained that, “Rather than sending you a note saying, ‘Hey, we need this test done first,’ [consultants] cancel it” without further explanation.

To avoid these communication breakdowns, some providers used additional EHR features to communicate about a consultation, but noted that this non-standard practice can lead to lapses in communication: "I can write a note on the consult, and the person who wrote the consult should see it and respond. Should. I know from habit certain people do and certain people don’t."
Because information exchange via the EHR was insufficient, providers also used phone, email, IM or in-person methods, often trying multiple modes due to variability in communication preferences. Providers noted that face-to-face contact with other services facilitated referrals: “I’ve been successful if I’ve gone to visit them physically, if I took the elevator ride and went knocking on somebody's door and said here's what I need.”

Referrers and consultants reported disagreement about responsibility for tasks such as ordering tests and communicating results to patients. One referrer said, “[Consultants] should just…order whatever test that they are gonna be the ones that are gonna be following up on it.” Understaffing and VA-wide mandates to see a patient within a certain number of days also put pressure on consultants to deny referrals or transfer patients to other services for care, leading to further delays. Finally, referral requests to non-VA specialists create their own challenges. Lack of EHR interoperability between VA and outside health facilities force providers to use fax and scans, and even rely on patients to carry their own information.

Discussion

Although EHR-based request forms are designed to improve quality and speed of referrals, participants indicated that their automated and rigid nature fostered rather than eliminated inefficiencies. Improvements to referral processes should include a fresh examination of how to design and use EHRs to enhance communication between referrers and consultants, while optimizing completeness of information. In addition, EHR systems cannot completely replace interpersonal communication regarding consultations. Instead, services should establish agreements about roles and responsibilities within the referral, consultation and follow-up processes. Problematic referrals should prompt direct discussions between consultants and referrers, potentially decreasing cancellations and wait times for patients. EHRs should include more guidance for referrers, as well as pre-populated diagnostic test results or other pertinent details.

Our findings have relevance for both VA and non-VA care. Many problems identified relate to lack of EHR interoperability and can be seen in health systems nationwide. Significant wait times for care outside the VA may also be related to EHR-based processes. In a 2014 national study, the average cumulative wait time to see a physician in five specialties was 18.5 days, with a range of one to 256 days. Our study has limitations. Participants may not reflect all specialties in medicine, and the targeted medical centers may not reflect all medical centers, but we have no specific evidence that our findings are skewed.

Principles of effective consultations have been known for decades, but our findings suggest that opportunities still remain for improving referral communication between requesting and consulting services.

Policies and Procedures on Governance of Data Use to Support Health Information Exchange in Low- and Middle-Income Countries

Lauren A. Wu, MHS1,2, Theresa Cullen, MD, MS1
1Regenstrief Institute Global Health Informatics Group, Indianapolis, IN; 2Office of the National Coordinator for Health Information Technology, Washington, DC

Abstract

Low and middle-income countries (LMIC) are increasingly contemplating electronic health data sharing architectures using the health information exchange (HIE) approach. Successful large-scale interoperability depends on effective policies and procedures for data sharing. We undertake a review of policies and procedures for HIE in LMIC to determine the current state of and identify a high-level potential pathway to successful development and implementation of policies and procedures focused on data use and governance.

Introduction

Clinical care, community surveillance, and program evaluation activities are enhanced by a milieu where health data is easily shared. Health information exchanges (HIE) are a common architectural approach for electronic health data sharing, but their success is dependent upon the development and implementation of data governance at a country or institutional level. As low- and middle-income countries (LMIC) move towards increasing HIE and interoperability, developing a logical framework to resolve these sociotechnical ambiguities for a given environment becomes more critical.1,2 We undertook a global review of policies (e.g., laws, national strategies, legal agreements) and procedures (e.g., implementation guidance, standards) (P&P) for health information exchange in LMIC, focusing on data use and governance. Our goals were to add to the existing knowledge and identify key focal areas for a potential framework that country decision-makers should consider when developing effective P&P for HIE.

Methods

We performed a mixed-method review of P&P for HIE in LMIC as defined by the World Bank from February-March 2016. HIE was defined as either the verb of electronically exchanging health-related data or the noun in the form of organizations dedicated to the secure exchange of health-related data (http://www.himss.org/library/health-information-exchange).

For the non-systematic literature review, we reviewed the published literature indexed in PUBMED and MEDLINE using keywords “low- and middle income country,” “health information exchange,” “interoperability,” “big data,” “policy,” and “governance.” We also reviewed articles referenced by the published literature as well as the gray literature including countries’ eHealth strategies, legislation, and other P&P relating to HIE.

For the semi-structured interviews, we contacted individuals working in LMIC through the OpenHIE community (http://ohie.org). The OpenHIE community improves the health of the underserved through open and collaborative development and support of country-driven, large scale health information sharing architectures. Experts varied in expertise but generally have been involved in the development and implementation of country eHealth strategies or direct implementation of HIE systems within countries. Experts were invited to individual or small group (by country or geographic area) hour-long semi-structured phone interviews regarding P&P for HIE. When phone interviews were not possible, experts provided written information via e-mail. This review was qualitative in nature and thus the results presented represent the general themes and overall findings. It does not represent a quantitative perspective.

Results

Literature Review and Interviews. We reviewed 32 articles (9% from LIC, 22% from MIC, 38% from a mix of MIC and LIC, 31% generally applicable to all countries) and 125 documents from the gray literature (72 P&P documents; 20 reports, guidance, and toolkits; and 33 eHealth strategies). Twenty-nine LMIC interviews (or email interactions) were performed (21% from LIC, 38% from MIC, 35% from a mix).

Use Cases for HIE. We gathered information on 28 LMIC and one regional network in Asia. The use cases and value proposition for HIE vary and appear to reflect country and funder priorities. For example, in some African and Caribbean LMIC, HIE focuses on infectious diseases, often due to program monitoring and evaluation (M&E) requirements of donors. Other LMIC, such as in Asia and South America, are developing enterprise-wide HIE with

160
a goal of universal health coverage. Most LMIC are prioritizing data exchange within the country rather than cross-border data exchange. Only one regional network in Asia was identified as working on two fronts—exchange within countries and cross-border exchange through a regional HIE “lab” structure that has a foundational commitment to the use of common standards and formats.

**eHealth Strategy and Data Stewardship/Ownership.** Countries’ eHealth strategies and HIE approaches generally address high-level governance and partnerships; enterprise architecture; patient identification; standards for interoperability; and privacy and security (P&S). In most countries, the data collector or the place where data is physically located is seen as the “owner” or steward of the data. Generally, this has been the Ministry of Health (MoH) in the public sector; where there is a strong private sector, regional or local hospitals and clinics can also “own” or steward the data. However, there is an increasing shift toward discussing the patient as the true owner of their health data. Despite the shifting mindset, few LMIC offer individuals access to their electronic health data.

**Governance.** While all countries’ eHealth strategies featured some governance structures, their implementation and maturity vary. In countries focusing on enterprise-wide architecture and universal health coverage such as in South America and Asia, governance tends to take priority and is implemented early. Countries with a strong centralized government and/or MoH have been able to develop and implement governance from the “top-down,” but enforcement remains an issue. Where there are health issue silos and a strong dependence on donor and private sector funding, governance may not exist nationally and may vary in structure by the health issue.

**Data Use, Exchange, and Patient Identification.** A number of countries have concerns about how data will be reused; this has manifested through policies that require individual-level data remain at the site where the data was collected to one-way data flow to the national/MoH level but not back down to the point of care for real-time care decision makers. Data are frequently reported to the MoH at aggregate levels, supporting M&E reports for donors. However, most LMIC envision HIE supporting individual level health exchange. As expected, patient identification was identified as an important concept for matching records.

**Legal Tools for Data Exchange, P&S.** Where the MoH is the main player and policy setter, there normally exist data use and exchange guidance promulgated from the MoH. However, only one LMIC informant in the review indicated a legal data use and exchange agreement was in place. While many LMIC are investing in data infrastructure and standards, the majority indicated challenges in establishing business agreements for data exchange. Some LMIC have laws or policies in place regarding P&S of health information. There appears to be a dearth of overarching legal frameworks for P&S, though procedures have usually been established through individual projects and implementations.

**Discussion**

These findings provide a snapshot of HIE efforts in LMIC across the globe, illustrating significant variability in the completeness of and success implementing policies and procedures that support in-country HIE and governance of data use. Great attention is being paid to HIE; however LMIC have experienced challenges moving from strategy to implementation. Variation exists around the establishment and implementation of P&P for use cases, governance models, data stewardship, patient identification, composition of legal agreements, and the role of P&S. This review identified a major high-level barrier is the lack of an agreed-upon policy or procedure in the aforementioned areas at the country level directing HIE decision-making and implementation, indicating a need for tools to help countries establish and implement such policies and procedures.

Technology solutions are available for HIE but the implementation of business processes and legal tools, such as data use agreements, have lagged behind the technology. Based on these findings, we suggest that 1) countries and regions should ensure there is a consistent governance model for HIE and interoperability, and 2) development of a global framework for the key policy and procedure decisions supporting HIE and interoperability can accelerate the actualization of data sharing, leading to improved data use and better health outcomes. A global framework for HIE policy and procedures will also need to examine the costs and feasibility of policy and procedure decisions.

Probabilistic Population-level Modeling of Disease Event Timelines

Stephen T. Wu, PhD\textsuperscript{1,2}, Yanshan Wang, PhD\textsuperscript{2}, Sunghwan Sohn, PhD\textsuperscript{2}, Chung-il Wi, MD\textsuperscript{2}, Elizabeth Krusemark\textsuperscript{2}, Hongfang Liu, PhD\textsuperscript{2}, Young J. Juhn, MD\textsuperscript{2}
\textsuperscript{1}Oregon Health & Science University, Portland, OR; \textsuperscript{2}Mayo Clinic, Rochester, MN

Introduction
The relative timing of a patient's clinical event can be crucial in diagnosing and treating chronic diseases. But timely identification of disease events is a challenging task, even for medical professionals: Molis et al. reported that 65% of their asthmatic population had a delayed diagnosis of asthma with the median delay of 3.3 years (1). In this work, we take a data-driven approach, probabilistically modeling the temporal relationships between clinical events in patient timelines. To aid generalization across patients, we build our models on population-level data.

As part of our previous work on patient-level temporal aggregation (2), we utilized kernel density estimation (KDE) to estimate relationships between observed natural language processing (NLP)-derived features (e.g., nighttime cough, bronchodilator use) and asthma status. More specifically, we defined probability density function (PDF) embodying temporal relationships between an observed asthma-indicator-feature and an observed asthma status (where observations are themselves events extracted from the text of clinical notes in the EHR).

In this work, we present a generalization of our previous temporal modeling framework (2) to arbitrary sequential events (e.g., any time-stamped symptom, test, or disease status). Also, we report the implementation of this probabilistic, population-level model in a corresponding to-be-released open-source software package, adept (Aggregation of Disease Evidence for Patient Timelines), and illustrate its capabilities on the use case of pediatric asthma progression (i.e., disease status progresses as: no asthma, positive asthma, remission, then relapse).

Structured clinical data has been visualized effectively by systems such as LifeLines (3) or TimeLine (4), these tools primarily enable interaction with the data. While our work also deals with categorical variables expressed temporally, our work enables automatic computation utilizing the data. Namely, probabilistically modeling these temporally situated events lays the groundwork for more accurately reasoning at the patient level.

Methods
First, we extend our previous framework (2) to allow for multiple sequential events in a patient timeline, beginning with the Index Date Temporal Density. We defined probability density functions (PDFs) connecting features to asthma statuses as \( p(t) = P(\text{index\_date} = t | f(0) = 1) \). The index\_date is defined as the first date on which a patient should have been considered to have asthma, by manual record review. Binary features (such as a "wheezing" symptom) as discovered by NLP techniques in a clinical note are denoted as \( f(\tau) \), where \( \tau \) is a relative indicator of time. Below, \( t \) is the time elapsed since feature \( f \) was observed at time \( \tau = 0 \).

We could rewrite this equation to straightforwardly extend the model to multiple event types:

\[
\text{Event Start Temporal Density} \quad p(t) = P(\text{start\_date}(e_b) = t | e_a(0))
\]

For asthma, \( e_b \) could be \{no, asthma, remission, relapse\}, and \( \text{start\_date}(\cdot) \) would choose the first date with documents attested in features taking a particular value.

More generally, we model the probabilistic temporal relationship between two event timelines, \( e_a \) and \( e_b \), which are each an array of time-stamped event values. Since event timestamps in \( e_a \) and \( e_b \) may not coincide, we first do an extrapolating step, inferring event values at a specified set of dates/times. Subsequently, we do a differencing step, in which the temporal gap between event timelines are calculated as samples.

For example, consider the timelines \( e_a = (\text{broncho}, t_0), (\text{broncho}, t_2), (\text{nobroncho}, t_3), (\text{broncho}, t_4) \) and \( e_b = (\text{asthma}, t_1), (\text{remission}, t_2), (\text{relapse}, t_4) \). These show the correlation of bronchodilator use with asthma progression. The \( \text{start\_date}(\cdot) \) function is a no-op extrapolating step. The samples used to estimate the temporal densities for remission are the output of the differencing step: \( t_3 - t_0, t_3 - t_2, 0, t_3 - t_4 \). Further generalizations of the models, which we elide here for space, employ other extrapolating and differencing strategies and allow us to handle absent symptoms differently than missing data.
We implemented the estimation of temporal densities (and the aggregation methods from previous work) in a new Python package called \textit{adept}, which will be released to the open-source community as future work.

\textbf{Results}

Preliminary analyses were carried out on a small subset (n=35) of the Mayo Clinic Sick Child Cohort used in previous studies. Each member of this subset had been identified by manual chart review as having asthma; in addition, 17 of these progressed to remission; 10 of those 17 patients then progressed to relapse. We excluded 2 cases where the patient experienced a second remission after relapse.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{temporal_densities.png}
\caption{Several temporal densities. In each plot, time $t=0$ corresponds to the time at which a FEATURE (e.g., \textsc{asthma\_medication} in the legend) is observed to be present. Each line is a different FEATURE $e_{jt}$; features shown here were the most common of those designed to detect remission and relapse. Each plot shows a different asthma status as $e_{jt}$. The x-axis is relative time in days, while the y-axis is probability mass (area should sum to 1.0).}
\end{figure}

Figure 1 shows temporal relationships between features (each line) and 3 stages of asthma progression (each plot). The features plotted here were designed by medical experts to detect asthma remission and relapse. The top plot shows significant probability mass to the left of $t=0$ for all features. This indicates that significant symptoms and tests were observed subsequent to the initial diagnosis of asthma. The middle plot shows significant probability mass at about 1000 days after a feature is observed; thus, remissions typically occurred about 3 years after (corroborating our clinical criteria for remission) asthma symptoms abated. The bottom plot does not have a consistent trend, showing that the relationship between this feature set and relapse may not be meaningful.

\textbf{Conclusion}

We have probabilistically modeled the relationships between multiple, temporally-situated chronic disease events at a population level, and reported its implementation in \textit{adept}. In future work, we will utilize a larger data set, explore multivariate modeling, and measure the effect of these models on evidence aggregation.

Transferring Homegrown Medication Knowledge Assets to a Commercial EHR: Overview of the Approach and Lessons Learned

Eileen Yoshida, RPh, MBA, Karen Bavuso, RN, MSN, Shirley Xiang Fei, RPh, PharmD, Ronelle Stevens, RPh, PharmD, Ana Delgado, RPh, PharmD, , Irina Kofman, RN, Saverio Maviglia, MD, Roberto Rocha, MD, PhD

Introduction
In 2012, our institution decided to replace our internally developed clinical systems with an integrated commercial electronic health record (EHR) system, supported by a commercial medication knowledge base vendor. We will describe our experience in migrating internally curated medication clinical decision support (CDS) assets to a commercial EHR that primarily utilizes medication CDS assets from a commercial knowledge vendor.

Methods
Partners Healthcare is a Boston-based integrated healthcare delivery network. For many years, the different facilities have been using different clinical systems within their organizations, duplicating efforts to develop and maintain knowledge assets and functionality, and also propagating inconsistency in practice. Over the years, several proprietary medication knowledge bases and CDS were shared among some of our institutions. These activities have been described and evaluated in detail. We performed a gap analysis for five of our proprietary knowledge bases to identify the key differences in functionality between current and future state. A structured form guided the analysis. Representatives from the EHR vendor participated. Potential future state implementation options were identified. The executive summary of the gap analysis and proposed options were presented to the governance committee responsible for CDS within the new EHR. The CDS Committee includes approximately 40 clinician members from across the enterprise, representing a variety of clinical roles, including our Quality and Safety group.

Results
Please see summary table of decisions made for the five knowledge bases (Table 1). There were differences in both content and functionality that needed to be reconciled. The most prominent functionality differences were (i) the lack of tiered user interfaces for different severity levels in the vendor system (all alerts are interruptive, and hard stops are not supported), (ii) the presentation of all medication warnings generated in an order session altogether at the time of signing instead of individually at the time the warning is generated by an order, and (iii) the inability to accommodate non-commercially available medications (such as investigational drugs and compounded agents).

Discussion
Kuperman et al proposed customizing commercial medication knowledge bases for local use and also as a means to share the burden of knowledge development and maintenance. Our presentation will summarize our experience in the context of these recommendations and feedback from users. We were able to customize the commercial medication knowledge base to filter out specific interventions, and to adjust severity levels using both knowledge base and EHR tools. In some cases, we successfully added new rules to the vendor knowledge base, or created new rules to maintain existing content. Varying levels of effort were required. In other cases, we were not able to replicate original content and functionality due to tool limitations. It was sometimes difficult to ascertain if a rule from our homegrown systems existed in the vendor knowledge base since the rules were expressed in different formats and terminologies. Better tools for browsing and comparing the knowledge and standardized rule architecture and terminologies would be helpful. Content that was readily accepted in our homegrown systems was not always accepted in new system, given functionality differences. While progress has been made, our work demonstrates that opportunities for future development still exist. Commercial medication knowledge base solutions may be a good starting point, but organizations like ours invariably need to be able to extend the knowledge and customize using both knowledge base and EHR tools.
Table 1: Summary of Results

| Duplicate Therapy: 34 classes based on medication vendor classes, augmented with non-commercial medication concepts (investigational drugs and compounded medications); customizable messages; alerts fired interruptively and individually as each order entered. | Vendor EHR recommends enabling all available 861 duplicate therapy classes from medication vendor using 2 different severity levels; alert fires in the Medication Warning screen during order signing (with all other medication warnings generated in the ordering session). | Implemented 34 duplicate therapy classes to match initial state using one severity level; non-commercial medications were included; after 7 months of experience, are starting to turn off these alerts in certain phases of care; small work effort to mimic the current state content, using EHR tools. |
| Drug pregnancy alerts (n=1800): Warnings fire for patients who are pregnant (as inferred by lab values), or of child bearing age, for medications with FDA drug pregnancy category D, X at time of ordering; in addition, implemented a custom category of very high risk medications; 3 levels of severity displayed in tiered presentation. | Medication vendor knowledge base contains FDA drug pregnancy category information for all medications; vendor EHR recommends displaying warning in the Medication Warning screen for categories D, X only; warnings appear together with all other medication warnings at the time of signing new orders, if “Pregnant flag” has been manually set by a user (lab values and age/gender are not considered). | Implemented drug pregnancy warnings for categories D, X; alerts fire based on manually set “pregnancy flag”; to accommodate the custom category of high risk medications, a different type of alert was used; small work effort to configure medication warnings to fire for only categories D, X; medium work effort to develop additional alerts for very high risk medications; using vendor EHR provided tools. |
| Drug-drug interactions (n=8,500): 3 levels of severity were displayed in tiered presentation to ordering providers at the time of ordering; locally vetted knowledge base; includes medication concepts not available in commercial knowledge base. | Medication vendor knowledge base contains ~500,000 DDIs categorized into 4 severity levels; Vendor EHR recommends customizing medication vendor content using medication vendor tools; alerts display to user together with all other medication warnings in the Medication Warning screen at the time of signing (but no ability to implement hard stop or non-interruptive warnings). | Implemented only those DDIs available in initial state; non-commercial medications included; unable to implement all DDIs (~36% not available in vendor knowledge base); submitted to vendor knowledge base for consideration, not all accepted; after 7 months, based on feedback from users citing alert fatigue, filtered out DDIs which were non-interruptive in initial state; large work effort using medication vendor tools. |
| Dose modification for elderly and renally impaired patients (n=350 and ~280, respectively): Modified dose list with default dose and modified frequency presents based on patient’s age or renal function, respectively; interruptive alert will also appear if substitute medication is recommended; locally vetted messages; trumping rules can be set between 2 knowledge bases so only one set of rules fire. | Vendor EHR recommends using medication vendor dose range checking module for both; also recommends geriatric precaution module for elderly; former provides inline warning messages when ordered dose falls outside set of “min/max” range; non-interruptive if dosing is within range, but interruptive if dosing exceeds min/max; latter provides interruptive alert for medications contraindicated or strongly recommended to be avoided in elderly. | Implemented dose range checking; implemented geriatric precautions for medications in initial state; to accommodate substitute medication functionality we implemented a different type of rule; small work effort to configure vendor knowledge bases; large work effort to develop additional alerts for substitute medication functionality. |

Data-driven Clinical Pathway Learning and Outcomes Prediction for Chronic Kidney Disease

Yiye Zhang¹, Rema Padman²
¹Department of Health Policy and Research, Weill Cornell Medicine, New York, NY, USA; ²The H. John Heinz III College, Carnegie Mellon University, Pittsburgh, PA, USA

Introduction
The best available medical evidence for clinical management of complex, multi-morbid patients is conveyed to frontline healthcare providers through clinical practice guidelines (CPGs) and CPG-derived clinical pathways. Currently, most clinical pathways adapt evidence-based recommendations from CPGs to local practice workflows, and are used by more than 80% of all US hospitals. Clinical pathways aim to reduce variations in treatments, support clinical decision making when faced with multiple or ambiguous care options, improve quality of care, and control costs. However, there are significant challenges in using them at the point of decision making and tracking the continuously evolving impact of interventions on disease progression. CPG-driven clinical pathways are known to suffer from drawbacks such as lack of physician agreement, and most importantly lack of consistency on the strength of evidence underlying them.

An exemplar is Chronic Kidney Disease (CKD), a complex chronic condition that affects 1 in 10 US adults, where patients gradually lose their kidneys’ functions in 5 stages. Most CKD patients suffer from comorbidities such as hypertension and diabetes, resulting in higher medical expenses than many other health conditions. In addition, CPGs for CKD are often consensus-based, due to the lack of large and high-quality clinical trials. Early identification and treatment of individuals at risk as they progress through the 5 stages of CKD can potentially mitigate adverse events such as episodes of acute kidney injury (AKI), hospitalizations, and death. This research investigates data-driven clinical pathway development by analyzing CKD patients’ demographic and detailed treatment data captured in electronic health records (EHR) as part of routine care delivery. We propose a clinical pathway learning algorithm that models 5 types of clinical information: encounter type, diagnosis, procedure, medication, laboratory records, and time, to deduce data-driven clinical pathways and provide predictions for patients’ future health conditions. Leveraging a rich and unique clinical dataset extracted from the EHR of a community nephrology practice, this study learns clinical pathways from data by modeling the longitudinal, multi-dimensional treatment process as a hidden Markov model (HMM).

Methods

Existing clinical pathway learning models tend to produce spaghetti-like structures that are too complex to interpret, make unrealistic assumptions for disease management, or are challenged by the number of clinical activities that can be analyzed and discovered. In this research, each patient’s clinical history is organized as a chronologically ordered pathway of visits to providers and hospitals. Patients’ pathways diverge as their health conditions and corresponding treatments evolve in different ways. Therefore, we use longest common subsequence (LCS) distance metric to measure pathway similarity regarding clinical factors and treatment frequencies. Further, hierarchical clustering is used to cluster patients into subgroups based on the similarity of their pathways, measured with LCS distance. Within each subgroup, each patient pathway is modeled as a HMM, comprising of a sequence of observations and a corresponding sequence of hidden states. The sequence of hidden states is a time-homogeneous
\( k \)-th order Markov chain\(^4\), where \( k \) stands for the number of relevant prior visits for making clinical decisions for the future. Each hidden state variable captures information about each pair of transitional visits: encounter types, diagnoses, procedures, medications, and duration between two visits. Each observation variable captures information about one or multiple laboratory measurements categorized into appropriate levels such as “normal” and “abnormal.” Figure 1 depicts the modeling framework. In this research, we derive data-driven clinical pathways by computing the most probable sequence of hidden states that corresponds to a sequence of observations in an HMM, using the Viterbi algorithm\(^2\). Maximum likelihood estimate of the parameters in the HMM are obtained using the Expectation Maximization (EM) algorithm\(^4\). In addition, the modeling of the Markov chain state variables facilitates prediction of patients’ next visit. As illustrated in Figure 1, computing the last hidden state variable (in red), which captures the contents of visits \( t+3 \) and \( t+4 \), provides prediction for visit \( t+4 \) (in yellow), the visit that has yet to occur. In other words, it allows us to identify the most likely events to happen in a potentially critical upcoming visit such that patients who may be at risk can be identified early.

Results
Data from 2009 to 2013 on 663 CKD patients were extracted from EHR. Variables include encounter types: office visit and hospitalization; diagnoses: ICD9 codes for CKD stages 1-5, End stage renal disease, Hypertension, AKI, Hyperparathyroidism, Anemia, Proteinuria, Acidosis, Hyperphosphatemia, Glomerulonephritis, Urinary obstruction, Volume depletion, Rhabdomyolysis as diagnoses; drug classes of medications: ACE inhibitors, ARB, Diuretics, Statins, and Proton pump inhibitors (PPI); procedures: Doppler and ultrasound; and laboratory measurements: Albumin, Calcium, Bicarbonate, Creatinine, and Phosphorus. All states and observations in the HMM are categorical variables. Laboratory measures were classified into “low”, “normal”, and “high” according to a current clinical practice guideline in CKD\(^5\). Clinical pathways were generated using patients’ initial 3 visit records. From this dataset, clustering analysis identified 4 subgroups. Within each subgroup, pathway learning and prediction were evaluated using a 5-fold cross validation. Predictions of next visit indicate an accuracy rate of up to 60%, 50% and 72%, depending on if we include as diagnoses all diagnoses mentioned above, CKD alone, or AKI alone, and under a fixed time interval between visits. All other variables from encounter types, drug classes and procures are always included in analysis. When considering episode of AKI as a main outcome, average false positive and negative rates across 4 subgroups are 1% and 30%, indicating our method’s potential but also due to low incidence rate of AKI in certain subgroups. Accurate learning of entire clinical pathway is still underway, and current accuracy is up to 67% for 3-visit pathway when considering AKI only as diagnoses, and all variables from 3 other categories. We anticipate further evaluations and improvements with larger datasets and parameter tuning.

Discussion
Significant diversity and complexity in patients’ EHR data, lack of comprehensive quality standards and performance measures, ad hoc care delivery processes, and the continuously evolving scientific knowledge pose a challenge for efficient pathway learning and prediction. While partly due to the nature of the disease and variability in patients’ conditions, it also urges a review of practices, for treatment variations, inconsistent EHR usage, and improved data capture. Data-driven clinical pathways have the potential to help healthcare providers review their current practices against CPGs, standardize them, and customize them into personalized, patient-centered pathways of care delivery. Future steps include evaluation of the derived pathways by expert clinicians, inclusion of medical costs and critical clinical outcomes into the pathway model, and extension of analytical methods for better accuracy.

Accountable Care Organization Provider Network Design:
A systematic data-driven approach

Thomas White, M.D.\(^3\), Jeremy Pickreign\(^3\), Gigi Yuen-Reed, Ph.D.\(^2\)

\(^1\)IBM T.J. Watson Research Center, Yorktown Heights, NY, USA; \(^2\)IBM Watson Health, Yorktown Heights, NY, USA; \(^3\)Capital District Physicians’ Health Plan, Inc. (CDPHP ®)
Albany, NY, USA

Introduction

In recent years, there has been an increasing emphasis on enabling value-driven health, aimed at improving outcomes, lowering costs, and increasing overall access to care for patients. A prominent example of value-driven delivery systems is the formation of patient-centric Accountable Care Organizations (ACOs). ACOs are groups of physicians, facilities and other healthcare providers, who come together to provide coordinated care to their patients. This study uses prior care patterns to identify groups of provider communities that service the same set of patients. Providers belonging to these naturally-occurring preexisting networks may be more ready to be accountable for managing the health of a population by sharing the risks and benefits of being part of a shared savings program\(^1\), \(^2\).

The proposed method utilizes past care delivery data to detect communities of providers with a higher than expected number of shared patients. We examine the makeup of provider specialties, services, patients, and provider organizations (typically a legal entity composed of multiple providers) related to each community. We prioritize the provider organizations based on their participation and contributions to the patient care in the community in order to find sets of legal entities that are good candidates for shared savings contracts. Communities may share a set of patients for several reasons—professional connections, geographic convenience, or focus on treatment of certain condition(s).

Methods

The data included one year of health insurance claims and enrollment data from a commercial health insurance payer. We study over 100,000 adult patients enrolled in commercial health plans, living in an area where the payer has a large presence. One commercial payer may have limited information about the providers’ interactions and relations to other payers. However, providers often have imperfect health information exchanges, and a payer may be able to provide insight about where their patients receive other services. To focus on patients’ individual providers and specialist referral patterns, we limit our analysis to individual providers (Type I NPIs) and exclude hospitals and pharmacies. We extract the patient identifier, the NPI and the date of the visit from the claims data to construct a mapping between patients and providers. The connections between pairs of providers are weighted by the number of patients the two providers shared. Fast greedy community detection\(^3\) is used on the graph of providers to find communities of NPIs. This is a bottom-up approach, merging sets of NPIs in order to increase the modularity score. This method produces communities of varying size, some of which are too large for contracting purposes. We run the detection algorithm recursively with the requirement that each resulting community has at least 25 NPIs. Any lower bound could be used for community size, but even small numbers of NPIs sharing patients may indicate potential for closer collaboration between their larger organizations.

For contractual reasons, shared-savings programs typically work with provider organizations, the legal entities of the servicing provider groups (taxID). In order to prioritize taxIDs for inclusion in an organization-level ACO, we introduce two key measures for each community and taxID: 1) participation in the community, i.e., the percentage of NPIs contributing to the community; 2) coverage in the community, i.e., the percentage of NPIs contained in the community. For each NPI-level community, we use an F-score based on these two measures. Intuitively, organization-level ACOs approximate the NPI-level communities by maximizing the number of overlapping NPIs while minimizing the number of non-overlapping NPIs. The F-score equation is: 
\[
(1 + 4) \left( \frac{\text{participation\%} \times \text{cover\%}}{4 \times \text{participation\%} + \text{cover\%}} \right)
\]

Results

Considering the 5,500 individual providers servicing over 100,000 patients, our method detected 132 provider communities, ranging from 25 NPIs to over 500 NPIs. Figure 1 shows the dynamics of the recursive community
detection, with each node as one community. The inner circle shows the community candidates from first round of detection, and bigger communities are then further split up into smaller ones. Figure 2 shows an example of how many and which taxID should be contracted together for one community. The F2 Score, which is a weighted measure between participation and coverage, is used to determine the inclusion rules for provider organization.

The resulting communities were heterogeneous across multiple dimensions (geographic location, major conditions of patients, risk scores of patients, % of NPIs with primary care specialties, % of patient care provided by community NPIs). In order to better understand the key factors that drive the formation of such network structure, we explored provider level information for each community, including providers’ affiliation, servicing specialties, and whether providers were primary care providers. To better describe the patient composition in each community, we compiled patient level information (based on the primary care provider of the patient), such as home location, claims cost, conditions, and health risk scores. We segmented patient population by demographic and risk factors to understand the challenges faced by the different communities. Although the literature on what makes a successful ACO is still limited, these traits were examined to determine the strengths and challenges of each community.

Conclusion

We proposed a data-driven method to enable a systematic approach in identifying candidates to form ACO-like provider groups, based on patients’ past utilization history. As much as possible, patients could continue receiving care from their primary care provider and primary care providers could continue making referrals to the same specialists. The payer can now provide evidence of a set of shared patients receiving many of their services from a set of NPIs or taxIDs, in order to increase buy-in to participate in shared savings. We developed key measures to support a payer contracting provider organizations to create shared saving programs. The proposed method will help reduce care disruption in the ACO and have a higher chance to deliver high quality and coordinated care. These programs can help providers succeed by preparing them for a market moving toward value-based care.

Automatic identification and extraction of design patterns of EHR-driven phenotyping algorithms

Yizhen Zhong, BS1; Luke Rasmussen, MS1; Justin Starren, MD, PhD1; Yuan Luo, PhD1
1Northwestern University, Feinberg School of Medicine, Chicago, IL

Introduction: The electronic Medical Records and Genomics (eMERGE) network [1] is an NHGRI-sponsored initiative to further the development and implementation of EHR-derived phenotypes across multiple institutions. The phenotyping algorithms developed, validated and implemented through multi-site collaboration are primarily recorded as text documents [2] and are re-implemented in a computable format at each site. There is a need to apply best practices to ensure consistent implementations derived from narratives. This is complicated not only by the nuances of how data is collected within the EHR, but also by the heterogeneity across EHR vendors, implementations and individual use. Awareness of these differences and accounting for them up front in the phenotype development process may increase the efficiency of the development process, and the accuracy of the resulting phenotype.

Methods: To facilitate consistent and reproducible phenotyping algorithm development, we previously proposed “phenotype design patterns” [3]. A phenotype design pattern is intended to address a commonly seen issue in the use of EHR data, and provide guidance to a solution. The initial proposed set of phenotype design patterns was developed by a review of existing phenotypes, and leveraged expert opinion. The process was time-consuming, and would not scale as more phenotype algorithms are defined. Thus, automated approaches to identify and extract candidate patterns would advance our understanding on best practices in the field of phenotyping. Using the narrative description of each phenotype algorithm downloaded from Phenotype KnowledgeBase (PheKB.org) with a status of Final or Validated [3], one of the authors (LVR) extracted fragments that described aspects of the data elements and/or logic used in the algorithm. In this pilot study, we focused on the phenotype design patterns as shown in Table 1. The data consists of 160 fragments of 2290 words in total extracted from 41 phenotyping algorithms. We substituted all the numbers with _number, removed stop words, and stemmed all remaining words. We experimented with features including bag-of-words, sites of the phenotyping algorithms, targeted conditions (e.g., T2DM), UMLS concept unique identifiers (CUIs), and UMLS semantic types (STs). The CUIs and STs were obtained by running MetaMap [4] over the text fragments, and are included to battle the word sparsity problem. The site and condition features are included to account for possible site- and condition associated biases. Observing that synonyms may occur frequently in narratives, we also experimented with word embedding that was trained on a large corpus of EHRs from the MIMIC II dataset using the word2vec toolkit [5] with the embedding dimension set to 200. We performed classification and clustering of design patterns using features above-mentioned to demonstrate the feasibility of automatic identification and extraction of design patterns. As one sentence may have multiple labels, we formulated the classification problem as building multiple one-versus-rest classifiers. We split the data into a training set and a test set according to a 7:3 ratio stratified by the percentage of fragments for each pattern. We trained a linear kernel support vector machine (SVM) with parameters C and l1/l2 regularization tuned by cross validation on the training set. The number of fragments for clustering was 126 with the removal of fragments with multiple labels. The clustering was performed using k-means algorithm (k=8).

Results: The classification and clustering performance was evaluated on the held-out test set using f1score for each class and macro/micro averaged f1 for overall assessments as shown in Table 2 and Table 3. The tables show combinations of different types of features with either bag-of-words model or embedding model. The maximum micro averaged f1 is 0.73 for classification using features of bag-of-words and condition. We obtained 0.49 micro averaged f1 for clustering using bag-of-words model. The overall performance demonstrates moderate evaluation scores suggesting the practicability of automatic identification and extraction of phenotyping design patterns.

Discussion: From Table 2, it does seem that the site and condition preferences may add to the classification accuracies of design patterns including “Disease”, “Dates”, “Rule of N” and “Evidence” as reflected by the increased f1. It is also interesting that embedding, by capturing the word semantic relatedness, leads to increased f1 for the “Med”. For example, the fragments “there was no indicator of topical or cream in the flanking text” which was incorrectly classified using bag-of-words model was better represented by embedding model as key words “topical” or “cream” are semantically related to “medic”. From Table 3, embedding model outperformed bag-of-words model for “Dates” and “Evidence” classes which may because for example the word pair “separate” and “distinct” from one fragment has similar embedded vector representations to word pair “days” and “dates” from another fragment. Without class specific feature engineering, the overall moderate performance shows the promise of automated classification and clustering
ing of phenotyping design patterns. We are extending our algorithm to extracting more design patterns from phenoty pe algorithms.

An Error Analysis of Dictated Clinical Documents at Different Processing Stages

Li Zhou, MD, PhD1,2,3, Warren W. Acker1, Adam B. Landman, MD1,2,3, Evgeni Kontrient, MD4, Raymond Doan1, Suzanne V. Blackley1, David Mack5, David W. Bates, MD, MSc1,2,3, Foster R. Goss DO, MMSc5

Introduction

Clinical documentation represents one of the most time-consuming and costly parts of using an electronic health record (EHR) system. Speech recognition (SR), the computer recognition of spoken language into text, has been a promising technology for clinical documentation since the 1980s. Recent studies reported that 90% of hospitals plan to expand their use of SR technology. SR can assist clinical documentation at the back end, where a clinician uses a telephone to dictate, the captured recording is then recognized by an SR engine, and then the SR generated text is edited by a medical transcriptionist before sending it back to EHR for review and signature. However, issues including documentation quality, productivity, and physician satisfaction have not been widely studied. This abstract presents findings from part of a larger ongoing study and focuses on analyzing errors generated by back-end SR.

Methods

Our preliminary dataset includes a stratified random sample of 50 dictated notes from Brigham and Women’s Hospital and 10 notes from the University of Colorado Hospital. Both institutions use the same transcription vendor. The note types include clinic notes, operative notes, progress notes and discharge summaries. We reviewed each note at each of the four processing stages of dictation, namely 1) the original audio file that was dictated by the provider, 2) the note generated by SR engine of the vendor transcription service (SR note), 3) the note edited by a professional medical transcriptionist (MT note), and 4) the final note reviewed and signed by a clinician (SN note). In order to create a gold standard note, under a practicing physician’s supervision, a PharmD candidate or a medical student listened to the original dictation, edited the MT note to reflect that dictation, and also confirmed medical information with the patient’s chart.

To analyze errors we used Knowtator, an open-source annotation tool to annotate differences from the gold standard in notes at different processing stages. We adopted the annotation scheme of Zafar et al and modified it after consultation with a speech recognition expert and our experience with a small sample of notes. Our annotation scheme was broken into three levels: 12 general error types (e.g., insertion and enunciation), 14 semantic error types (e.g., medication and diagnoses), and clinically significant errors. Errors were considered clinically significant if they could potentially impact clinical care and these errors were validated by physician researchers.

We determined the length of time to dictate a note and the turnaround time for each note version. We analyzed differences in the SR note, MT note, and SN note from the gold standard. We determined error rate (number of errors divided by the number of words), the percentage of each error type by overall errors (number of errors of that error type divided by the total number of errors), and the percentage of notes with at least one clinically significant error (number of notes with one or more clinically significant error divided by the total number of clinical notes). We repeated these analyses for SR, MT and SN notes, for each note type, and across all note types.

Results

From BWH, 41 clinic notes, 5 operative notes, and 4 progress notes were analyzed; UCH provided 5 operative notes and 5 discharge summaries. Each note on average contained 516 words (median: 395 words; range: 44-1790 words). Average dictation time was 5 minutes (median: 4 minutes; range: 21 seconds-31 minutes). On average, the turnaround time for a dictated note was 4 hours (median: 1.3 hours; range: 10 minutes-23 hours) from completion of the dictation to upload into the EHR system.

Detailed results of our error analysis were shown in Table 1. In SR notes, there were 1631 errors in total and 27 errors per note, with an overall error rate at 6.9% and 87% of notes containing errors. There were 515 (31.6%) deletion errors, 444 (27.2%) enunciation errors and 335 (20.5%) insertion errors. We identified 203 (12.5%) errors were about clinical information, including 52 (3.2%) diagnoses, 41 (2.5%) symptoms, and 38 (2.3%) medications. 66 (4.1%) errors were judged to be clinically significant and 24 (40%) notes had at least one clinically significant error.
In MT notes, there were 88 errors in total and 1.5 errors per note, with an overall error rate at 0.4% and 47% of notes containing errors. There were 30 (34.1%) enunciation errors and 29 (33.0%) deletion errors. We found that 13 (14.8%) errors were about clinical information, including 4 (4.6%) diagnoses, 4 (4.6%) procedures, 2 (2.3%) symptoms, and 1 (1.1%) medication. Four (4.6%) errors were judged to be clinically significant and 4 (6.7%) notes had at least one clinically significant error.

In SN notes, there were 27 errors in total and about 1 error every two notes, with an overall error rate at 0.1% and 20% of notes containing errors. There were 10 (37.0%) insertion errors and 8 (19.6%) enunciation errors. Five (18.5%) errors were of clinical information, including 2 diagnoses, 1 lab, 1 image and 1 symptom. Three (11.1%) errors were judged to be clinically significant and 3 (5%) notes had at least one clinically significant error.

*% is number of errors and % is error rate which is defined by total number of errors divided by the total number of words in the notes. ***% is the number of errors of that specific type divided by the total number of errors. **% is defined as the number of notes containing at least one clinically significant errors divided by the number of notes.

Discussion

Our results showed that back-end dictation service had a relatively quick turnaround time and a low error rate. While many errors were generated by SR, most (~94%) were corrected by the medical transcriptionist manually. This suggests that the addition of a human editing a SR-generated note is invaluable. A recent study of EHR related malpractice cases found that 20% were due to incorrect information in the EHR, although the percentage due to dictation is unknown.

Errors still left in the signed note suggests that some providers may not review their dictated notes thoroughly or at all. For example, we also found that 3% of signed notes contained a blank space the transcriptionist marked as “??___??” (e.g., one was on the dosage of Vicodin), indicating they were unsure of the word and for the physician to fill it in. These cases indicate if physicians use SR directly, they may have to spend a considerable amount of time correcting the SR-generated text, although the errors should be less than our results as the SR can be trained by the individual physician. Automated error detection may help improve the accuracy of dictated documents.

Conclusion

Clinical dictation systems using back-end SR technology have a quick turnaround. SR-generated documents contain a high error rate and clinically significant errors. Fewer errors in signed documents show that medical transcriptionists and human editing play a critical role in quality assurance.

Abstract
Confidentiality in the medical encounter is crucial to providing adequate patient care. Health data is therefore privileged and protected by legal mechanisms. Health systems use electronic records and large-scale databases. Increasingly consumers use also IT to collect, store and share data about daily life and health behaviors. Sharing data via network-based systems or storing it ‘in the cloud’ produces multiple ‘digital selves’, health ‘data doubles’ and ‘virtual patients.’ With so many stakeholders involved much data is produced without clear governance structures, blurring the view of what is done with the data. These problems are exacerbated through the networked, distributed nature of health data collection and convergence of protected hospital systems, commercial collection and aggregation of data and consumer health technologies. This brings patient privacy into the realm of cybersecurity. This panel explores how cybersecurity impacts the governance of critical IT infrastructures and mitigation of threats, what sociotechnical challenges are related to protection of large-scale HIT systems, how surveillance and bioethics studies seek to understand threats to personal privacy in the context of networked technologies and finally what changes to laws and regulations would be required.

Keywords: Patient privacy; data protection; cybersecurity; legal, ethical and regulatory issues; governance

Introduction
“If you need to be convinced that you’re living in a science-fiction world, look at your cell phone,” writes Bruce Schneier in the introduction of his book Data and Goliath [1]. He paints a picture of how massive amounts of data are gathered and the public’s perception of privacy is changing drastically. The public accepts that in exchange for being connected, service providers know at all times where they are and what they do. Health data are not excluded. In return for services, consumer exchange and store their data on network-based systems or ‘in the cloud’ and create digital identities, for example as ‘virtual patients.’ Often governments and private businesses make a distinction between data and metadata. Data is about content, and metadata is about context. However, as NSA and CIA director Michael Hayden said, “Metadata tells you everything about somebody’s life.” Schneier argues that the difference is largely illusory [1].

Data collection and use can threaten individual privacy. Much data is produced without clear governance structures and stipulations concerning who will use which data and to what end. Lack of such structures and lack of transparency about those that do exist, result in patients, professionals and institutions having an insufficient view of what is done with the data [2]. Another risk includes healthcare information systems’ infamous weaknesses that result from complex code and software insecurity [3]. These problems are exacerbated through the networked, distributed nature of health data gathering and use, especially increasing convergence between protected hospital systems, commercial collection and aggregation of data, and consumer health technologies, such as health apps on mobile devices and wearable sensors.

Most institutions are insufficiently prepared to handle system shutdown resulting from internal network malfunction or external attack on critical infrastructures, bringing issues of data protection and patient safety into the sphere of cybersecurity. Directed attacks on both commercial and institutional systems threaten the privacy of
individuals’ personal data [4]. Medical identity theft is already an economic and social concern, and disclosures about personal health can have other consequences for individuals [2, 5].

At the same time, public perceptions of privacy and security are changing. This is evident in the push toward more ‘publicness’ of health data and new pay-for-value and cost-effectiveness reimbursement structures that require a greater sharing of data and health information exchange [6]. Moreover, privacy is not absolute, but rather a relational property; individuals may be more or less willing to trade off privacy depending on the situation and perceived benefits [1,7]. Shifts in the boundary between public and private, together with more use of distributed, networked technologies in clinical practice and research have led to concrete legal, ethical and infrastructural barriers and challenges related to computational agents, transmission protocols, care practices and legal tools.

Currently, five separate arenas of study address governance issues related to cybersecurity, privacy, and the protection of (health) data: (1) cybersecurity studies examine the socio-political and technical governance of critical infrastructures and mitigation of threats to systems such as botnets; (2) patient safety examines concrete sociotechnical and organizational challenges related to the protection of large-scale HIT systems; (3) surveillance studies and (4) studies in bioethics each examine different aspects of (potential) threats to personal privacy through networked technologies, and (5) legal studies examine (proposed) changes to the laws and regulations that govern data creation and exchange.

The panel

This panel explores how governance structures for protecting patient privacy in cyber environments are translated into concrete laws and regulations, institutional policies and procedures, and technical protocols for health practice. More specifically the panelists will explore following questions:

- What are current ethical-legal challenges and how are they related to practice and governance?
- What legal and regulatory changes are required to insure patient privacy in a cyber context?
- How can institutions safeguard integrity, privacy and confidentiality in a cyber context?

The panelists

**Samantha Adams**, PhD is associate professor of eHealth Governance and Regulation at the Tilburg Institute for Law, Technology and Society (TILT) in Tilburg, the Netherlands. Adams has more than 15 years’ experience in researching ethical, politico-legal and social issues related to the use of HIT. She has advised both government and healthcare institutions in the Netherlands about responsible implementation and use of networked systems for health and currently advises three European-based research projects. She is a multiple-term appointee to the Ethics Committee of the American Medical Informatics Association (AMIA) and an active member of three working groups. She is an expert in innovative qualitative research methods. In 2015, Dr. Adams led a comparative review project of Cybersecurity Governance in 5 countries commissioned by the Dutch Ministry of Security and Justice. Dr. Adams will briefly discuss the current state of research on the cybersecurity of critical infrastructures and the place of healthcare in this research. She will then outline pending changes to the General Data Protection Regulation in Europe and the consequences of these changes for healthcare institutions. She will conclude by showing how these changes are operationalized in practice by health institutions and government regulatory bodies in the Netherlands and reflecting on what lessons can be learned from these practices.

**Bonnie Kaplan**, PhD, FACMI, of the Yale Center for Medical Informatics, is a Yale Interdisciplinary Bioethics Center Scholar, and a Faculty Fellow of the Yale Law School’s Information Society Project. She has long experience in evaluating effects of health information technology on people and organizations. Her research addresses informatics ethical, legal, and privacy issues; user perspectives and experiences with health information technology; and ethnographic sociotechnical evaluation. Most relevant to this panel, she recently published papers on health data privacy in *The Cambridge Quarterly of Healthcare Ethics*, and the paper she co-authored on ethical issues in telemedicine has been among the most cited since its publication there in 2008. She is a past chair of the American Medical Informatics Association’s (AMIA) Ethical, Legal, and Social Issues Working Group; AMIA’s People Organizational Issues Working Group; and the International Medical Informatics Association’s (IMIA) Organizational and Social Issues Working Group. She is an elected Fellow of the American College of Medical Informatics. Dr. Kaplan will address ethical-legal challenges concerning privacy and security for clinical and patient-produced data, especially identifying problems in US regulation and gaps in public understanding of privacy protection. She will suggest changes to better protect patient privacy.

**Paul R. DeMuro**, JD, PhD is a health information technology attorney with over 35 years of health law experience. He is Of Counsel to the law firm of Broad and Cassel, based in Fort Lauderdale, and Associate Professor in the College of Pharmacy of Nova Southeastern University in Fort Lauderdale. He is Chair of the
Finance and Investment Committee of the American Medical Informatics Association and a member of its Ethical, Social and Legal Issues Working Group. His research areas include the use of health information technologies to improve quality and reduce costs in value-based purchasing, and the legal considerations involved. Dr. DeMuro will discuss a number of the legal considerations involved in health systems with respect to cybersecurity, including HIPAA privacy and security, patient privacy, data protection and governance, particularly those arising from hacking, and how to protect from hacking. He also will address institutional preparedness, including education of employees, implementation of a data backup plan, retention schedules, incident response procedures, access rights, and anti-malware tools. Finally, he will address the importance of compliance programs in this context.

Tony Solomonides, MSc is Director of Clinical Research Informatics at NorthShore University HealthSystem, Evanston. After a twin-track academic career as a biomedical informatician and as a computer scientist, culminating in his work in ‘health grids’ and serving as Vice-President and Chair of the Scientific Board of HealthGrid from 2006 to 2010, Tony was invited to join NorthShore, in late 2011. In this position, he has contributed to the design and analysis of clinical data in a number of projects and is now co-PI on the PCORI-funded CAPriCORN clinical data research network in the Chicago area. He is chair-elect of AMIA’s Ethics, Legal and Social Issues Working Group. Tony’s broader vision is to enhance the role of the patient as ‘expert’ in his or her own condition and in maintaining contact both as a means of improving accuracy and of continuing informed consent for the use of healthcare data for research. Safeguards of the integrity, privacy and confidentiality of the data would be maintained through formal ‘norms’ and annotation-enriched data. Tony will discuss the potential of data annotation, the possibility of norm- rather than rule-based privacy management, and use of the concepts of formal institutions and agents.

Jos Aarts, PhD, FACMI is associate professor of biomedical informatics at the University at Buffalo and assistant professor in the Institute of Health Policy and Management of Erasmus University Rotterdam. His research interests are the sociotechnical perspective of health IT in relation to professional work practices and workflow, usability and safety of HIT. He is an elected fellow of the American College of Medical Informatics. He is a past-chair of AMIA’s People and Organizational Issues Working Group. Following the panelist’s presentations, the moderator will start the discussion by asking a few questions to help the audience understand the similarities and differences among the various perspectives. He will then open the floor for a free-ranging discussion of all aspects of protecting patient privacy in cyber environments.

Learning objectives

After participating in the session, the attendant should be able to:

• Describe institutional practices that safeguard against external and internal threats to network-based health systems and breakdowns in networked information systems;
• Identify current ethical and legal challenges related to protecting patient privacy in cyber environments;
• Reflect on areas of improvement for governance structures and policy for protecting against cyber attacks.

Conflict of interest

The participants have no conflicts of interest to declare.

Abstract

Human microbiome, the collection of all microorganisms cohabiting the human body, is making an impact on a broad range of biomedical fields. Actionable associations of the host microbiota with health conditions span many health areas, such as oral and dental health, inflammatory bowel disease, metabolic syndrome, and other systemic conditions, and cancers. The technologies for microbiome science are inherently heavy on informatics. Many leading microbiome scientists would admit inadequate involvement of informatics experts is currently the key obstacle to progress. The informatics-related challenges and opportunities include issues with representation of multi-species data, creation and validation of reference databases for genes and genomes, benchmarking and validation of computational and analytic techniques for microbiome data upstream processing and downstream analysis, and integration of microbiome data with clinical data and other multi-omic data both for research and at bed side. In addition, the White House Precision Medicine Initiative specifically calls the biobanking and sharing of microbiome cohorts an important characteristic that will enable health care providers to tailor treatment and prevention strategies to individual patients. The new National Microbiome Initiative announced in May 2016, is further underlying the national importance of this area. This panel will stimulate the development of specific action plan to address the challenges and capitalize on opportunities for informaticists in translational microbiome science.

Panel description

Microbiome is a term used to describe the collection of all microorganisms that colonize our bodies. Early estimates posed 1-to-10 overabundance of microbial cells to human cells in a typical human body. These have recently been corrected towards parity, which is still overwhelming in terms of the potential for functional interactions between the host and the microbe. Whereas understanding the human genome has received enormous amount of attention in the last 15 years, the impact of host associated microbiome genomes (the metagenome) and its function in human health and disease is still in very early stages of being conceptualized. The recent surge in microbiome science has been afforded by increasing availability of technologies, such as high-throughput DNA sequencing, mass spectrometry, automated cell sorting, etc. Most notably, of course, the ability to sequence hundreds of individual microbiomes in a single run of a sequencing instrument has resulted in a perfect storm of microbial community profiling datasets addressing a vast array of biomedical questions. Most notably microbiome has made contributions in the areas of inflammatory bowel disease, C. difficile infection (CDI) management, the metabolic syndrome and pre-diabetes. It is the better understanding of the interplay between the host and its microbiota that has allowed for innovative fecal transplant treatments to be successfully used to treat CDI. Increasingly, microbiome is being utilized for hospital associated infection management and more recently to build personalized precision medicine approaches to clinical decision support.

The complexity of the microbiome itself and the sophistication of the microbiome assay technologies necessitates involvement of quantitative scientists in many branches of knowledge including informatics. Many data challenges are still outstanding in the microbiome arena. For example, there is currently a gap in standards and standard reference resources for microbial identification. This results in lack of comparability of outcomes of different experimental groups. Poor reproducibility of results is a major barrier to translating the findings into useful application. Another translational roadblock is the fact that the experimental microbiome data is typically far removed from the health record data. A standard for integration of microbiome assay results into clinical reports does not currently exist.

This panel brings together experts in microbiome science and biomedical informaticists to discuss a plan to capitalize on the opportunities to improve healthcare using the vast biological knowledge afforded by studies of the microbiome.
Brief description of each panelist’s presentation

- Dr. Alekseyenko, “The Human Microbiome in Health and Disease”
  Technology has enabled characterization of the host and microbiome physiological state on many dimensions in essentially panomic way. These technological advances in microbiome research have enabled discoveries across the biomedical spectrum. In this presentation, we overview the promise that microbiome carries for novel discoveries in key biomedical areas.

- Dr. Becich, “The Role of Computational Pathology and Biomedical Informatics in Microbiomics and Precision Medicine”
  Computational Pathology is the academic discipline that has grown from Pathology Informatics community. The Association for Pathology Chairs has declared the development of computational pathology as critical to the academic research mission of forward thinking Medical School Departments. This presentation will discuss the synergies between biobanking, computational pathology and biomedical informatics in the microbiome era and where we are headed in building programs at the University of Pittsburgh to support a Center of Excellence in Microbiomics, which will greatly serve the mission of the Precision Medicine Initiative Cohort.

- Mr. DeSantis, “Selecting Therapeutic Candidates from Mucosal Biospecimens Using Network Analyses”
  Microbiome insight comes from integrating host transcriptomics, microbe meta-transcriptomics, metabolomics and 16S analyses, often without a definitive Rosetta Stone. Integration of these new data with existing public and proprietary curated host-side interaction networks presents many challenges in discovering actionable biomarkers. This presentation describes how to leverage these host-side and similar microbe-side resources and how to set up validation screens.

- Dr. Gilbert, “The Hospital Microbiome Project: Ecology and Epidemiology”
  The bacteria, fungi and viruses that are shed from our bodies create a dynamic ecosystem in our built environment. The hospital environment is no different, and was characterized in our study by examining how microbes found associated with patients and staff, colonized and persisted in the hospital rooms and nursing stations. This dataset suggests that the microbial community found in the patient’s room, and the microbial interactions between patients and staff likely influence patient health outcomes, and we therefore propose that the microbial environment of the patient should be taken into consideration when considering treatment strategies.

- Dr. Gerber, “Prediction of Patient Outcomes from Longitudinal Microbiome Data”
  The microbiome is inherently dynamic, changing in response to the host, the environment, and interactions among the microbes. This presentation will highlight the challenges of designing and analyzing longitudinal microbiome studies. Longitudinal studies currently being conducted at the Massachusetts Host-Microbiome Center investigating the role of the microbiota in food allergy and in Clostridium difficile recurrence will be discussed as examples. Progress on new computational methods that specifically address the challenges of analyzing longitudinal microbiome data, including sparse and irregular temporal sampling, noisy count-based data, phylogenetic structure, complex dynamics, unmeasured host and environmental processes, and model interpretability, will also be discussed.

Relevance of topic and anticipated audience:
The White House precision medicine initiative, which is likely to shape the research funding policy in the next few years, specifically calls microbiome an important characteristic for Precision Medicine. Recently the White House Office of Science and Technology Policy has announced the launch of the National Microbiome Initiative, which aims to foster the integrated study of microbiomes across different ecosystems. The original call for information prior to the launch has specifically indicated that informatics involvement is key to microbiome science by declaring that “The development of platform technologies, reference libraries, and databases useful for microbiome research in all habitats” is an example of work relevant to OSTP goals. The final announcement calls for new tools to and technologies to develop knowledge necessary to “manage microbiomes in a manner that prevents dysfunction or restores healthy function”. We anticipate that this panel will be interesting to attendees working in the translational informatics realm, specifically those focusing on precision medicine.
Discussion questions:
1. What resources to support translational microbiome science currently exist?
2. What key expertise is lacking or inadequately present on the microbiome arena?
3. What translational value does the microbiome hold and in what specific areas of medicine and health?
4. What are the national and regional centers for microbiome research and what opportunities for involvement exist?
5. How is microbiome science incorporated in biomedical informatics training?

Learning objectives:
1. Recognize the technologies exist to survey the human microbiome and the biological aspects they capture;
2. Identify areas where microbiome has made an impact on patient treatment, hospital policies, or understanding disease processes;
3. Identify areas with existing opportunities for improving care, policies, and knowledge using microbiome science;
4. Identify informatics challenges for wide and uniform adoption of microbiome science in healthcare.

The organizer confirms that all participants have agreed to take part on the panel.
Who Watches the Watchers: tools and practices for monitoring and measuring CDS performance and assessing CDS effectiveness and value
Organizer: Jan Marie Andersen, MA

Abstract: (150-200 words)
Health IT (HIT), and clinical decision support (CDS) systems in particular, can improve the safety and effectiveness of health care when correctly implemented and effectively used. Over time, HIT and CDS have become more complex and pervasive, necessitating better monitoring of their efficacy and functionality. In some case, CDS alerts fire incorrectly or stop firing without warning, adversely affecting care quality and putting patients in danger. The issue now becomes, who shall watch the watchmen?

In this panel we present approaches to this issue from four sites’ perspectives, together with recommendations for best practices for monitoring CDS effectiveness. We also discuss how the value of an organization’s CDS can be measured.

The panelists will discuss the software and/or management plans they have developed in order to monitor CDS, the implementation of said software and plans, and the lessons learned. All four institutions represented on this panel are currently running self-developed CDS monitoring dashboards: Brigham and Women’s Hospital (Andersen), UT Physicians (McCoy), Cedars-Sinai Health System (Weingarten) and Memorial Hermann (Murphy) and have also formed CDS committees and governance approaches to oversee their large and diverse decision support implementations.

Description:
The overall outline of the talk is given in the abstract. The panel will be organized as follows:
<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 min</td>
<td>Wright (moderator)</td>
<td>Introduction, overview of need for CDS monitoring and current approaches, through both software development and dedicated committees</td>
</tr>
<tr>
<td>15 min</td>
<td>Andersen</td>
<td>Predictive Analytics for CDS Effectiveness (PACE) dashboard</td>
</tr>
<tr>
<td>15 min</td>
<td>McCoy</td>
<td>InSPECt: Interactive Surveillance Portal for Evaluating Clinical support</td>
</tr>
<tr>
<td>15 min</td>
<td>Murphy</td>
<td>CDS Monthly Operating Report and CDS committee at Memorial Hermann</td>
</tr>
<tr>
<td>15 min</td>
<td>Weingarten</td>
<td>Cedars-Sinai CDS analytics dashboard</td>
</tr>
<tr>
<td>5 min</td>
<td>Wright</td>
<td>Summary of topics discussed</td>
</tr>
<tr>
<td>20 min</td>
<td>Panel</td>
<td>Discussion and questions from audience</td>
</tr>
</tbody>
</table>

The specific topics covered by each presenter will be:

1. **Wright (introduction):** Introduce the topic and panelists, including a brief description of what each panelist will be talking about and their affiliations. Provide an overview of the history of.

2. **Andersen:** Discuss the ongoing development and implementation of the Predictive Analytics for CDS Effectiveness (PACE) CDS alerts dashboard for Brigham and Women’s Hospital, which is focused on detecting malfunctions and anomalies in CDS [1]. Review the process of expanding the dashboard to other sites, feedback from test users, and current results.

3. **McCoy:** Present the development, multisite implementation, and evaluation of InSPECt (Interactive Surveillance Portal for Evaluating Clinical decision support), a web-based, Electronic Health Record (EHR)-independent dashboard for evaluating clinical decision support alert performance across sites with diverse healthcare settings, EHRs, and CDS configurations.

4. **Murphy:** Discuss the Memorial Hermann CDS Committee’s experience overseeing a large and diverse package of decision support, as well as their use of a Monthly Operating Report, focusing on alert performance using override rates and clinicians’ responses.

5. **Weingarten:** Discuss the development and use of the Cedars-Sinai CDS analytics dashboard. Review the Cedars approach to designing and measuring the financial impact of a package of CDS interventions based on the ABIM Choosing Wisely campaign.

6. **Wright:** Summarize topics discussed, identify common themes and outline the panel’s recommendations for best practices.

7. **Panel:** After the presentations, the panel will briefly discuss additional issues and then open for questions from and discussion with the audience. Audience members will be invited to address questions to specific panelists, or to the panel as a whole.

**Importance:**

Although the vast majority of hospitals and practices have now implemented some type of CDS (HealthIT.gov reported a 72.8% adoption rate of CDS in 2013), the ability to effectively monitor CDS alerts is currently lacking from most implementations. System upgrades, changes in rules, changes to external data sources such as a drug dictionary, or unintentional changes can cause alerts to spike, slow down, or completely stop firing, and without monitoring this can often go unnoticed for days, weeks, or as long as years. Consequences of these alert anomalies can range from mild (e.g. suggesting mammograms for a healthy 2-year old boy) to severe (e.g. an allergy alert failing to fire, resulting in a fatal allergic reaction).
Most hospitals and institutions completely lack the ability to monitor their CDS systems, and there is no standard tool to provide this functionality. A survey of chief medical information officers (CMIOs) found that 93% of CMIOs had experienced CDS malfunctions, and 62% were not confident that their current monitoring methods and tools could detect or prevent CDS malfunctions [1]. Despite this, the vast majority of medical institutions have no ongoing operational management plan for how to handle these malfunctions.

In order to monitor CDS, developers are often forced to rely on ad hoc reports which can be time-consuming to produce and intermittent. Consequently, it’s difficult to accurately assess if or how much CDS is adding value to the system as a whole, or to create a plan to optimize CDS. Furthermore, in HIT, there is often a disconnect between the developers implementing and maintaining the technology, and the clinicians using the technology. CDS data are usually stored on databases that require technical programming skills to access, creating a barrier to non-programmers who wish to monitor CDS alerts. Because there is currently no specific commercially-available software dedicated to CDS monitoring and no widely-accepted “best practices” for how to insure CDS is functioning correctly, many hospitals and institutions have chosen to develop their own software and/or management plans in order to address these issues, including CDS alert dashboards to access and display the data, and the formation of committees to oversee CDS implementation and functionality.

In this panel, we present the experience of CDS monitoring and evaluation from four different organizations. We focus on (1) detecting CDS malfunctions, (2) measuring CDS efficiency through alert acceptance rates and clinician feedback, and (3) evaluating CDS value in terms of clinical outcomes, safety, and cost savings.

We believe that monitoring and regularly assessing CDS is of critical importance to any organization that utilizes CDS. This panel will help to guide the discussion of CDS monitoring and work toward developing standards for CDS assessment that can be adopted by any organization with CDS.

Discussion Questions:
1. What tools and approaches can best help to detect CDS malfunctions and errors?
2. What are best practices for monitoring CDS and detecting and addressing CDS malfunctions?
3. How can organizations develop and employ effective approaches for CDS monitoring?
4. What are the limitations of CDS monitoring software?
5. What were the challenges encountered and lessons learned by the different organizations as they developed CDS monitoring methods and tools?
6. What are current unfilled needs and future potential for improvement in CDS monitoring practices?
7. How do you determine if your investment in CDS is yielding safety, quality and cost-effectiveness returns and which parts of your CDS are most valuable?
8. How can CDS monitoring improve CDS?

Participation statement:
All proposed panelists are aware of this panel submission, and have agreed to participate in the panel if the proposal is accepted.
PEDSnet: from building a high-quality CDRN to conducting science

L. Charles Bailey\textsuperscript{a}, MD, PhD, Michael G. Kahn\textsuperscript{b}, MD, PhD, Sara Deakyne\textsuperscript{b}, MS, Ritu Khare\textsuperscript{a}, PhD, Katherine Deans\textsuperscript{c}, MD

\textsuperscript{a}The Children’s Hospital of Philadelphia, Philadelphia, PA, \textsuperscript{b}Children’s Hospital Colorado, Aurora, CO, \textsuperscript{c}Nationwide Children’s Hospital, Columbus, OH

Abstract

Collaborations across multiple institutions are essential to achieve sufficient cohort sizes in clinical research. Within the national PCORnet research network, clinical data research networks (CDRNs) aggregate electronic health record (EHR) data from multiple sites and provide a unified platform to conduct large-scale studies, while dramatically increasing the capabilities to conduct a wide range of scientific studies. There are two critical facets of building a functional CDRN data resource: (i) to address the characteristic data provenance and quality issues that arise from the data’s orientation toward clinical operations rather than research, from semantic heterogeneity across systems, and from clinical data peculiarities, and (ii) to assess and improve the usability of network data to conduct scientifically valid studies. This panel focuses on a pediatric-specific CDRN, PEDSnet, to discuss its recent evolution from initial data collection and generic data quality assessments, to tailoring data characterization to scientific utility, developing a data-compatible approach to constructing computable phenotypes and conducting pilot observational studies.

Learning Objectives:

1. To understand the full CDRN cycle from validating network data quality to preparing tailored datasets for scientific studies
2. To learn about the iterative framework, guided by scientific requirements, for conducting data quality assessments and stabilizing network-wide ETL conventions in PEDSnet
3. To learn about challenges and opportunities in using the CDRN data for designing computable phenotypes and observational studies

Panel Description

PEDSnet, a pediatric learning health system, is a PCORI-supported CDRNs focused on child health. It aggregates EHR data from eight of the nation’s largest children’s hospitals. The digital infrastructure of PEDSnet has been iteratively developed through multiple data cycles with the participating sites over the last 2.5 years. PEDSnet has successfully addressed internal and external data quality requirements, and is conducting a number of observational studies as a test of network utility. In this panel, we invite leaders, developers and consumers of PEDSnet to discuss the journey of building, evaluating, and using this network for conducting scientific studies. The moderator leads the data coordinating center in PEDSnet, and the four panelists include (i) the PEDSnet informatics co-PI, summarizing the procedures for data specification and quality assessment in PEDSnet, (ii) a clinical informatician involved in the PEDSnet computable phenotype development program, (iii) a data scientist facilitating PEDSnet contribution to a PCORnet-wide study of medication exposure and child growth, and (iv) a clinical researcher, directing a study of diagnostic radiation dosage in collaboration with PEDSnet.

Moderator: Welcome and session overview
L. Charles Bailey, MD, PhD

Panelist #1: Promoting Data Quality Using Systematic Assessments and Structured ETL Conventions
Michael Kahn, MD, PhD (10 minutes followed by 5 minutes discussion)

Dr. Kahn will discuss the iterative framework of validating data quality in PEDSnet. The topics will include design of element-level data quality assessments, use of a structured document to validate and manage network wide ETL conventions, and external validation of the PEDSnet data against community standards and published results.
Panelist #2: Developing Computable Phenotypes in PEDSnet
Sara Deakyne, MS (10 minutes followed by 5 minutes discussion)

Ms. Deakyne will discuss her work on cohort identification in large-scale datasets. The topics will include definition and validation of computable phenotypes and case-finding algorithms in PEDSnet that could be replicated across other CDRNs.

Panelist #3: Designing Observational Studies on Antibiotics using PEDSnet
Ritu Khare, PhD (10 minutes followed by 5 minutes discussion)

Dr. Khare will discuss using PEDSnet as a testbed to support a PCORnet wide study of antibiotic exposure in infancy and subsequent obesity risk. The discussion will cover topics including characterization of exposures using clinical prescription, dispensing, and diagnosis data, and constructing growth assessments from primary data.

Panelist #4: Using PEDSnet data to conduct an observational study on radiation dosage
Katherine Deans, MD (10 minutes followed by 5 minutes discussion)

Dr. Deans will discuss her experience in designing a study of diagnostic radiation exposure using a combination of core PEDSnet data and study-specific radiation dosimetry. This talk will discuss the ways in which the study makes use of network data and collaborative infrastructure to answer specific research questions.

Moderator: Facilitated discussion and closing
L. Charles Bailey, MD, PhD (25 minutes)

Significance of Panel
PEDSnet has been recognized as one of the first functional CDRNs by PCORI. This panel will serve as a learning model for use of CDRN multi-site digital infrastructure to support large-scale scientific studies.

Discussion Questions
The following guiding questions will be used to facilitate discussion:
1. What are the key challenges in building a “high-quality” CDRN from informatics and science perspectives?
2. What unique opportunities does a CDRN offer investigators interested in conducting large-scale clinical research?
3. What are the main bottlenecks in conducting feasibility and scientific studies on network-based data?
4. What do we learn about data quality assessments based on the experience of computable phenotyping and designing observational studies?

Moderator Attestation
The four panelists, Dr. Kahn, Ms. Deakyne, Dr. Khare, and Dr. Deans, have all agreed to participate in this didactic panel.
From the Trenches- Issues Facing Clinical Informatics Administrative Clinicians in the Primary Care Setting

Deepti Panditia, MD\textsuperscript{1}, Curtis Boehm, MD\textsuperscript{1}, Jill Tiongco, MD\textsuperscript{2}, David Dorr, MD, MS\textsuperscript{4}
\textsuperscript{1}Park Nicollet-Health Partners Health System, Minneapolis, MN; \textsuperscript{2}Peninsula Primary Care, Carmel, CA; \textsuperscript{3}Oregon Health Sciences University, Portland,

Abstract
As primary care providers struggle to survive in an ever changing health care arena, 2016 is rapidly becoming the year of change. Primary Care Clinicians are increasingly taking on additional roles of Clinical Informatics Specialists and taking on challenging administrative roles along with Clinical Roles. This panel will illustrate some of the struggles faced by primary care providers in informatics related administrative roles such as CMIO and EMR champions, share examples of some of the major challenges and explore possible solutions that others can apply to their own health care setting. This will include strategies to manage change, meeting complex mandates, managing clinician expectations with changing work flows that impact and engage the entire care team and ultimately influence system design.

Introduction
As more and more Primary Care Clinicians are getting board certified in Clinical Informatics and taking on administrative roles in their health care institutions they feel that they are “in the trenches” without any support from rest of the administration due to the unique nature of their job. They also have to deal clinician opposition to change and inertia when it comes to embracing technology. This creates some unique challenges and clinicians who have done this for a while have valuable insight and possible solutions for these challenges.

Learning Objectives
1. Leadership and Governance strategies to improve adoption of EMR technology.
2. Understand barriers to Clinician acceptance to changes with HIT and EMR adoption
3. Understand complex workflow changes after EMR implementation and change management skills for managing these changes.
4. Challenges when transitioning from one EMR to another or merging EMR’s

Intended Audience
Any Clinician Informatics Specialist, Informatics and EMR Clinician Administrators, Primary Care and Specialty providers

Challenges facing CMIO and other similarly positioned Clinicians
Clinical leadership in healthcare informatics is an exercise in diplomacy, expectation setting and education. Dr. Boehm will address three topical areas of leadership in a large care delivery organization. Setting the stage and making the case for change. Evaluating the benefits of change for the organization, Tools of change management and adaptation.

Making the case for change: System changes should align with the organizations overall strategic plan. A key part of the CMIO role is to aid clinical leaders in understanding the capabilities of IT systems and partnership to develop a strategic IT plan.

Evaluation of systems to move from return on investment to organizational value: Traditional evaluation of system benefit has focused on return on investment. While this remains an important aspect of the evaluation needed, benefits accruing in clinical care include other dimensions that are not as easily quantified. Improved quality of care as reflected in quality metrics, reducing patient costs and improved patient and family experience are components that benefit the organization in less tangible ways much more difficult to quantify, such as patient loyalty and brand equity.
The importance of change adaptation strategies to achieve success: Clinical care teams live in an environment of constant change, awareness of the environment and a systematic approach to proactively create an environment supporting adoption increases the likelihood of achieving the goals of the project.

Understand barriers to Clinician acceptance to changes with HIT and EMR adoption

Crucial to any implementation of health systems is the ability to identify potential barriers to adoption. Dr. Tiangco will focus on what could hinder adoption to HIT and EMR changes in order to facilitate better implementation. Organizational experience, peer discussions and literature review have led to the proposal of two conceptual groupings of barriers to clinician acceptance. Identification of these type of barriers can alleviate the burden on users as it aims to identify "who can act on what." Numerous clinicians feel that barriers exist because of the intrinsic limitation of the health systems itself. Some however feel that barriers exist because of the limitations of what we, as clinicians could humanly do. The fact is, these are all true. Identifying the root cause of such barriers can therefore lead to overcoming them. So what are these barriers?

1. Static barriers: These are mostly finite resources. Finite resources include clinician’s time and money and vendor technical support. Various articles have made efforts to identify barriers and clearly, cost of implementation, decline in productivity during implementation, time required for data entry, EHR technical limitations and down times have been identified as the usual suspects. We then ask, can acknowledgement of these fixed and finite resources help modify and manage expectations and improve acceptance? How can stakeholders address these barriers?

2. Dynamic Barriers: These evolve and devolve. These include the need for constant workflow changes, policy changes, EHR transitions and changes, variances in metrics by payor etc. These barriers are so dynamic that the frequency of change itself leads to more frustration and lack of acceptance. The result is a constant yearning from clinicians for stability in the work environment to create efficiency. To attain stability is seemingly a unicorn at present day. Can clinician engagement facilitate acceptance?

Understand complex workflow changes after EMR implementation and change management skills for managing these changes.

Implementation of an EHR is only the start of the work for a clinical informatician in the trenches. In a seven year role as chair of the Clinical Decision Support Committee and as the leader of several innovative primary care programs for risk stratified care management, Dr. Dorr will discuss major issues around managing change to both workflow and future EHR “enhancements.” Specific discussion points will highlight: 1) the inter digitation of primary care workflow changes, especially population management, more care planning, and transitions of care, with the EHR changes made for implementation and needed for better alignment; 2) proactive management of EHR changes suggested by vendors and requested by users; 3) “anomaly” detection from EHR changes that disrupt workflows or break other functions in the EHR; and 4) the planning and implementation process for more complex endeavors. Specific topics covered will be primary care versus institutional governance of the process, encouraging learning both by induction and deduction, and overviews of the various workflows over time and how we broke and tried to fix them.

Challenges when transitioning from one EMR to another or merging EMR's

When transitioning from one EHR to another or transitioning for one version of the existing EMR to another there are several barriers experienced. Dr. Pandita will discuss the experience at Park Nicollet with their transition from legacy EHR to current EPIC EHR and now after we merged with Health Partners (HP) Health system we are in the process of transitioning Existing EPIC EHR to the HP Platform which brings its own set of complexities. The challenges with these changes are at several levels:

1. Technical challenges: Merging tools are based on classical logic and are forced to avoid inconsistencies which may cause valuable information loss which is an undesirable consequence as the lost information may serve as an
integral component in healthcare record. Avoiding redundancy in transition is another technical challenge. Backloading of data from legacy systems creates another interesting challenge particularly as it related to images, drug lists and problem lists.

2. User Acceptance: The changes in how clinicians and ancillary staff interact with “inbasket”, refills, phone notes, alerts and reminders and other messages can change with transitions and testing these ahead of time and including end users in training development is imperative.

3. Integration of legacy and new system with ancillary system vendors: This includes systems such as lab software, Cardiology and Radiology systems, ICU device integration and many more. Some face redundancy so might need to be abandoned and some need upgrades to be compatible with new EHR.

**Statement of Agreement and Support**
All members of this panel are in agreement to participate in this discussion. This panel is endorsed by the Primary Care Informatics Working Group.
VISUALIZATION OF PATIENT-REPORTED OUTCOMES

Adriana Arcia, PhD, RN¹, Kenrick Cato, PhD, RN ¹², Ruth Masterson Creber, PhD, RN¹, Yalini Senathirajah, PhD³ and Sunmoo Yoon PhD, RN¹

Abstract
Patient-reported outcomes (PROs) are outcomes that patients self-report either through self-administered questionnaires or interviews. Examples of PROs include symptoms, functional status, and health-related quality-of-life. While visualizations of PROs can facilitate communication between client and clinician and inform patients’ efforts to self-manage health, the visualization creation process is often arduous.

This panel is intended to provide researchers, clinicians, educators, and policymakers with an introduction to methods for development and testing of visualizations of PROs. To this end, each panelist will discuss issues specific to each phase of visualization development for PROs (design, automation/programming, testing, and selection/deployment) with a particular focus on those generated by the Patient Reported Outcome Measurement System (PROMIS).

Learning objectives.
After participating in this session, the learner should be better able to:

- Provide rationales for the use of visualization.
- Describe the phases of the visualization process and the key activities of each phase.
- Understand the triangulation approach to selecting visualizations based on qualitative and quantitative methods.

Panel Description
The first presentation will focus on the Design Phase of the visualization process. Case studies will serve to illustrate key activities of the design phase including: defining desired outcomes, matching data types to graphical formats, drawing on culturally appropriate graphical conventions, and iterative prototyping with feedback from the intended audience. The case studies feature tailored infographics of self-reported health data, including PROMIS measures, from Washington Heights/Inwood Informatics Infrastructure for Community-Centered Comparative Effectiveness Research (WICER) and the New York City Hispanic Dementia Caregiver Research Program.

The second presentation will focus on automation and programming using a mental health example. The first step is to collect data from non-expert patients about their health experiences and mental states, using technologies such as tablets which must be appropriate to the language and levels, technology knowledge, privacy concerns and other patient characteristics, often at home or in a clinic setting. The second
step requires the clinician to perform close management and rapid interpretation for making a diagnosis or for treatment monitoring, over time as well as in single instances. Patients and providers are limited by time for learning so the design must be appropriately simple and either convey affordances quickly for one-shot experience or leverage known conventions. The same is true for researcher stakeholders.

The purpose of the third presentation is to demonstrate how tailored infographics, based on a comprehensive symptom assessment, can serve to influence a patient’s mental model of their symptoms. Using qualitative interviews with both patients and providers, we will test whether specific visualizations from a novel mHealth app can effectively represent patients’ symptom burden. We will also test whether or not they are useful tools for effectively communicating symptoms between patients and providers.

The last presentation focuses on the selection and deployment of visualizations after applying triangulation approaches following multiple evaluations. This section will walk through a triangulation strategy to choose the right visualizations from qualitative (e.g., interview, focus group, think-aloud) and quantitative (e.g., eye tracking, comprehension test) studies with the following three multi-method visualization projects; 1) visualizations for clinicians in an acute-care setting, 2) visualizations for patients in a community setting, and 3) visualizations for health researchers in a research institute setting.

**Questions**

- What infrastructure and cooperative agreements would be required to set up a bank of visualizations of PROMIS and other self/patient reported outcomes?
- A systematic approach to visualization is a substantial undertaking. When is it worth the effort?
- How do factors such as language, culture, and health literacy affect visualizations’ effectiveness?
- Can we make a decision on choosing visualizations based on focus groups?
- What are the implementation barriers perceived by researchers and how could implementers ease this burden?

The OpenMRS Community’s Experience: A Decade of Developing and Implementing Medical Record Systems Within Resource Constrained Countries

Theresa Cullen, MD, MS1,2, Paul Biondich, MD, MS1,2, Burke Mamlin, MD, MS1,2, Judy Wawira, MD, MS2, Hamish Fraser, MRCP3
1Global Health Informatics, Regenstrief Institute, Indianapolis, IN; 2Indiana University School of Medicine, Indianapolis, IN; 3Leeds Institute of Health Sciences and the Yorkshire Centre for Health Informatics, Leeds, United Kingdom

Abstract
In 2016, the Open Medical Record System (OpenMRS) community celebrates its ten year anniversary. OpenMRS, a collaboratively developed free and open platform for building electronic medical records (EMR), is currently in use in over 1200 facilities, and supports care provision to over 5 million patients [1]. These software components are developed and supported through the OpenMRS rapidly evolving and engaged multinational open source community.

This panel is designed to share the experience of the last ten years from the vantage point of key community participants who have helped lead the community over the last decade. The panel will discuss the history of OpenMRS, current state (including a technical overview and description of the close alignment with standards development activities), implementation challenges faced, and future growth plans. The panel presentations will emphasize lessons learned, including predictive factors for a successful open source health information technology community [2].

Introduction and Background
The benefits of open, collaboratively developed health information technologies (HIT) have been well described, and strongly advocated for over the past decade [3]. However, most have found it difficult to successfully instigate, grow, and maintain these initiatives. As the number of sustainable open-source HIT solutions appear to wither within the US, the ongoing experiences within the rapidly growing OpenMRS community provide a potent reminder of the possibilities and promise of open source HIT.

While the origins of OpenMRS have their roots in work that started in 2004, the initiative is currently celebrating its tenth anniversary as an open source community. OpenMRS represents a successful collaborative action network, where many disparate organizational and individual collaborators commit to a shared mission of developing and implementing EMRs for underserved populations, and work together on and through shared governance, technologies, standards, principles, and resource gathering.

Panel Description
Dr. Terry Cullen will lead a panel discussion on the history and current status of OpenMRS, and in doing so will help the audience better understand the importance of open source communities, the many collateral benefits that emerge from them, and the potential for using the OpenMRS experience to help inform current US based healthcare conundrums. The panel will include a review of various implementation activities and the factors that contributed to their success. The panel will also discuss the historical and future management strategies employed by project leadership, which will provide details on the nuanced decisionmaking that proved fundamental to the initiative’s
success. The experiences and lessons learned from this global health informatics initiative are likely applicable to not only HIT development and implementation initiatives working under fiscal and human constraints, but to the US situation as well. Given that AMIA strives to be a professional home for global health informatics activities, it is well suited for this conference.

**Presenters**

**History of OpenMRS (Fraser)**

The panel will begin with Dr. Hamish Fraser’s overview of the early history of the initiative. Dr. Fraser is currently the Associate Professor of eHealth at the University of Leeds, and was one of the original founders of the OpenMRS community. He will briefly describe the original collaboration between two global health informatics groups both seeking to support EMR implementations within two diverse clinical care settings in sub-Saharan Africa. He will describe how this work evolved into a global consortium of hundreds of developers, implementers and end users of e-Health technology focused on improving the health of and empowering the underserved. This will include a review of the mission, vision, and values of the community, and a description of the community processes designed to encourage broad participation of individuals and organizations within the OpenMRS community. This presentation is designed to familiarize the audience with the project and begins to help elucidate the factors (such as a shared mission, vision and values) that are foundational to the community’s continued growth and success. These factors have meaning within the global community at large.

**Technical Overview and Development Community (Mamlin)**

Dr. Burke Mamlin is an associate professor of medicine and the Chief Architect of OpenMRS. In his presentation, Dr. Mamlin will describe the technical underpinnings of OpenMRS, including its data model, its application programming interface (API), and flexible user interface framework. In describing the specifics behind the modular, extensible platform, he intends to demonstrate how OpenMRS can be and has been so broadly implemented in diverse clinical settings. His presentation will demonstrate how OpenMRS has benefited from and contributed to standards over the past decade, including work on interoperability. He will describe how the OpenMRS Developers Community is itself being developed, undergoing ongoing continuing improvement and finding innovative ways to motivate and recognize developers in the community. Finally, he will discuss how OpenMRS is leveraging many of the latest technological advances including RESTful web services, support for FHIR, and integration with Observation Health Data Sciences and Informatics (OHDSI) community [4]. The prescience of OpenMRS to develop and support a modular and flexible user framework should help inform the next generation of US HIT systems.

**Implementation (Gichoya)**

Dr. Judy Gichoya is currently a third year radiology resident at Indiana University, where she previously completed a health informatics fellowship. She has been active in the OpenMRS community for the last decade, and has been responsible for several successful OpenMRS implementations. Today, OpenMRS is implemented in well over 1200 facilities. Evaluation of these implementations has shown that there are key factors to successful implementation, independent of location. These factors include community involvement and ownership, support from the Ministry of Health or appropriate local organizations, and a commitment to local empowerment [5] [6]. Dr. Gichoya will give a presentation on the factors that contribute to successful implementations of medical record systems such as OpenMRS within constrained environments. She will illustrate this through sharing her personal experiences implementing OpenMRS in health care facilities in downtown Nairobi, and through highlighting other representative implementation examples around the world. Additionally, Dr. Gichoya will share results of the qualitative work she is currently performing within the OpenMRS community specifically focused upon critical implementation success factors. This presentation will once again illustrate the consistency of factors that contribute to implementation success independent of locale.
Future Directions and Lessons Learned (Biondich)

Dr. Paul Biondich is one of the founders of OpenMRS and serves as the executive project lead for the OpenMRS community. OpenMRS now serves as a foundational technology for a half dozen national-level EMR implementation activities in countries both in Africa and Southeast Asia. This substantive commitment to the platform and the community provoked a recent strong emphasis upon strategic planning and community governance. Large scale implementation activities also necessitate the development of regional business ecosystems and substantive international workforce training programs. Dr. Biondich will review the OpenMRS 2016 Community Strategic Plan [7][8], and discuss the approaches designed to respond to current demands and their rationales based upon previous experiences. Dr. Biondich will additionally synthesize overarching lessons learned both from the previous panel presentations that can help address the HIT questions facing the US health care system such as care coordination.

Discussion Questions

1. What are the top three benefits and challenges of open source development for global health IT?
2. Is there a role for AMIA in helping identify and sustain open source HIT communities, either within the US or globally?
3. How can AMIA leverage the lessons learned from global HIT development, like OpenMRS, to benefit the US HIT and health informatics community?
4. What are appropriate licensing options to support community growth in open source HIT?
5. What can AMIA do to assist the global health informatics community?

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

Didactic Panel: **Watson Cognitive Computing for Electronic Medical Records**

Moderator:

Murthy V. Devarakonda, PhD, IBM Research, Yorktown Heights, NY

Panel Members:

1. Neil Mehta, MBBS, MS, Cleveland Clinic, Cleveland, OH
2. Christopher Nielson, MD MPH, VHA, Reno, NV
3. Kenney Ng, PhD, IBM Research, Yorktown Heights, NY
4. (Ms.) Preethi Raghavan, PhD, IBM Research, Yorktown Heights, NY

**Abstract**

With the explosive growth of data, the human brain is substantially overloaded with more information than it can make sense of. This is painfully clear in patient care where critical information may be buried in the mountains of data entered into the Electronic Medical Record (EMR) system while clinicians struggle to make sense of this information at the point of care. Cognitive computing, exemplified by Watson, offers the promise to transform this data to an intelligent assistant that provides precise insights when needed. This didactic panel examines recent advances in the specific capabilities of such cognitive computing and prospective benefits of these capabilities in patient care. The panel will discuss cognitive needs of practicing physicians. Watson capabilities of automatically summarizing a patient record and natural language question-answering on a patient record as examples of intelligent assistance cognitive computing can provide. The panel will also discuss complementary technologies from massively large scale data analysis and knowledge management that will play a role in cognitive computing. The learning objectives include developing an appreciation for working examples of cognitive computing for Electronic Medical Records, and an understanding of how these capabilities could mitigate physician’s cognitive load.

**Description of the Panel and Issues Examined**

The panel consists of two practicing physicians, Drs. Neil Mehta of Cleveland Clinic and Christopher Nielson the Veterans Health Administration, and two highly experienced IBM Watson technology researchers, Kenney Ng, PhD, and (Ms.) Preethi Raghavan, PhD. Dr. Mehta has additional research interests in technology enhanced teaching and medical informatics. Dr. Nielson has deep experience in big data and predictive analytics. Mr. Ng is a research scientist and a technical manager at IBM research specializing in patient similarity and predictive analytics. Ms. Raghavan is a research scientist in IBM Watson Health and specializes in discovery of semantic structure in natural language text using statistical machine learning and its application to medical informatics.

The panel will examine the potential of Watson and Watson-like technologies to meet the information needs of physicians in patient care, in the context of Electronic Medical Records. IBM Watson has unveiled an era of cognitive computing, and a broad set of applications are possible using the technologies. One particular area of immediate and urgent need is to apply the technology to address the cognitive load on physicians in using the patient data in Electronic Medical Records. To be effective in this context, it is necessary for the technology to support the workflow and the information requirements within the workflow. Prior to a patient visit, a physician may be seeking information such as, “What was done at the last visit? What data has accumulated since the last visit? What is overdue or needs to be addressed today?” without being overwhelmed with irrelevant information. Furthermore, it is also important to understand pain-points with the state of the art.

**Dr. Neil Mehta** will open the discussion with a practicing physician’s perspective of the informational challenges in using EMRs. It is well documented that there is a low physician satisfaction with most EMR systems as they fail to live up to their potential. Physicians and other providers spend a lot of time and effort entering data into the EMR (often following exhaustive institutional requirements of structured input and completeness) but do not see
tangible results commensurate with that investment and with their expectations created by the other internet
technologies. As the amount of data in the EMR increases, it takes more time and effort to get back useful
information from the EMR that would help with diagnosis and decision making. Caregivers are well-aware of
systems that have revolutionized other industries and are frustrated with the slow pace of change. A well-
designed effective cognitive computing system can play a huge role in solving this problem by giving valuable
“smart” information to the caregiver based on information in the EMR and evidence in the literature. Such
contextualized evidence based information would help EMRs live up to their potential and bring out a positive
change in healthcare of patients and populations.

Building an effective cognitive system takes many components. IBM Watson technology has demonstrated the
ability to analyze large volumes of medical literature. More recently IBM Watson has evolved to analyze the clinical
notes and structured data of a patient record into a meaningful summary of the record, centered around
automatically generated problem list. In order to build these EMR-centric analysis and even more advanced
decision support, millions of existing records can be an invaluable source of knowledge complementing the
knowledge from the medical literature.

Dr. Christopher Nielson will provide another perspective of the effects of increasing amount of data in patient
records, and in addition he will focus on how millions of such records can be analyzed to help develop knowledge
that enables cognitive computing. As increasing amounts of electronic data becomes available, fundamental
relationships that are critical to diagnosis and medical management may be obscured by irrelevant data. Although
the need for optimized data presentation is well recognized, manual identification of important relationships
between thousands of data types is impractical. The VA EMR database includes 30 million records with 15 years of
continuous data including nearly all data domains. The availability of such a large database permits probabilistic
evaluation of relationships between data domains with respect to needed associations, including frequency,
specificity and temporality. Rather than providing data simply organized by alphabetical order or location,
information can be presented with the patterns that are critical to diagnosis and management. Probabilistic
relationships create a foundation for decision support as well as a problem oriented approach to medical
management.

Kenney Ng will explore the power and promise of predictive modeling and patient similarity analytics with
concrete examples of how these methods can be applied to improve patient care. Experience shows that the
predictive models can generate actionable insights in addition to the risk score. In addition to identifying the top
risk factors, methods can also identify patient specific, time dependent risk factors. Patient similarity analysis, a
complement to the predictive modeling, is an approach to support personalized medicine. In this approach, a
similar patient cohort is first determined for a given individual patient and, machine learning and data mining
techniques can then be applied to the similar patient cohort to derive actionable insights. Customized models can
identify patient specific risk factors instead of just population level risk factors. Another application is to combine
patient similarity with drug similarity to tailor treatments to individual patients based on their likelihood to
respond to a therapy. The discussion will present results from studies on patient data.

Preethi Raghavan will discuss the potential and the promise of natural language question answering (QA) based
approach to managing the cognitive load in accessing EMR content. There is a wealth of patient information buried
in EMRs even as they are being recorded using today’s EHR systems, and we want to enable efficient discovery of
that information. The challenges include interpreting and making inferences from the structured and unstructured
text (without imposing additional requirements on the data entered) in the EMR to provide physicians with the
required answers to support clinical decision-making. Multiple strategies are being explored to navigate the vast
amounts of information about a patient. Some of these strategies, such as proactively summarizing important
patient information and a concept-based search in clinical notes and structured data, have been prototyped in IBM
Watson as well as in other research projects with encouraging results. However, the ability to precisely answer
patient-specific questions at the point of care would be even more effective. For example, “Were there any
complications of the patient’s RYGB surgery?” could be answered with very specific phrases, passages and
structured entries from the patient record. The discussion will examine different challenges associated with question answering on EMRs when compared to open-domain factoid QA, and how advanced natural language processing and patient modeling techniques can address these new challenges in QA on an EMR.

**Demonstration of IBM Watson:** We will demonstrate the present prototype IBM Watson patient record summarization and semantic search capability as an example of the cognitive computing discussed here.

**Relevance of the Panel and Anticipated Audience**
Cognitive load in accessing patient-specific information an EMR is a clear and present challenge. Physicians are frustrated with the current EMR technology. Cognitive computing exemplified by IBM Watson appears to have the potential to alleviate the cognitive load. A discussion of how these two trends intersect with a positive outcome is educational and deserves a detailed discussion. It is particularly interesting when the panel involves clinical informatics researchers and patient care practitioners on the same stage. Because of the panelists experience and their current research, it becomes possible to see how these possibilities go beyond just a hope and translate into results with real data. Because of the significance of these results in patient outcomes, this panel would be a significant attention grabber.

The audience for the panel will be from a very broad spectrum of the AMIA membership. Members with medical background, practicing or otherwise, would be interested to learn the cognitive computing capabilities that are feasible and can potentially help in patient care. Members without the medical background but with statistical and computer science background learn the cognitive needs of physicians and the state of the art for the cognitive computing analytics. Students, post-docs, and other early career researchers learn realistic challenges in patient care and how concrete examples of cognitive computing applications.

**Discussion Questions**
1. What is the precise nature of the cognitive needs of a practicing physician?
2. Why is there a cognitive needs gap?
3. How can big data analytics of millions of existing patient records help cognitive computing?
4. What is the current status of IBM Watson-like cognitive computing in the context of EMRs?
5. What are the results that indicate cognitive computing helps physicians?
6. How can predictive analytics be customized for individual patients?
7. How can patient similarities help derive actionable insights and tailored treatments?
8. What are the challenges of natural language question answering on an EMR?
9. What are the promising solutions for developing natural language question answering on an EMR?

**Statement of Participants’ Agreement**
I received positive acknowledgement in the form of email messages from the panel participants agreeing to participate in the panel.
Wait, my patient is where? Promises, challenges, and impact of automated event notification systems

Abstract
Electronic event notifications, also called alert or subscription services, provide real-time automatic alerting of patient health care encounters to healthcare providers at other institutions. For example, an ambulatory primary care provider might use the service to sign up for alerts when his/her patients are admitted to regional emergency departments or inpatient departments. In this didactic panel, panelists will discuss use cases for event notification systems, the current state of the evidence about whether these systems affect healthcare quality or cost, sociotechnical considerations in developing these systems, and ongoing evaluation work to move the evidence forward.

Keywords
Health information exchange; workflow; organization and administration; evaluation

Introduction
Event notification is the real-time, electronic, automatic alerting of providers to their patients’ contact with other health care facilities\textsuperscript{(1)}. Also referred to as an alert or subscription service, event notifications are messages triggered by specific patient activities, such as visit being registered in a hospital's admission-discharge-transfer (ADT) system. Triggers often involve an inpatient admission, discharge, or emergency department visit. Event notification systems fall under the broader category of health information exchange (HIE) technologies because electronic patient information is being shared between different organizations\textsuperscript{(1)}.

Event notification may address some of the information and communication challenges created by a fragmented health care system\textsuperscript{(2)}. A typical use case for event notification is as mechanism to inform an ambulatory primary care provider in near real-time that one of his or her patients has been admitted to a local emergency department or inpatient facility\textsuperscript{(3)}. In some instances, the event notification message be routed directly to a physician. More commonly, health care organizations receive event notifications and rely on members of a health care team, such as a case manager, care coach, or patient navigator to receive, manage and respond to alerts\textsuperscript{(4)}.

Event notifications offer several potential opportunities for improving health care quality. Event notifications are a new source of information about patients, thereby increasing providers’ general awareness of patients’ complex medical histories\textsuperscript{(5,6)}. Additionally, informing the provider by event notification creates opportunities for immediate intervention where appropriate\textsuperscript{(1)}. For example, health care providers may be able to contact the emergency department prior to inpatient admission to share information about the patient. Likewise, if the patient is still at the emergency department or hospital, the ambulatory primary care provider could support the coordination of post-discharge transitions and services, potentially improving the quality of care for a patient\textsuperscript{(3)}. Also, event notification may help identify patients for referral into care coordination programs\textsuperscript{(7)}. Alternatively, it is possible to structure event notification to identify missed health care contacts like a no show for specialist appointment or failure to obtain a prescription refill.
Event notifications appear to be a popular service as they have quickly been adopted by various HIE initiatives around the U.S. Additionally, they theoretically support the population health aims of integrated delivery systems(3). The evidence base for the effectiveness of event notifications is just beginning to grow. Few studies have examined these systems in real-world settings.

The panel

This panel seeks to summarize the challenges associated with event notification systems and the potential impact of these systems on care and decision making processes. Questions the panel will address are:

1. What are the use cases for event notification systems?
2. What is the role of organizational capacity and workflow fit in the implementation of event notification systems?
3. What are the challenges associated with effective implementation and use of event notification systems?
4. What is the relationship between event notification systems and other forms of health information exchange such as query-based exchange or DIRECT secure messaging?
5. What is the evidence that event notification systems can affect care delivery?

Panelists

The panelists have researched and evaluated event notification systems in diverse settings, with differential evaluation approaches, and from different organizational and theoretical perspectives.

Dr. Brian Dixon is an informatics researcher at both the Regenstrief Institute and the U.S. Department of Veterans Affairs. Dr. Dixon has worked with the Indiana Health Information Exchange to implement event notification services to private health system customers. Furthermore, he is currently the Indianapolis site lead for a new grant within the VA that is evaluating event notification services for older Veterans at two VA medical centers. In the VA project, Dr. Dixon is establishing triggers for when older adults seek care outside the VA. The notification messages will notify the Veteran’s primary care provider and, for those enrolled in the intervention arm of the study, a care coordinator in the Geriatrics service within VA. The care coordinator will work with the patient’s inpatient or ED facility to coordinate a discharge back to home where the VA can then provide intensive home-based care plus scheduling the patient for a follow up visit with his or her primary care provider. Dr. Dixon will describe the study design and early lessons to date rolling out the intervention across the Indianapolis VA region.

Dr. Jason Shapiro will discuss the differences between subscription-based event notification services and analytics-based notification services. Subscription-based event notification services usually require that a list of patients on whom notifications are desired be generated by the provider organization and sent to the health information exchange where surveillance is then done for trigger events. Analytics-based event notification services use a set of pre-determined criteria to define a cohort of patients on whom notifications should be sent using specific rules for trigger events. Examples of each will be given, and potential future use cases will be discussed.

Dr. Jessica Ancker will describe a survey of health care professionals who receive event notifications as part of their daily practice or job. The research, adopting a sociotechnical perspective, sought to identify the role of organizational features, workplace policies and procedures, and individual attitudes on perceptions of event notification quality, efficiency and satisfaction. Findings suggest that health care organizations with appropriate processes, workflows, and staff roles may be better positioned to use event notifications. Additionally, information quality remains critical in users’ assessments and perceptions. The work also identified specific instances where providers reported event notifications changed medical decision making and clinical activities.

Dr. Joshua Vest will describe the findings of a quantitative assessment of the impact of event notification on hospital readmission rates. Dr. Vest and his colleagues examined the event notifications offered in the Bronx, NY in a cohort of Medicare beneficiaries over a period of 54 months. Their evaluation compared the demographics and risk of the beneficiaries subscribed to event notifications and those beneficiaries who were not subscribed. Additionally, they found event notifications were associated with lower readmission rates.

As Moderator, Dr. Saira Haque will introduce health information exchange and event notification. She also will identify common themes across Drs. Dixon, Shapiro Ancker and Vest’s presentations. Dr. Haque will also review cross-cutting facilitators, barriers and considerations with event notification across sites.
**Learning objectives**

After participating in this session, the attendant will be able to:

- Understand the goals and basic functioning of an event notification system.
- Identify the challenges associated with event notification systems.
- Suggest methods to improve the fit of event notification systems into ambulatory care practice.
- Describe the evidence-base on the effectiveness of event notification systems.

This panel has been endorsed by both the Evaluation (Eval) and the People and Organizational Issues (POI) working groups.

Ensuring Reproducibility in Observational Research: 
Building and Sharing Knowledge Resources in the OHDSI Network

Jon D. Duke, MD MS¹, George Hripcsak, MD MS², 
Patrick Ryan PhD³, Nigam Shah MBBS, PhD⁴
¹Regenstrief Institute, Indianapolis, IN; ²Columbia University, New York, NY; ³Janssen Research and Development, Titusville, NJ; ⁴Stanford University, Palo Alto, CA

Abstract
The Observational Health Data Sciences and Informatics collaborative (OHDSI, pronounced ‘Odyssey’) was formed in 2013 with the goal of creating reliable scientific evidence through large-scale analysis of observational health data from around the world. To ensure transparency and reproducibility in our research, we have created tools to share knowledge artifacts and other resources efficiently amongst OHDSI community members. We have also worked to facilitate best practices in the validation and governance of these resources. In the proposed panel, we will discuss our approach to building shareable knowledge assets, conducting research using these assets, and supporting access to these resources beyond the OHDSI community.

Organizer: Jon D. Duke, MD, MS

Background and Panel Description
The Observational Health Data Sciences and Informatics collaborative (OHDSI, pronounced ‘Odyssey’) was formed in 2013 with the goal of creating reliable scientific evidence through large-scale analysis of observational health data from around the world. To advance this goal, OHDSI has had to rapidly expand its scientific, technical, and community infrastructure. OHDSI has now grown to over 140 participants from 16 countries. Across the collaborative, there are 84 databases covering over 600 million patient lives that have been transformed into a common data model. OHDSI has conducted multiple international network-based observational research studies using this infrastructure. In this panel, we focus on resource sharing in the OHDSI community. Specifically we will discuss how knowledge assets such as clinical phenotypes can be consistently generated for reuse and consumption by a variety of stakeholders. By the end of this panel, attendees will gain an understanding of the issues and approaches to resource sharing in large-scale observational research.

Panel Importance and Target Audience
The proposed panel demonstrates how international collaborative research can be conducted in a transparent and reproducible fashion through shared resources. The availability of common knowledge artifacts and tools to create and share such resources addresses a critical need for researchers and supports the recent NIH guidelines on transparency and reproducibility in biomedical research.¹ This panel will provide attendees with insight into the opportunities and challenges of conducting reproducible research across diverse datasets as well as a clear path to utilizing OHDSI resources to support reproducible research, even outside the OHDSI network. The target audience includes health informaticians, clinical and health services researchers, health IT leaders (e.g., CMIOs), implementation scientists, epidemiologists, biostatisticians, and data scientists.

Presentations

Enabling Reproducible Research from Concept to Publication (P. Ryan)
Reproducibility - the ability to duplicate results from an experimental procedure - is a cornerstone of the scientific method. Analyses of observational health data have been challenged due to their apparent lack of reproducibility, but different researchers with access to the same data or researchers applying the same methods to different data. In
In this context, the problem can be deconstructed into two challenges: 1) the lack of standardized processes that can be transparently and consistently applied to a given dataset to replicate an analytical result; and 2) inconsistent generalizability across populations that can arise from patient-level heterogeneity. The OHDSI community is working together to establish consensus scientific best practices for clinical characterization, population-level estimation, and patient-level prediction, and is embedding these best practices through open-source software that enable standardized analytics that generate real-world evidence is a reproducible fashion. We will argue that through standardizing the design, execution, and reporting to community-consensus and empirically-based best practice, we can simultaneously improve the efficiency, accuracy, and reproducibility of observational analyses.

**A Shared Library of Validated Computable Phenotypes for Observational Research (J. Duke)**

Phenotype definitions are a central component of observational research. Patient cohorts must be transparently and explicitly defined to allow others to interpret and replicate a research study. In the OHDSI community, we are seeking to facilitate best practices in development, validation, and sharing of patient phenotypes through the establishment of an OHDSI Cohort Definition Library. All cohort definitions in the OHDSI Library should include 1) a human readable cohort definition listing all inclusion rules, exclusion rules, and referenced concept codes; 2) a machine-computable JSON syntax explicitly representing the above definition; 3) a validation study configuration to support consistent evaluation of cohort definition performance (e.g., precision, recall) across multiple datasets; 4) additional metadata on provenance, supporting literature, and performance results where available. It is hoped that by incorporating computable definitions of not only the phenotypes but of their validation criteria as well, we will encourage greater consistency in constructing and validating cohorts for collaborative research.

**Building Integrated Knowledge Resources for Drug Safety (N. Shah)**

Drugs are among the most common interventions examined via observational studies. Given the volume of research activity in drug-safety research, and the widespread use of spontaneous reporting systems (SRS) data for hypothesis generation and validation of newer approaches, there is an urgent need to create integrated knowledge sources that support evaluation of drug safety surveillance methods. We will describe a freely available, curated and standardized version of the US Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS) data, which we call AEOLUS for Adverse Event Open Learning through Universal Standardization. In the creation of this public resource, as part of our work in the OHDSI community, we remove duplicate case records, apply standardized vocabularies to source codes and terms, mapping drug names to RxNorm concepts and outcomes to SNOMED-CT concepts, and pre-compute summary statistics about drug-outcome relationships. We make this resource, along with the source code to refresh the dataset, freely available to reduce the amount of time spent performing data management on the source FAERS reports, improve the quality of the underlying data, and enable standardized analyses using common vocabularies across disparate evidence sources.

**Embedding Large Scale Analytics at the Point of Care (G. Hripcsak)**

Modern research and modern medicine require access to information. Institutions sometimes struggle with providing clinical data to its research and clinical staff, usually offering a clinical data warehouse and a finite number of analysts to answer questions, generally after an approval process that may involve an institutional review board and other institutional committees. To facilitate information access, Columbia offers to its 12,000 research and clinical staff immediate access to an OHDSI database using the OHDSI Atlas tool set to query and analyze data. The data are de-identified, and IRB permission has been obtained on behalf of staff to query the database directly and immediately. The Atlas tool set helps users to navigate the terminologies, assemble correct queries, and visualize the results.

**Discussion Questions**

- What are the main challenges associated with performing reproducible research?
- What is the value of computable knowledge assets such as clinical phenotypes?
- What is gained and what is lost in the process of creating a computable phenotype?
- How can phenotype performance be consistently evaluated across diverse institutions?
- What is the difference between coded data and standardized data?
- How can the quality of a transformed data set be evaluated and, where necessary, improved?
- What are the barriers to sharing aggregate clinical data to providers within an institution?
- How can the interpretation of aggregate clinical data be facilitated by common reporting libraries?

Assurance
The organizer Jon D. Duke vouches that all listed participants have agreed to take part on the panel.

The Best of Imaging Informatics Research 2016

Panelists: Charles E. Kahn, Jr., MD, MS¹, William Hsu, PhD²
¹Department of Radiology and Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA; ²Department of Radiological Sciences, University of California, Los Angeles, CA

Abstract

The field of imaging informatics is rapidly advancing in its ability to address challenges related to clinical big data and harnessing this information for precision medicine. In the past year, the field has experienced growth in a variety of areas including radiomics (the generation of high dimensional features from images), development of new ontologies and standards for capturing information from images and reports, and unsupervised learning from images to predict the course of a disease and treatment response. In addition, we have seen a remarkable growth in novel approaches that go beyond pixel data by integrating imaging with other biomedical data, standardizing imaging workflows, and improving the quality and utility of image-derived information in clinical practice. In this session, we will review key advances in imaging informatics research published this past year.

Overview

Biomedical informatics spans a spectrum from basic to applied research, and from molecular to population scale. Imaging informatics is a discipline that focuses on improving patient outcomes through the effective use of images and imaging-derived information in research and clinical care. In the past, imaging informatics at AMIA has focused primarily on management, processing, and analysis of imaging data. As the storage and display of multidimensional image data has become commonplace, imaging informatics has evolved from primarily characterizing information from pixels and voxels in images to integrating evidence from images and other biomedical data sources to provide a systems-level understanding of disease etiology and progression. These developments have underscored the need to engage individuals from different disciplines to address shared challenges in managing heterogeneous datasets, developing common standards, and interpreting multiscale evidence for precision medicine. This session provides attendees with a topical review of new and interesting developments in imaging informatics in areas such as health policy, ontologies, standards and interoperability, reporting, radiogenomics, and deep learning. We expect this session to appeal to AMIA attendees given its emphasis on shared challenges and techniques such as data standards, information extraction, and predictive modeling that are broadly studied and applicable across the biomedical informatics field.

Methods

Searches using PubMed and Google Scholar will be performed relevant imaging informatics keywords and filtered for the previous twelve months. In addition, the abstracts of articles published in publications such as Radiology, RadioGraphics, Journal of the American Medical Informatics Association, Journal of Biomedical Informatics, and Journal of Digital Imaging, arXiv, Journal of Pathology Informatics, Neuroimage, Medical Image Analysis, and Academic Radiology will be reviewed. These searches will be supplemented by a call for nominations from luminary imaging informatics groups, including the Biomedical Imaging Informatics Working Group of AMIA, the Radiology Informatics Committee of the Radiological Society of North America (RSNA), the Informatics Commission of the American College of Radiology, and the Board of Directors of the Society for Imaging Informatics in Medicine (SIIM).

Dr. Kahn will present the best of research in ontologies, structured data capture, decision support, and other science focusing on data other than the images themselves. Dr. Hsu will highlight advances in radiomics, data integration and modeling, and novel healthcare applications.

Panel Organizer Statement

The panelists listed above have agreed to present the material and lead a discussion. A similar session will be presented at the annual meeting of the Radiological Society of North America (RSNA) annual meeting in December, 2016. This session is supported by the RSNA, the Society of Imaging Informatics in Medicine (SIIM), and the AMIA Biomedical Imaging Informatics Working Group.
Using Patient-Generated Data for Wellness and Biomedical Research: From Behavioral Sensing to Decision Support

Abstract
The rise of consumer health awareness and the recent advent of personal health IT has contributed to another shift in healthcare landscape and the accumulation of patient-generated data. Despite the rise of health consumers, the impact of patient-generated data remains to be validated. Transforming patient data for wellness and biomedical research poses many challenges. Besides the fact that patient data has been generated in large quantities that exceed what humans can consume directly, its quality and reliability vary. In this panel, we would like to review the status quo of existing evidence and present user scenarios where hybrid knowledge-augmented, data-driven methods are coupled with visualization tools to overcome barriers of interpretation and increase adaptability. We are also looking for decision support tools to better incorporate patient data for prevention and in extended care settings. This panel aims to share with leading practitioners and researchers at AMIA their efforts in using patient-generated data for wellness and biomedical research. After participating in the session, the audience should be able to assess the basic requirements for putting such data in action from the clinicians and biomedical researchers’ perspectives.

Panelists
• Prof. Fernando Martin-Sanchez, PhD, FACMI, FACHI, Weill Cornell Medicine, New York, NY.
• Prof. Katherine Kim, PhD, MPH, MBA, University of California Davis, Sacramento, CA.
• Prof. Susan Peterson, PhD, MPH, University of Texas MD Anderson Cancer Center, Houston, TX
• Cagatay Demiralp, PhD, Research Staff Member at IBM T.J. Watson Research Center, Yorktown Heights, NY.
Moderator: Pei-Yun Sabrina Hsueh, PhD, Research Staff Member at IBM T.J. Watson Research Center, NY.

Introduction
Over the last few decades, the rise of consumer health awareness has been driving the shifting of healthcare landscape, partly as a response to population aging and rise of chronic disease prevalence. In the past decade, the shift has accelerated owing to the advance of Internet and personal health management tools. More recently, a third wave of transformation is starting to take place. On the one hand, the movement of Quantified Self, e-patients, DIY healthcare, and citizen science are gaining momentum [1], with the aid from the significant improvement of health tracking capabilities on consumer devices, including mobile and wearable devices that can monitor a wide range of physiological measures (e.g., heart rate variability) and lifestyle information (e.g., physical activity and nutrition log). Polling data of 2,300 consumers shows that the adoption of mobile app for health has doubled in two years, reaching 33% in 2016, and, a majority believed that patient data is beneficial for maintaining health [2].
On the other hand, the introduction of value-based care concept has led to payment reforms. With the federal government policy initiatives such as Affordable Care Act, the focus on quality of care and the reimbursement of non face-to-face chronic care management further added fuel to the adoption of connected health technologies for self-care and just-in-time interventions. Under Medicare, 85% of provider payments are expected to tie to quality of care in 2016 [3]. It has also led to increasingly diverse channels, e.g., the nurse-led clinics and case management [4]. As a result of reconciling the two shifts, the consumer-driven healthcare is becoming a significant trend, and in turn it has driven the consumers to become pro-active. More than 90% of patients are willing to participate in shared-decision making with clinicians [5], and nearly 40% will use alternative channels for health services [2].
Despite the rise of health consumers, the impacts of patient-generated health data (PGHD) remain to be validated. Recently, some PGHD measures have been shown to correlate with the onset and progression of a variety of disease states, e.g., depression [6]. Others have shown effectiveness for patient activation in positive behavior change of physical activity and healthy eating behavior [7] and medical conditions such as obesity [8]. In the domain of disease prevention and management, researchers are moving the needle by incorporating more patient data, ranging from health and treatment history (from portal or EHR), biometric data (from lab tests and devices) to patient-reported outcomes (PRO) (e.g., survey, screening, questionnaire of medication adherence and risk assessment) [9].
In particular, the incorporation of PRO has been reported to increase patient-centered care coordination and the meaningful personalization of electronic health records. It helps assess the efficacy of treatments. For example, Geisinger Health System in northeastern Pennsylvania uses PROs to assess patients’ status before and after treatment. It can also help understand multi-domain health risk assessment (HRA) and health-related quality of life (HRQOL) [10]. In clinical trials, the use of PRO can help determine the eligibility of patients for certain clinical trials and enable comparative effectiveness on an individual basis, which becomes the basis for the N-of-1 trial framework of personalized medicine [11]. In the field of psycho-pharmacology, ecological momentary response (EMR) methods have been shown to increase the sensitivity of assessments [11] and are more amenable to the study of endpoints, as well as the determination of patient adherence and reasons for non-adherence [12]. Different frameworks are being investigated to support the generation of evidence and the subsequent design of personalized health interventions with participatory technologies (such as social media or Self-Quantification) [13,14]. However, the quality and reliability of the different PGHD data sources varies. For example, evidence is strong for the reliability of using patient health wearable data for physical activity measures, but weaker for sleep pattern and heart rate variability measures [15]. Clinical trials have been conducted to examine the clinical value of PGHD from connected health devices and PRO in different conditions, yet the results also vary widely, with some showing no improvement over standard care [16]. Further examination of the benefits of incorporating PGHD shows an increase of self-motivation to perform self-care and the timeliness of feedback for just-in-time adaptive intervention [17]. Despite that there are now initial evidence on reliability, the jury is still out there for the validity of patient-generated health data, it has been conjectured that the approach based on user-generated health data need to be coupled with incentives, incremental feedback and other strategic initiatives and careful program designs to make it work [15].

Panel Description and Learning Objectives

This panel will review the status quo of existing evidence and present success stories where hybrid knowledge-augmented, data-driven methods are coupled with visualization tools to overcome barriers of interpretation and increase adaptability. We are also looking into decision support tools in other fields to look for inspirations of possible ways to better incorporate patient data for prevention and in extended care settings. This panel aims to share with leading practitioners and researchers at AMIA their efforts to gather requirements for the next-generation healthcare delivery and population health management systems to depict the action items needed for putting patient-generate data in action. After participating in the session, the audience should be able to:

- Demonstrate how PGHD is generated through examples in participatory health and mobile health research.
- Describe emerging tools for transforming PGHD into actionable knowledge for patients and clinicians.
- Discuss gaps, drivers, barriers, and opportunities to promote the generation and application of PGHD to improve patient and clinician decision-making.

During the panel discussion, the panelists will further help address the following questions:

- How can PGHD contribute to successful provider-patient communications, risk reduction, and increase in early interventions?
- Can PGHD support shared decision making or help calibrate just-in-time intervention to patient’s values?
- Do the providers’ and patients’ beliefs and support of PGHD and approaches affect patient usage?
- Can dynamically configured healthcare IT help improve helathacer quality and patient behavior using a scalable technology-enabled platform?

Description of Speaker Topics

The panel will be organized as a series of short presentations, followed by a question and answering session in the end. The topics each speaker will cover are as follows. First, Prof. Kim will talk about patient generated data in coordination of complex chronic conditions and the emerging work in cancer and heart failure. In particular, she will report on two studies that utilized participatory and user-centered design methodologies in development of mobile platforms for care coordination for complex conditions. The first involves a personal health network for community-wide care coordination for chemotherapy, and the second focused on integrated mobile applications for heart failure. Key functionality included a shared care plan, medication management, symptom management, appointments, and integration of data and workflow with EHRs with patient-generated data incorporated into each. Considerations in designing with and for patients and implications for technology adoption and health outcomes will be discussed. Prof. Peterson will continue on reporting on the collection and use of patient-generated data in cancer prevention, clinical care, and survivorship. She will describe use cases and studies that have developed and implemented e-health and mhealth applications for behavioral assessment and intervention in several populations, including

204
individuals and families at risk for hereditary cancer, patients undergoing cancer treatment, and adolescent and young adult cancer survivors. Dr. Peterson will also describe how PGHD generated through sensor-based and mobile technology applications can guide clinical decisions and patient support for clinically relevant outcomes to cancer survivors, including therapeutic adherence, dehydration prevention, physical activity, and tobacco cessation. In addition to the role that PGHD plays in healthcare and health prevention scenarios, Dr. Martin-Sanchez will discuss PGHD can also be very useful for biomedical research purposes. Precision Medicine requires the integrated analysis of all sources of individual health data, and participatory technologies (health, social media, self-quantification) can be considered as interfaces to the Human Body and the Human Exposome (life-long exposure to environmental risk factors). Several examples of characterizing individual environmental data with mobile technologies will be presented and discussed.

Dr. Demiralp will introduce how visualization of PGHD can be applied to understand the present and future self from patient’s point of view. The goal is to help people understand and reason about their data. To that end, visualizations ease and amplify the work of cognition by re-coding information so as to exploit the perceptual abilities of the eye, which is evolved for capturing patterns and outliers. The ultimate success is to improve comprehension and decision making. In his talk, he’ll describe how data visualization principles can be easily applied to everyday visualizations. He’ll then discuss data visualization examples facilitating better decision-making by effectively conveying uncertainty and risk and present examples of using PGHD for wellness research.

**Statement of Participation**

Each of these panelists and the organizer has confirmed via email that they agree to take part in the proposed panel.

Senior Vice-President & Chief Medical Officer, IBM Watson Health/Explorys
Consulting Staff, Department of Internal Medicine
Cleveland Clinic, Cleveland, OH USA

Abstract
Electronic health data has been generated and made accessible in unprecedented quantity and richness in the last decade. More recently, there has been much hype about applications of big data for healthcare and life sciences. This hype is due in part to a growing collection of success stories involving advanced data analytics bringing about real impact ranging from addressing unmet information needs for patients, clinicians, administrators and policy makers, to novel scientific research results from carefully constructed observational studies. However, at the same time, there has been much skepticism voiced citing limitations of data derived from insurance claims, electronic health records (EHRs), and other types of observational resources. The goal of this panel is to bring together experts from both academia and industry to share examples and thoughts on what precautions need to be taken in performing analytics on real world data, how careful modeling and investigation can help prevent bad science from being performed on imperfect data, and the types of useful insights that can be derived when the analysis is carried out appropriately. Learning objectives include an appreciation of both the promise and the limitations of observational health data, and practical guidance on how to leverage advanced analytics to harness useful insights from such data.

General Description
Traditional medical research approaches are hypothesis-driven and based on deductive reasoning carried out on relatively small amounts of data collected in a highly controlled manner, such as
randomized clinical trials. With the arrival of big data there is increasing recognition that many types of research questions and information needs can be addressed through inductive learning that starts with observations and develops models that lead to novel insights. Such approaches open up vast new possibilities of discovery and also help circumvent the confirmation bias that limits hypothesis-driven investigations. The key, however, is to understand what types of questions can be best addressed with observational studies and how to test the consistency of the results and ensure the validity of the conclusions.

This panel will seek to address a range of related questions including:

- What is useful and how does it depend on the end user? For example, for research, useful means advancing our knowledge about the basis of medicine, whereas in operations, useful means making sure the right patients get the care they need at the right time.
- How should we measure data quality and potential distortion from point of care to final analytical results?
- What data standardization is preferred to address heterogeneity in populations and the data capture process for the purpose of phenotyping and analytics?
- How do we facilitate and measure reproducibility across databases or research networks?
- How can we validate and expand known associations into new discoveries?
- Can we leverage longitudinal modeling to smooth out irregularities in data?
- Under what conditions can subphenotyping strategies uncover mixtures of groups and why imperfect is not always incorrect?

Prof. Shah will examine the use of aggregate patient data in an informatics consult in a research setting. A few years ago, researchers at Stanford demonstrated how data from a research clinical data warehouse could be used to drive evidence-based medicine (http://www.nejm.org/doi/full/10.1056/NEJMp1108726). Prof. Shah will discuss recent progress towards helping clinicians leverage aggregate patient data for decision-making at the point of care. He will illustrate the idea with a demo of a search engine built to support such an informatics consult, and review how decisions about data pre-processing affect phenotyping as well as downstream analyses that estimate treatment effects from imperfect data.

Prof. Malin will present research conducted at Vanderbilt University on discovery of complex phenotypes, stratification of patients, and predictive modeling using data from multiple large academic healthcare systems including Northwestern Memorial Hospital and Vanderbilt University Medical Center. He will illustrate how they were able to discover inconsistencies in vocabulary usage and subsequently design techniques to define core phenotypic topics that enabled an alignment of disparate patient populations. He will also review how longitudinal modeling, in combination with risk stratification, can enhance stability in the prediction of blood pressure control. The presentation will conclude with a discussion on how data privacy protections could be considered a form of generating imperfect data and how appropriate design of such mechanisms can enable both validation and discovery.

Dr. Ryan will discuss the evolving role of observational data analysis in generating and disseminating real-world evidence about disease, health service utilization, and the effects of medical products. He will highlight the role of the pharmaceutical industry in establishing and promoting best practices in the appropriate use of observational data by conducting methodological research, developing standardized analytics tools and demonstrating successful applications to important clinical questions.
He will illustrate how three core methodological issues – reproducibility, generalizability, and heterogeneity- represent the primary challenges to observational health data sciences, and how collaborating in open source communities with other stakeholder groups offer a viable path forward.

Dr. Jain will discuss the opportunities and challenges of utilizing electronic health record data and claims data generated from healthcare systems that are undergoing payment and delivery transformation. Using examples from implementations at several health systems, the presentation will show how real-world data exhaust generated by these systems can both accelerate net new knowledge discovery and support population health focused data sciences to drive innovations as academic and non-academic health centers are faced with diminishing margins. Despite advances in supporting interoperability between information systems, the ongoing need to further curate real-world data will be discussed. The presentation will conclude with a demo visualizing how this imperfect data can be used to predict health care utilization in the setting of population health management.

**Explanation of Urgency of Topic**

The promise of big data for healthcare and life sciences lies not in the generation of the data itself, but in how it is used. We are marching towards bigger, broader, and more complex systems with more fine-grained detail on patients coming from diverse data sources. At the same time, we are increasing the distribution and reuse of data beyond its initial primary setting and context of collection. As data science becomes more popular, there will be substantial interest in applying arrays of unsupervised and supervised machine learning models to this data. However, the extent to which the results are reliable and useful will be contingent on recognizing bias, inaccuracy in data collection (and subsequent filtering), and using multiple modes of evidence to obtain consistency in discoveries and predictions. There is thus an urgent need in the community to have an informed and thoughtful discussion around the methodological considerations needed to realize the potential of big, heterogeneous, imperfect data.

**List of Questions**

1. What should be the role of observational evidence compared to other sources of evidence?
2. How much confidence can be taken from observational analysis?
3. Will initiatives in reproducible research and transparency resolve concerns in such investigations?
4. How do you validate findings from imperfect data?
5. How do you access data quality, and how do you factor that into your analysis?
6. How do you evaluate utility of the insights (AUC vs. Net reclassification for example).
7. How can we instill trust in the findings discovered from imperfect big health databases?
8. Under what circumstances can discoveries made in one setting be translated into another?

**Statement of Participation:**

All participants have agreed to take part on the panel.
Standardizing Research Common Data Elements: Initiatives, Exchange Formats and Current Use by Patient-Level Trial Results Databases

Vojtech Huser¹, Murat Sincan², Dikla Shmueli-Blumberg³, Rachel Hess⁴

Abstract

Sharing of de-identified patient level data from clinical trials is increasingly becoming a norm and this trend is increasing the importance of research Common Data Elements (CDEs). CDEs have the potential to increase the value of trial data by making it easier to integrate data across multiple trials. CDEs can reduce study start-up costs, improve the quality of collected data, and facilitate cross study comparisons, data aggregation and meta-analyses. This panel will (1) describe current CDE initiatives, highlight several trial data sharing platforms (including their use of CDEs), and describe CDE informatics standards; (2) describe a case study a site using REDCap Electronic Data Capture system and their CDE experience; (3) describe a case study of a trial data sharing platform of the National Institute on Drug Abuse; and (4) showcase a multi-site observational study that first selected suitable CDEs and implemented collection of trial data directly within an Epic EHR.

General Description (including ‘Why the topic of this panel is timely’)

Sharing of de-identified patient level data from clinical trial is increasingly becoming a norm to ensure reproducibility of analyses, increase public trust in research enterprise, and to avoid wasting research resources. To further facilitate comparison and aggregation of data from multiple research studies, use of Common Data Elements (CDE) is increasingly encouraged by public research funders, such as the National Institutes of Health. CDEs have the potential to increase the value of data collected in clinical trials by making it easier to integrate data across multiple trials. CDEs can reduce study start-up costs, improve the quality of collected data, and facilitate cross study comparisons, data aggregation and meta-analyses. Several trial data platforms now have multiple year experience with hosting and distributing trial data, including the effort to use medical terminologies and CDEs for semantic data integration.

This panel will describe the current state of the clinical research informatics of CDEs and showcase examples of their use in clinical research studies and trial results databases.

Speakers:

Vojtech Huser will introduce the topic of common data elements. He will describe a clinical trial lifecycle and impact of CDEs during the trial design stage and impact of CDEs on secondary use of data (during data sharing). He will provide an overview of data platforms that allow individual patient level data from clinical trials and the current adoption of CDEs by trial data platforms. See Table 1 for overview of trial data sharing platforms ordered by size (number of trials with data). In the second part, Dr. Huser will give a brief overview of several CDE initiatives (e.g., NIH initiatives: PhenX, PROMIS, cancer CDEs; non-NIH initiatives: CDISC Therapeutic Area (TA) standards or FDA [Food and Drug Administration] standards, namely Study Data Tabulation Model and Define-XML standard). Finally, he will also describe where CDEs can currently be downloaded and what informatics standards are being used to import and export empty Case Report Forms (CRF) or form-collected patient data (e.g., National Library of Medicine (NLM) CDE repository at https://cde.nlm.nih.gov, REDCap shared library at https://redcap.vanderbilt.edu/consortium/library or University of Muenster’s repository at http://medical-data-models.org).

Murat Sincan will describe an implementation of a REDCap Electronic Data Capture system at the National Institute of Dental and Craniofacial Research (NIDCR) and how principal investigators at NIDCR are currently impacted by CDEs. He will provide an EDC user perspective on informatics issues with importing CRFs with common data elements from the NLM’s CDE Repository or other external repositories. He will describe how CDEs can be incorporated into project CRFs and the practical issues that arise during the lifecycle of a project with an emphasis on change management and data harmonization.
Dikla Shmueli-Blumberg will approach the topic of CDEs from the perspective of a trial results database. She will describe the National Institute on Drug Abuse (NIDA) Data Share website. The website provides a platform for timely sharing of de-identified research data from NIDA Clinical Trials Network (CTN) studies after their completion. In addition to the data files (available as ASCII or SAS format), descriptive metadata, research protocols, annotated case report forms, and listings of assessments used in the studies are also provided. This effective and user-friendly method of dissemination of results to the larger research community has been effective at promoting secondary data analyses and providing valuable information to the field of substance use treatment.

Rachel Hess will describe efforts of the PaTH PCORNet Clinical Data Research Network (CDRN) to integrate patient-reported outcomes into research embedded within clinical care. The team worked with clinical, patient, and operational stakeholders to identify and integrate PROMIS and disease-specific quality of life measures. The PaTH team chose PROMIS instruments because of their validity across a wide variety of disease states and future ability to use computer adaptive testing to make questionnaires even briefer. PaTH clinical stakeholders identified disease-specific instruments that had high clinical relevance, would contribute to advancing the understanding of the experience of that condition, and were practical within routine care. Patient stakeholders validated the domains of interest and ensured that measures chosen were reflective of their experience of their health condition. Operational champions worked closely with research and technical teams to deploy questionnaires in Epic’s MyChart personal health record. This allowed information to flow into the electronic health record and be used for clinical care and research. The PaTH experience served as a proof-of-concept for two health systems (participating in PaTH) to integrate patient-reported outcomes into clinical care. These teams used local resources as well as Epic’s Boost program to ensure timely implementation. For individuals without personal health record access (either because they chose not to sign up or their institution did not have questionnaire capability in the personal health record), questionnaires were available via REDCap or paper. All paper questionnaires were entered into REDCap by staff; REDCap-based responses were not available for clinical care.

Panel type: Didactic; All participants have agreed to take part on the panel
Anticipated audience: clinical research informatics researchers, clinical study PIs, research clinicians, EDC users and administrators, research coordinators, medical terminology experts, data scientists reusing data

Discussion points:
1. What is the current adoption of Common Data Elements and does it differ by domain (e.g., cancer, asthma, stroke, rare diseases)?
2. How can different CDE initiatives be harmonized (avoid creating multiple CDEs for similar research concepts)?
3. Are existing CRI standards sufficient to import a form (or a set of CDEs) from one system to another? What is the current adoption of these standards by different electronic data capture systems?
4. What is the relationship of CDEs (that try to conceptualize clinical research) to biomedical terminologies (that try to conceptualize routine medical care [e.g., SNOMED])?
5. Is it currently possible to track actual usage of CDEs across medical domains? How long after introduction of CDEs can we demonstrate that CDEs are truly adding some value to the research enterprise?

List of speakers: (1) Vojtech Huser, Staff Scientist at National Library of Medicine; member of the CDE Working Group of the Trans-NIH BioMedical Informatics Coordinating Committee (BMIC); (2) Murat Sincan, Staff Scientist at National Institute of Dental and Craniofacial Research (NIDCR), provides informatics leadership to the NIDCR REDCap server within NIDCR intramural research program; (3) Dikla Shmueli-Blumberg, Project Manager at EMMES Corporation for NIDA Clinical Trials Network; (4) Rachel Hess, Professor of Population Health Science and Internal Medicine, University of Utah School of Medicine, representative of the PaTH PCORnet Clinical Data Research Network

⁴Geisinger Health System, Danville, PA, ⁵Apervita, Inc., Chicago, IL

Abstract

Commercial electronic health record (EHR) systems such as Epic and Cerner are increasingly offering powerful interoperability frameworks for extending their capabilities through interfaced applications and software services. These interoperability frameworks include application programming interfaces (APIs) for reading and writing data from the EHR, embedding Web applications seamlessly into the native EHR user interface, and consulting external clinical decision support Web services from within the EHR’s native rules engine. Importantly, several of these APIs utilize standards-based, vendor-agnostic interfaces such as the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) data interface. In this panel, leaders from four leading healthcare organizations will describe how their institutions have established operational programs for developing applications and services that extend the capabilities of their EHR systems to improve clinical care. Example applications and services that have been developed by the panelists’ organizations include an integrated rheumatology management application; patient-facing medication compliance applications; a pediatric growth chart application; and a sepsis predictive modeling service. The panelists will also describe some of the key challenges and lessons learned, solicit additional insights from the collective experience of the audience, and provide guidance for colleagues seeking to extend their EHR systems at their respective organizations.

Dr. Middleton will serve as the moderator and introduce each of the panel members and their organizations. Dr. Middleton will provide an overview of the exciting opportunity that has been made available by many commercial EHR vendors to extend their capabilities through interfaced applications and services. This overview will be followed by presentations by the panelists, who will describe why their organizations have made a commitment to interoperable applications and services; their strategy, governance, and approach; their progress to date and roadmap ahead; and lessons learned. Each panelist will also showcase novel capabilities developed by their organizations through these programs. These presentations will be followed by a panel discussion with the audience moderated by Dr. Middleton.
Bloomfield: Dr. Bloomfield is Director, Mobile Technology Strategy and Assistant Professor of Internal Medicine and Pediatrics at Duke Health. Starting in the Spring of 2014 Dr. Bloomfield and the team at Duke began exploring the integration of the SMART and FHIR APIs with their Epic EHR. It was determined that this was not only feasible, but could help accelerate development and innovation throughout the health system. By January 2015 Duke had built the required infrastructure to make this a reality, and was able to demonstrate several SMART/FHIR apps (open source and proprietary) running within the Epic desktop environment as well as within the provider-facing mobile apps. This infrastructure based on FHIR Draft Standard for Trial Use Release 1 (DSTU1) was approved for production use in August 2014, becoming the first use of FHIR in a production Epic system. Since that time, the infrastructure has been updated to DSTU2 and work is ongoing to add support for patient-facing use-cases as well as write support. This work will be complete in March 2016 and is part of Duke’s commitment to the White House from the summer of 2015 with respect to patient-facing use cases for precision medicine. Dr. Bloomfield is currently working on ways to streamline the process for app integration to enable this technology to quickly scale. He will present an overview of this work, lessons learned, and give a demo of the technology.

Erskine: Dr. Erskine is Chief Clinical Informatics Officer at the Geisinger Health System. He is responsible for sequencing future and innovative technologies at Geisinger and for harmonizing data across the clinical care, research and health plan enterprise. Dr. Erskine heads the Division of Applied Research and Clinical Informatics (DARCI) which engages staff in the design and configuration of Geisinger’s clinical information systems and vendors for extension and associated standards.

Kawamoto: Dr. Kawamoto is Associate Chief Medical Information Officer, Assistant Professor of Biomedical Informatics, and Director of Knowledge Management and Mobilization at the University of Utah. He also co-leads the University of Utah’s Interoperable Apps and Services (IAPPS) initiative, which is a multi-stakeholder effort to enable standards-based, interoperable applications and software services to improve health and health care. Dr. Kawamoto will describe why the University of Utah initiated the IAPPS program, its governance model and resourcing, and the inter-disciplinary collaboration of groups including the Epic EHR team, biomedical informatics, the computer gaming graduate program, and the Center for Medical Innovation. He will discuss the initiative’s central strategy of enabling various groups from within and outside the organization to innovate and contribute, as well as the tactics being pursued to enable such crowd-sourced development while ensuring security and maintainability. He will also describe OpenCDS (www.opencds.org), an open-source clinical decision support framework being leveraged within this initiative, and the initial set of provider and consuming-facing applications and services that have been developed, such as for “gamifying” medication compliance for patients and integrating a sepsis prediction module into the native EHR rules engine. Dr. Kawamoto will also discuss key lessons learned, such as the tension between EHR-agnostic interoperability and the desire to leverage EHR-specific, more advanced APIs; and the need for additional semantics to be defined within FHIR to enable true interoperability.

Narus: Dr. Narus is a Medical Informatics Director and Chief Clinical Systems Architect at Intermountain Healthcare. He also leads and participates in technical direction for the Health Services Platform Consortium (HSPC). Dr. Narus will discuss Intermountain’s efforts to partner with Cerner to develop an open, standards-based service layer on Cerner’s EHR infrastructure in order to allow broader capabilities for in-house and third party application innovation. He will describe internal efforts to develop and implement applications on this new service layer, and lessons learned. He will also describe Intermountain’s participation in HSPC, which is seeking to expand the idea of open, standards-based services and application interoperability across EHR and healthcare organization boundaries.

Middleton: Dr. Middleton is Chief Informatics & Innovation Officer at Apervita, Inc., the provider of the largest marketplace for the creation, exchange, and use of data and analytics in healthcare. He is immediate Past-Chair of the Board of Directors of the American Medical Informatics Association (AMIA), and Instructor in the Harvard TH Chan School of Public Health in the Departments of Health Policy and Management, and Policy Translation and Leadership Development. Previously, he was a Professor of Biomedical Informatics, and/or of Medicine, at Stanford, Harvard, and Vanderbilt Universities, and he held executive leadership roles at MedicaLogic/Medscape, Partners Healthcare System, and at Vanderbilt. Dr. Middleton’s work is focused on clinical informatics – the applied science surrounding strategy, design, implementation, and evaluation of clinical information systems in complex environments. Dr. Middleton will provide an overview of the opportunity for innovating and extending the functionality of EHR systems. He will also provide a brief overview of the main mechanisms offered by EHR vendors for extension and associated standards.
evolves Geisinger’s facilities to take advantage of ultramodern technologies. Dr. Erskine will describe how his team is using SMART and FHIR to contribute to the emerging healthcare Web App ecosystem in an EHR-agnostic manner. Dr. Erskine will describe the unique functionality developed at Geisinger, such as a workflow-optimized and visually rich rheumatology Web application (https://gallery.smarthealthit.org/xg-health-solutions/enrg-rheum). In addition, he will describe the technical approach used, including getting FHIR from Geisinger’s interface engine (Rhapsody v6.2), from middleware (Sansoro Emissary product), from Epic Corp (through its available native FHIR support), and from Cerner’s Healthe Intent platform. Dr. Erskine will also describe how Geisinger has organized a FHIR-based dev/ops process branded “SynrG”, which is designed to incrementally invest in home-grown applications based on merit/outcomes and compliance with standard FHIR-based data resources. Dr. Erskine will also discuss the many lessons learned through the Geisinger journey in interoperable applications and services.

**Middleton:** Dr. Middleton will lead a moderated discussion with the audience. The objectives of this discussion will be to answer questions from the audience, engage in a stimulating exchange of ideas, and gain further insights on the topic from audience members’ collective experiences. The discussions questions listed below will be used to stimulate this discussion.

**Significance of panel topic and anticipated audience**
Whereas home-grown EHR systems served as the platforms for innovation in biomedical informatics for many years, there is a clear trend for home-grown systems to be replaced by commercial EHR systems. Thus, it is imperative that biomedical informaticists become experts of commercial EHR systems and how to innovate within and in conjunction with those systems. This panel will help audience members working through this transition to better understand how biomedical informaticists can thrive and make essential contributions by leveraging EHR systems’ currently available and continually improving frameworks for interoperability.

**Discussion questions**
What experiences have you had with extending your EHR system’s functionality, and what lessons have you learned?
What recommendations do you have for standards development and implementation in this area?
What gaps do you see in the current interoperability frameworks offered by EHR systems?

**Participation statement**
All proposed panelists have agreed to participate in the panel if the proposal is accepted.
Report from the ED-WG Frontline: Biomedical and Health Informatics
Baccalaureate (BHIB) Course

Saif Khairat, PhD, MS1, Glynda Doyle, RN, MSN2,
Indra Neil Sarkar, PhD, MLIS3, Jeff Williamson, MEd4,
1University of North Carolina, Chapel Hill, NC; 2British Columbia Institute of Technology,
Vancouver, Canada; 3Brown University, Providence, RI; 4AMIA, Washington, DC,

Participants
• Organizer and Panelist: Saif Khairat, PhD, Carolina Health Informatics, University of North Carolina
• Panelist: Glynda Doyle, RN, MSN, British Columbia Institute of Technology
• Panelist: Neil Sarkar, PhD, MLIS, Center for Biomedical Informatics, Brown University
• Panelist, Moderator: Jeff Williamson, MEd, AMIA

Abstract
Biomedical Informatics training at the graduate and post-graduate level has expanded to include almost all clinical specialties. Whether it is a Masters, PhD, or the fellowships in the Sub-Specialty in Clinical Informatics, graduate students or returning professionals have various informatics training options. However, informatics education at the undergraduate level is not as well established. Despite initiatives such as TIGER1 and the Health Information Technology Scholars Program2, as well as a limited number of undergraduate degree programs (e.g., at Arizona State University3), there is still a need to provide interprofessional informatics education at the baccalaureate level.

The Education WG has endorsed and supported undergraduate education as its priority since AMIA 2014 panel4. Education WG members have been leading efforts to develop a Biomedical and Health Informatics course that addresses fundamental concepts and core competency skills. Panelists aim to further report on the expectations of the AMIA community with regards to using an undergraduate, interprofessional informatics course. The goal is to present students with an overview of the role of biomedical informatics in clinical, research, and operation practices. This panel will announce the completion of AMIA’s first undergraduate course geared towards various health and IT specialties including medicine, nursing, and allied professions.

Learning Objectives
• Discuss the scope and content of the BHIB course
• Reflect on core undergraduate informatics competencies (general and specialty specific)
• Learn about on-going and future efforts to integrate informatics in baccalaureate education
• Discuss feedback on usability of the course nationally and internationall
• Identify and invite qualified Informatics professionals to keep content updated as a sustainability plan
• Provide a report summarizing course development since AMIA 2014

Audience
Due to its timeliness and relevance, this session will be of interest to all health and biomedical informatics educators.

Background and report of discussions and feedback from AMIA 2014 Symposium interactive panel
Biomedical Informatics training has expanded to include almost all clinical specialties. Whether it is a Masters, PhD, or fellowship in Sub-Specialty in Clinical Informatics, graduate students or returning professionals have various informatics training options. However, biomedical informatics education at the baccalaureate level is not as well established (with very few notable exceptions, like Arizona State University3). Despite initiatives such as TIGER, ONC HIT Workforce Development, the Health Information Technology Scholars Program, and others, there is still a need to provide interprofessional education at the baccalaureate level. As the field of biomedical informatics becomes increasingly relevant in myriad healthcare settings, aiming to leverage more and complex and data, there is
a growing need to introduce fundamental concepts to undergraduate students to enhance their knowledge base and stimulate interest in career paths in biomedical informatics.

The AMIA Education Working Group (ED-WG) has been leading efforts to develop an Interprofessional Informatics course for Baccalaureate healthcare students that address fundamental informatics concepts and core competency skills. The ED-WG has built an undergraduate course that includes core informatics competencies for various clinical specialties including medicine, nursing, allied health professions, and computer science. The proposed course is designed to serve as a foundation for faculty, students, and other educators striving to increase biomedical informatics literacy and basic knowledge in a realm where much confusion exists about the domain. This effort provides fundamental knowledge of biomedical informatics to pre-med, nursing and allied health majors, as well as computer and information science undergraduate students. The course is designed to serve as a foundation for health professionals, which is different from the advanced ONC-funded Health IT Workforce Curriculum Components. Moreover, this course would complement the current AMIA efforts towards high school and post-graduate education, and promote the development of a “pipeline” of biomedical informatics professionals.

**Explanation of proposed course/modules and proposed process**

The AMIA ED-WG developed a course that includes 18 modules that cover fundamental and core biomedical informatics competencies. We invited AMIA professionals to develop these modules as per their area of interest. Each module will be offered as voice-over PowerPoint’s with learning objectives, content, questions and answers, and case studies relevant to all healthcare professions. The AMIA 10x10 courses provide a good example and possible framework for this program.

The modules could either be taken as a full course (15-16 weeks), or individual modules could be pulled from the program and be used by an educator in their individual course. For example, a nursing instructor teaching an Ethics course could integrate the “Ethical/Legal Issues in Health Informatics” into their course. Or, a Pharmacology instructor could use the “Precision Medicine” module in their course. The program would be applicable and available internationally (including countries that biomedical informatics may have a practical impact, e.g., Malaysia, India, and South Africa). It is a goal to make this program available as an Open Education Resource.

**Proposed Modules:**

1. What is Biomedical Informatics?
2. Tools of Biomedical Informatics
3. Terminologies/vocabularies/data sets
4. Computation
5. Clinical application
6. Ethical/legal issues
7. Research methods/ evidence-based practice
8. Telehealth
9. Global health informatics
10. Public Health Informatics
11. Mobile health technologies
12. Consumer health informatics
13. Human Factors
14. Personalized Medicine
15. Digital Literacy
16. Precision Medicine
17. The future of Biomedical Informatics
18. Careers in Biomedical Informatics

**Engage AMIA audience in discussion about:**

- Suggestions around course usability and circulation
- Potential sustainability plans
- Possible dissemination channels

**Panelist Presentations**

Saif Khairat, PhD, has been involved with Health Informatics since 2006. He is assistant professor at the Carolina Health Informatics Program and School of Nursing at the University of North Carolina- Chapel Hill. Dr. Khairat’s research focuses on the intersection of EHR usability and patient safety. Dr. Khairat was co-Principal Investigator to a federal grant award from the Health Resources and Services Administration (HRSA) entitled “Telehealth Resource Center Grant Program”, at the University of Minnesota. Dr. Khairat earned his PhD in Health Informatics at the Informatics Institute at the University of Missouri with a focus on ICU clinical communication. During his Informatics training, Dr. Khairat worked as a Research Fellow at the Division of Clinical Informatics at Harvard.
Medical School. Dr. Khairat is lead author to numerous publications and serves as a scientific reviewer to national and international conferences and journals.

Dr. Khairat is currently the Chair of the Education Working Group at AMIA, member of the AMIA Working Group Steering Committee, and in the past, he has served on Student Working Group committees. Dr. Khairat will talk about the course structure, the need for highly trained informaticians to participate in content development, and the need for content reviewers. He will pose questions to the audience related to the need for an undergraduate informatics course.

Glynda Doyle, RN, MSN teaches at the British Columbia Institute of Technology (BCIT) in Vancouver, British Columbia. She completed her MSN at the University of British Columbia in 2011. Ms. Doyle is focused on the integration of informatics into the BCIT Bachelor of Science in Nursing (BSN) and Specialty Nursing curricula. She is particularly interested in the role of mobile technologies and their impact on nursing student’s clinical judgment and decision making.

Ms. Doyle is a co-investigator in several inter-disciplinary research projects within BCIT and also in collaboration with other Canadian nursing schools studying the impact of mobile devices laden with clinical resources, social networks and e-portfolios on nursing students and their education. Ms. Doyle recently co-developed an open source education resource/textbook (Clinical Procedures for Safer Patient Care) funded by BC Campus. Glynda is a peer leader in BC for the Canadian Association Schools of Nursing and Canada Health Infoway Digital Health Faculty Peer Leader Network. Ms. Doyle will discuss the national and international need for a course such as this at the undergraduate level and its value to the field of informatics and the AMIA community.

Neil Sarkar, PhD, MLIS, is director of the Center for Biomedical Informatics at Brown University with broad interests in biomedical informatics research and education. He is also the immediate past chair of the AMIA Education Committee, where he first identified the need for AMIA to develop a comprehensive pipeline for a biomedical informatics workforce, akin to how other STEM-C disciplines have approached similar challenges. His research focuses on the development of methodologies for linking biomedical data across heterogeneous sources, leveraging work in ontologies, information retrieval, and natural language processing, with particular application to the study of complex disease phenotypes (e.g., pre-term birth) as well as identification of putative new medical knowledge (e.g., medicinal plants). He has developed full semester courses as well as short (one-week) immersion educational experiences that cover fundamental introductory and methodological concepts biomedical informatics, which have been taken by both undergraduate, graduate, and post-graduate learners. Dr. Sarkar will describe his experiences in teaching traditional courses in biomedical informatics that includes undergraduate students, and offer a broad perspective of how such courses are essential in the development of a pipeline of biomedical informatics professionals.

Jeffrey J. Williamson, M.Ed., Vice President of Education and Academic Affairs, will moderate this session. He has been with AMIA since 1998. Jeff’s portfolio of programs and activities at AMIA’s includes oversight of annual conferences, e-learning activities, the American College of Medical Informatics, the Academic Forum, and providing continuing education benefits for members. He is the lead staff member responsible for Clinical Informatics Board Review Course, certification and accreditation. Mr. Williamson will discuss AMIA’s vision and endorsement for undergraduate education, logistics around course availability and hosting, and AMIA’s sustainability plan for the BHIB course.

All panelists agree to participation if the panel is accepted.

The Medication-use Process: Current Challenges and Potential Solutions

Wing Liu, PharmD; Lori Idemoto, MS, RPh; John Poikonen, PharmD; Sarah Alameddine, PharmD; Scott D. Nelson, PharmD, MS

1Vanderbilt University Medical Center, Nashville, TN; 2Swedish Medical Center, Seattle, WA; 3Avhana Health, Cambridge, MA; 4Nova Southeastern University College of Pharmacy, Palm Beach Gardens, FL

Abstract

The medication-use process (MUP) is complex, often misunderstood, and can have serious downstream consequences in the accuracy and communication of medications, resulting in patient safety concerns or harm. It is imperative that informaticists understand the MUP to minimize potential adverse events and unintended consequences. The panel will highlight a patient’s journey, focusing on the areas where their healthcare delivery is impacted by the nuances of the MUP. The audience will experience how interoperable medication lists, medication order timing, electronic controlled substance prescribing, and their socio-technical aspects provide opportunities for health information technology to improve patient safety and process efficiency.

Learning objectives:
1. State some of the common obstacles to sending and receiving accurate medications lists.
2. Explain strategies for improving and interpreting interoperable medication lists.
3. Identify variables in their institution that may cause timing discrepancies.
4. Formulate an approach to develop solutions that prevent timing discrepancies.
5. List e-prescribing enhancements that can improve provider and community pharmacy communication.
6. Describe obstacles to electronic prescribing communication enhancements.
7. Learn and describe strategies that can be used to reduce the impact of medication-use process errors.
8. Gain a greater awareness of the socio-technical issues that impact the electronic medication-use process.

General Description

The medication-use process is a complex integration of prescribing, perfecting medication orders, preparing, dispensing, administering, monitoring, and educating patients about medications. There is an unmet need for informaticists to not just simply understand the context surrounding the medication-use process, but also participate in continuously improving its nuanced challenges. Due to the complexity of the process and growing regulatory requirements related to medication management, health information technology can play a significant role in improving patient safety and process efficiency. Therefore, it is imperative that informaticists understand the medication-use process and engage in a scientific approach to minimize potential adverse events and unintended consequences. The objective of this panel is to describe a patient journey and the various stages of the medication-use process they touch, with each presenter putting a spotlight on a particular aspect of its subsequent safety or efficacy ramifications. Challenges and considerations of the medication-use process will be highlighted, such as socio-technical aspects, medication order timing, electronic controlled substance prescribing considerations, and interoperable medication lists. The presenters for this panel are pharmacists, informaticists and experts in the medication-use process that will share some of their experiences, insights, and potential solutions related to these medication-use process challenges.

Importance

Understanding some of the current and common challenges of the complex medication-use process is critical for informaticists in order to improve patient safety and care. Participants will get value from learning how to organize and access health information data using available technology and processes, and understand how to apply it to improve practice patterns. The intended audience will be informaticists and clinicians that are unaware of the medication-use process, and experienced informaticists that would like to apply the strategies described to their own institutions. Participants will be encouraged to share their experiences and views, and will have opportunity for group discussion questions, provide feedback, and question the panel. Focusing on the patient journey and effectively leveraging technology in the medication-use process provides the essential context for delivering higher quality and safer care for all patients.
Moderator and introduction (Scott Nelson)
The medication-use process will be introduced along with a brief introduction to the patient journey.

Medication lists, searching for the truth (Sarah Alameddine)
Over the past few years, Meaningful Use requirements have established terminology standards for communication between EHR systems to promote health information exchange. This exchange of documents has enabled providers to share important patient information, such as medications the patient may be taking. However, the day-to-day use of these medication lists has raised many concerns. Interoperable medication lists are often an inaccurate reflection of the source, as they commonly contain free text medications, absent or inaccurate medication end dates, imprecise RxNorm codes, and unreliably documented “patient reported” medications. Understanding the gaps and inconsistencies in the medications lists is an important part of using this important medication information particularly in the monitoring and educating medication use process, effectively. This presentation will discuss some of the common challenges of and some strategies for improving the usability of interoperable medication lists.

Timing is everything (Wing Liu)
As one of the medication administration "five rights", medication timing is critical for patient safety; however, actual medication administrations typically do not occur as ordered in CPOE. While CPOE can reduce some errors, it may have difficulty with the functionality and logic surrounding medication timing and cannot fully predict the clinical intent of the user. These limitations often result in timing discrepancies, such as ‘now/stat’ orders being administered too close to the next scheduled dose, system limitations to hold medication doses, or limitations in addressing the temporal relationship of a patient’s temporary health status (such as pregnancy). This presentation will focus on the application of informatics in the design, development, and implementation of decision support and guideline systems pertaining to the various challenges of medication timing in the administration phase of the medication-use process.

Controlled substances and e-prescribing (John Poikonen)
Electronic prescribing (e-prescribing) has increased significantly across the nation, and this electronic communication between prescribers and pharmacies may reduce medication errors and increase patient safety. However, not all changes to medication therapy are communicated between prescribers and pharmacies, such as prescription cancelations form the prescriber or notification of prescription pickup from the pharmacy. Additionally, there are many issues that must be taken into consideration when e-prescribing and dispensing controlled substances. Implementation of Prescription Change transactions, Cancel Prescription transactions, electronic prescribing of controlled substances, and prescription drug monitoring programs could support improved communication and feedback with the medication-use process in the ambulatory setting. Although standards for these electronic prescribing enhancements have been established, implementation may be delayed based on existing functionality of EHRs and community pharmacy dispensing systems. This presentation will discuss various challenges and obstacles to the electronic prescribing process and these prescribing communication enhancements and the pharmacists role in “perfecting” and dispensing in the medication use process.

Socio-technical considerations (Lori Idemoto)
The rapid adoption of electronic health records (EHRs) and computerized provider order entry (CPOE) have changed the roles and ways healthcare professionals care for their patients and interact with each other. While these informatics tools have made improvements to the medication-use process, they have also introduced unintended consequences and new types of errors that have negatively impacted patient safety. Changes in workflow and communication along with an over dependence on technology have created false expectations and results in the emergence of new errors and an increase in the frequency of specific medication use process errors. This presentation will focus on socio-technical changes that may adversely impact the medication use process.

Discussion Questions
1. In your experience, how accurate do you think the medication lists are that you receive?
2. What are some of the challenges you or your organization have experienced in medication list accuracy?
3. How do you or your organization use external medication lists (CCDA/MU) for medication reconciliation?
4. What medication timing issues have you or your organizations encountered in your clinical systems?
5. What approaches have you or your organizations used to solve the medication timing issues mentioned?
6. If your organization allows medications to be placed on hold, what does the process look like and what issues have you encountered?
7. Has your organization experienced a patient safety event caused by a patient continuing to take a medication that was intended to be discontinued?
8. How does your organization communicate discontinued medications to primary care providers or pharmacies?
9. If your organization electronically prescribes controlled substances, what has your experience been implementing such a feature?
10. What approaches have you or your organizations taken to mitigate the impact of these socio-technical issues related to the medication-use process?
11. What socio-technical issues have you or your organizations observed affecting the medication-use process? How are they similar or different to those described here?

**Participation statement**
The authors listed in this panel have agreed to take part in the panel.

Clinical Informatics Fellowship – Future Workforce Development

J Edward Maddela, MD¹, Umar Iqbal, MD², Yumi DiAngi, MD³,
Erika Green, MD⁴, Daria Ferro, MD⁵

¹,²University of Arizona College of Medicine, Phoenix, Arizona; ³Stanford University and Hospital Systems, Palo Alto, California; ⁴Regenstrief Institute Center For Biomedical Informatics, Indianapolis, Indiana; ⁵The Children’s Hospital of Philadelphia, Philadelphia, Pennsylvania

Abstract

Clinical Informatics (CI) is the newest addition to the American Board of Medical Specialties (ABMS), with its first board certification issued in 2013 to 456 physicians¹. The American Medical Informatics Association (AMIA) was first to recognize the importance of formal physician training to meet the growing need for a CI workforce. AMIA has designed both the Core Content and Program Requirements for the new subspecialty training programs in 2008². Today, 20 Accredited Council for Graduate Medical Education (ACGME) fellowship programs exist nationally with more programs expected to join. Little is known about the structure of the various training programs. In this didactic panel we will: 1) review examples of four ACGME accredited CI fellowship programs, 2) seek opinions from healthcare organization and academic medical center leadership, and other key stakeholders in physicians' CI education concerning the skillset needed for graduating fellows, and 3) discuss the challenges of the programs as they evolve to educate and train the next generation of CI physician workforce.

General Description of Panel

As a new and unique subspecialty, Clinical Informatics (CI) arose from the need of physicians to be integrally involved with the appropriate use of clinical information systems. Beginning in 2018, physicians who seek Board Certification in Clinical Informatics must complete a 2-year Accredited Council for Graduate Medical Education (ACGME) Clinical Informatics Fellowship. Designed to prepare fellows for a career in CI, these programs provide them with the skills necessary to support informatics enabled solutions of clinical services in various settings. With this didactic panel, we will present and discuss the diverse curricula among four ACGME Accredited CI Fellowship programs: The Children’s Hospital of Philadelphia, Regenstrief Institute, Stanford Children’s Hospital, and the University of Arizona – College of Medicine in Phoenix. After a brief introduction, each program will spend 10 minutes presenting their distinctive curriculum and 9 minutes seeking feedback and/or addressing questions from the audience. The final 10 minutes of this panel presentation will be open for a general discussion.

Intended Audience

The intended audience of this panel includes but is not limited to Clinical Informatics fellows, hospital and academic medical center leadership, CI Fellowship Program Directors, CI Fellowship Faculty, physicians seeking CI Board Certification, residents, medical students, non-physician clinicians, and the general audience interested in the education of the future CI physician workforce.

Explanation of Topic Urgency

This topic is urgent and timely because physicians pursuing board certification in CI need to decide if an ACGME CI fellowship or the Practice Pathway is more suitable for them. Even though information about these fellowships can be accessed through their websites, specific details about and comparisons between each fellowship program are not readily available. Additionally, a formal discussion about the structure and content of these fellowships has yet to take place on a national platform. With many more fellowship programs seeking ACGME accreditation, we anticipate the dialogue that will arise from this didactic panel presentation will bring value to the intended audience.

Brief Description of Presentations

The Children’s Hospital of Philadelphia (CHOP)

The CI Fellowship Program at CHOP is now in its second year, led by ten Faculty Physician Board-certified Clinical Informaticists. The program is housed in the Department of Biomedical and Health Informatics (DBHi), CHOP’s home for the development of innovative solutions to healthcare's immediate and long-term informatics needs. CI
Fellows at CHOP are exposed to and receive support from not only Clinical Informaticists, but also those working in a variety of areas of Biomedical Informatics, leading to interdisciplinary and enriching experiences.

CHOP’s CI Fellowship curriculum is composed of core clinical rotations as well as longitudinal leadership and research fundamentals based primarily at CHOP. Didactic training takes place through master’s degree level courses, online (Oregon Health & Science University) and locally (the University of Pennsylvania), in addition to regular small group sessions (e.g. journal club). There is purposeful flexibility designed in the schedule to allow exploration and professional development for each fellow based on individual objectives and career goals. This professional development is supported by close personalized mentoring, and is considered by the fellows to be one of the highlights of the program at CHOP.

In this presentation, we will explore the general structure of CHOP’s CI Fellowship curriculum and highlight the importance of an individualized approach to each fellow’s career goals in order to maximize the benefits of CI Fellowship training.

**Regenstrief Institute, Center for Biomedical Informatics**

Regenstrief Institute has established its Clinical Informatics fellowship program prior to ACGME accreditation and is currently lead by JT Finnell MD MSc FACEP. Regenstrief Institute has a rich legacy in informatics research dating back to the late 1960’s. It has developed one of the nation's first electronic medical record (EMR) system and computerized provider order entry (CPOE). It is well known for development of the nation’s first coding standard for laboratory tests and clinical measurements LOINC® and the Indiana Health Information Exchange.

The presentation will include an overview of the current structure of the program, research opportunities with Regenstrief faculty, several options to work with our partners that vary from public health institutions to private tech companies, and opportunities for fellows to gain operational experience in two health systems using Epic and Cerner.

**Stanford Health Care, Stanford Children’s Hospital, and Stanford University**

This is the first ACGME accredited clinical informatics program nationally. It has now accepted its third year of fellows. Leadership and support for the program comes from both the adult and children’s hospital, the University, Santa Clara Valley Hospital System (safety net hospital system), and industry.

The presentation will:

1) Cover core rotations, elective, clinical, and leadership opportunities at the University and health system
2) Highlight operational and research activities of the fellows
3) Communicate challenges and evolving program changes
4) Discuss post fellowship job opportunities

**University of Arizona, College of Medicine-Phoenix**

This two-year fellowship in CI is comprised of eight 12 week quarters spread across 5 major teaching institution hospitals in Phoenix, Arizona. The first 2 quarters are divided into 6 months of core basic knowledge – similar to that of basic sciences in medical school: Architectural Overview, Safety & Quality, Process Improvement, Clinical Decision Support, Privacy & Security, and Business Processes. Quarters 3 and 4 involve a 3-month short term project, followed by a 1-month elective, and then a 2-month data analytics rotation. Quarter 5 starts with a 2-month quality improvement project. The remainder of the time is spent in community and self chosen electives. Quarter 6 to 8 is heavily focused on the final long term project, which entails an initiation, execution, and reporting phase respectively. All projects have a written deliverable and presentation. Every Wednesday, fellows spend the day at the University of Arizona campus where there are monthly activities including didactic sessions presented by faculty, fellow led journal club, grand rounds, and monthly reviews. Concurrently, fellows are obtaining core content knowledge via Oregon Health & Science University’s Clinical Informatics Fellowship Education Programs which consists of eight courses totaling 24 credits resulting in a Graduate Certificate in Biomedical Informatics. Fellows also spend 15 percent of their time providing direct patient care in their specialty area in order to maintain clinical skills and deepen their experience in clinical environments.
Learning Objectives

After participating in this session, the learner should be better able to:

<table>
<thead>
<tr>
<th></th>
<th>Bolster the general structure of CI fellowship. This includes the core rotations, content of curriculum, research opportunities, clinical time, elective opportunities, national involvement, and leadership opportunities as well as resources needed to support the fellow.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Define the acquired skill set and expected competencies of a CI fellow. This includes listing job opportunities following fellowship and the skill sets that would prepare the fellow for those positions.</td>
</tr>
<tr>
<td></td>
<td>Describe possible roles that the CI fellow can support within a health system. This includes leadership on informatics tasks, sharing lessons learned from health system projects, and supporting change management and innovation within health systems.</td>
</tr>
</tbody>
</table>

Discussion Questions

1. What were your interests in Clinical Informatics prior to starting your fellowship?
   a. How has the fellowship supported, shaped, shifted these interests thus far?
2. How do you envision yourself using your CI training in your professional career?
3. What opportunities has the fellowship afforded that you would not likely experience learning CI as a practitioner without formal training?
4. In what ways can CI fellows act as ambassadors of the field?
5. For those already working in CI leadership roles, what are the skills that you think are the most needed for a Clinical Informatician?
   a. Do you perceive that the fellowships are training individuals to meet these needs?
6. Please provide the top 3 learning objectives that a CMIO would see as critical in graduating CI fellows?
7. What level of importance and training should CI fellowships place in the subject areas of business processes, organizational finance, governance, budgeting, and strategy?
8. Which kind of roles do you foresee CI fellows assuming after graduation?
   a. How many years of experience would anticipate before seeing them in leadership positions if they started fellowship straight from residency?
9. Do you anticipate or encourage other disciplines starting similar formalized training programs – i.e. nursing, pharmacists, physician assistants, and how could these disciplines collaborate or take lessons learned from current CI fellowship programs?
10. What kind of involvement should fellows training in ACGME accredited CI fellowship programs have with AMIA?
11. What do you know now that you wish you knew before you started the CI fellowship?
12. What advice would you give to someone considering a fellowship in CI?

Statement from Panel Organizer

All presenters listed above agree to participate in this Didactic Panel. - J Edward Maddela, MD

Abstract

In this didactic panel, we will review an emerging and growing field of investigation within medical informatics, interactive systems in healthcare. A set of panelists with complementary areas of expertise and substantial experience in biomedical informatics and human-computer interaction will provide an overview of the field, highlight examples of cutting-edge investigations, discuss grand challenges, and outline training and career opportunities. The information presented during the panel will be informed by the Workshop on Interactive Systems in Healthcare (WISH 2016) co-hosted with the SIGCHI conference on Human-Factors in Computing Systems, CHI 2016. Given the growing interest in this area, we expect the panel to be educational and allow for a lively discussion of topics relevant to AMIA members.

Introduction

Health Information Technology (HIT) has the potential to transform healthcare by positively impacting quality, efficiency, and cost-effectiveness. Similarly, new self-monitoring technologies and data science methods open unprecedented opportunities to inform decisions and choices of individuals who must manage their health and chronic diseases at home. However, despite ongoing efforts by many government agencies, HIT continues to experience low levels of adoption\(^1\). Moreover, a growing body of research questions its impact on medical care\(^2\), for example by highlighting the unintended consequences of HIT\(^3\), and medical errors that result from poorly designed computing systems\(^4\). Researchers have argued that many of these negative consequences result from a mismatch between the reality of conducting clinical work and the structure of computing applications that are meant to support it\(^5\). Similar concerns are raised in regards to the usefulness and longevity of technologies for health and wellness\(^6\).

To address these limitations and remove barriers to the successful adoption of HIT, new research initiatives are focusing on a better alignment of HIT and clinical practices, and an approach to system design that is informed by best practices in Human Factors and Human-Computer Interaction (HCI). However, these efforts currently exist in several disjointed research communities, without established pathways for transfer of knowledge and expertise. These communities include but are not limited to Biomedical Informatics, HCI, Computer Science, Social Sciences, and Behavioral Medicine, among others. Each of these fields has its own venues for disseminating research results that rarely overlap. Therefore, researchers and practitioners interested in designing patient and clinician-centric HIT have little opportunity to interact and develop a shared body of knowledge across these communities. As a consequence, there exists a potential to create deeper and more profound connections among the biomedical, informatics, human-computer interaction, medical sociology and anthropology communities that would lead to the development of new methods, approaches, and techniques for removing barriers to the adoption of HIT.

In response to these challenges, the American Medical Informatics Association (AMIA) and the Association of Computing and Machinery (ACM) have co-sponsored a series of Workshops on Interactive Systems in Healthcare (WISH). The overarching goal of these workshops is to establish lasting and meaningful connections between these communities, and bring together students and researchers from various disciplines who are working on creating, implementing, and evaluating innovative health technologies. The first workshop in the series, WISH 2010 was co-hosted with CHI 2010 in Atlanta, GA. The workshop was sponsored by the NSF, ACM, SIGCHI, and Microsoft Research. It attracted close to 150 participants and included both invited panels and peer-reviewed technical program. From 2011-2014, WISH was co-hosted with the Annual Symposium of the American Medical Informatics Association. In 2016, WISH is co-hosted with CHI as a two-day workshop, including an open symposium during the first day, and an invitation-only meeting of the WISH steering committee during the second day.

In this panel, we will outline a broad research agenda for Interactive Systems in Healthcare and provide highlights from WISH 2016.
Panelists and their Qualifications

The panelists are well-known researchers in the fields of Human-Computer Interaction, Computer Science, and Biomedical Informatics who bring their expertise and interdisciplinary perspective to advance the agenda of the workshop. Three of the organizers have served as co-chairs for previous WISH (Drs. Mamykina and Reddy in 2011, Dr. Siek in 2012) that were co-hosted with AMIA. All co-organizers are prominent members of HCI and Biomedical Informatics communities and have served as members of the program committees for CHI and AMIA for multiple years.

*Lena Mamykina, PhD,* is an Assistant Professor of Biomedical Informatics in the Department of Biomedical Informatics at Columbia University. Her primary research interests reside in the areas of Biomedical Informatics, Human-Computer Interaction, Ubiquitous and Pervasive Computing, and Computer-Supported Collaborative Work. Dr. Mamykina’s broad research interests include individual and collective cognition, sensemaking and problem-solving in the context of health, health care, and health management.

*Dr. Madhu Reddy, PhD,* is a Professor of Health Communication in the Department of Communication Studies and a core faculty member in the Center for Communication and Health at Northwestern University. Previously, he was in the College of Information Sciences and Technology at Penn State University and helped start Penn State’s Center for Integrated Healthcare Delivery Systems. Dr. Reddy’s primary research interests are at the intersections of Medical Informatics and Computer Supported Cooperative Work (CSCW).

*Katie Siek, PhD,* is an Associate Professor in Informatics at Indiana University Bloomington. Her primary research interests are in human computer interaction, health informatics, and ubiquitous computing. More specifically, she is interested in how sociotechnical interventions affect personal health and well being. She has actively participated in the CHI community (PC member 2012 and 2013) and AMIA community (PC member 2011 and Vice Chair for the AMIA Annual Symposium 2013) and other conferences and workshops integrating computing and health.

*Gabriela Marcu, PhD,* is an Assistant Professor of Human-Centered Computing in the College of Computing and Informatics, and a Research Fellow with the A.J. Drexel Autism Institute, at Drexel University. She holds a Ph.D. in Human-Computer Interaction from Carnegie Mellon University, and a B.S. in Informatics from the University of California, Irvine. Dr. Marcu’s research seeks to improve coordination and collaborative reflection in health and social services through technology.

*Leslie S. Liu, PhD,* is a postdoctoral fellow in Informatics at Indiana University Bloomington. Her primary research interests lie within the intersection of human computer interaction, computer supported cooperative work, and health informatics. She both studies and designs technologies for patient populations.

In the proposed panel, Dr. Liu will serve as a moderator, and Drs. Mamykina, Reddy, Siek, and Marcu will serve as panelists.

Proposed Topics

We propose the following general topic for discussion during the panel:

1. **Overview of the field and main areas of investigation (Dr. Mamykina)**

In the first presentation, Dr. Mamykina will review a history of interactive systems in healthcare and how transformations in interactive technologies impacted healthcare practice. In addition, Dr. Mamykina will review recent work on advancing interactive systems in healthcare and outline prominent areas of investigation. These include, but are not limited to, mobile applications for health and wellness self-management, interactive systems for clinicians’ communication, interactive information displays for patient care teams, among many others.

2. **Representative presentations from WISH 2016 illustrating contemporary work within the field (Dr. Marcu)**

To illustrate contemporary research in interactive systems in Healthcare, Dr. Marcu will provide an overview of the five original manuscripts presented during WISH 2016. These manuscripts will be selected based on their scientific merit and also to represent the diversity of investigations.

3. **Grand challenges (Dr. Siek)**

Dr. Siek will highlight grand challenges for interactive systems in healthcare identified during the meeting of the WISH 2016 steering committee. These challenges will outline opportunities for new research as well suggest
priorities for funding agencies. In addition, Dr. Siek will discuss the vision for future Workshops on Interactive Systems in Healthcare developed during WISH 2016.

4. Training and career opportunities (Dr. Reddy)

In the last presentation, Dr. Reddy will discuss different skills necessary to conduct impactful research in interactive systems in healthcare and opportunities for fostering these skills within academic institutions and industry-oriented training programs.

After the initial presentations, we plan to open the discussion to the audience. We will begin by asking the panelist to comment on the following set of general questions:

1. What unique opportunities and challenges exist in relation to design methods as well as evaluation methods appropriate for health-oriented interactive systems?
2. What opportunities for innovation in interactive systems in healthcare exist within the current landscape of Health IT?
3. What opportunities for funding and publishing work related to interactive systems in healthcare exist within the different research communities?

In addition, we expect new questions from the audience that will explore a variety of topics related to interactive systems in healthcare.

Conclusion

Given the growing interest to interactive systems in healthcare and growing adoption rates of Electronic Health Record systems, we believe this panel will provide a valuable overview of this area to both newcomers to AMIA as well as to members who are conducting active research and develop new interactive tools for improving health and delivery of healthcare.

All panelists agreed to take part in the panel.

Building a Research Ecosystem upon the Early Success of ResearchKit

Panel Moderator
Kenneth D. Mandl, MD, MPH
Boston Children’s Hospital
Harvard Medical School
Boston, Massachusetts

Panelists
Richard Bloomfield, Jr., MD
Duke University
Durham, North Carolina

Deborah Estrin, PhD
Cornell Tech
New York, New York

Stephen Friend, MD, PhD
Sage Bionetworks
Seattle, Washington, Washington

Pascal Pfiffner, MD, PhD
Boston Children’s Hospital
Harvard Medical School
Boston, Massachusetts
Abstract
In March of 2015, Apple introduced ResearchKit, an apps framework and tool chain for conducting clinical studies that begin when subjects discover and interact with a smart phone app. ResearchKit enables investigators to readily inform and consent patients into medical and health studies. Once a subject is enrolled, ResearchKit facilitates collection of personal health data, device data and patient reported outcomes (PRO) from distributed populations. The framework launched with five initial studies that immediately demonstrated unprecedented brisk enrollment of subjects “in the wild.” Because ResearchKit is open source, extensions and adaptations began immediately. This panel explores new use cases and platforms for the technology. Topics for presentation and discussion include the role of ResearchKit in Precision Medicine, the value of connecting HealthKit to the research enterprise, transposition of the framework to the Android platform, connection of ResearchKit to the i2b2 ecosystem, and alternative enrollment pathways, including “prescribing” ResearchKit apps to selected subjects in a trial.

General Description of Program
Accrual to clinical trials has traditionally been an expensive, time consuming, and labor-intensive process. The process has been fraught, in that consents are often difficult to understand, electronic data capture from patients often uses customized and unfamiliar solutions, researchers lose contact with subjects, and biometric measurement on patients is time consuming and costly.

Because hundreds of millions of people carry smartphones in their pockets, an alternate paradigm becomes possible. If a patient can be made aware of a study, the pathway to enrollment is as easy as opening up a smartphone app. ResearchKit commoditizes the introduction to research studies, instantiates a crystal clear consent process, facilitates both active and passive collection of device data, and makes reporting of PROs trivially straightforward.

The initial release of ResearchKit has been focused on subjects “in the wild” finding a study and choosing to participate. But direct-enrollment of subjects is only one of several study designs that could be supported by the platform. Further, while ResearchKit arose on the iOS platform, an analog for Android -- ResearchStack extends the reach of the approach to much larger populations.

Statement of Need
This panel will be held about 18 months after the initial release of ResearchKit. We suspect that a significant representation within AMIA will be using it creatively. This panel brings together key leaders and innovators advancing the capabilities and possibilities for smartphone-based trial designs who will bring participants up to the cutting edge, and also catalyze a discussion and perhaps even identify new directions for the project within our community.

Kenneth D. Mandl, Director of the Boston Children’s Hospital Computational Health Informatics Program, and a Professor of Biomedical Informatics at Harvard Medical School, will begin with a brief overview of the initial work done in ResearchKit and paint a picture of how it could be widely extended within the biomedical and health research enterprise and specifically for precision medicine. Each panelist will then be invited to make a presentation in an area of his or her expertise for 10 minutes. The total presentation time will be kept to under one hour to allow lively discussion with the audience.

Stephen Friend, President of Sage Bionetworks, and a creator of ResearchKit, will motivate the creation of ResearchKit and through the lens of the mPower study of Parkinson’s disease, discuss the power of app-based enrollment in clinical trials, collection of digital phenotypes using smartphones, and open data.

Ricky Bloomfield, Assistant Professor of Pediatrics, Duke University, will discuss experience with a pediatric ResearchKit study Autism and Beyond; a ResearchKit study of children between 1 and 6 years demonstrating the feasibility of at-home video facial analysis for screening of childhood mental health disorders. While a prior, Duke-only study had recruitment of about 100 individuals over a 12-month period, after release of the ResearchKit app there were over 250 individuals consenting to the study in just the first weekend alone, with almost 1200 in less than 5 months.

Deborah Estrin, Professor of Computer Science at Cornell Tech and a Professor of Public Health at Weill Cornell Medical College, will discuss the transposition of ResearchKit to ResearchStack, an SDK and user interface framework for building research study apps on Android. ResearchStack will help developers and
researchers who have existing apps on iOS more easily adapt those apps for Android. The Research and ResearchStack SDKs have similar, though non-identical functionality, but the a common framework and naming scheme are hoped to greatly speed up adaptation of ResearchKit apps to Android and vice versa.

Pascal Pfiffner, Faculty in the Boston Children’s Hospital Computational Health Informatics Program and Lecturer at Harvard Medical School, will talk about the marriage of ResearchKit and Fast Healthcare Interoperability Resources (FHIR) in the C3-PRO tool chain, and how this combination simplifies survey delivery and response collection in a standardized, portable fashion. Additionally, the C3-PRO tool chain not only handles end-to-end research data delivery from participants’ smartphones to i2b2, it also enables researchers to “prescribe” a research app to patients already in the health system, extending (research) data collection to the mobile domain.

Questions for audience discussion

● Have any of you designed ResearchKit apps?
● Have you participated in a ResearchKit study?
● Have you extended the ResearchKit open source framework
● What digital phenotypes might you define with smart phone data collection?
● What types of studies would you like to see enabled?

Statement from the Organizer

Each participant has agreed to take part on the panel.
Secure Record Linkage for Precision Medicine and Patient Centered Outcomes Research

Daniella Meeker, PhD1, Toan Ong2, Xiaoqian Jiang, PhD3, Abel N. Kho, MD, MS4, Jason N. Doctor1

1University of Southern California, Los Angeles, CA; 2University of Colorado, Anschutz Medical Campus, Aurora, CO; 3University of California, San Diego, La Jolla, CA; 4Northwestern University, Chicago, IL

Abstract

The ability to link records across multiple sources enables richer data for a wide variety of applications in patient-centered outcomes research and precision medicine. The standard implementation of a linkage system uses personally identifying information from different sources to perform a probabilistic or deterministic identity match, with manual inspection to resolve uncertainty. While there are established commercial record matching systems for treatment purposes and Health Information Exchange, regulations, risks and risk tolerance differ in the context of research. Furthermore, if existing systems can be improved upon from the standpoint of both performance and privacy protection, disclosures required for manual adjudication can be limited. Each of the panelists will describe their experiences with implementing a privacy-preserving record linkage (PPRL) approach, and then discuss the pragmatic implications, and share results of a comparative evaluation. The methods discussed will include using seeded one-way hashing, Garbled Circuits, multi-party GMW (Goldreich-Micali-Wigderson), Intel® Software Guard Extensions, weighted and order-preserving encryption methods, and approaches using count queries across parties to infer a total ordered data from partial orders. We will describe how different data elements, weighting strategies, and order-preserving hash functions can impact match performance. Panelists will directly address issues associated with the HIPAA Privacy Rule and implementation of different methods in the presence or absence of a trusted broker. The panel will present considerations for privacy, security, trust, accuracy, and computing resources that merit attention, giving attendees an overview of the different feasible options for privacy-preserving record linkage.

Introduction

Patient Centered Outcomes Research and Precision Medicine share the challenge that a single entity rarely holds all of the information necessary to conduct meaningful research. Creating a collection of patient-centered records that includes data from multiple entities distributed over space and time that can be used for research is a significant challenge. Frequently, consent is raised as a solution to privacy risks that limits liability and compels record release. While a virtuous first step, consent does not eliminate the need to link identities across independently managed data systems in a reliable and secure way. The identity of the individual providing consent still needs to be resolved and validated before records are released – a person volunteering for research participation recruited from the internet must be linked to a definitive identifier when she requests that her health records are released for research. Furthermore, consent reduces liability of data holders, but consent does not protect privacy.

Technical barriers to protect participant and institutional privacy are coupled with concerns of legal liability and privacy risks. In absence of universal identifiers, record linkage relies on matching methods that typically require use of personally identifying information. Effective research must meet competing requirements for precision, privacy, security, efficiency, and data completeness. While there are widely adopted commercial solutions in use by service providers of all types, research presents distinctive challenges. Research is in certain settings an optional activity - data holders have no obligation (and often minimal incentives) to release records for research. For outcomes research and precision medicine, records are typically requested in large batches rather than one-by-one, as it is the case in health information exchange. The extent to which health information exchange solutions easily translate into research solutions requires weighing of different desired features.
Implementers of record linkage systems have a variety of options for architecture, algorithms, procedures, and data management. Matches can be made in deterministic or probabilistic ways – selecting decision thresholds for probabilistic methods may favor sensitivity or specificity. Which data elements are employed, how they are weighted in matching algorithms, and how they are cleaned and processed to account for misspelling, keystroke errors, and aliases all impact both the performance of the match and the likelihood that privacy may be compromised. Encryption methods that do not preserve string lexicography or numeric order may provide simple solutions but limit flexibility for identifying matches. Also, implementers must consider whether it is a greater risk to create a persistent identifier that is reused over time or if it is desirable to recreate fresh linking identifiers with every data use. Discrepancies in organizational policies, computing or data quality resources may impact how different parties coordinate their efforts and assess feasibility. Finally, purpose for use must be considered – the cost of mistakes in matches for an observational data analysis is typically substantially lower than a mistake that results in patient contact or disclosure. Panelists will describe how the methods in question perform not only on metrics related to matching, but on the broader range of pragmatic issues necessary for implementation.

Best practices for data sharing in research should minimize avoidable disclosures. These practices include using analytic methods that remove requirements for centralizing data, replacing identifying information in research records with encrypted identifiers, etc. Performing privacy-preserving record linkage is a frequently neglected topic that is crucial to enable joint analytics. We will address this critical issue in this panel.

Panelists

Abel N. Kho, MD will present a pragmatic system in use by multiple collaborating health systems in the Chicago Area Patient-Centered Outcomes Research Network (CAPriCORN). He will describe the procedures for data cleaning, preprocessing, and hashing of patient identifiers, which removes all protected health information prior to matching. He will describe the rationale for selecting data elements used for matching – including combinations of dates of birth, names, social security numbers, and soundex variants. The method employed an intentionally conservative deterministic approach – minimizing false positives. Dr. Kho will describe the common organizational concerns raised and steps taken to enable real-world implementation.

Toan Ong, PhD will describe novel algorithms and procedures that address challenges associated with missing data in probabilistic clear-text and privacy preserving record linkage. In contrast to more conservative deterministic methods, Dr. Ong will present algorithms designed to maintain computational efficiency while maximizing the accuracy of weighted probabilistic linkage mechanisms. The first approach Weight Redistribution removes fields with missing data from the set of quasi-identifiers and redistributes the weight from the missing attribute based on relative proportions across the remaining available linkage fields. Distance Imputation imputes the distance between the missing data fields rather than imputing the missing data value. Linkage Expansion adds previously considered non-linkage fields to the linkage field set to compensate for the missing information in a linkage field. The rationale for the methods and constraints applied in the algorithms will be described. Comparison of performance of these methods to the deterministic approaches for both clear text and encrypted data will be included.

Xiaoqian Jiang, PhD will present an approach that eliminates requirements for trusted brokers and compare security and computational efficiency. His presentation will compare three secure multi-party computation (MPC) algorithms for record linkage. These approaches do not require centralized architectures and the privacy of each party can be guaranteed. The Garbled Circuit (GC) based patient linkage algorithm and will be compared to a method based on Intel® Software Guard Extensions (SGX) and another method based on Goldreich, Micali, and Wigderson algorithm. The relative flexibility and computational efficiency of these approaches will be described.

Jason N. Doctor, PhD will describe methods that do not require sharing row-level data with a broker and rely on (1) shared encryption algorithms and (2) infrastructure that many research networks have implemented that allow for querying the number of patients meeting a specific criteria and sharing of count statistics with restrictions on the size of cells that can be shared. He will describe how sorting algorithms are related to minimizing the number of queries required to assign and identify overlapping members between sites. He will describe the number of data elements that are required to support this approach and the privacy risks that might be introduced in a probing attack.
Discussion Questions

1. These methods have been implemented in heterogeneous networks including the VA, FQHCs, and Academic Medical Centers – how do the policies of different institutions/environments influence design and implementation?

2. How can these methods facilitate Open Data and Open Science initiatives for PCOR and Precision Medicine?

3. Should these methods be applied in a way that allows them to persist over time across a research network, or should new linkages be computed for each data use? What are the privacy and efficiency considerations?

4. How much of security is derived from the different encryption methods vs. limiting access control?

5. What is the best way to communicate to a regulatory expert the pros and cons of these different methods?

6. How should privacy concerns associated with these approaches be presented to an IRB or a research participant weighing the risks and benefits of participating?

Statement of Participation

All panelists have agreed to participate in the panel.

Panel Proposal

Calibration of Predictive Models for Clinical Decision Making:

Personalizing Prevention, Treatment, and Disease Progression

Lucila Ohno-Machado, MD, PhD,1 George Hripcsak, MD, MS,2 Michael Matheny, MD, MPH,3 Yuan Wu, PhD4, Xiaoqian Jiang, PhD1
1Dept. Biomedical Informatics, University of California San Diego, La Jolla, CA
2Dept. Biomedical Informatics, Columbia University, New York, NY
3Dept. Biomedical Informatics, Vanderbilt University, Nashville, TN
4Dept. Biostatistics, Duke University, Durham, NC

Abstract

A large number of clinical decision support applications rely on predictive models for binary outcomes. These models usually estimate the probability for an outcome of interest (e.g., probability of breast cancer). Given that clinical decisions rely on these probability estimates, it is critical that they be well calibrated (i.e., the estimates are sufficiently close to the true underlying probability that the event will occur). Surprisingly, the evaluation of predictive models rarely includes an assessment of calibration [1–3], while essentially all include an assessment of discrimination (e.g., AUC: areas under the ROC curve). In this panel, we will describe the perils of using non-calibrated models for making clinical and administrative decisions and describe various methods to recalibrate existing models or to include calibration in model development algorithms. We will conclude with a discussion of future directions for research on model calibration.

General Description of the Panel and the issues

Predictive models are used in clinical practices to generate individualized estimates for medically relevant outcomes. Examples include NCI’s model for breast cancer [4], MELD for end-stage liver disease [5], APACHE score for ICU mortality [6], the Framingham calculator for coronary heart disease risk [7]. These models often deal with binary outcomes (e.g., event=1 means death and event=0 indicates survival). Output probability estimates for the event of interest are typically produced. Differently from typical classification algorithms that focus on the discrimination (i.e., whether cases receive higher estimates than controls), the estimated probabilities of outcomes matter in a clinical context because these estimates are often used to determine individual risk for a particular patient, and can guide important clinical decisions like the initialization of anti-lipid pharmacotherapy for an individual at high risk for cardiovascular disease [8] or referral for chemoprevention trials or radical mastectomy for a woman with high chances of developing breast cancer [9]. Therefore, we need to measure the calibration of the estimate or prediction on an individual level, by checking how close the prediction is to the underlying probability for each patient. Because we cannot evaluate this for a single patient (i.e., a stratum with \( n=1 \)), certain proxies are necessary. For example, we can assess the probability of the event in a group of “similar” patients to determine whether individualized estimates are well calibrated or not. Adequate calibration is often coupled with adequate discrimination but a highly discriminative classifier (e.g., a classifier with a large AUC [10]) is not necessarily well calibrated. The consequences for an individual can be quite impactful hence it is very important for predictive models to be well calibrated. The panel will focus on various aspects of calibration for predictive models in the healthcare context.

Structure of the Proposed Panel

The goal of this panel is to provide an overview of recent research in the field of predictive model calibration. The panel will include four recognized researchers in biomedical predictive modeling. Each of these researchers will address a different aspect of calibration in predictive modeling and describe their experience with different applications.
The panel will be hosted by Dr. Lucila Ohno-Machado, Professor of Medicine and Chair of the Health System Department of Biomedical Informatics at UCSD. For many years she has been working on assessing the quality of individual estimates in decision support systems [11–13]. She will provide an overview of the opportunities and challenges in developing calibration techniques for clinical decision support.

The first panelist will be Dr. George Hripcsak from Columbia University. Dr. Hripcsak is Chair and Vivian Beaumont Allen Professor of Biomedical Informatics. He has extensive experience with predictive models and temporal analysis [14–16]. He will share his insights on related calibration issues.

The second panelist will be Dr. Michael Matheny. He is Assistant Professor of Biomedical Informatics and Biostatistics from Vanderbilt University, and studied discrimination and calibration for clinical applications [17,18]. Dr. Matheny will share his insights of discrimination and calibration in post-procedural mortality in interventional cardiology studies.

The third panelist will be Dr. Xiaoqian Jiang. He is an Assistant Professor in the Health System Department of Biomedical Informatics at UCSD. Dr. Jiang has developed algorithms for calibration of predictive models [19–21] and is currently employing them in various contexts. He will provide a comparison of different calibration techniques and contextualize their application.

The fourth panelist will be Dr. Yuan Wu from Duke University. Dr. Wu is Assistant Professor of Biostatistics and Bioinformatics. He has been working on survival analysis and calibration of predictive models using statistical tools [22]. He will share his experience from a statistician’s perspective.

**Urgency of the Topic and Relevance for AMIA**

Data-driven predictive models serve as important tools for informaticians, biostatistician, epidemiologists, and clinical researchers. They are used for personalized prevention, treatment and clinical outcome prediction [23–25]. This panel addresses the evaluation of important building blocks for clinical decision support: predictive models for binary outcomes such as hospital readmission and mortality estimates. A large portion of AMIA members are involved in these activities as users, developers, or educators. The anticipated audiences include, but not limited to healthcare policy makers, biomedical researchers, as well as other stakeholders (e.g., patients, clinicians, etc.)

**Discussion questions**

Potential discussion questions include, but not limited to:

- How to measure calibration?
- What are consequences of non-calibrated models?
- How can we improve state-of-the-art risk prediction models (risk scores in intensive care units, renal transplantation, congestive heart failure) using calibration?
- Can we build models that exhibit high discrimination but poor calibration or vice-versa?
- How to recalibrate models so they can be applied in a particular population?
- What are the pros and cons of different calibration methods?
- How to build models with calibration guarantees?

**Statement from the Organizer**

All of the panelists have approved the writing of this proposal and have agreed to take part on this panel.

Electronic case reporting: 360° perspective by public health, informatics, and healthcare stakeholders

Catherine Staes, BSN, MPH, PhD\textsuperscript{1}, Shu McGarvey, CBAP, CSM\textsuperscript{2}, Shan He, PhD\textsuperscript{3}, Ryan Arnold, MPH\textsuperscript{4}, Laura Conn, MPH\textsuperscript{5}

\textsuperscript{1}Biomedical Informatics, Salt Lake City, Utah; \textsuperscript{2}Northrup Grumman, Atlanta, GA, \textsuperscript{3}Intermountain Healthcare, Salt Lake City, UT, \textsuperscript{4}Houston Health Department, Houston, TX, \textsuperscript{5}Centers for Disease Control and Prevention, Atlanta GA

Abstract

This panel brings together key perspectives on the challenges and strategies used for public health case reporting, a Meaningful Use (MU) requirements for the electronic health record incentive program recently included in MU Stage 3. As public health and health care enterprises, and electronic health record vendors prepare for electronic case reporting, there are questions about the proposed strategies, current functionality, and readiness of the systems required to move from vision to reality. This panel includes presentations that will allow the audience to understand the need and systems from the public health (receiving) perspective, the informatics methods and tools being leveraged, and early experiences with performing case reporting from a health care enterprise. Questions will be posed for 30 minutes of discussion at the end to garner the perspectives and input from an audience of informatics experts working with the systems and technologies required to realize electronic case reporting.

Background

Electronic Case Reporting (eCR) is a priority activity for moving public health surveillance from a predominantly manual and paper-based process to an electronic one. In fact, the Center for Medicare and Medicaid has expanded the Meaningful Use requirements for the electronic health record incentive program to include case reporting in Stage 3.\textsuperscript{1} eCR is complex, and requires changes to process, policy, and technology for both healthcare and public health systems. The complexity and segmented funding for eCR requires a divide and conquer approach with work distributed across multiple public health partners. This presentation brings together the perspectives of three major stakeholders, and presents a consolidated picture that illustrates the eCR vision.

The topic of this panel is timely, particularly for the target audience attending AMIA. Many healthcare institutions grapple with the unfunded, yet legally required, mandate to report information to public health authorities when patients present with particular conditions. It is well-documented that reporting of communicable diseases is incomplete and untimely, and providers often are not aware of reporting requirements.\textsuperscript{2} Advances in technology and information standards (both semantic and syntactic) enable eCR, but are not sufficient. Several threads of enabling work are currently underway, and advances in clinical decision support and knowledge management make the vision for eCR possible. The widespread use of electronic health records in both inpatient and outpatient care\textsuperscript{3}, further increase the opportunities for eCR. Public health reporting can move from a largely manual, fax- and phone-based process to an ongoing, systematic and automated process that manages most of the reporting requirements and supports information exchange during public health emergencies. Systems are needed to manage communication of common conditions under surveillance (e.g., vaccine-preventable diseases, such as measles and pertussis) as well as rare, emerging or re-emerging events (e.g., ebola or zika virus).

Currently, several federal agencies and local partners are collaborating to develop infrastructure and knowledge resources to implement eCR during the coming year. This panel is intended to share the status of the concurrent efforts and discuss the challenges and potential opportunities associated with eCR with an audience of experienced informaticists.

Objective

Our objectives are to: 1) update the informatics community on the current state of electronic case reporting from healthcare to public health settings; 2) describe informatics methods and tools leveraged for this use case; and 3) share the strengths and limitations of efforts to date and discuss potential challenges and unrealized opportunities.
Panel description

This didactic panel is organized to present differing perspectives on the current status, benefits, and challenges with eCR. The first speaker will provide the vision, describe the need, and share the nuts and bolts of the current status. In addition, the first speaker will share the federal public health view. The second speaker will discuss informatics strategies being used, and the similarities with other efforts, such as the provisioning of knowledge about quality measure reporting requirements. The third speaker will provide a perspective from a healthcare organization based on their participation in several pilot efforts. Finally, the discussion leader is an epidemiologist from a local health department, which is where the ‘rubber meets the road’, and leads the Public Health subject-matter expert workgroup that provides feedback on reporting specifications being developed for the RCKMS project. This experienced team of presenters will be supported by Shu McGarvey, the moderator for this session.

Panel presentation 1: The public health perspective

Laura Conn, Director of the Health Information Strategy Unit in the Center for Surveillance, Epidemiology and Laboratory Services at the CDC, and co-leader of the CDC-funded Reportable Condition Knowledge Management System (RCKMS) project, will provide the big picture of case reporting including the case reporting life cycle from healthcare to state/local jurisdictions, and how it relates to notifiable condition reporting to the CDC. Automating case reporting involves collaboration across public health partners and includes tools, services, and standardized reporting specifications for all reportable conditions. Centralization of services is a focal theme to ease the implementation burden for both jurisdictions and reporters, and part of the electronic case reporting solution includes hosting on the public health community platform (PHCP). The PHCP provides an accessible, flexible, and secure public health information technology platform of interoperable shared solutions governed by and responsive to the public health community. The PHCP will serve to connect clinical EHRs and public health agencies, and integrate RCKMS as a centralized public health decision support tool to determine if a case is reportable and to which jurisdiction(s). Oversight and management of the eCR are key to managing improvements and updates to both tools and content. This presentation includes an overview of the governance strategy and regulatory guidance to support eCR.

Panel presentation 2: Informatics perspective

Dr. Catherine Staes, an informaticist and co-leader of the CDC-funded Reportable Condition Knowledge Management System (RCKMS) project, will describe the informatics-related aspects of the infrastructure presented during the first presentation. For example, the data flow, standards, and knowledge management strategy will be described. The various implementation guides will be ‘pinned to the tail’ on the processes. More importantly though, the components and strategies will be mapped to other efforts currently involving healthcare and public health agencies to illustrate similarities and differences with these other activities. For example, the trigger codes for eCR will be provisioned similar to codes sets required for quality measurement, leveraging experience already implemented for a different MU requirement. Finally, the current status of the eCR components will be shared and potential challenges will be described.

Panel presentation 3: Healthcare perspective

Dr. Shan He, an informaticist with Intermountain Healthcare, will share perspectives on case reporting from a healthcare enterprise. Intermountain has had over 5 years of experience working with early efforts to implement electronic laboratory reporting (ELR) and electronic death reporting to Utah Department of Public Health by developing standard interfaces and integrating clinical decision support (CDS) logic into healthcare workflow. In 2015, Intermountain collaborated with public health authorities, a CDS vendor, and the CDC/CSTE RCKMS team in a pilot project to demonstrate the feasibility of using a centralized public health CDS to replace the current ELR.

As a reporter, Intermountain participated in four areas of work in the pilot: 1) terminology mapping for trigger codes from RCKMS; 2) trigger configuration on the local CDS platform; 3) EHR data extraction for the initial case evaluation payload; and 4) standard payload construction and service connection with the central RCKMS CDS. Trigger code mapping validated the comprehensiveness of the trigger codes defined by RCKMS, even though only a small percentage (2%-15% depending on the condition and the code system) of the set were actively used at Intermountain. Local trigger rules were configured to filter case requests sent to the central CDS service, which complies with the HIPAA minimum necessary requirement and alleviates performance concerns of the central
service. Existing health information technology (HIT) infrastructure including Intermountain terminology lookup and mapping services, decision support services, EHR data extraction services created for HITECH (Health Information Technology for Economic and Clinical Health) certification, and health information exchange (HIE) services were leveraged to the maximum extent in this pilot. Implementation workload will be summarized.

Intermountain also evaluated the effectiveness and timeliness of the condition reporting criteria from RCKMS by analyzing its EHR data. Quality and availability issues of certain data elements used in the reporting criteria were identified. Most laboratory results were recorded in a structured and coded format, whereas diagnoses and symptoms were not always documented in a structured format by physicians. Timely documentation of structured and coded information will improve the completeness and timeliness of electronic case reporting. In the 2015 pilot, an email alert for reportable cases was sent to the designated personnel who will manually send the case report using the specified mechanism. Intermountain is participating the second stage of the pilot in 2016, which supports automated electronic case report generation using EHR data. Findings and lessons learned will also be presented regarding this effort.

**Audience Discussion**

While questions can be addressed after each of the panelist’s presentations, we will reserve 30 minutes at the end for an in-depth discussion with and among the audience. Questions will be posed, such as:

- From the health care enterprise perspective, do the requirements and systems for implementing eCR leverage your existing infrastructure and make case reporting more efficient? Are there unintended consequences that we should be thinking about?
- Do you envision synergy with requirements, systems and processes related to quality measurement and reporting?
- From the informatics perspective, is the current approach leveraging informatics methods and tools to the greatest extent possible? What should be considered for future enhancements? What are the similarities and differences, from your perspective, between phenotyping for research and quality measurement and for case detection for public health reporting. Similarly, what is the same or different between creating a case report for public health and clinical research?
- From the public health perspective, do electronic health records change the thinking about case reporting?

**Conclusion**

Moving to electronic case reporting requires automation of a process that was designed for and conducted by humans. This change requires strong collaboration across public health organizations and eCR activities; a shared mindset toward building robust solutions that support long-term evolution; and governance to support policies, guidelines and security to ease the transition to the new paradigm of eCR.

Building Software Platforms that Integrate with the EHR: Implementations, Frameworks, and Industry Experiences

Marc Tobias, MD¹, Robert W. Grundmeier, MD¹, Joshua Mandel, MD², Aaron Neinstein, MD³, Janet Campbell⁴

¹The Children’s Hospital of Philadelphia, Philadelphia, PA, USA; ²Harvard Medical School Department of Biomedical Informatics, Boston, MA, USA; ³University of California San Francisco, San Francisco, CA, USA ⁴Epic Systems Corporation, Verona, WI, USA

Abstract
Despite billions of dollars invested nationally and decades of enthusiasm for better interoperability between electronic health record (EHR) systems, successfully integrating custom software applications is not widespread. In some cases, barriers to disseminating these shareable apps arise even when attempting to share with other institutions using the same EHR product. The recent emergence of readily implementable standards such as Fast Healthcare Interoperability Resources (FHIR) and application platforms built upon these standards are rapidly changing the landscape. Additionally, vendor-specific “app-sharing” frameworks are providing new ways for customers to share their developments. These initiatives have taken the form of institutional research vehicles, open standards frameworks, and commercial endeavors. The panelists will describe their experiences developing and implementing platforms that can embed software-like web applications. Example projects will include the use of web services to implement complex decision support rules, shared-decision making projects that directly engage patients, and workflow tools that facilitate communication across health disciplines.

Learning objectives:
1. Describe the current barriers to sharing customized software applications
2. Understand the present-day impact of successful sharing efforts
3. Describe emerging efforts that seek to facilitate the sharing of locally-developed tools

Panel Description
The panelists will describe the motivation and experience with building and implementing software platforms that integrate with the EHR. They will discuss technical and non-technical barriers to their research and implementation efforts, and how they have overcome these barriers to achieve success. Limitations of current technology and future directions, including workflow and usability aspects of app integration, will be presented.

Moderator: Welcome and session overview
Marc Tobias, MD (5 minutes)

Panelist #1: Ten Years of Epic Customization
Robert W. Grundmeier, MD (10 minutes, followed by 5 minutes discussion)
For over ten years, Dr. Grundmeier has been aggressively modifying the Epic Systems EHR to support a wide variety of clinical informatics research efforts. This has been primarily achieved through the Care Assistant, which is The Children’s Hospital of Philadelphia’s (CHOP) internal software integration platform. Unfortunately, despite the local success of these customizations, dissemination beyond CHOP has been a major problem. Dr. Grundmeier will describe how the Care Assistant has been received by clinicians and administration, as well as research that shows
improved patient outcomes through its use. He will also describe the challenges that have hindered dissemination efforts.

Panelist #2: SMART on FHIR
Joshua Mandel, MD (10 minutes, followed by 5 minutes discussion)
Dr. Mandel has helped to foster an ecosystem where third-party health apps can easily connect to data in EHRs, patient portals, and data warehouses. Dr. Mandel will describe the process by which a growing community including FHIR, SMART, and the Argonaut Project is producing open specifications, developer documentation, sample apps, RFP language, and supporting national policy for data access. He will discuss the role of academia, private industry, and government in contributing to improving data access, security, and privacy.

Panelist #3: Cisco-UCSF Connected Health Interoperability Platform
Aaron Neinstein, MD (10 minutes, followed by 5 minutes discussion)
The Cisco-UCSF Connected Health Interoperability Platform (CHIP) leverages emerging interoperability specifications and standards along with Cisco’s broad technology portfolio. Dr. Neinstein will describe how CHIP enables digital health innovators to develop, commercialize, and distribute their applications at scale -- with enterprise-grade features such as security, data virtualization, and data integration. CHIP will facilitate access to EHR data and beyond, including consumer health devices, the Internet of Things, and other new data sources. CHIP will start with an eye toward specific healthcare use cases and workflows that are common pain points.

Panelist #4: EHR Interoperability
Janet Campbell (10 minutes, followed by 5 minutes discussion)
Janet Campbell is a software developer at Epic Systems Corporation. She will specifically discuss the challenges and successes in supporting innovation-sharing among their customers. Supporting issues that arise in customer-authored applications necessitate new approaches, as resolving problems is more difficult when support staff do not have direct access or ability to change source code. System response time may be degraded by poorly written custom software, and the vendor’s role in adjudicating these problems may be unclear. Cultivating a successful and safe application-sharing ecosystem requires new approaches across the software development cycle, from architectural design to end-user support.

Moderator: Facilitated discussion and closing
Marc Tobias, MD (25 minutes)
The facilitated discussion will explore strategies for institutional administrators to offer effective and secure applications within their own EHR. Additionally, the discussion will attempt to provide guidance to software developers regarding how best to approach the current landscape of EHR application integration.

Discussion Questions
The following guiding questions will be used to facilitate discussion:
1. Given what you learned from your projects, what new innovations or changes do you envision in the upcoming years to more meaningfully impact clinical outcomes?
2. How difficult was it to implement tools developed externally within your own health system?
3. What are the biggest barriers to expanding your current platforms?
4. What has been the perception and response to your platform in regards to hospital administration and outside software developers?

Moderator Attestation
The four panelists, Dr. Grundmeier, Dr. Mandel, Dr. Neinstein and Janet Campbell, have all agreed to participate in this didactic panel.
Engaging older adults in the design, implementation and evaluation of Health IT

Anne M. Turner, MD, MLIS, MPH1, George B. Demiris, PhD, FACMI1, Amanda Lazar, PhD2, Blaine Reeder, PhD3
1University of Washington, Seattle, WA; 2Northwestern University, Evanston, IL; 3University of Colorado College of Nursing, Aurora, CO

Abstract
Over the past decade there has been a growing interest in encouraging individuals to take a more active role in their health and health information management. This movement towards greater patient engagement is closely tied to patient centered technologies including patient portals, decision making tools, home based telehealth, sensor technologies and patient access initiatives such as Open Notes. Although older adults make up 18% of the US population and are the largest users of healthcare, their uptake of information technology has traditionally lagged behind that of other age groups. Unfortunately, the needs of the largest group of health care consumers are often not considered because of difficulties involving this age group in research and the misperception that older adults are technology adverse. This panel demonstrates the potential of information technology to improve the health and independence of older adults, and showcases the application of participatory design methods to empower older adults in their health care management and decision making. Panel members will discuss their experience in conducting research with and for older adults in various settings including independent living, retirement communities and assisted living facilities.

Panel Description
The concept of patient engagement refers to greater involvement of patients in plans for health maintenance and clinical decision-making. Patient engagement has been shown to improve health outcomes and patient satisfaction and has the potential to save healthcare costs. Newly emerging technologies such as mobile apps, wearable sensors and patient centered health records are viewed as key components to involving patients in their health care. However, these technologies are often not designed with older adults in mind, despite the fact that individuals over 60 years of age make up 18% of the US population and are the largest consumers of health care dollars. In terms of engagement, this group is often viewed as vulnerable, dependent, and unwilling or unable to try new technologies. As a result their needs are often left out of the design process. How do we encourage participation by older adults in their healthcare and ensure their needs are incorporated into the design of health information tools? Participatory user centered design methods tailored to older adults are being successfully applied in the design of health information technologies including smart homes, information kiosks and personal sensing devices. Each of our panel speakers will discuss their experience developing and using evidence based informatics solutions to help assess and meet the dynamic needs of older adults and their caregivers.

Intended Audience: This panel is intended for designers and researchers who are interested in working with and designing information systems which serve the needs of older adults, their caregivers and other vulnerable populations.

Learning Objectives:
In this session, participants will learn to:
• Discuss approaches to engaging older adults and families and facilitating a shift to patient-centered geriatric care.
• Be able to cite at least four examples of the use of behavioral sensing to identify health issues and provide usable data to elders, their caregivers, and their health care team.
• Identify the major barriers to technology acceptance by elders and ways to overcome these barriers.
• Address factors such as privacy, financial and ethical factors that may complicate conducting research with older adults living in diverse settings and with diverse disabilities.

Panel Organizer and Participants
Anne M. Turner, MD, MLIS, MPH (Panel Organizer)

Dr. Turner is a clinician and public health informatics researcher at the University of Washington, with a primary research interest in how to incorporate the needs and practices of diverse populations into the design of healthcare technologies using user-centered design methods. Dr. Turner oversees the AHRQ funded five-year SOARING project investigating the personal health information management needs and practices of older adults (www.soaringstudy.org). The results of this research will be used to identify design requirements and develop guidelines to better meet the needs of aging populations. Dr. Turner will serve as the moderator for the session.

**Topic Focus:** Panel speakers will discuss their use of participatory design methods to inform the design, implementation and evaluation of health information technologies (HIT) for older adults in the context of a particular project, intervention, or research interest.

George Demiris, PhD

Dr. Demiris is a Professor of Biomedical Informatics at the University of Washington. He will describe the use of “smart home” technologies that facilitate passive monitoring of older adults in their homes with the goal to understand patterns of mobility and overall activity, detect abnormalities and prevent or even predict adverse events with the ultimate goal to support aging in place. He will showcase the potential of behavioral sensing tools to engage patients and their families. Findings from a project based on the deployment of motion and environmental sensors in apartments of 48 community dwelling older adults will be presented. He will also highlight ethical and technical challenges associated with smart home applications as well as opportunities to engage older adults and their families in the design of such systems, as well as the implementation of visual analytics resulting from these large data sets that are meaningful and support clinical decision making. This presentation will focus primarily on ways to engage older adults in the definition of relevant research questions and solicit their feedback, needs and preferences in designing user interfaces that summarize and visualize behavioral sensing data in a way that facilitates understanding and shared decision making.

Amanda Lazar, PhD

Dr. Amanda Lazar is a Postdoctoral Fellow at Northwestern University with research interests focused on older adults with cognitive impairments. Older adults with dementia are often left out of formative research on technologies designed to address psychosocial aspects of dementia. A variety of difficulties with recruitment, logistics, and unclear guidelines regarding ethical issues complicate working with this population. Despite these challenges, it is vital to include the perspectives and experiences of older adults with cognitive impairments in all phases of the technology design and evaluation process. Dr. Lazar will draw on two years of field research in a specific clinical context: art therapy for older adults with dementia. She will discuss findings from her field work within an art therapy program, in which data were gathered through observations of art therapy sessions, interviews with art therapists, and the design and evaluation of new technologies to support sharing. Dr. Lazar will discuss the potential benefits of new technologies that support sharing therapeutic artwork and tensions inherent in encouraging sharing within a protected health context. She will highlight issues that arose regarding ethics, privacy, and empowerment. This presentation will focus primarily on issues related to ethics, privacy, and empowerment that arise when conducting participatory research with individuals with cognitive impairments.

Blaine Reeder, PhD

Dr. Reeder is Assistant Professor of Health Care Informatics in the College of Nursing, University of Colorado. He will discuss the differences in usability and usefulness of smart watches and smart home sensors for health-related data collection. Dr. Reeder will present the results of a technology acceptability study that enrolled 10 older adult women (young-old and middle-old) for interviews that compared perceptions of wearable activity monitors and home-installed motion sensors. In addition, he will present an overview of current Pebble smart watch technology with a focus on smart watch potential to facilitate participatory design research with older adults. Smart watch features that improve upon current research-grade activity monitors will be highlighted, including: built-in design for translation based on consumer-grade device availability; real-time access for physical activity data; wrist-based mini-surveys; bi-
directional communication with researchers and providers; and older adult cohort familiarity with watches as a wearable technology that enhances acceptability and eliminates medical device stigma. Lessons learned from smart home and wearable device studies that engaged older adults and the potential for smart watch integration with Internet of Things platforms will be presented as takeaways. This presentation will focus primarily on how perceptions of wearable and home-installed sensors can inform participatory design of technologies for older adults.

Participation
All participants have agreed to take part in this panel.

Discussion Questions:
- How do we engage family caregivers and other stakeholders in the design, implementation, and evaluation of health IT?
- How do attitudes and values of elders differ from those of family members and caregivers?
- Can design features overcome stigma associated with being older?
- What are some techniques for reaching out to older adults with cognitive and physical limitations in participatory research?
- How do we encourage technology designers and commercial vendors to consider older adults in the design of HIT?
AMIA Fall Symposium 2016

Panel Proposal

Transforming Clinical Documentation: Nursing and Big Data Working Group 10’s Recommendations and Action Plan

Organizer: Charlotte A. Weaver, RN, PhD, FAAN

Panelists
Charlotte A. Weaver, RN, PhD, FAAN, AMIA Co-Chair to ANI, (caweaver2011@gmail.com)
Judith Effken, PhD, RN, FACMI, FAAN, Professor Emerita, University of Arizona, College of Nursing (jeffken@nursing.arizona.edu)
Kelly Cochran, MS, RN, Policy Advisor, HIT, American Nurses Association, (kelly.cochran@ana.org)
Rebecca Freeman, PhD, RN, PMP, Chief Nursing Officer, Office of the National Coordinator, (Rebecca.freeman@hhs.gov)
Ann O’Brien, MSN, RN, CPHIMS, Sr. Director Clinical Informatics, Kaiser Permanente, (ann.o’brien@kp.org)

Abstract
In acute care, nursing documentation in today’s electronic health records systems (EHR) has become so burdensome that its sheer volume ensures that virtually no member of the care team reads it, not even nurses. EHR documentation was created in the image of the paper chart with a focus on data capture. Consequently, data views that could assist clinicians in assessment, on-going evaluation, and team communication/data sharing are mostly woefully absent. Thus, instead of promoting nurses’ core functions of monitoring and early-warning surveillance, this data-rich but information-poor (DRIP) state undermines patient safety by not supporting effective sharing of information among nurses or with the care team. This panel will describe how nurses view current EHR systems and how they restrict nurses’ ability to provide optimal, safe, efficient, and quality patient care. Panel members will present current initiatives addressing some of these pain points and offer specific recommendations for how the best-practices resulting from these initiatives might be rapidly shared with others through a vendor-neutral repository.

Learning Objectives: After attending this panel presentation, attendees will be able to:
1. Describe the current documentation burden built into today’s EHRs for nurses.
2. Discuss academic research on EHR usability, design, and nurse satisfaction with EHRs.
3. Describe 3 current initiatives by nurse leaders for transformative change in clinical information systems design.
4. Describe the recommendations and action plan of the Nursing and Big Data’s Working Group 10.

Description
In 2014, a group of informatics and nurse leaders from practice, academia, and the vendor community formed because of a growing recognition that current EHR systems were not supporting evidence-based, nursing practice and lacked the key functionality needed for clinical decision support and safe patient care. The recommendations and action plan that will be presented by this Panel draw upon two years of work by the Working Group that emerged from the initiative. AMIA’s EHR 2020 report aptly described the limitations and vulnerabilities of current state EHRs for supporting safe, effective and efficient care, but focused on the documentation burden imposed on physicians. In 2014, the nurse leaders attending the University of Minnesota’s “Nursing and Big Data” conference issued a similar call to action. Underlying this call was the recognition that nurses’ issues about the challenges of EHRs to meet their needs was rapidly reaching a tipping point. The experiential evidence reported by conference attendees has been corroborated by recent studies reporting poor nurse satisfaction scores related to EHR documentation requirements and excessive time needed to complete admission assessments and a demand that documentation support nurses’ practice and improved patient outcomes rather than prioritizing the legal, regulatory, reimbursement needs of the organization. Nurse practice leaders are expressing concern that at some point, nurses will organize around and become increasingly vocal about their EHR dissatisfaction.
Current EHRs are not designed to guide the delivery of highly reliable, evidence-based nursing or team care practice\textsuperscript{4,6,9}. Even when a health care organization purchases an EHR system, they must design, build and implement it without the benefit of best practices benchmarks. There are few mechanisms available to leverage lessons learned from other organizations or to access a “best practice” central repository that holds “how to” examples, such as data sets complete with clinical terms mapped to the standardized terminologies of LOINC and SNOMED-CT. Instead, each health care organization starts from their vendor’s basic system and must depend on their singular-threaded expertise. Often, the clinical personnel tapped to design and build the new clinical system are nurses, physicians, and health professionals who show an interest in the project but have no formal informatics education or certification. A major theme for nurses is that their documentation burden has steadily increased because of the addition of new regulatory mandates, quality report requirements, or overzealous interpretation of these requirements\textsuperscript{6,8,10-11}. Unfortunately, as new requirements are added nothing is removed. One nurse informatics leader described it like a home that had been lived in through all the family life cycle, with nothing ever given away and every room filled—including the attic\textsuperscript{10}. A drastic change is needed in the way we design and build our EHRs so that we can benefit from lessons learned. We also need system functionality that provides the following: multiple technologies for documenting care; support of nurses’ workflow with real-time decision support; and, flexible data visualization and screen presentations that can be specific to and changed by the clinician. Added to these needs are enhancements that allow nurses to capture and share the patient’s story clearly and concisely so that team communication is optimized.

In acute care organizations, nurses represent the largest users of health information technology and are responsible for more documentation than any other group of health professionals\textsuperscript{12-13}. For that reason, if goals for transforming our healthcare systems’ quality, safety and costs are to be achieved, nursing has to be included and given tools that optimally support these care delivery goals. Currently, there is little understanding of how EHRs should be built to support nurses’ ability to deliver safe, evidence-based care. Thus, our Working Group’s first year report aimed to share the available evidence broadly among nursing leadership, and was published in the Nursing Administration Quarterly rather than in an informatics journal\textsuperscript{6}. This 2015 report outlines the problems with the EHR, and also sets out principles and specific recommendations for optimizing EHRs to improve the processes of care delivery and generate actionable information for nursing care decisions and quality outcomes improvement. Now we are bringing our work into health policy and informatics domains\textsuperscript{14}. This Panel will present a specific set of go-forward actions detailing the starting content for a vendor-neutral best practices repository, possible hosting sites, and a plan for assuring the repository’s maintenance and sustainability over time.

Panel Organization:
Intro/Scope/Problem  Weaver  15 minutes
Academic Work      Effken  15 minutes
Policy             Cochran  15 minutes
Exemplar          Freeman  15 minutes
Q & A             O’Brien  30 minutes

Panelist Roles:
Ann O’Brien, MSN, RN, CPHIMS. Ms O’Brien, Working Group 10 Chair, will moderate the panel discussion and audience questions.

Charlotte A Weaver, PhD, RN, MSPH, FAAN. Dr Weaver (panel organizer) Working Team Chair will present the scope of work completed, the problem being addressed and the intended approach to identifying best practices for designing optimum, evidence-based documentation and exemplars mapping nursing problems to LOINC and SNOMED-CT, including those resources available at NLM and on other web sites.

Judith Effken, PhD, RN, FAAN, FACMI. Dr Effken, Working Team Co-chair, will highlight the major academic initiatives informing the recommendations, approach and content for a Library of Best Practices demonstration project.

Kelly Cochran, MSN, RN. Ms Cochran will highlight the policy perspectives that support this initiative to transform clinical documentation with the driving priority being improving patient safety and quality while cutting costs. The Washington DC landscape and multiple entities that represent stakeholders and supporters will be discussed.

Rebecca Freeman, Ph.D, RN, PMP. Ms Freeman will present a vendor-neutral technical specification approach for streamlining nursing documentation developed at a large, national healthcare system using multiple EHR vendors.

Participation Statement
All proposed panelists are aware of this panel submission and have agreed to participate in the panel if the proposal is accepted.

This Panel is a NIWG sponsored submission
Informatics to Transform Med Wreck to Medication Reconciliation

Mark G. Weiner, MD, Charlene Weir, PhD, RN, Terrence J Adam, PhD, MD, Edgar Chou, MD

1Department of Clinical Sciences, Temple University School of Medicine, Philadelphia, PA
2Department of Biomedical Informatics, University Of Utah, Salt Lake City, UT
3Institute for Health Informatics, University of Minnesota, Minneapolis, MN
4Division of Internal Medicine, Drexel University College of Medicine, Philadelphia, PA

Abstract: Appropriate conduct of Medication Reconciliation is a fundamental component of meaningful use, and an important contributor to patient safety. In the ambulatory setting, medication reconciliation aims to ensure that the patient and provider are in synch with the medication regimen. In the inpatient setting, the process mandates that medications from a prior treatment location are appropriately addressed in the transition from one level or location of care to another. At discharge, medication reconciliation requires thoughtful decisions about continuing inpatient medications into the ambulatory setting, with appropriate recognition of prior outpatient medications that should be stopped or changed. This panel will discuss some of the informatics, workflow, communication, and human challenges that interfere with optimal completion of medication reconciliation and several institutional initiatives designed to address these challenges.

Learning Objectives:
1. To develop a systematic approach to identifying and addressing problems in medication reconciliation
2. To understand the patient perspective in managing medication reconciliation
3. To identify the implicit cognitive goals involved in medication reconciliation and their implication for display designs.
4. To explore informatics solutions that ease the process of conducting medication reconciliation for clinicians and patients.

Documentation of pharmacologic orders in the inpatient and ambulatory settings has been greatly improved in the era of Electronic Health Records. While some ambulatory scripts are still written on old paper scripts, most medication ordering takes place through the EHR, creating the unprecedented ability to track all medications that have been ordered for a patient. However, the simple availability of these medication orders does not always translate into a simplified medication reconciliation process that successfully aligns active medication lists in the EHR with what the patient has been taking, and what the patient SHOULD be taking. While medication reconciliation is required at all ambulatory visits, and at all transitions of care in the inpatient setting, there are a number of factors that make this process more difficult than is commonly realized. Medications can still “fall off” the medication list. Patients can still take medications in a manner differently than prescribed. Most pharmacies are still not receiving orders to discontinue medications, so patients often pick up refills of “old” medications, while also receiving new prescriptions that were intended to replace the old medications. In addition, medication reconciliation results in significant cognitive demands on the part of the provider and unnecessarily breaks up the flow of care. Informatics tools can present a more complete picture of medications that have been prescribed from other providers, and can also show medications that the patient has retrieved. If properly designed and operationalized, the use of informatics solutions can reduce cognitive burdens on provides and facilitate a higher quality medication experience for patients.

This panel will explore medication reconciliation at 4 institutions, and discuss the human, workflow and technology issues faced and solutions being implemented in each setting.
Mark Weiner, MD, Temple University Health System

Temple University Health System currently runs Epic Ambulatory and is the final phase of implementation of the Inpatient product. The Ambulatory workflow for medication reconciliation begins with Medical Assistants who asks the patients about each medication in their medication list and whether or not they are taking or not taking it. However, often times they are not sure, or even if they carry a medication list they have received elsewhere, they still may not be sure what they are taking. Through the course of the visit, the physician has access to data on meds picked up through Surescripts, and can also link to medication lists at other sites through Epic Everywhere. This establishes a discussion of what medications the patient may be taking, though a great deal of ambiguity exists. In the primary care setting, the broad range of health issues addressed often allows for thoughtful decisions about revising the medication list, though in specialty settings, the focus of the visit may not allow reconciliation of medications outside the domain of the clinical specialty. When medications that the patient has stopped on their own are removed from the medication list, the after visit summary associated with the visit informs the patient to stop the medication, making it appear that the provider had recommended the discontinuation at the time of the visit. Medications that get renewed are given a start-end date interval associated with the interval from the prior instance of that medication which, if it is too short, may make the medication fall off the list much sooner than expected. Dr. Weiner will outline and categorize these and other pitfalls in the medication reconciliation process.

Charlene Weir, PhD, RN, University of Utah

The VA currently has integrated a number of tools and policies designed to ensure continuity of medication treatments, including note templates, policies for discharge follow-up, software that identifies refill rates and the use of pharmacists in the inpatient and outpatient care settings. Across a series of ethnographic observations, cognitive task analyses, focus groups and interviews, VA researchers have identified some key barriers to the design and implementation of informatics solutions for effective medication reconciliation. The first is that the “task” and meaning of medication reconciliation varies always across roles, with each role bringing different goals and perspectives to the process. Med Rec can range from a simple matching task, to a deep assessment of the appropriateness of treatment across patient and disease. The implication is that medication reconciliation policies must identify who’s responsible and informatics solutions need flexibility in display. The third issue is that medication reconciliation is often viewed as an assessment task alone, when often it is associated with decisions and actions that need support. Finally, the task of medication reconciliation at times is disembodied from the patient-provider interaction because it is not part of the natural workflow. Dr. Weir will describe assessment, workflow and logistical requirements to enhance the medication reconciliation process.

Terrence J Adam, PhD, MD, University of Minnesota

The care transition process has the potential to create patient safety concerns due to problems of communications, logistics and care complexity issues. The care transitions create a need for the health system to effectively understand the patient’s condition and pass pertinent information from care facilities to other care facilities, patients and caregivers. A particular transition of care problem is patient communication, verification and management of medication regimens. The acute care setting can create a number of confusing messages for patients who are experiencing illness and may hear from multiple specialists during their care experience.

To address this problem, a structured data approach based on the pharmacist drug therapy problem framework can help identify pertinent medication issues and help provide guidance for their resolution. The University of Minnesota and affiliated Fairview health system have used EMR driven business process rules to identify at-risk patients and facilitate transition of care management of medication regimens. By using a mix of information management solutions and care process follow-up, the University-affiliated health system has created a mechanism to systematically identify patients and intervene with pharmacist review using in-person and phone based follow-up.
Dr. Adam will discuss the role of informatics in supporting an improved medication reconciliation process, with a special focus on care transitions.

**Edgar Chou, MD  Drexel University**

Drexel University College of Medicine began the journey of its ambulatory electronic health record implementation, Allscripts Touchworks, in 2006. Drexel is the academic affiliate with its partner hospital, Hahnemann University Hospital, which has its separate electronic health record, Cerner. Similar to most multispecialty practices, challenges are abound in ensuring the medication list is adequately reconciled, ranging from patient’s literacy to the numerous players that now impact whether a medication is currently being taken or not or can continue to be taken or not for the primary care physician and for the medication list to be truly “reconciled” - these extend beyond the specialist to include the insurance payer (changes in formularies and coverages and participation in Surescripts), the pharmacy benefit plan, and outside institutions (hospitals, skilled nursing, rehab) and agencies (home health) that are involved in the care of the patient. Informatics solutions have addressed challenges in the electronic prescribing process over these years. We now have the ability to initiate prescriptions to pharmacies, and receive information on filled prescriptions that providers can verify before importing into our EHR. Providers receive prescription renewal requests automatically through the EHR, and see drug formulary reminders at the time of placing prescriptions or renewals. Lastly an increasing number of providers have the dual factor authentication required to prescribe controlled substances directly to pharmacies across all 50 states. Despite these technological advancements, time has still been the greatest barrier in achieving this across our institution. We have embraced this reality with incorporating additional resources to assist with the process. We have expanded certified Medical Assistants’ roles and incorporated nursing staff to assist with this process. Dr. Chou will describe how informatics solutions have been incorporated into clinical workflows to improve medication reconciliation.

**Intended Audience and Timeliness**

The intended audience includes physician and nurse informaticists as well as academic informaticians interested in the understanding trends and limitations in technology designed to foster medication reconciliation and the continued need for workflow improvements and trained people in the process. This is an especially timely topic as improved interoperability of information systems and the associated increased access to medication data from pharmacies, payers, and other institutions provides better information substrate for medication reconciliation, and more opportunities for recognition of important medication conflicts. In addition to robust technology, true medication reconciliation requires a team approach to fully address the detail from multiple information sources and the complexity of many patients’ medication regimens.

All participants have agreed to take part on the panel.  

This submission is endorsed by the Primary Care Informatics Working Group

**Discussion Questions**

- What are the unique information needs in managing medications through transitions of care?
- How does interoperability both help and add to the complexity of conducting medication reconciliation?
- How can the drug therapy problem framework help in systematically identify at-risk patients?
- Does the use of drug therapy problems help improve post-discharge patient follow-up?
- How do institutions organize teams to manage complex medication regimens?
- What are the remaining informatics and workflow challenges in medication reconciliation?
Abstract

Often the focus of public health informatics is narrowed down to application of IT systems and other technology solutions in public health settings. We argue that actually that scope should be broadened, first, to analysis and improvement of business practices utilized by public health agency program; and second, to a much wider application of information and computer science technology to promote and improve the public’s health, well beyond the reach of public health agency programs. This panel will provide a variety of perspectives on use of business analysis techniques for typical public health informatics projects.

Learning objectives. After participating in this session, the participant should be better able to:

- Formulate an approach to application of business analysis techniques to document institutional knowledge, analyze and improve performance of key functional aspects of public health programs, and develop requirements for technology solutions.
- Reduce complexity of a typically complex public health program by using business analysis to break it into component parts to explore how parts work together to create an efficient whole.
- Replicate the approach and apply lessons learned on how methods of business analysis have been used to develop operational best practice guidelines for immunization information systems and in other settings.

Panel Description

This panel will provide a variety of perspectives on use of business analysis techniques for typical public health informatics projects. Often the focus of public health informatics is narrowed down to application of IT systems and other technology solutions in public health settings. We argue that actually that scope should be broadened, first, to analysis and improvement of business practices utilized by public health agency program; and second, to a much wider application of information and computer science technology to promote and improve the public’s health, well beyond the reach of public health agency programs.

Issues that will be examined:

- Role of the business analysis component in public health informatics.
- Using business analysis techniques to analyze and improve public health operations and processes.
- Using business analysis techniques for clinical decision support for immunizations.
- Other examples of using business analysis techniques to improve public health practice and outcomes.

Moderator: Warren Williams, MPH

Brief Description of Presentation 1: Role of the business analysis component in public health informatics. Patrick O’Carroll, MD, MPH.

Public health informatics is primarily an engineering discipline. Engineering techniques of business analysis should be applied to understand the business of public health – to elucidate in concrete terms exactly what the public health agency does. This step, seemingly straightforward, can in fact be the most difficult and time-consuming element. It involves the development of models of the business by use of formal modeling techniques.

Brief Description of Presentation 2: Using business analysis techniques to analyze and improve public health operations and processes. David Lyalin, PhD.
Business analysis and facilitation techniques, as well as consensus building methodologies were used to explore immunization information systems (IIS) processes and operations. IIS experts analyzed existing practices, collaborated to identify process details, evaluated and combined various operational practices, and achieved a consensus regarding best practice recommendations. These best practice recommendations offer practical guidelines on the most challenging operational areas for IIS, such as data quality assurance, reminder-recall, deduplication of immunization records, patients eligibility for public programs, vaccine inventory management, coverage assessments. Also, developed guidelines serve as a source of requirements for IT solutions, illustrating the notion that operational needs should drive technological solutions, not the other way around.

A number of business modeling techniques have been used to capture best practice recommendations. For example, we have applied domain modeling in a variety of public health areas, providing a common vocabulary and establishing a foundation for other model types. Decision models, such as business rules and decision tables, were utilized to unambiguously document high-level policies, institutional knowledge, and operational-level decision-making. Process models, such as use cases (structured description of operational scenarios) and a variety of process diagrams, have been employed to describe processes and process participants. Event models helped us to analyze events that lead to change of statuses for various public health concepts (e.g., status of a vaccine dose during its life cycle). These analysis models supported three stages of our collaborative work: discovery (where the stakeholders documented understandings of how exactly the current program operations work, which sometimes isn’t clear to everyone, in all areas of operations), assessment (i.e., what is working well and what isn’t, as well as discussions of improvement options), and specification (i.e., agreed-upon program requirements that should be implemented).

Independent evaluation findings indicate that application of these best practice recommendations in the IIS domain of state and local health departments resulted in improved data quality, reduced staff time, and increased efficiencies across immunization programs. Vendors are using these guidelines as a reference source to implement operational best practices a variety of IT platforms.

Brief Description of Presentation 3: Using business analysis techniques for clinical decision support for immunizations. Stuart Myerburg, JD.

Immunization clinical decision support (CDS) is an automated process that occurs within Immunization Information Systems (IIS) and Electronic Health Records (EHRs) to determine the recommended immunizations needed for a patient and deliver these recommendations to the healthcare provider. These recommendations are developed by the Advisory Committee on Immunization Practices (ACIP). After ACIP recommendations were published, technical and clinical subject matter experts (SMEs) worked to interpret and integrate them into their CDS engines. The translation of that clinical language into technical logic was time-consuming, complex, and done mostly independently within each system. As a result, CDS engine outputs often varied and did not always match the expectations of clinical SMEs.

The Clinical Decision Support for Immunization (CDSi) project was begun to provide a single, authoritative, implementation-neutral foundation for development and maintenance of CDS engines. Business modeling techniques were used to develop the CDSi resources. Domain and process models, along with decision tables and business rules, were used to capture ACIP recommendations in an unambiguous manner and improve both the uniform representation of vaccine decision guidelines, as well as the ability to automate vaccine evaluation and forecasting.

The target audience for the CDSi resources includes business and/or technical implementers of immunization CDS engines. CDSi provides them with a bridge between the clinical recommendations and the rigorous technical logic needed for their systems. The business modeling used in CDSi provides uniformity and reduces ambiguity, assuring patients receive the right immunization at the right time.

Brief Description of Presentation 4: Examples of using business analysis techniques to improve public health practice and outcomes. Bill Brand, MPH.

This final section will highlight several examples of using business process analysis and re-design to improve practice and efficiency. The examples will include automating previously manual workflows, designing public health processes to better match clinical workflows in healthcare settings, innovative approaches and design in
surveillance, and development of shared services to meet common needs across organizations. It will close the didactic portion of the session with overall principles and guidance that distill the need for and benefits of collaborative approaches to business analysis in public health as it seeks to modernize its processes and information systems.

**Why the topic of this panel is timely, urgent, and needed**

Implementation of formal scientific methods of statistics for data analysis defines public health as an applied science and provides a basis for policy and operational decision-making. At the same time, systematic analysis of operations and processes where information originates has limited implementation in the public health enterprise. Methods for such business analysis have been developed within a field of industrial and systems engineering. Application of these methods helps to document institutional knowledge, analyze and improve performance of key functional aspects of public health programs, and develop requirements for technology solutions.

As complexity of the public health enterprise increases, systematic analysis techniques help to deal with that complexity. Specifically, business analysis allows to break a typically complex public health program into its component parts, i.e., common perspectives of why, who, how, where, what, when. Such a partition makes it easier to both understand the program (from its policies to technical implementations) and to explore how its parts work together to create an efficient whole. Benefits of using the business analysis are illustrated with case studies from several public health informatics projects.

Anticipated audience includes public health informatics professionals from government, private sector, and academia.

**List of discussion questions:**

- What more can be done to educate public health students and practitioners in informatics principles and approaches, such as business analysis?
- How can business analysis techniques enable public health and healthcare organizations to better understand each other’s workflows and business requirements? In what areas could we collectively do more to ensure synergistic processes?

**A statement from the panel organizer:**

All participants have agreed to take part on the panel.
Mental Health/Substance Use Disorder Care, Privacy, and HIT—Can We Make It All Work?

David W. Bates, MD1, Alisa B. Busch, MD, MS2,3, Marissa Gordon-Nguyen, JD, MPH4, Paul C. Tang, MD, MS5

1Brigham and Women’s Hospital, Boston, MA; 2McLean Hospital, Belmont, MA; 3Department of Health Care Policy, Harvard Medical School, Boston, MA; 4US Department of Health and Human Services, Office for Civil Rights, Washington, D.C.; 5Palo Alto Medical Foundation, Palo Alto, CA

Abstract

Electronic health records (EHRs) enable easier, more complete sharing of health information across a patient’s providers. Mental health and substance use disorders (MH/SUDs) are common, and often cause or exacerbate other medical conditions, so patients could benefit from integration of MH/SUD information into EHRs and other health information technology. However, patients view some health conditions as more private than others and would like more control over how, or to whom, their health information is shared. For example, patients expect, and some federal and state regulators require, special privacy protections for MH/SUD care, which can pose challenges for EHRs and health information exchange (HIE). Overcoming the challenges of applying additional privacy protections to specific data categories in EHRs and HIE has important implications for patient autonomy, care-seeking, and healthcare quality and safety. It also has important implications for behavioral health providers’ ability to participate in HIE, and for our healthcare system to move towards increasingly efficient, higher quality, and safer healthcare. Recent federal and state efforts are aimed at addressing some of these issues. The goal of this interactive panel is to discuss the ethical, medical, public health, regulatory and technological challenges and controversies of addressing privacy in EHRs and HIE.

Intended Audience: Clinicians, informaticists, policy makers

Introduction

There are important technological, political, and clinical challenges to meeting the goals of respecting patient autonomy in information sharing using electronic health records (EHR) and health information exchange (HIE), while also meeting the medical and public health goals of data sharing and a robust learning medical system. A 2014 Office of the National Coordinator (ONC) survey finds that while the proportion of individuals who worry about the privacy of their healthcare records declined recently, a substantial minority (30%) remain concerned, and 5% reported withholding information due to their concerns. Similarly, studies in primary care samples have found that about one-third would restrict access of sensitive information to at least one healthcare provider in their EHR. These statistics reflect privacy concerns broadly and for a variety of sensitive medical conditions. Mental health and substance use disorders (MH/SUDs) represent illnesses for which patients often have heightened privacy concerns related to discrimination and stigma, at times from their healthcare providers.

As a result, federal and state policies regulating the disclosure of MH/SUD records are often more stringent than for healthcare in general, even for treatment purposes. The MH and SUD privacy regulatory environments differ somewhat, but both pose challenges to EHR implementation and HIE. For mental health, the federal Health Insurance Portability and Accountability Act (HIPAA) privacy regulations protect the privacy of individually identifiable health information and generally does not distinguish between information about mental health and other types of health information. However, states commonly have mental health privacy laws that augment HIPAA. In contrast, the federal SUD privacy regulation, 42 CFR Part 2, rarely is augmented by state law. Proponents of integrated, HIT-enabled care argue that 42 CFR Part 2 is outdated and contains requirements that are
extremely difficult to implement in HIT.\textsuperscript{9,10} Others argue that its protections are necessary to avoid discrimination in personal and patient care experiences.\textsuperscript{11}

Recognizing the importance of patients with MH/SUDs being able to benefit from HIT (including healthcare delivery integration and an enhanced ability to assess and improve healthcare quality), the importance of respecting patient autonomy for consent, and the unique medical record privacy regulatory environment of MH/SUD care, there are a variety of active federal efforts to address these issues. For example, the ONC and the Substance Abuse and Mental Health Services Administration (SAMHSA) are working to address HIE technological challenges of data segmentation and consent.\textsuperscript{12,13} And in recognition of the challenges posed by 42 CFR Part 2, in February 2016 the SAMHSA released proposed changes for public comment.\textsuperscript{14}

Despite the gains from these efforts, much policy and technological work remains. For example, data segmentation was not deemed ready enough to be required in the October 2015 EHR Certification Final Rule\textsuperscript{15}. And, while the proposed rule change to 42 CFR Part 2 has provisions for HIT environments, it is unclear whether the changes will adequately both address public concerns about discrimination, and dismantle the barriers to EHR implementation and HIE in MH/SUD care. Also, patient restricting authorization for clinical information sharing across providers can have important adverse consequences for the quality and safety of healthcare. Emerging evidence finds that developing the appropriate technology and privacy policies will be inadequate absent robust patient education about the implications of their choices.\textsuperscript{2}

This panel topic is both timely and controversial because of the active federal and state efforts to address MH/SUD data segmentation and privacy, support HIE of MH/SUD treatment, and revise a controversial federal policy (42 CFR Part 2) which impedes HIT, HIE and integrated healthcare for individuals with SUD but is also seen by some as providing needed protection against healthcare discrimination. These efforts are in the context of an emerging but not quite ready technology and policy landscape to enable granular consent of information, nor a clear understanding of what patients will need to support them in making educated decisions about information sharing. Also, these efforts are in a healthcare policy context in which alternative models of payment and healthcare delivery are making coordinated and integrated general medical and MH/SUD care an increasing imperative and reality—often absent MH/SUD information about patients that could have important implications for care.

Panel Aim and Expected Discussion: The aim of this interactive panel is to discuss the ethical, medical, public health, technical and policy/regulatory challenges of HIT privacy in the context of MH/SUD care, and the changing practice models of integrated, coordinated healthcare.

Expected Contribution of Each Speaker: All panelists have agreed to participate in this panel. **David W. Bates, MD** is a general medical internist, the Chief Innovation Officer at Brigham and Women’s Hospital, and an expert in quality and safety in electronic medical records, and health information technology policy. Dr. Bates will serve as moderator and also discuss how mental health issues and substance use are actually being managed in one large integrated delivery system, including the challenges of data segmentation and anonymization. There is considerable variability among both systems and states in terms of how data around MH and SUD are both represented and especially transferred. **Alisa Busch, MD, MS** is a psychiatrist, the Chief Medical Information Officer, and Director of Clinical Performance Measurement and Health Services Research at McLean Hospital. She is also an attending psychiatrist in the McLean Hospital Alcohol and Drug Abuse Treatment Program. Dr. Busch will discuss the state of HIT implementation in MH/SUD care, the privacy regulatory landscape unique to MH/SUD programs and implications for data sharing within EHRs, and federal and state efforts to facilitate EHR implementation and HIE in MH/SUD providers. **Marissa Gordon-Nguyen, JD, MPH** is a Senior Health Information Privacy Policy Specialist at the US Department of Health and Human Services, Office for Civil Rights, Washington, D.C. Ms. Gordon-Nguyen will discuss the HIPAA provisions that address quality assessment/improvement and care coordination, as well as guidance materials related to mental health disclosures. **Paul C. Tang, MD, MS** is the Vice President, Chief Innovation and Technology Officer at the Palo Alto Medical Foundation, and Vice Chair of the Health IT Policy Committee for the Office of the National Coordinator for Health Information Technology Committee (HITPC). Dr. Tang will discuss HITPC recommendations on sensitive health information, including Part 2 information.

New Pathways Into Biomedical Informatics: Educational Outreach Programs for High School Students

Panelists: David Boone, PhD1, John T. Finnell, MD2,3, Kim M. Unertl, PhD4
Moderator: Indra Neil Sarkar, PhD, MLIS5

1Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA; 2Regenstrief Institute, Indianapolis, IN; 3Department of Emergency Medicine, Indiana University School of Medicine, Indianapolis, IN; 4Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 5Center for Biomedical Informatics, Brown University, Providence, RI

Abstract

Biomedical informatics education in the United States started with a focus on the graduate and post-graduate level. As the field has evolved, educational opportunities have expanded into new areas, such as certificate and undergraduate programs. More recently, biomedical informatics programs have begun exploring a new frontier for the field: educational outreach to high school students and high school teachers. Questions remain about these outreach efforts. At a foundational level, why is educational outreach to high school students important to biomedical informatics? At a more pragmatic level, what types of structures are necessary to support meaningful involvement of high school students in research? Panelists representing different models of high school outreach will give an overview of program design at their institutions. The panel will then collectively discuss what has gone well in their programs, along with the barriers or challenges they have encountered. The panel will have an interactive format to enable a robust discussion around both foundational and pragmatic questions about the role of educational outreach to the high school level in the future of biomedical informatics.

Introduction

Biomedical informatics is a rapidly evolving field, with growing needs for a wide range of interdisciplinary skillsets. The field is also rapidly expanding with the advent of Meaningful Use, Precision Medicine, and other major initiatives focused on applying computational approaches to health and healthcare. Biomedical informatics education originated with an emphasis on graduate and post-graduate education; as the field has grown, the need and opportunity for outreach to broader educational levels has also grown. Several biomedical informatics educational programs have explored the idea of developing undergraduate education programs, including formal degree programs, through approaches that include both didactic coursework and research experiences1,2. Looking to engage students even earlier in their educational trajectories, several programs have also explored outreach to the high school level, through a variety of different approaches. Little is documented in the literature about the scope of high school outreach efforts, the impact of high school outreach on students and researchers, and what components are needed for successful and meaningful outreach to the high school level.

Since its inception, the American Medical Informatics Association (AMIA) Annual Symposium has supported dissemination of research conducted by students at the graduate and undergraduate level through programs such as the Student Paper Competition. To support dissemination of research conducted by high school students working with biomedical informatics researchers, the AMIA High School Scholars Program (HSSP) was introduced at the 2014 AMIA Annual Symposium3. The AMIA HSSP, guided from its inception by Finnell, Sarkar, and Unertl, provides an opportunity for selected high school students to present their research and participate in a major scientific meeting. Over the past several years of working with the AMIA HSSP, we have received many questions about how to get started with outreach to the high school level, the benefits and challenges of working with high school students, and the role of high school outreach in the future of the field. Despite substantial support for the AMIA HSSP, we have also repeatedly encountered the perception that engaging students earlier in their education presents significant challenges to potential mentors and to biomedical informatics educational programs.

Aim of the panel discussion

The idea of engaging high school students in Biomedical Informatics has seen substantial support within AMIA and in biomedical informatics programs at several universities. Many questions remain, however, about how to get
started with outreach to the high school level, what types of elements are needed for a successful engagement with high school students, and effective approaches for researchers seeking to work with high school students. Our panel aims to answer these questions based on our extensive experiences with high school outreach and to have a discussion with the audience regarding perspectives of audience members on high school outreach.

As the AMIA HSSP enters its third year, the time is ripe to engage the AMIA community in a discussion about:

1. Why it is important to expand biomedical informatics outreach to the high school level,
2. Potential roles for biomedical informatics in advancing STEM-C (Science, Technology, Engineering, and Math, including Computing) education in the United States, and
3. How individual researchers and organizations can overcome barriers to working with high school students.

The interactive panel format will allow the panel and the audience to engage in a robust discussion around these key issues and concerns, and also potentially to contribute to future directions of the AMIA HSSP.

**Description of panelist contributions**

The panel brings together panelists representing different approaches to high school outreach and a moderator with extensive experience with the AMIA HSSP.

**David Boone** is an Assistant Professor in the Department of Biomedical Informatics (DBMI) at the University of Pittsburgh with research interests in long noncoding RNAs, breast cancer biology, and cancer transcriptomics, in addition to a keen interest in education and outreach. He is the Director of the Computer Science, Biology and Biomedical Informatics (CoSBBI) high school summer research program and the new Internship in Biomedical Research, Informatics, and Computer Science (iBRIC) for undergraduates. CoSBBI was founded in 2011 by Michael Becich, the chair of the DBMI at the University of Pittsburgh. The CoSBBI program brings a diverse group of high school students to Pittsburgh for 8-weeks of authentic and mentored research and career preparatory experiences. Students are matched with research mentors, who direct the scholars’ work on independent research projects aligned with the interests of the mentor. Additionally, students are exposed to workshops, seminars, journal clubs, and research roundtables that teach students research and career skills and expose them to various biomedical informatics topics. To perpetuate the pipeline, students that successfully complete CoSBBI are invited to apply for a paid summer research internship as part of the iBRIC program for the duration of their undergraduate education. The program continues to expand, with 10 CoSBBI scholars and 6 interns participating in the summer of 2015 and plans for 10 CoSBBI and 20 iBRIC students for the upcoming summer. CoSBBI is funded by the NIH, Doris Duke Charitable Foundation, University of Pittsburgh Cancer Institute, University of Pittsburgh Medical Center, and other charitable and foundation giving as part of the UPCI Academy, an outreach effort that spans multiple departments at the University. David is the executive director of the UPCI Academy. iBRIC is funded by the DBMI, NIH, PA-CURE, and other charitable giving.

**JT Finnell** is the director of the Clinical Informatics Fellowship at Regenstrief Institute and is a Research Scientist focused upon operational research with the emergency department. Dr. Finnell was Director of graduate program for Indiana University School of Informatics and computing. Dr. Finnell has extensive experience with curricular development, and has facilitated the involvement of high school students at the Institute. The high school outreach effort at Regenstrief is on an individual student scale. He currently co-directs the AMIA High School Scholars Program.

**Kim Unertl** from the Department of Biomedical Informatics (DBMI) at Vanderbilt University is a researcher focused on the interaction between clinical workflow and health information technology. In addition to her research program, Dr. Unertl works with her department’s high school outreach program and co-directs the AMIA High School Scholars Program. Vanderbilt DBMI currently partners with a local Nashville public high school, Martin Luther King Jr. Academic Magnet High School. This partnership involves recruiting 1-3 students from MLK High School for research internships lasting 8 weeks in the summer, funded through a R25 grant from the National Library of Medicine. Our partnership with the high school allows us to have a direct connection to the students, and we work with administrators and teachers in the intern selection process. Students at MLK High School have the opportunity to take an AP Computer Science course as part of their high school curriculum, which assists us with identifying potential interns. Dr. Unertl has mentored two high school students as summer research interns, both of whom have presented at an AMIA conference.
Neil Sarkar is director of the Center for Biomedical Informatics at Brown University with broad interests in biomedical informatics research and education. He is also the immediate past chair of the AMIA Education Committee, where he first identified the need for AMIA to develop a comprehensive pipeline for a biomedical informatics workforce, akin to how other STEM-C disciplines have approached similar challenges. His research focuses on the development of methodologies for linking biomedical data across heterogeneous sources, leveraging work in ontologies, information retrieval, and natural language processing, with particular application to the study of complex disease phenotypes (e.g., pre-term birth) as well as identification of putative new medical knowledge (e.g., medicinal plants). He is also a co-director of the AMIA High School Scholars Program. He has worked with high school students in the context of biological science, and is a leader for a Brown pre-college summer course aimed at teaching high school students fundamentals of biomedical informatics and data science. Dr. Sarkar will moderate the session, soliciting questions from the audience and guiding the panel discussion.

Discussion of anticipated audience

The intended audience for the panel includes a wide range of AMIA attendees, including researchers interested in educational and mentoring experiences, graduate students seeking mentoring opportunities, individuals involved in directing or managing biomedical informatics educational programs, individuals working with funding agencies and organizations focused on education, and, broadly speaking, any AMIA attendees interested in future directions for the field. The interactive format of the panel makes the panel of interest both to those already engaged in outreach to the high school level and those interested in getting started with outreach efforts. The panel will also welcome conversation around the foundational questions of whether this type and level of outreach is appropriate and important for the field. Based on conversations we have had over the last several years with individuals from across the United States and around the world, the type of cross-organizational information sharing about educational outreach the panel plans to engage in would be of great interest to AMIA symposium attendees and could provide necessary encouragement to expand high school outreach in Biomedical Informatics.

Expected discussion

Although a wide range of topics could be discussed during this panel, we anticipate topics falling into two main categories: foundational and pragmatic. Foundational topics involve fundamental questions around why educational outreach to high school students is important to the biomedical informatics and what kinds of roles biomedical informatics can play in high school educational experiences. These foundational topics could also include discussions around the role of AMIA in supporting or promoting high school outreach activities and about what kinds of funding mechanisms can support these activities. While foundational topics focus more on the why of educational outreach, the pragmatic topics that we anticipate being discussed focus on the what and the how. For example, we plan to discuss the many different approaches that educational programs in biomedical informatics have taken towards designing educational outreach opportunities for high school students, the positive and negative aspects of these different approaches, and the strategies that have worked well for integrating high school students into research opportunities. Over the last several years, we have learned that there are several challenges in engaging high school students in research, including difficulties related to communication styles and interaction expectations. We plan to discuss these challenges and how we have dealt with them as part of the panel discussion. Finally, we anticipate discussing how programs can get started with involving high school students in research experiences and identifying routes to provide meaningful experiences for high school students and their research mentors.

Statement of participation: All panelists have agreed to take part in this panel.

Patient Generated Data: the Missing Link in Patient-Centered Care?

Noémie Elhadad, PhD¹, Lena Mamykina, PhD¹, XinXin Zhu, MD, PhD², Eileen Koski, MPhil²

¹Columbia University, New York, NY; ²IBM Watson Research Center, Yorktown Heights, NY

Abstract

In this interactive panel, we aim to engage the audience in an in-depth discussion on the topic of patient-generated data, as captured through smart phones and wearable devices. As patient-generated data receive increased attention from the patient, clinical, and research communities alike, there are numerous synergies and avenues for informatics research. We expect a lively discussion around existing use cases and a diverse set of axes (technological, analytics, human-computer interaction, varied stakeholders).

Introduction

In recent years, patient-generated data have received increasing attention from both clinical and research communities. In the context of health and healthcare, they are commonly defined as data generated outside of the clinical settings that can have an impact on an individual’s health, improve outcomes, and facilitate patient-provider communication¹. From the individuals’ perspective, self-monitoring has long been established as an important component of self-management for many chronic conditions, including asthma, hypertension, and diabetes, among others²,³. Novel technologies provide an unprecedented opportunity to capture and monitor data related to health and wellness. Individuals around the world already use mobile and wearable devices to track their diets, physical activity, sleep, and stress levels. From the healthcare perspective, patient-generated data is often viewed as having a potential to improve treatment and long-term post-treatment survivorship⁴. Perhaps as a result, the Institute of Medicine (IOM) recommends that providers are required to collect standardized social and behavioral data within their Electronic Health Record (EHR)⁵. Finally, under the research agenda of precision medicine and advancing medical scientific knowledge, patient-generated data hold the promise to act as the missing piece in providing a full picture of a patient and capturing data that would not have been possible to acquire in traditional observational settings⁶.

However, together with this general enthusiasm, there remain multiple concerns about patient-generated data and their ability to impact healthcare and self-management or advance medical knowledge. From the perspective of an individual, previous studies raised concerns regarding individuals’ ability to interpret and understand these data and incorporate them into their actions and choices⁷,⁸⁹. From the healthcare perspective, the typical concerns about patient-generated data include those about quality, reliability, and completeness. Moreover, lack of common standards for collection of patient-generated data presents challenges for its integration within EHR, and can potentially lead to duplication of data, if it is collected via multiple channels⁵. Finally, there exist multiple barriers for integrating such data within existing clinical work practices, and temporal and effort-related constraints¹⁰. From the perspective of informatics research, many questions remain as to the availability of computational methods for analyzing patient-generated data.

In this panel, we will present several different perspectives (technological, analytics, human-computer interaction, and the different stakeholders including patients, providers, and biomedical researchers) on patient-generated data and discuss opportunities and challenges related to their wide adoption. The intended audience for this panel consists of informaticists who are either considering including patient-generated data in their ecosystem, building tools for collecting patient-generated data, or platforms to leverage and make sense of patient-generated data.

Aims and Expected Discussion

For this interactive panel, we aim to engage the audience in an in-depth discussion about emerging solutions and approaches to gathering patient generated data for various goals (disease management, monitoring and prevention of disease progression, advancing understanding of disease) and to feeding it back to various stakeholders (patients themselves, healthcare providers, and biomedical researchers). The goal of the panel is to identify common challenges and opportunities across informatics research and practice around patient-generated data. As such, we expect the discussion to evolve around the following axes.
From a technological standpoint, what are the challenges to building tools and solutions for gathering patient-generated data? In particular, many sensors are available to gather a wide range of variables from patients, but most sensors operate on proprietary platforms. Within and outside the informatics community, what are the initiatives to establish standards and models for different types of sensed data streams?

From an analytics standpoint, what is the state of the art for making sense of patient-generated data and turning streams of observations into actionable knowledge? There are several tasks involved towards this goal ranging from low-level tasks like linking often sparse, temporal signals to outcomes to high-level ones, like identifying meaningful sub-groups of patients with respect to outcomes. The characteristics of patient-generated data, including heterogeneous variables, temporality at different time resolution across variables, missing data, accuracy and usefulness of self-reported vs. sensed data (each with their own biases) raise a need for appropriate analytics techniques.

From a human-computer interaction, what are the mechanisms to engage patients and sustain tracking? As a counterpart to engagement, what are the mechanisms to feed actionable knowledge back to patients, for instance to help them learn from the collected data and use this new knowledge to improve individuals’ health?

From the points of the different stakeholders (patients, providers, scientists), what do they want out of patient-generated data and how do they envision it will help striving learning health systems? What are they worried about? As a trigger for discussion, we will explore some use cases on which the panel participants actively work: leveraging a mobile health application to phenotype diseases that are not well understood, such as endometriosis; leveraging smart tools to help diabetes patients learn from their own glucose monitoring streams and nutritional data and manage their conditions, as well as building tools to translate patient-generated data into better clinical insights and actions (identify silent ischemia using sensors, or continuous blood pressure monitors to avoid white coat effect). We will discuss potential pitfalls for each stakeholder. For instance, for providers, information overload needs to be addressed when adding these data to the already complex set of data points available to them. For researchers learning from these data, how to identify the biases of patient-generated data and account for them (whether noisy data from sensors or self-reported data with inherent uncertainty associated to them). For patients, factors such as health literacy, behaviors, and attitudes all impact whether and how they will collect and make sense of their own data and the data of their peers.

Finally, we will expect a discussion from the audience and the panel participants about ways to foster the informatics community interested in patient-generated data and what type of community activities might help propel forward research in this area.

Contributions of the Speakers

Noémie Elhadad, Ph.D. together with her research group develops techniques that aim to support clinicians, patients, and health researchers in their information workflow by automatically extracting and making accessible information from unstructured, large clinical datasets (e.g., the electronic patient record) and patient platforms (e.g., online health communities). She designs novel computational approaches that infer models of health phenomena and translate the learned models into actionable knowledge and robust systems within the healthcare ecosystem. She will discuss the role of data science for making sense of patient-generated data as well as their use for advancing precision medicine and scientific medical knowledge.

Lena Mamykina, Ph.D. has over 10 years of experience with novel technologies for self-monitoring and self-management of chronic diseases. She is a PI on a NIDDK-funded project to design and evaluate a mobile application for facilitating problem-solving in diabetes self-management, that specifically targets individuals from underserved communities and ethnic and linguistic minorities. Dr. Mamykina will discuss opportunities to use patient-generated data to inform and guide individuals’ health self-management.

XinXin Zhu, M.D., Ph.D. is a physician and healthcare informatics professional with more than a decade of experience in wellness management, health informatics research, advisory and consulting, as well as an established track record of developing creative solutions to complex business challenges. Her current research focuses on human-centric health promotion, behavior modification, and patient-provider engagement through telehealth. Dr. Zhu will discuss opportunities for leveraging patient-generated data from the providers’ perspective.

Eileen Koski, M.Phil. is a Program Director for Health Data & Insights at IBM Thomas. J. Watson Research Center. Prior to joining IBM she was with Columbia University (1978-1995), Quest Diagnostics (1995-2009), Medco/Express Scripts (2009-2013) and Northwell Health (2013-2015). Ms. Koski has worked in medical
informatics throughout her career and has been responsible for a broad array of data-related initiatives spanning academic and commercial settings, including population health analytics; data mining; health data visualization and graphical laboratory report design; biosurveillance and pandemic preparedness; clinical trials; enterprise data governance programs; and representing the interests of both the laboratory industry and academic medical centers in numerous government initiatives, task forces, committees and panels as a recognized subject matter expert. Ms. Koski is currently Chair-Elect of the AMIA Knowledge Discovery and Data Mining Working Group. Ms. Koski will be the moderator for this panel.

**Statement from Panel Participants**

All participants have agreed to take part on the panel.

Women in Informatics Leadership Forum

Rebecca Jacobson, MD, MS 1, Suzanne Bakken, RN, PhD 2, Wendy Chapman, PhD 3, Valerie Florance, PhD 4, and Jessica D. Tenenbaum, PhD 5

1 University of Pittsburgh, Pittsburgh, PA; 2 Columbia University, New York, NY; 3 University of Utah, Salt Lake City, UT, 4 National Library of Medicine, Bethesda, MD; 5 Duke University, Durham, NC.

Abstract Biomedical Informatics is a diverse field encompassing many different areas of study and providing many different potential career paths. Our field has benefited greatly by the intersection of different disciplines which enhance the diversity of Biomedical Informatics as well as the demographics of its contributors. While women have always represented a significant fraction of the discipline, there have been far fewer women in leadership positions in biomedical informatics, particularly in traditional academic roles and professional organizations. Anecdotally, we observe that there are an increasing number of women entering training programs and early academic positions in biomedical informatics. What can we do now to increase the potential for a larger cohort of women leaders in Biomedical Informatics within the next decade? This AMIA Panel will consist of two parts intended to form a single cohesive experience for participants, although participants may choose to participate in either one or both of the related events.

Panel Discussion. The panel discussion will provide brief five to ten minute introductions to the discussion topics by each of the five speakers, followed by discussion of other participants, and then discussion by audience members. Specific topics will include (1) the spectrum of career trajectories and leadership opportunities within them (2) challenges and opportunities for women leaders, (3) mentoring and networking as important success factors and (4) leading within a female dominated field (e.g., nursing informatics) - what’s the same, what’s different, and what can we learn?

Career Guidance Workshop. On the evening following this Interactive Panel, we will hold a 2 hour workshop targeted towards early-career and mid-career women in informatics. The two hour block will be divided into four one-to-one career guidance consultation sessions. Each session will last 30 minutes, and participants may request or be asked to participate in multiple sessions during the workshop. Consultants will be senior and mid-career women with widely ranging titles, roles and interests recruited in advance of the conference. Approximately one month before the meeting, participants wishing to have a career guidance session will submit their Curriculum Vitae or Resume to us along with a ranked list of consultant choices. All participants will be notified of matches in advance of the conference.

Aim of Discussion. The panel discussion and audience interaction components will focus on increasing awareness about potential leadership roles for women. We will discuss challenges for attaining such roles along with practical guidance for overcoming these challenges. An important aspect of the discussion will center on what women in biomedical informatics can do along with professional organizations such as AMIA to increase the ability of women to successfully advance their careers along their chosen trajectories. The topic is of importance to all biomedical informaticists (both male and female) as we endeavor to further expand the pool of future leaders within AMIA and also within biomedical informatics in general.

Intended Audience: The intended audience for the panel discussion includes all biomedical informaticists (both male and female) who interested in enhancing leadership positions for women within our field. Attendees may be primarily interested in better understanding pathways to leadership with their own organizations, or within professional organizations such as AMIA. They may also be interested in identifying resources and strategies for enhancing recruitment and advancement of women into leadership positions in Biomedical Informatics.

Contributions of Each Speaker

Suzanne Bakken, PhD, RN, FAAN, FACMI, is the Alumni Professor of Nursing and Professor of Biomedical Informatics at Columbia University where she directs the Center for Evidence-based Practice in the Underserved
and the Reducing Health Disparities Through Informatics Pre- and Post-doctoral Training Program and is on the Executive Committee of the Irving Institute for Clinical and Translational Research. She currently serves as President of the American College of Medical Informatics and Associate Editor of the Journal of the American Medical Informatics Association. Dr. Bakken will compare and contrast her lessons from leadership positions in nursing and from interdisciplinary initiatives.

Wendy Chapman, PhD, FACMI, is the chair of the Department of Biomedical Informatics at the University of Utah. She discovered biomedical informatics serendipitously on a journey from Elementary Education to Linguistics to Chinese Literature and fell in love with the field. Since receiving her PhD in 2010, Dr. Chapman was a faculty member at the University of Pittsburgh then UC, San Diego. She is the chair of the AMIA Student Paper Awards Committee, and is an elected member of the AMIA Board of Directors. Dr. Chapman will discuss leadership of academic informatics units

Valerie Florance, PhD, FACMI is an Associate Director of the National Library of Medicine, NIH. There, she directs NLM’s extramural grants program. She also serves as program director for NLM’s highly-regarded university-based training programs in biomedical informatics. Dr. Florance is a member of the Executive Committee for the NIH Big Data to Knowledge (BD2K) initiative. Before coming to NLM in February 2001, she spent 3 years leading a visioning project at the Association of American Medical Colleges (AAMC) to help the association’s members understand the power of computers and networks for managing health information. Before that, she held faculty and administrative positions at three U.S. academic medical centers. She has graduate degrees in medical anthropology and biomedical information sciences, and was elected to the American College of Medical Informatics in 2005. Dr. Florance will focus mainly on informatics leadership options in non-academic settings.

Rebecca Crowley Jacobson, MD, MS, FACMI is Professor of Biomedical Informatics at the University of Pittsburgh. She is the Director of the NLM-funded Pittsburgh Biomedical Informatics Graduate Training Program, and Chief Information Officer for the University of Pittsburgh Institute for Personalized Medicine. She is also the incoming Chair of the Biodata Management and Analysis (BDMA) NIH Study Section. Dr. Jacobson will introduce the panel discussion. She will also discuss the critical role of networking and mentoring.

Jessica Tenenbaum, PhD is an Assistant Professor in Duke's Department of Biostatistics and Bioinformatics, Division of Translational Informatics. She plays a leadership role in the American Medical Informatics Association, serving as Chair of the Genomics and Translational Bioinformatics Working Group and as an elected member of the Board of Directors. She is an Associate Editor for the Journal of Biomedical Informatics and serves on the advisory panel for Nature Publishing Group's Scientific Data initiative. After earning her bachelor's degree in biology from Harvard, Dr. Tenenbaum worked as a program manager at Microsoft Corporation in Redmond, WA for six years before pursuing a PhD in biomedical informatics at Stanford University. She was the Associate Director for Bioinformatics for the Duke Translational Medicine Institute for 7 years before taking on a faculty role at Duke in 2015. Dr Tenenbaum will address the importance of, and best practices for, networking and what she views as the most valuable takeaways from Sheryl Sandberg’s well known book Lean In.
Global e-Health: The Latin American Perspectives

Heimar F. Marin, PhD, FACMI1, David Novillo, PhD2, Alexandre Barbosa, PhD3, Fernan Gonzales B. De Quirós, PhD, FACMI4

1Universidade Federal de São Paulo, São Paulo, Brazil; 2Pan American Health Organization, Washington DC, USA; 3Regional Center for Studies on the Development of the Information Society – Cetic.br, São Paulo, Brazil; 4Hospital Italiano de Buenos Aires, Argentina.

Abstract

Health systems around the world face considerable challenges in providing health care services. Governments of the Latin America region have also realized the importance of e-Health and the need to create adequate policies and national strategies that could facilitate international and regional cooperation in this area. This panel will discuss the vast possibilities of ICT in health care focusing on research and initiatives developed by countries in Latin America to influence policy makers for fostering ICT use in health care to improve health conditions for the population.

Introduction

Advances in science and technology in global healthcare demand innovative solutions to address complex problems that are common across countries such as the aging of the population, chronic diseases, high costs of care delivery, economic constraints to assure continuity, quality, and cost benefits of treatments, including care for emerging and re-emerging diseases. To face this scenario, countries are seeking to improve their health systems, enhancing the efficiency and operative capacity of the national health programs, decreasing mortality and morbidity and improving the quality of life through informatics based systems. Governments of the Latin America region have also realized the importance of e-Health and the need to create adequate policies and national strategies that could facilitate international and regional cooperation in this area. Thus, considering the challenges that Latin America and Caribbean countries are facing, information and communication technology (ICT) is a key instrument that potentially can support effective, equitable and efficient way to improve access to healthcare services. ICT can increase the availability of healthcare resources by optimizing processes, shortening distances, reducing patient transportation, providing timely care and cutting costs for families and the health system.

Health care systems models are affected by several factors, including aging of population and the consequent change in the way that health services are requested, changing on epidemiological profile of populations (decrease of infectious diseases with higher prevalence on non-communicable diseases, resurgence of infectious diseases of the old agenda such as tuberculosis, dengue, cholera, and the emergence of new infectious diseases such as AIDS, Ebola and hantaviruses), significant alteration on the way knowledge is diffused that generate important modifications in the willingness of people related to consume health services. It can also mention the health professional’s models of working by division and tasks that deconstruct the necessary inter and trans-disciplinarily in health and turns the patient into a victim of multiple professionals. The technological revolution (not ICT) that offers new alternatives without necessarily abandoning the previous one, causing extra costs1.

Among all factors, aging of population can be highlighted as an example of how each of these factors affect the whole healthcare system. Due to the progressive aging, people’s greatest expenditure on health occurs during the final decade of their lives. For this reason, health systems allocate a significant part of their resources to the provision of curative and palliative services2. Within this scenario, countries in Latin America and the Caribbean are expected to increase their expenditure on health between 3% and 9% of GDP by 2040. In 2014, IDB has warned that public healthcare spending in Latin America is not consistent with the current demand and as a consequence, governments would face financial burdens over the decade. The conclusion was obtained from analyses of healthcare benefit plans in seven countries – Argentina, Chile, Colombia, Honduras, Mexico, Peru and Uruguay3. On the other hand, spending more
does not guarantee quality and equity in healthcare access and better life conditions. Strategies for development of e-health, policies, and evaluation measures play a key role in promoting adoption of e-health technologies and cost-effective development and implementation. Efficient use of ICT in health care can be translated in terms of clinical, organizational ad financial benefits. In general, some are more tangible to measure. Most recent studies show that financial benefits are not immediate postponed after the initial deployment. Systems that were implemented during the last 40 years, now are able to demonstrate efficiency and maturity to consider their rapid generalization.

Considering those factors and the need to evaluate e-health scenarios in the region, this panel will discuss the vast possibilities of deployment, focusing on research and initiatives developed by countries in Latin America to influence policy makers for fostering ICT use increasing the sustainability of projects to advance management on the national health systems.

**Objectives**

These panels intend to discuss political and societal aspects of health information technology in the Latin America region. The presentations will briefly discuss experiences based on regional countries and PAHO/WHO recommendations but will explicitly draw generalizable conclusions intended to provide insights and information for those who attend the session. The goal is to equip attendees with ideas and recommendations for how to improve eHealth strategies in their own environments.

**Panel Description**

Dr Marin will introduce the theme addressing how the strategies for development of e-health, policies, and evaluation measures play a key role in promoting adoption of e-health technologies and cost-effective development and implementation. Efficient use of ICT in health care can be translated in terms of clinical, organizational ad financial benefits. In general, some are more tangible to measure. Examples will be provided by most recent studies that show financial benefits are not immediate postponed after the initial deployment and by systems that were implemented during the last years that now are able to demonstrate efficiency and maturity to consider their rapid generalization.

Dr Novillo will address the main actions taken by PAHO, among which are research, capacity building, creation of technical guidelines and building knowledge networks. A lack of political commitment is one of the main obstacles to implementing eHealth-based systems and services. Political commitment is key to realizing its full potential, through sustainable, appropriate, and integrated implementation of eHealth initiatives. In the region of the Americas, almost all the countries have plans to use ICTs in the health sector. This does not necessarily mean that all have developed national eHealth strategies or plans. PAHO has seen that political commitment and the adoption of measures on eHealth have increased steadily, encouraging resource mobilization to adopt and develop digital services that allow better access, expand coverage and increase financial efficiency of the health care systems.

Dr Barbosa will describe how since 2012 Cetic.br has worked with an OECD Expert Group responsible for developing a model of the survey questionnaire and a set of indicators to approach ICT adoption, availability and use in the health sector. Based on these efforts and on the experience accumulated in the development of first survey, Cetic.br has also participated in the ICT Work Group from the Statistical Conference of the Americas (SCA) of the Economic Commission for Latin America and the Caribbean (ECLAC) in the effort to establish a common module for measuring the adoption of ICT in the Latin American healthcare sector. This model was approved in 2014 and contains methodological directives and a model questionnaire for disseminating this methodology, which can help guarantee the future production of comparable indicators in the region. After Brazil, Uruguay was the second country in Latin America and the Caribbean to adopt the methodological framework created by OECD.

Dr Fernan Quiros will address the 20 year experience of developing and implementing a Health Information Systems in a complex scenario of a not for profit academic medical center such as Hospital Italiano de Buenos Aires. This experience has been extended to other institutions across Argentina, Uruguay and Chile. The lessons learned from this experience could be useful to others developing countries, since the challenges that the healthcare system at national level are very similar all throughout this countries that have not completely embraced the concept of the benefits that ICT can provide. He will also describe the common pitfalls that most institutions both public and private need to address in order to integrate both the clinical and administrative layers for a successful implementation. In other aspects, the involvement of patients as main actors of a HIS that would benefit their well-being and the relationship with the healthcare team, can also help to establish the base for a Learning Health System that can be extended to a local, national and regional level.

**Panel Structure and Participants**

265
The panelists will offer prepared remarks to introduce the theme and share their experiences across countries. Dr. Marin, as the moderator will introduce the topic and assure that time allocations are respected by all participants.

Panelists

Joining Dr. Marin are three panelists with experience and expertise in the area of e-health, policies and biomedical informatics:

Heimar de Fatima Marin, RN, MS, PhD, FACMI is Professor and Director of the Graduate Program in Management and Health Informatics, Universidade Federal de São Paulo. She is also Editor-in-Chief of the International Journal of Medical Informatics and the Scientific Coordinator of the ICT Health Survey in Brazil.

David Novillo, MLIS, PhD is the coordinator of the eHealth Program of the Pan American Health Organization, Regional Office of the World Health Organization for the Americas (PAHO / WHO) in Washington, D.C. He also leads the WHO eHealth portfolio in Latin America and the Caribbean (LAC), providing technical, managerial and policy advice in areas such as knowledge management, telemedicine, mHealth, electronic health records, standardization and interoperability of health information systems, digital literacy, and social media for public health.

Alexandre Barbosa, MS, PhD is the head of the Center for Studies in Information and Communications Technologies (CETIC.br), an Unesco Category II Center for the development of information society based in Sao Paulo, Brazil. Responsible for several nationwide ICT Survey projects in Brazil aimed at the production of ICT-related statistics and indicators.

Fernan Quiros, MD, FACMI is the Vice Director of Strategic Planning in the Hospital Italiano de Buenos Aires (HIBA) Argentina where he has developed research and educational programs in Medical Informatics, Disease Management, Internal Medicine and Physiology. He is the head of the Area of Research at the Internal Medicine Division. He has created a 4-year Medical Informatics Residency Program that started in 2001 at HIBA. More than 20 fellows have been trained in these programs under the supervision of the Department of Research and Education at HIBA. Dr. Quiros' research focuses on the development of electronic medical records and disease management programs.

Expected Attendees

Although the panel is intended for those who are involved with research, governance and policies in the use of e-health, the topic is of interest of the health informatics communities since we will discuss current aspects on organizations policies guidance that will impact locally on decision making process and policy makers.

A Forum on Qualitative Research in Biomedical Informatics: Controversies, Challenges, and Opportunities

Laurie L. Novak, PhD¹ (moderator); Rupa Valdez, PhD²; Tiffany Veinot, PhD³; Jan Talmon, PhD, FACMI⁴; Nancy M. Lorenzi, PhD, FACMI¹

¹Vanderbilt University, Nashville, TN; ²University of Virginia, Charlottesville, VA; ³University of Michigan, Ann Arbor, MI, ⁴HI-way, Sint Odilienberg, The Netherlands

Abstract

Qualitative research has a long history in biomedical informatics. It has often been used in investigations regarding the social influences on emerging technologies, the impact of technology on individuals and groups, and in improving design and implementation of informatics tools. However, researchers using qualitative approaches may face controversies and challenges in obtaining funding, interfacing with researchers using different methods, and in communicating their work. This panel will engage the audience in addressing critical issues facing qualitative researchers and discussing emerging opportunities that impact the direction of the field. Panelists will briefly discuss their experiences in the following areas: Dr. Lorenzi will discuss organizational qualitative research; Dr. Valdez will discuss home- and community-based qualitative research; Dr. Veinot will discuss funding strategies and Dr. Talmon will discuss issues and opportunities for publication of research findings. The subsequent interactive discussion with the audience will build on the panelist comments, creating a forum to explore a variety of challenges and opportunities.

Intended Audience

The intended audience for this panel includes all AMIA attendees who are interested in the state and direction of qualitative research within the informatics community, those who are consumers of qualitative research such as technology designers and implementers, and individuals who seek to collaborate with qualitative researchers.

Introduction of the Topic

Qualitative research in biomedical informatics has existed in tension with both the assumptions of technology designers [1] and the positivist foundations of biomedical science [2,3]. Elsewhere these tensions have recently manifested in a vigorous debate about the utility of qualitative research as assessed by the publication frequency of qualitative papers in a leading medical journal [4,5]. Qualitative researchers reckon with these issues in their everyday work as they describe the details and benefits of qualitative approaches to funding agencies, coach colleagues on using the methods, and develop new, innovative ways to improve efficiency and value of the methods. Meanwhile, the field of medical informatics is becoming heavily influenced by methodological trends in data science, an increasing focus on patient-centeredness and precision medicine, and the emergence of new resources for research ranging from genomic data to social media. Given this dynamic landscape, qualitative researchers have requested more time at AMIA to share experiences and discuss the place of qualitative approaches within our field. This panel will be a forum for making sense of controversies, identifying challenges and ways to address them, and sharing information about opportunities on the horizon.

Aim of the Discussion

To discuss controversies, challenges, and opportunities associated with qualitative research in biomedical informatics, and to produce insights for future directions based on the expert panel and audience input.

Panelist Contributions
Nancy M. Lorenzi, PhD, FACMI, will discuss qualitative research before, during, and after the implementation of information technology in health care settings. Understanding the people-process-organizational impacts of technology creates the potential to influence or change implementation strategies for greater success. Methods that build on prior informatics research in organizations [6] present opportunities for rapid assessment and “diagnosis” of organizational and technological issues. However, while these studies are critical to better understanding the impact of technology on organizations they can also be controversial [7]. The qualitative researchers are often employees in the organization they are studying and want to maintain good relationships with colleagues who may be participants in interviews, focus groups, and observations. A continued positive relationship with the vendor might be critical for future collaborative work. An in-house organizational researcher faces many challenges such as making time available to implement the research, coordinating the research study with the technology implementation, working with health system operational units while maintaining the rigor of research methods, and reporting both positive and negative findings to the organization and to the greater public.

Rupa Valdez, PhD, will discuss qualitative research to guide the design of consumer health informatics applications intended for use in home and community settings. Achieving patient-centered solutions requires deeply engaging all individuals involved in a patient’s self-management process, including healthcare professionals, informal caregivers, and care partners. Common challenges of this deep level of engagement through qualitative approaches include gaining access to the population, developing the trust and relationship necessary to allow for prolonged interaction during an iterative design process, and the time required by both the researcher and participant to participate in data collection and analysis. New technological developments including social media and automated text analysis present opportunities for mitigating these challenges. Research approaches drawn from fields such as global development, including community partners as co-PIs, also have the potential to promote new ways of engaging in community-based informatics research.

Tiffany Veinot, PhD, will discuss the challenges of obtaining funding for qualitative research in health informatics. Researchers working primarily from a qualitative paradigm may struggle to obtain needed funding to support their research. There are few funding opportunities that explicitly solicit research using qualitative methods, and review panels may struggle to see the value of proposals for projects with a large qualitative focus. This presentation will focus on strategies for conceptualizing and proposing qualitative research to funding agencies. Such strategies include careful selection of funding opportunities, the formation of multidisciplinary teams, clear delineation of the contribution of qualitative data collection/analysis in a larger project, methodological innovation, and design of research that moves beyond descriptive goals.

Jan Talmon, PhD, FACMI, will discuss publication of qualitative research in biomedical informatics. Much of the research published in leading biomedical informatics journals is still about algorithms and methods, which may or may not become part of routine clinical practice. Some of these journals are more interested in how these tools work in practice. There are, however, challenges in this approach. Although quantitative approaches may help to understand the extent of the impact of ICT in health care; such studies may have less explanatory power regarding why such tools do or don’t work nor on the unintended consequences. Qualitative studies are designed to shed light on those issues. The major challenge to get such research published is that it often reflects the local situation and results may not necessarily be of more general interest. For this reason, emphasizing broader theoretical implications is a critical aspect of communicating qualitative research results.

Expected Discussion

After the introductory presentations, the panel and audience will engage in a discussion of various topics, facilitated by the moderator. Topics relevant to this panel are:

- What are the major challenges to obtaining funding for qualitative research?
- How can research proposals be written to emphasize the value of qualitative and mixed methods research for a given problem?
- What are the major challenges to publishing qualitative research?
- How can researchers clearly present the transferability of their qualitative research findings to others?
- How can we clearly articulate the value of the qualitative research in mixed methods studies?
• How can qualitative methods integrate with data science methods?
• How can approaches to making qualitative analysis more “efficient” be integrated with more traditional approaches to qualitative analysis?
• How can qualitative field studies be “scaled up” for large implementation studies?
• What balance should be achieved between engaging deeply and in person with a local population and engaging broadly and virtually with a more geographically dispersed population?
• What are the implications of larger debates about publishing qualitative health sciences research for the biomedical informatics community?

Timeliness of the Topic

This panel is timely because rapid changes in the field of biomedical informatics have created new opportunities for funding and collaboration, and qualitative research is considered to be a key component of major programs such as the Precision Medicine Initiative. Widespread implementations of electronic health records in many organizations have also created awareness of the need for qualitative studies that incorporate organizational context into data gathering and analysis. Similarly, the proliferation of consumer facing health IT solutions that are often abandoned after initial use has created awareness of the need for studies that deeply engage patients and others involved in their care at home and in the community. Yet, despite these increased demands for qualitative research, barriers to funding, execution, and publication remain. The sharing of experiences stimulated by this panel will serve as a foundation for methodological advancements, collaboration, and advocacy for rigorous qualitative research within biomedical informatics.

All panel participants have agreed to take part in this panel.

Population Health Informatics: Connecting Consumers to Care

Harm J. Scherpbie, MD MS\textsuperscript{1}, Vincent A. Emanuele II, PhD\textsuperscript{2}, Jane Sarasohn-Kahn, MA(Econ.), MHSA\textsuperscript{3}, Mark Scrimshire\textsuperscript{4}

\textsuperscript{1}Jefferson College of Population Health, Philadelphia, PA; \textsuperscript{2}Wellcentive, Atlanta, GA; \textsuperscript{3}THINK-Health, Valley Forge, PA; \textsuperscript{4}Centers for Medicare & Medicaid Services, Baltimore, MD and Medyear, New York, NY

Abstract

This Interactive Panel Discussion explores the challenges to use Informatics tools and methods to connect patients and consumers to their care givers and make them active participants in their care. In this panel we bring together perspectives from providers, consumers, data science, and technology firms, to engage with the audience participants to discuss technology approaches for connecting consumers and patients to their care: How far we have come? What are the challenges ahead? What are the obstacles that we need to overcome? What will it take to bring the consumer role in health care to the same level as the consumer in retail, entertainment, and other industry sectors? And most importantly, what will that do to the quality and efficiency of our care?

Introduction

This Interactive Panel Discussion explores the challenges for using Informatics tools and methods to connect patients and consumers to their care givers, and make them active participants in their care. One of the pillars of the Meaningful Use program was “Patient and Family Engagement”, and this created a surge in Patient Portals, View/Download/Transmit capabilities, Secure Messaging options between patients and providers, and targets for providers to achieve patient participation in these initiatives. Patient and Family Engagement is also one of the major components of any Population Health initiative: most Population Health Management Systems include a module or method for Patient Engagement. The result of these patient engagement initiatives are mixed, and while many patients use portals, and communicate with their providers, the majority do not. There likely are multiple causes, or reasons, for the lagging adoption – technical, psychological, organizational, cultural, economic, and more. This panel discussion explores the challenges and obstacles for using information systems and tools for population health – from the perspective of a provider organization, the consumer, the technology firm, and the population health data scientist.

Panel Members and Perspectives

Harm Scherpbie MD MS (Moderator). From his perspective as prior CMIO for a large health system, Dr. Scherpbie focuses on the provider side of the customer / care relationship. EMR systems are now widespread in physician practices, hospitals, and health systems. The next pressure on providers is the transition from Fee for Service-based care to Fee for Value – the transition to Population Health. Harm will discuss how providers plan to use information systems to manage care and reimbursement under the new rules, and how they will use information systems to communicate with and care for patients and consumers.

Vincent Emanuele PhD. Dr. Emanuele is a data scientist at Wellcentive, a Population Health Management firm. He will explore what population health systems, from a data perspective, tell us about patients and consumers, and how we can use data and analytics to do a better job in identifying consumers and engaging patients. What do claims data and EMR-derived clinical data tell us about populations, and about the providers who care for them? How do socio-economic data help characterize segments of the population, and how does this affect the patient engagement strategies? Data scientist look at this from the highest level, and Vince will bring this perspective to the conversation.

Jane Sarasohn-Kahn, MA, MHSA. Mrs. Sarasohn-Kahn is a Health Economist and Advisor, a frequent blogger and social media participant, with a large number of followers, and from this platform she monitors trends in consumer approaches to health care. The spectrum of consumer engagement and participation goes from the highly connected and engaged, to the hard to reach, disengaged patients who may or may not need care. What determines where a consumer is on this spectrum? – and how can we move people toward engagement? Jane’s perspective includes behavioral, societal, cultural, but also technical and social-media related aspects of consumer behavior in healthcare.

Mark Scrimshire. Mr. Scrimshire comes from the perspective of the technology industry as CTO of Medyear, a start-up Population Health Record firm. As Entrepreneur-in-Residence at CMS, he is familiar with the policy aspects of technology in healthcare. Mr. Scrimshire will discuss how BlueButton+ and FHIR can move us from EMR-tethered
portals (current state) to patient-tethered portals and patient-controlled health records. Mark will discuss his perspective on the technology industry’s ability to deliver on this promise, and whether consumers will be ready to take up this new technology.

Most important for this panel discussion will be the role and participation of the audience. The panelists’ introductions will be short and to the point, and the focus of the discussion will be the questions and comments from the audience. These three factors make this panel discussion successful and timely:

- Everyone in health-care today can relate to this topic – whether you work for a provider organization, research institution, technology firm, or consumer-oriented organization. Everyone has an experience and an opinion on this topic, and we look forward to a forum where these topics come to the floor.

- The transition to population-based care, the rapid shift in technology, increasing interoperability in EMRs and the removals of data blocks put us in a time of rapid change. This is promising and threatening at the same time, and we need to consider the challenges and obstacles ahead.

- Panelists representing providers, consumers, technology firms and data scientists can share their perspectives and different points of view.

**Conclusion**

Consumers and patients will play a strong role in their care. Healthcare providers transition to population-based care models and value-based payment models. Both of these trends are reliant on data and information technology. This interactive panel discussion engages participants to discuss the future outlook, and the road ahead to connect consumers to their care.
Interactive panel:
How informatics are being applied in industry: challenge and opportunity

Xia Wang, PhD1, Jorge Caballero, MD2, Zhaohui Cai, MD, PhD3, Elizabeth S. Chapman, MS, CPHIMS4, Shahram Ebadollahi, PhD5, Matvey B. Palchuk, MD, MS6

1 AstraZeneca Pharmaceuticals, Gaithersburg, MD, USA; 2 Distal, Menlo Park, CA, USA; 3 Celegene, Summit, NJ, USA; 4 Department of Veterans Affairs (VA), Jackson, GA, USA; 5 IBM Watson Health, New York, NY, USA; 6 TriNetX, Inc., Cambridge, MA, USA

Abstract: Due to its multi-disciplinary nature, informatics is a field with applications in a variety of settings, among them the secondary use of health care data in industry represents exciting opportunities and challenging career paths for informaticians. These individuals are required to possess innovative thinking and mastery of the cutting-edge technologies, to work on complex, real-world problems in areas such as big data mining, novel treatment development, precision therapies, clinical decision support, mHealth applications and device data analytics, with the ultimate goal of each patient having access to the highest quality and personalized care options. On this panel, representatives from AMIA’s corporate members will share various use cases and discuss how the informatics innovations are being applied in industry to address challenges and make break-throughs. The panel will also share their own career path and how they arrived at their current positions, discuss the important characteristics they are looking for in career seekers and the challenging opportunities residing within the industry. Following individual presentation, the panelists will take questions from the audience on a range of topics related to how informatics is being applied and the role of informaticians in industry.

Learn objectives:

1. Understand the specific applications of informatics innovations in various health-related industries
2. Identify the unique challenges and suitable opportunities in industry to start a career or execute a career transition
3. Obtain the recommendations for developing skills and value-creating innovative thinking that are critical for practicing informatics in industry

Panel description:

The panel will focus on specific use cases of how informatics is being applied in diverse health-related industry settings. The panelists will present the unique challenges regarding secondary use of healthcare data in industry and how informatics innovations are being applied to make break-throughs. During the presentations, the panelists will also talk about their own career paths and how they landed in their current position. They will share their perspectives on exciting
opportunities in industry for informaticians and provide constructive recommendations for audience via interactive discussion.

**Introduction**: Xia Wang, PhD, will introduce the topic, panel and moderate the session.

**Presentations 1**: Creating a data ecosystem that makes health information easily accessible and meaningful for everyone. Jorge Caballero, MD, will discuss why individuals with informatics skills sets that are simultaneously broad and deep are poised for success in rapid-growth environments. He will also share how Distal relies on its team of clinicians, scientists, and engineers to enable data-driven care with a personal touch. To close, he will offer specific suggestions for those looking to apply their informatics training to overcoming the challenge of delivering sophisticated, personalized data analyses to a diverse audience on-demand, and at scale.

**Presentation 2**: Developing a Learning Healthcare System – what’s the role for informaticians in the biopharma industry? Zhaohui “John” Cai, MD, PhD, will discuss on a vision for pharma to leverage big healthcare data for patient benefit by working together with other sectors in the healthcare ecosystem – the biopharmaceutical company of tomorrow is one that is not only able to excel in product discovery, development, and commercialization, but one that is able to accelerate, optimize, and transform its core activities by embracing advancements in data and technology. He will share how the Celgene Medical Informatics team is helping the company to achieve that vision through a combination of partnership strategies, innovative approaches and analytics, as well as leadership and career development specific to informaticians.

**Presentation 3**: Boots on the ground – the battle on the front lines. Elizabeth S. Chapman, MS, CPHIMS, will discuss the interprofessional nature of informatics and the challenges and opportunities at the point of care. Despite the Department of Veterans Affairs’ (VA) long and storied history in the application of information technology in health care, usability, workflow integration, interoperability and mining the vast amount of data to yield actionable insights remains challenging. Ms. Chapman will discuss ongoing efforts in VA to define the informatics workforce and equip staff with the requisite knowledge and skills to implement and support information technology that improves healthcare quality, safety and efficiency.

**Presentation 4**: Watson Health: Enabling Computational Health in the Era of Big Data. Shahram Ebadollahi, PhD, MBA, will provide an overview of IBM Watson Health and then will focus on the innovations leading to establishing a new business unit focused on analytics and health informatics within a large corporation. He will share his views and experience in the role of informaticians, their importance and place in multi-disciplinary teams required for innovating in the area of analytics in healthcare applications.

**Presentation 5**: Accelerate clinical trials design and recruitment – from art to data-driven science. Matvey B. Palchuk, MD, MS will focus on secondary use of clinical data for research. He will describe how TriNetX is relying on applied informatics to enable queries across a globally-distributed federated database of heterogeneous clinical data. Dr. Palchuk will discuss challenges of working with various sources of data, mapping data to standard coding systems, assessing data quality, creating innovative analytics and aiding users in designing, executing and interpreting results of patient cohort identification queries. He will highlight the role of informatics professional in a startup company targeting innovative data-heavy solutions in healthcare and life science markets.
Panel organizer and participants

Xia Wang PhD, Principal Scientist and informatics lead, Global Medicines Development, AstraZeneca Pharmaceuticals, Gaithersburg, Maryland, USA

Jorge Caballero, MD, CEO of Distal, Menlo Park, CA, USA

Abstract

Personalized and precision medicine has been an interesting topic of discussion, with few examples of large-scale, replicable, population-wide programs - until now. In 2014 Aetna completed one of the first health-plan sponsored programs using genetic testing in a large population to enhance diagnosis and target treatment for persons at-risk for metabolic syndrome. The original pilot was based on sound science, however the shortcomings of current knowledge on the use of genetics for diagnosis and treatment are apparent. Not as obvious, however, are the proven benefits to population health. Based on published findings from the pilot and lessons learned, we are refining the original study and expanding to other conditions. Goals of this panel include: discuss the different genetic tests useful for metabolic syndrome and other chronic conditions, determine appropriate pre-screening procedures using big data and novel predictive analytics, understand the probabilistic nature of genetic variants and implications for precision medicine, acknowledge provider, payer, and patient skepticism of the promise of genetic testing, and identify other conditions currently appropriate for personalized medicine studies base on existing genetic knowledge and return on investment. This submission is sponsored by the AMIA Genomics and Translational Bioinformatics Workgroup.

Introduction - Why the Panel is Timely and Controversial

Metabolic syndrome is a serious and growing global health problem. Persons with metabolic syndrome are twice as likely to develop cardiovascular diseases, and five times more likely to develop diabetes mellitus. Thus, the ability to more easily identify persons at-risk for metabolic syndrome, and intervene with appropriate wellness options, is critical. The original pilot was a first-of-its-kind program using a novel predictive analytics approach to identify candidates appropriate for further testing, and genetic testing to intervene in a condition in a large-scale setting. The pilot resulted in significant advancements in identification of persons with metabolic syndrome and intervention to prevent further morbidity and reduce costs.

There are, however, shortcomings to the study, some of which can be addressed going forward, but others are inherent in this nascent field and may not be avoidable. To begin, there is a relatively low probability of the few (three) common genetic variants indicative of metabolic syndrome to actually result in obesity or metabolic syndrome. In addition, effectiveness in widespread population screening for certain chronic conditions has been questioned, as there are usually many genes involved in a disease state, each having a small effect. As a result, it is not always clear whether any particular genetic variant (whether SNP, copy number variant, or insertion/deletion) is harmful, and what specific action should be taken. Some suggest whole genome sequencing is more important to identify persons at-risk for chronic conditions, but that is still expensive – and it is unclear how persons will react or know how to evaluate risks or probability of a condition. Nevertheless, significant benefits were identified for persons who participated in the pilot program, in both improved wellness and reduced costs. Moreover, personalized and precision medicine cannot wait for the perfect program to be developed, you have to start somewhere, so any improvement in health quality, outcome, or cost is beneficial and will move the field forward. The plan is to expand the pilot to more persons and additional conditions. The question is how best to accomplish this task given the current state-of-art in data and genetic science.

Personalized and Precision Medicine Pilot

We designed and implemented a novel predictive model for metabolic syndrome risk to predict subsequent risk of metabolic syndrome at both population and individual levels.\textsuperscript{2} Once identified, persons with elevated risk were invited to participate in a targeted treatment program, which included a limited genetic profile, a traditional psychosocial assessment, and high-intensity coaching in a randomized controlled study. Results of the study included sustained patient engagement, weight loss, improved clinical outcomes, and reduced health care costs. We also learned important lessons in patient behavior and willingness to participate and engage in genetic testing and
programs designed to improve health and wellbeing. Reduced health care costs are critical for the return on investment necessary for personalized and precision medicine to make sense economically and result in widespread adoption. We anticipate similar results for the other chronic conditions under consideration.

**Intended Audience:** Providers, Healthcare Executives, Clinical Geneticists, Health Plan Executives, Data Scientists, Entrepreneurs, anyone considering implementation of a large-scale personalized or precision medicine project with a defined return on investment

**Contribution of Each Speaker**

Dr. Lewis Frey – Moderator, shall give an overall introduction, and mediate between panel participants

Dr. Ken Yale – Proponent, who represents the aspirational perspective of personalized medicine, and shall emphasize the potential for genetic testing to intervene in chronic conditions in large-scale, population health settings, significant advancements in identification of persons with metabolic syndrome, intervention to prevent further morbidity and reduce costs, and potential for other chronic condition diagnosis, early intervention, and treatment.

Dr. Danny Sands – Physician skeptic, who represents perspective of the physician community regarding how genetic information is presented to patients, concerns of patients about how best to use genetic data in their own care, and the lack of clarity about actions to take with the information.

Dr. Nephi Walton – Genetics expert and clinical informaticist, who represents the perspective of clinical genetics in practice, challenges faced by patients, and the need for greater education of patients, providers, and payers about the promise and limits of genetic tests. He shall discuss the promise of precision medicine in light of the limits of our current state of genetic testing and knowledge about common diseases. In addition he will address the inadequacies of our current health IT infrastructure to process and store genomic information and the work that needs to be done to remedy these problems.

**Conclusion** - Personalized and precision medicine hold great promise, but also peril. Early results of large-scale implementations in real-world population health environments are promising. But there is significant misunderstanding among providers and the public about the benefits and drawbacks of using genetics to diagnose and treat patients. Further education and discussion is needed to inform the appropriate use of precision medicine at scale.

Expanding access to high-quality plain-language patient education information through context-specific hyperlinks

Jessica S. Ancker, MPH, PhD,1 Elizabeth Mauer, MS,1 Diane Hauser, MPA,2 Neil Calman, MD2

2. Institute for Family Health and Department of Family Medicine and Community Health, Icahn School of Medicine at Mount Sinai, New York, NY

ABSTRACT
Medical records, which are increasingly directly accessible to patients, contain highly technical terms unfamiliar to many patients. A federally qualified health center (FQHC) sought to help patients interpret their records by embedding context-specific hyperlinks to plain-language patient education materials in its portal. We assessed the impact of this innovation through a 3-year retrospective cohort study. A total of 12,877 (10% of all patients) had used the MPC links. Black patients, Latino patients comfortable using English, and patients covered by Medicaid were more likely to use the informational hyperlinks than other patients. The positive association with black race and Latino ethnicity remained statistically significant in multivariable models that controlled for insurance type. We conclude that many of the sociodemographic factors associated with the digital divide do not present barriers to accessing context-specific patient education information once in the portal. In fact, this type of highly convenient plain-language patient education may provide particular value to patients in traditionally disadvantaged groups.

BACKGROUND
Providing patients with access to their medical records became a national priority with the federal electronic health record incentive program (the “meaningful use” program) mandating various forms of electronic release of data to patients (1-3). To provide patients with records access, healthcare institutions typically offer patient portals, web-based products that give patients access to data from the electronic health record (EHR) (4-7). However, because medical records are created for medical professionals, they contain technical vocabulary that tends to be unfamiliar to patients, including medication names, diagnoses, and procedures. This vocabulary is particularly challenging for patients with low levels of health literacy (8-10), which has been defined as the ability to obtain, understand, and communicate about health-related information to make informed decisions (10). Low health literacy is associated with increased rates of hospitalization, lower use of preventive care, and among the elderly, worse overall health status and higher mortality (10-12). One-quarter to one-third of Americans are estimated to have limited health literacy, and it is more prevalent among racial and ethnic minorities, the elderly, and those living in poverty (12-14). As a result, many of the patients most in need of information about their health are among those least likely to be able to use it (15).

One potential solution is to provide plain-language explanations of difficult medical terms in context. A precedent is found in the infobutton, a clinician-facing innovation that provides context-specific information in the EHR, which has been shown to help clinicians answer clinical questions quickly at the point of care (16). To provide infobutton-like resources for patients, the National Library of Medicine recently collaborated with EHR vendor Epic Systems Inc. and the Institute for Family Health (IFH), a federally qualified health center. The 3 collaborating institutions developed a service hyperlinking vocabulary terms in the Epic portal with MedlinePlus, the National Library of Medicine’s free online patient education resource (www.nlm.nih.gov/medlineplus). MedlinePlus is an encyclopedia of plain-language explanations of medical diagnoses, medications, and other medical terms, designed to be at the 8th-grade reading level. The service, MedlinePlus Connect, automatically renders medical terms in the electronic patient portal as active hyperlinks. Notably, by hyperlinking unfamiliar terms directly to related information in MedlinePlus, this service helps patients access relevant information without the additional barrier of using a search engine, and without encountering the irrelevant or low quality results that might be produced by a self-directed online search. The service, first implemented at IFH, is now available as a web service and has been implemented in other electronic health record and electronic patient portal systems across the country (https://www.nlm.nih.gov/medlineplus/connect/service.html).

In this study, we sought to evaluate uptake of the innovation by tracking use of the vocabulary hyperlinks by patients over the first 3 years of the service. We hypothesized that use of these vocabulary hyperlinks would be lower among the disadvantaged patient groups affected by the “digital divide” (17).
METHODS

Setting: The Institute for Family Health is a federally qualified health center with 18 sites in Manhattan and the Bronx, as well as clinics in rural areas and smaller towns to the north of the city in the Hudson Valley. Almost all physicians are family practice physicians. An early adopter of EHRs, IFH has offered its patients an English-language electronic patient portal (MyChart) since 2007, with the Spanish-language version added in 2011.

When patients log into their portal account, they can see the conditions listed on their EHR problem list as well as the billing codes from each encounter. Some of these medical conditions are rendered directly as ICD terminology, and a subset are rendered as “patient-friendly” equivalents (e.g., “strep throat” instead of “streptococcal infection of the throat”).

With MedlinePlus Connect (MPC), all of these medical conditions and procedures are automatically rendered as active hyperlinks. Each hyperlink contains the ICD code associated with the medical term, and automatically links to the most relevant MedlinePlus information, which is also indexed by ICD code. Data collection for this study was conducted before IFH transitioned to ICD-10, so all codes were ICD-9.

Study design and data collection: For this retrospective cohort study, all adult patients with a visit to an IFH site between February 2011 and February 2014 were eligible. The primary outcomes were frequency of patient portal access and frequency of use of MPC. For the predictor variables, deidentified reports of patient data were generated from the Epic database and included age, gender, race, ethnicity, insurance status, preferred language, location, number of clinic visits, and encounter diagnoses (during the course of this study, these were ICD-9 codes). We applied the Johns Hopkins Adjusted Clinical Groups algorithm to the ICD-9 codes to classify patients by number of chronic conditions. We attributed each patient to the provider he or she saw the most frequently (his/her “preferred” provider). As an indicator of the provider’s IFH-specific workload, we produced a count of all patients seen by that provider. The project was approved by the IRBs of Weill Cornell and the Institute for Family Health.

Analysis: Patient characteristics were summarized with descriptive statistics, and assessed for association with (A) portal use and (B) MPC use in bivariate analyses using chi-squared tests or independent sample t-tests as appropriate. We constructed multivariable logistic regression models for MPC use among patient portal users only. Model 1 incorporated variables that were significant at .05 in the bivariate analyses (with the exception of number of chronic conditions, which was so strongly correlated with number of encounters that it raised collinearity concerns and was omitted). Region was not included as it was not a significant predictor in bivariate analyses. However, because of the marked differences in the demographic profile of the 3 regions, we also constructed exploratory...
multivariable models stratified by region. These models (not shown) revealed a significant interaction between age and region, with age having different effects on MPC use in different regions. We therefore constructed multivariable Model 2 containing all variables included in Model 1 plus region and a region × age interaction term. After confirming that the Akaike information criterion (AIC) for Model 2 was smaller than the AIC for Model 1 suggesting improved fit, we selected Model 2 as the final model for the current paper.

For exploratory purposes, we also computed a “popularity” index for each vocabulary term that was clicked by the patients. This “popularity” index was the number of patients who clicked the term divided by the number of patients in whose medical record the term appeared. To simplify the graph (figure 1), we reduced the number of vocabulary terms by running the ICDs through the AHRQ/HCUP Clinical Classifications grouper, which groups closely related ICD-9 codes into clinical conditions (e.g., diabetes, endometriosis, etc.).

RESULTS

There were 129,738 adult patients with one or more clinical visits in the study period; 30,692 (24%) had portal accounts. A total of 12,877 (42% of portal users, or 10% of all patients) explored one or more MedlinePlus Connect links. Patients who used the vocabulary hyperlinks clicked a median of 2.0 times (maximum: 97) and a median of 2.0 different terms (maximum, 24).

Sociodemographic predictors of use of MedlinePlus Connect (bivariate)

As demonstrated in Table 1, use of the informational hyperlinks was associated with socioeconomic characteristics but not in the hypothesized direction. (Throughout Table 1, it is important to note that because of the large sample size, very small differences were sometimes statistically significant even if they are unlikely to be clinically significant.) Black patients were more likely to use MPC than white ones (43% compared to 40%), and Latino patients more likely to use the resource than non-Latinos (43% compared to 41%). When Latinos were further subdivided by their preferred language, it became clear that it was the English-preferring Latinos who were driving the use of this resource. Finally, patients covered by Medicaid were more likely to use MPC than privately insured ones (44% versus 43%).

Clinical predictors of use of MedlinePlus Connect (bivariate)

Use of MPC was associated with clinical characteristics in the expected direction. Women, patients with more encounters, and patients with more chronic conditions were more likely to use the resource. MedlinePlus Connect users were very slightly older than nonusers, due primarily to greater representation in the middle-aged (45-64 years) age bracket.

Health system predictors of use of MedlinePlus Connect (bivariate)

Patients of the least busy and most busy providers were least likely to use MPC. There were no differences by region.

Multivariable model of MedlinePlus Connect use

The final multivariable model included: age, gender, race, ethnicity with preferred language, insurance type, number of encounters, workload of preferred provider, region, and the region x age interaction term (Table 2). In this model, use of the informational hyperlinks remained positively associated associated with older age, female sex, black race,
English-preference Latinos, having private insurance, more clinical encounters, and provider workload (with MPC use being more common forms patients of less busy providers).

Interestingly, when we controlled for race and ethnicity in this multivariable model, patients with Medicaid were less likely to use the MPC resource. The positive relationship in the bivariate analysis was therefore due to the black and Latino patients who were using the resource. The multivariable results suggest that within each racial and ethnic category, patients with Medicaid (the lower income patients) were somewhat less likely to use the MPC resource.

As noted in the methods, we included the interaction term between region and age because we saw different age-related patterns in preliminary bivariate models that were stratified by region (not shown). These models showed that older patients were more likely than younger patients to use MPC in Manhattan but not in other regions. To confirm this finding in the multivariate models, we included an interaction term between region and age, and confirmed that it was statistically significant in the expected direction. In other words, as Manhattanites became older, they were more likely to use MPC, but this pattern was much weaker in the Bronx and not found at all in the Hudson Valley. We attribute this finding to the different demographic patterns in these regions. In Manhattan, the older population contains quite a number of people who are well-educated and have relatively high socioeconomic status, so they might be more likely to do research on their health conditions. By contrast, the Bronx and the small towns where IFH has a presence in the Hudson Valley are much less affluent, and elderly patients in those areas are likely to be less well-educated and less affluent members of minority groups.

**Frequently explored terms**

Diagnosis “popularity” (or proportion of times a diagnosis term was clicked) was fairly constant at an average of 14.5% regardless of how common the diagnosis was (Figure 2). “Popularity” appeared high for some of the rare conditions, but this was in fact an artifact of the rarity of the condition. For example, *multiple myeloma* had a very high popularity rating of 56%, but this was because only 9 patients had the condition and 5 of them clicked upon it.

![Figure 2: Each dot represents a diagnosis. Data labels are placed on a small number of “popular” terms for illustrative purposes.](image-url)
As Figure 2 shows, there was no obvious explanation for term “popularity.” To further explore “popularity,” we retrieved the 10 terms that were clicked by the largest numbers of patients (Table 3). No single unifying principle is immediately apparent to explain why these terms were frequently clicked. It is possible that in some cases, it is because the terms were unfamiliar and technical (“hyperlipidemia,” “unspecified essential hypertension”), prompting patients to seek a definition. It is also possible that people were more likely to click on stigmatized or contested diagnoses (e.g., “obesity,” “depression,” “anxiety”). In other cases, perhaps patients clicked when they were motivated to take action and do more research (“nicotine dependence,” which is likely to appear in the record of the patient already being treated for smoking cessation). A better understanding of why patients seek more information about certain conditions and not others would be a fruitful avenue for future quantitative and qualitative work.

DISCUSSION

Although providing patients with access to their medical records could help them better understand their health and healthcare, patients who do not understand the medical language found in these medical records are unlikely to benefit. Our study shows that a plain-language encyclopedia of medical terms, hyperlinked directly to the unfamiliar term, is frequently explored by patients with access to their medical records via an electronic patient portal. About 10% of all patients in this safety net population used the informational hyperlinks. The hyperlinks were appropriately used most by those with the greatest needs for medical information, i.e., those with more medical conditions and visits.

The sociodemographic analysis held some surprises. We and others have expressed concern that because of disparities in computer access as well as disparities in health literacy, any beneficial effects of patient portals are likely to be unequally distributed (19). However, counter to the main hypothesis of the current study, we found positive associations between MPC use, black race, being an English-speaking Latino patient, and being covered by Medicaid. The positive associations with black race and Latino ethnicity remained statistically significant in multivariable models that controlled for insurance type. However, in the multivariable model, Medicaid coverage developed a negative relationship with MedlinePlus Connect use. This can be interpreted to mean that Blacks and English-speaking Latinos within each insurance category are more likely to use the informational hyperlinks, although Medicaid (low income) patients are in general less likely to do so.

Latino patients who indicated that they prefer using Spanish in their clinical encounters were markedly less likely to use the resource. This was despite the availability of a Spanish-language portal and Spanish-language informational resources.

Overall, this study suggests that some of the factors associated with the digital divide which created barriers to accessing the electronic portal were not barriers to using the MedlinePlus Connect informational hyperlinks. However, the language barrier remains indicating the need for additional outreach and services to ensure Spanish-speaking patients have high-quality information about their health.

There are a number of potential explanations for why patients might click terms. One explanation is that patients with low health literacy (9, 11) would be less likely to understand a particular medical term and might be
more likely to click to find out more. Unfortunately, because we were using EHR data, we had no assessments of patient health literacy, so we cannot conclude definitively that patients with low health literacy were the ones who were clicking on the hyperlinks. However, the prevalence of low health literacy is known to be higher among minority and low income patients (9, 11), and our findings demonstrate that these groups were particularly likely to use the MPC links. If low health literacy is the explanation, this would suggest that the MedlinePlus Connect links are providing particular value to patients who have less familiarity with medical vocabulary. This could provide an explanation for certain of the most “popular” terms in Figure 2, such as aneurysm and endometriosis, multisyllabic words likely to be unfamiliar to lay audiences.

Other reasons why a patient might click a term could include being highly concerned about a diagnosis, needing more explanation than what the provider discussed, or feeling uncomfortable having an extended conversation with the provider. For example, it is possible that patients with sensitive, stigmatized, or contested diagnoses (20-22) might be interested in finding out more in private after the encounter, when visiting the patient portal. These could explain the high click rates for potentially sensitive terms such as obesity and psychosocial circumstances in Table 3, and for highly concerning diagnoses such as sickle cell in Figure 2.

**Limitations**

This was a study at a single center providing safety net care, and all patients used a single commercially available patient portal product, so generalizability to other products and populations is unknown. Analyses were limited to data available in log files or the EHR, and therefore no direct measurements of health literacy, access to computers, or patient perceptions were available. This study did not include any measurement of healthcare outcomes, so it is not known whether access to this information actually helped patients manage their own health or their healthcare.

**Conclusions**

Context-specific hyperlinks that provided plain-language explanations of medical vocabulary were heavily used by electronic patient portal account holders at a federally qualified health center, especially those with multiple office visits and clinical conditions. Socioeconomic factors that presented barriers to access to the portal (such as race and poverty) did not pose barriers to use of the vocabulary hyperlinks within the portal. In fact, hyperlink users were more likely to be black or English-speaking Latino than were non-hyperlink users. We conclude that context-specific medical vocabulary hyperlinks are valuable to patients with the greatest information needs because of greater use of healthcare services, and that they are of particular use to patients in disadvantaged populations.

Abstract

To determine how the Rapid Assessment Process (RAP) can be adapted to evaluate the readiness of primary care clinics for acceptance and use of computerized clinical decision support (CDS) related to clinical management of working patients, we used a unique blend of ethnographic methods for gathering data. First, knowledge resources, which were prototypes of CDS content areas (diabetes, lower back pain, and asthma) containing evidence-based information, decision logic, scenarios and examples of use, were developed by subject matter experts. A team of RAP researchers then visited five clinic settings to identify barriers and facilitators to implementing CDS about the health of workers in general and the knowledge resources specifically. Methods included observations, semi-structured qualitative interviews and graphic elicitation interviews about the knowledge resources. We used both template and grounded hermeneutic approaches to data analysis. Preliminary results indicate that the methods succeeded in generating specific actionable recommendations for CDS design.

Introduction

The majority of adults in the U.S. work, and on average they spend more than half their waking hours at work.¹ Therefore, primary care providers treating adults encounter many situations where the patient’s work environment affects their health and/or the management of their health conditions. And although primary care providers most often are the first to see patients with medical issues such as asthma symptoms that may be caused by workplace exposures, they do not routinely ask patients about their work.²⁻⁶ Occupational health physicians have developed evidence-based guidelines for helping to manage many such patients, but primary care providers are rarely aware of their existence.⁷ Though computerized clinical decision support (CDS) holds potential for increasing awareness and providing guidance in the care of working patients, it must be developed and implemented to fit the context and workflow of those who would benefit from having the information.⁸

This qualitative evaluation project was part of a larger project funded by the National Institute for Occupational Safety and Health (NIOSH) of the Centers for Disease Control and Prevention. The NIOSH project is designing, developing, and pilot testing clinical decision support (CDS) for the health of working patients in primary care outpatient settings. The first step in this project was the development of three knowledge resources (KRs) containing evidence-based information, decision logic, scenarios and examples of use. The KRs were prepared by three subject matter expert (SME) groups for three topics that are related to the health of patients who work and that were considered especially pertinent to a primary care practice. The SME groups were guided through the guideline and KR development process by an informatician with expertise in these procedures (Dr. Richard N. Shiffman). The three KRs focused on dealing with work environment factors that impact the management of a chronic disease (diabetes), guidance for return-to-work (RTW) after lower back pain diagnosis not related to work, and diagnosis and management of work-related/work-exacerbated asthma. The goal of the qualitative study was to identify the barriers and facilitators related to CDS for the clinical management of working patients in a variety of primary care settings, including assessment of the technical and organizational feasibility of implementing the CDS represented by each KR. Having used the Rapid Assessment Process (RAP) in the past, the research team members considered it most appropriate for this study.
RAP is a way of gathering, analyzing, and interpreting ethnographic data that is both effective and efficient. The process is expedited through the consistent use of structured tools, which are developed for each individual study and consolidated into a field manual. RAP can only be conducted by teams that include those inside the organization as well as outside researchers. RAP also provides feedback to internal stakeholders. In summary, RAP “depends heavily on triangulation of data from different sources. A field manual is developed prior to the study and generally includes 1) site inventory profiles, 2) observation guides, 3) interview question guides, and 4) rapid survey instruments.” As with traditional ethnography, methodological approaches must be tailored specifically to the needs of the project.

The RAP methodology has mainly been applied to assessing clinical systems that have already been implemented and within which CDS is embedded, but for this project we aimed to adapt it for assessing both the clinical context and the KR prototypes prior to full development and implementation. Because we needed direct comments about each of the three KRs, we explored using graphic elicitation interviewing techniques in addition to our classical semi-structured interview methods. Graphic elicitation interviewing involves asking the subject to look at a graphical artifact to stimulate discussion, providing “contemplative verbal responses.” Umoquit et al. have compared the use of graphic elicitation, which involves use of a visual aid available to both the interviewer and interviewee, with participatory diagramming, in which the interviewee is tasked with developing a graphic. They found that graphic elicitation was best for focusing on exactly what the researchers were interested in and for producing thoughtful verbal comments on researcher-identified issues. Participatory diagramming produced fewer detailed comments about those issues but it encouraged creativity and new ideas. For our purposes, to gather verbal commentaries about specific aspects of the KRs, we selected graphic elicitation as our method of choice along with semi-structured interviewing.

For the study described here, our research question was: How can RAP be further adapted for assessment of the readiness of the organizational and technological context for CDS and, in addition, for evaluation of the CDS content?

Methods

Selection of methodological approaches

Because of the timeline for the larger project and the need to request human subjects approval from NIOSH, OHSU and five different organizations serving as sites, we only had five months within which to conduct site visits, analyze data, and report results. We fortunately had a large enough team of trained researchers so that some visits by sub-teams could take place at the same time. Our most difficult decisions concerned maximizing the use of our interviews so that we optimized the use of interview time, learned about context, and also received detailed input about the KRs. We opted to conduct two-part interviews using two different interviewing strategies.

For gathering input on the KRs, we wanted interviewees to evaluate a CDS concept with which they may not have been familiar, especially if they were non-clinicians. Further, we needed them to react in an abstract way because the CDS was not yet built. We decided we needed a variety of tools to help us describe the CDS ideas to our subjects. We designed two artifacts in addition to the extremely detailed documents developed by each of the three SME groups: a brief easily understood one-paragraph description of the CDS and a flowchart showing what the CDS would do. We planned to get general assessments of the usefulness of the CDS from non-clinical and non-technical interviewees using these less detailed descriptions. For others, we used different artifacts depending on the expertise of the interviewee.

We also decided that interviews alone would not be sufficient. To learn about the workflow within which the proposed CDS might best fit, we opted to conduct observations. This form of methodological triangulation serves to verify whether or not workflow described during interviews is accurate. Researchers shadowed clinic staff and clinicians and observed work activities throughout each clinic while writing detailed field notes. These observations also provided an opportunity to see how patient work information was recorded in the EHR.
Development of a Field Manual

Our multidisciplinary team of nine occupational health experts and informaticians from four different U.S. locations convened in Portland, OR for three days of training and planning. The training had RAP as its focus since some team members were familiar with ethnographic techniques but not with RAP in particular. Decisions were made together as we developed the field manual for this study. For our field manual, we put together a “site inventory profile,” which was a checklist of kinds of CDS and other related factors. We gathered some information prior to our visit to help us develop our interview questions and lists of foci for observations and we also gathered some site inventory profile information on site. We conducted phone discussions with a contact person at each site to learn more about the site and to mutually identify individuals to interview and observe. As is our practice, our field manual included a master interview guide with all of the questions we wanted to have answered. For each individual, we selected the most appropriate questions depending on his or her role. As with other field manuals we have prepared, the field manual also included a fieldwork observation guide for use in writing field notes. It briefly noted foci for fieldwork at that particular site. Finally, we included the three different artifacts for each of the three KRs, which would help us with the graphic elicitation interviews.

Human Subjects Protection

This study was approved by the Institutional Review Boards (IRBs) at NIOSH, OHSU, and two of our study sites. IRB review and/or official determinations (if a site did not have an IRB, it had other mechanisms for reviewing our protocol) were also obtained from the other three sites.

Site selection

We deliberately selected geographically-diverse sites and both large and small organizations so that we could observe whether these differences might influence the ability to customize, implement, and gain user satisfaction with the proposed CDS; and to get a sense of capability, and applicability of our findings across a variety of clinical settings. We also purposely selected sites that varied in organizational structure and had different electronic health record systems (EHRs).

We conducted this qualitative assessment across several clinics within two Federally Qualified Health Centers (FQHC) using the NextGen EHR, two organizations of very different sizes that use Epic, and one very large, complex organization that uses AllScripts. Sites were located in California, Mississippi, New York, Massachusetts, and Ohio.

Subject selection

With the assistance of an inside contact person at each site, we selected individuals representing different roles on health care teams, including physicians, nurses, pharmacists, medical assistants, social workers, care coordinators, educators, clerical and administrative staff, and information technology and CDS specialists.

Data collection

The interviews explored present CDS usage in general, work information in commercial EHRs, capability for implementing new CDS, information needs related to managing care of working patients, workflow, and assessment of the three KRs.

We developed tailored interview guides for individuals depending on their roles in the organization. During the first half of the interview, we asked general questions about CDS, information to help manage care of working patients (such as availability of the patient’s work information in the EHR), technical issues, and workflow (Table 1). A sample of some questions asked of information technology-related staff is given in Table 2. Figure 1 shows an example of one of the three flowcharts used in the second part of the interview as a graphic elicitation tool. For the second part of each interview, we asked specific questions about the KRs (see Table 3 for an example), assisted by the artifacts (text description, flowchart, or full KR) selected as most appropriate. Subjects representing all roles were first shown the paragraph summarizing each of the proposed CDS modules. Subsequently, depending on the role of the interviewee and his or her level of understanding and use of CDS, we used the graphic elicitation technique. We often showed the flowchart in addition to the paragraph and on rare occasions we showed the full KRs.
We also adjusted our questioning during the interview so that we could probe intriguing topics. Two interviewers attended each interview, with a few exceptions due to scheduling. We tried to include one occupational health specialist and one informatics specialist on each team so that each team had the expertise to probe either clinical or technical answers given by interviewees. One interviewer was the official interviewer and the other remained silent until appropriate times when he or she was allowed to ask questions during the first part of the interview. In this way, the process remains true to recommended semi-structured interview techniques (e.g. it does not become a conversation), but the assistant interviewers have an opportunity to ask follow-up questions in their particular areas of expertise. Another important task for the assistant interviewer was to write field notes during the interview. They noted nonverbal interactions and areas to further explore as well as what the person was saying. For the second part of the interview, when we used the graphic elicitation technique to discuss the flowcharts and/or KRs, both of the interviewers played a more active role since more of a dialogue and question and answer interchange was necessary. All interviews were recorded and transcribed.

During our observations, we observed all activities throughout the clinic, from patient registration through patients leaving the clinic, so that we could trace workflow in a general sense. We shadowed individual
providers and staff members while they were interacting with patients and also when they were performing other duties. We also conducted informal interviews with those we were observing when there were opportunities.

At the end of each day, the team met to debrief about findings for that day, to share insights from each researcher’s unique perspective, and to plan for the next day. When we had two teams in the field in different geographic locations, we met via teleconference.

Data analysis

Preliminary data analyses took place between interviews. Using notes taken by the assistant interviewer, the researchers briefly reviewed what had been learned so that new questions for upcoming interviews could be developed as needed based on prior interviews. After completion of the site visits, interview notes and transcripts were entered into NVivo, (QSR International, Doncaster, Victoria Australia), a program that facilitates the organization and retrieval of qualitative data for analysis.

We used both grounded hermeneutic and template approaches to data analysis. For in-depth analysis of all data, we used the former, which begins with the words of our interviewees. Our core research team broke into dyads and each dyad was assigned a set number of transcripts. Individuals read the assigned transcripts, noting all recurring or potentially important expressions and key phrases, and the dyads then met to compare and agree on their findings. The researchers next met so each dyad could discuss results with the larger team, which reached consensus on meaning and terminology for themes. One dyad also analyzed and categorized all comments related to the KRs using a template of predetermined terms related to the questions we asked.

The interpretive process was both iterative and flexible. Our team met repeatedly to interpret the results. We wrote a short report of the findings for each site we studied for two reasons: first, we thought the organizations would find them useful, and second, the report was a form of “member checking,” a qualitative technique to further establish trustworthiness of results by asking insiders for feedback.
Results

We conducted five site visits over an 8-week period between July 21st and September 11th, 2015. Team members included two occupational health physicians, three NIOSH staff members (a scientist, a nurse, and an informatician), four informatics faculty members (a social scientist, a nurse practitioner, a physician, and a laboratory specialist), and a project manager. We interviewed 41 clinicians not deeply involved in

Figure 1. Flowchart for use during graphic elicitation interview: diabetes example

---

290
informatics, 23 individuals who were informaticians or information technology specialists, 15 managers or staff members, and four quality improvement specialists, for a total of 83 interviews. We spent a total of 30 hours observing in ten clinics within these five organizations. We believe we reached data saturation in that we reached a point where we were hearing the same answers repeatedly and not learning anything new.

Lessons Learned About Methods

Timeline: This was planned as a one-year project, but half of that time was needed to secure the necessary IRB approvals. Although we were able to gather a great deal of information in eight weeks, and to analyze it to produce the needed reports within a three month period after that, this time frame was too short to allow for truly in depth analysis within the contract period. Analysis was still ongoing three months later. Another problem with the short timeline was that, even with nine researchers available to conduct site visits, some had to be done simultaneously and therefore the lead investigator (JA) was not able to attend all visits. In the past, we have found that having the lead investigator attend all visits provided consistency in data gathering (J. Ash, personal observation).

Two-part interview format: The two-part interview strategy worked well most of the time. By progressing from questions about CDS in general to specifics about the KRs, we were able to set the stage so that interviewees knew the context of our questions and were more likely to be comfortable talking with us. We ran out of time during a few of the interviews, which were normally scheduled for a half hour. These occurrences could have indicated that the interviewees were comfortable with talking, but was likely due primarily to trying to cover so much during each interview.

Graphic elicitation interviews: These yielded immensely useful information about the KRs. We always started the second part of the interview by handing the interviewee one paragraph about one KR at a time (or paragraphs about all three KRs if the interviewee preferred seeing them all at once). For the interviewees with more expertise in clinical and/or technical areas, the paragraph started a dialogue, the interviewee asked questions, and the flowchart would then be discussed. This situation made the second
part of the interviews, collecting information about the KRs, especially challenging because the
interviewers not only had to adapt each question to the skill level of the interviewee, but also bring out the
graphical representation of the CDS at the right time. Usually semi-structured ethnographic interviews
using RAP are not dialogues: the interviewee answers questions posed by the interviewer, who tries to do
more listening than talking. However, we found that our subjects could not answer our questions without
the ability to ask interviewers about details of the CDS flow. The graphic elicitation interviews were used
to provide more details simply and quickly, in order to help the interviewees answer our questions and
move back to more of an interview (vs. a dialogue). In this manner, we saved considerable time by only
needing to bring out the full KR documentation a few times when interviewees had very specific questions.

Assistant interviewer: The role of the assistant interviewer was more important in this project than others
we have conducted because the site visits followed one another in such rapid succession that transcripts
from prior visits were not available to help us prepare for the next visit. In fact, it was very important that
the interview notes were detailed enough so that, because of the tight timeline, we were able to write
preliminary reports for each SME group. The reports made recommendations about each KR based on
these field notes without having all of the transcripts completed. Subsequent examination of the transcripts
provided more nuanced information, but did not change the big picture of the information collected.

Subject selection: By observing and interviewing staff in all roles, including clerical staff, we were able to
assess all activities in the clinics and gain a broad picture of clinic workflows and the way patient work
information data are currently collected in the EHRs. Some of these interviewees were unable to provide
much feedback about the KRs, but they all were able to describe their daily work and the way they used the
EHR in detail.

Observations: The notes from the observations provided critical insights into the use of the EHR and CDS.
They allowed us to obtain more detailed information about the workflow, availability of multiple roles
within the clinic, and differences in how these roles are used across the clinics. They also allowed us to
modify or verify our interpretations of what was said in the interviews about workflow and roles. Staff
members often fail to describe their work activities accurately and completely, most likely because they
take many of them for granted and are trying to be succinct during interviews. Observations serve to fill in
the gaps and proved to be another valuable technique for triangulating data.

Lessons Learned About CDS for Clinical Management of Working Patients
Preliminary analysis of the interview and observation data resulted in themes that reflect facilitators or
barriers to development and implementation of the proposed CDS and are indicative of the depth of
knowledge we were able to obtain using RAP. Full results will be reported when analysis is complete, but
analysis of the transcripts and field notes up to this point indicates that there are many facilitators related to
development and acceptance of decision support tools as outlined in the KRs developed by the SME
groups. The most important and somewhat unexpected finding was that it is technically feasible to develop
any of the three proposed CDS tools. There are also a number of barriers to implementation and use. Not
surprisingly, interviewees most consistently noted that the proposed CDS might add to their time burdens.

Responses about the Three Knowledge Resources
From the graphic elicitation interviews we learned that in general the three proposed CDS modules
included some terminology, especially when offering recommendations, that needed explanation. For
example, the term “safety sensitive activity” was not immediately understood and could be changed to
“activity with potential safety risks.” We learned that informatics innovations that facilitate patients
entering data about their work may have potential to relieve some clinic time burdens, that culturally
sensitive patient education materials are needed, and that providers do not necessarily need to be the targets
of the CDS. We were able to gain feedback on each of the KRs that was very detailed, especially when the
interviewee had both clinical and informatics knowledge. As an example, one interviewee with an
informatics background suggested ways to use a service-oriented architecture approach for one of the KRs.
Although we gained useful feedback from medical assistants and other non-provider staff about workflow,
we found that they were less interested in either the flowcharts or KRs.
Discussion

We believe that use of the Rapid Assessment Process is effective for gaining a good deal of information in a short amount of time. For this project, because of circumstances beyond our control, we were forced to work even more rapidly than usual. As others have found when conducting RAP evaluations, flexibility and creativity are needed so that the mix of methods can best fit the situation. Workarounds such as the use of detailed assistant interviewer notes and splitting up the team to conduct simultaneous site visits helped us to stay on schedule, but they are not optimal. On the other hand, we succeeded in gathering a great deal of information about the facilitators and barriers to developing and implementing CDS for the health of working patients in primary care settings based on a combination of interviews and observations.

Enhancing RAP by using graphic elicitation interviews such as those described by Umoquit to assess CDS ideas allowed us to gather rich and specific feedback about the KRs. Like Crilly et al., we found that the artifacts we presented to interviewees served as a reference point and were more effective with many interviewees than simply asking a series of questions. Additionally, like Larkin et al., we found the artifacts most useful for interviewees with the interest and ability to interpret them quickly. The modifications to RAP used for this study might be adopted for other studies of CDS with different content and contexts, though we would recommend a longer timeline.

Recommendations and Conclusion

The use of RAP to evaluate the content and concept of CDS after it has been outlined in a form that is understandable to users but before it has been built can offer a useful description of the perceived value and context within which the CDS can work best. By adding graphic elicitation interviews to the RAP process, researchers can gather detailed feedback for CDS developers and implementers.

Acknowledgements

This project was supported by CDC/NIOSH Contract 200-2015-61837 as part of NORA project #927ZLDN. We would like to thank the following for service on the research team: Sherry Baron, MD, MPH, Genevieve Barkocy Luensman, PhD, Margaret Filios, RN, MSc, Nedra Garrett, MS, Richard N. Shiffman, MD, MCIS, and James McCormack, PhD. We appreciate the help of the following at our sites: Rose H. Goldman, MD, MPH, Laura Brightman, MD, Stacey Curry, MPH, Larry J. Knight, MSA, MSHRM, Deborah Lerner, MD, Herb K. Schultz, Michael Rabovsky, MD, Joseph Conigliaro, MD, MPH, and Nicole Moodie Donoghue. Finally, we would like to acknowledge and thank the clinics and the clinicians and staff at each site for their participation and support of this work.

Abstract

The diagnostic workup for many diseases can be extraordinarily nuanced, and as such reference material text often contains extensive information regarding when it is appropriate to have a patient undergo a given procedure. In this work we employ a three task pipeline for the extraction of statements indicating the conditions under which a procedure should be performed, given a suspected diagnosis. First, we identify each instance in the text where a procedure is being recommended. Next we examine the context around these recommendations to extract conditional statements that dictate the conditions under which the recommendation holds. Finally, corefering recommendations across the document are linked to produce a full recommendation summary. Results indicate that each underlying task can be performed with above baseline performance, and the output can be used to produce concise recommendation summaries.

Introduction

Understanding which diagnostic procedure should be performed on a patient when presented with a set of symptoms or a suspected diagnosis is a difficult task that is at the heart of the diagnostic process. Often, the details surrounding when a test is appropriate are extraordinarily nuanced, making this a potential area for clinician error. As errors in this regard can put unnecessary burden on the patient and lead to higher costs, there is a potential role for automated systems or curated resources to help guide this clinical decision making.

Reference material text, such as the disease workup pages found on the Medscape reference website (http://emedicine.medscape.com/), provide clinicians with an overview of the recommended diagnostic course for a disease. Although these resources can be invaluable for clinicians in training or for casual reference, a higher-level summary of which procedures are appropriate for the diagnosis of a given disease would be beneficial for quick reference or for machine interpretation. Unfortunately, diagnostic recommendation involves more than simply declaring that a given procedure is appropriate in all cases, leading many existing resources to either give extensive detail or summarize generally over broad disease categories.

In practice, diagnostic recommendation is about understanding not just \textit{if} a procedure is a necessary part of the diagnostic process, but \textit{when}. For instance, consider the following passage describing the use of echocardiography for the diagnosis of acute coronary syndrome:

Echocardiograms play an important role in the setting of ACS. Regional wall-motion abnormalities can be identified with this modality, and echocardiograms are especially helpful \textit{if the diagnosis is questionable}. An echocardiogram can also help in \textit{defining the extent of an infarction} and in assessing \textit{overall function of the left and right ventricles}.

This passage not only gives an indication that echocardiography is an important diagnostic modality, but it also outlines specific circumstances under which it is helpful \textit{(if the diagnosis is questionable, in defining the extent of an infarction, in assessing overall function of the left and right ventricles)}. In this work we explore the automatic extraction of these conditional recommendation statements from reference material text, towards the generation of diagnostic guideline summary tables. We model diagnostic guideline generation as a series of three tasks: 1) mention-level recommendation detection, 2) conditional relation extraction, and 3) across sentence entity linking. Our results show that we can perform each task with above baseline performance, and that their output can be combined to produce concise procedure recommendation summary charts.

Related Work

While automatic extraction of conditional diagnostic guidelines – to the best of our knowledge – is a new task, its subtasks are closely related to a set of well-defined natural language processing tasks that have been applied in clinical settings, including sentiment analysis, event extraction, coreference resolution/entity linking, and text summarization.

Sentiment analysis. The recommendation identification task that we examine in this work is similar to the sentiment analysis task. Sentiment analysis, also called opinion mining, aims to determine an author’s attitude towards a specific
topic or the overall contextual polarity of a document. There has been a lot of existing work on mining reviews or other expressions of opinion on the Web\textsuperscript{1}. Particularly, in the medical informatics domain, Wallace et al.\textsuperscript{2} has conducted a large-scale sentiment analysis of online physician reviews using a statistical model guided by a small amount of annotated data. The three-way recommendation classification problem proposed in this paper is an ensemble of two typical sentiment analysis tasks: polarity classification and subjectivity identification. The former is to determine whether the expressed opinion is positive or negative (recommended vs. not recommended), whereas the latter is to determine whether a mention contains subjective information at all (recommended/not recommended vs. unspecified) and which part of the text is subjective\textsuperscript{1}. Existing approaches to sentiment analysis include those based on opinion lexicons (e.g. ontologies, semantic networks), statistical models (e.g. support vector machines, latent semantic analysis), and combinations of the two\textsuperscript{1}. In this work we present a hybrid approach to recommendation identification, where a set of recommendation keywords (lexicon) is derived from development data and used in conjunction with other word, concept, and NLP-derived features for supervised classification.

**Event extraction.** Event extraction aims to extract information about entities and the role they play in an event. The second task in our pipeline, conditional relation extraction, can be viewed as an event extraction task, where we aim to determine whether there is a conditional relation between a (recommended) procedure and a certain constraint such as a patient’s condition. There has been a substantial amount of work on event extraction published in the past decade. A typical example is molecular event extraction from biomedical literature\textsuperscript{4}. Another example in the medical informatics domain is the recent work of Botsis et al.\textsuperscript{5} on vaccine adverse event extraction from vaccine safety reports. To extract events, we need to identify the trigger/anchor word that signifies an event, and to figure out the role of each theme argument involved in the event. The presence of a candidate trigger may not necessarily suggest a relation between entities, and the problem becomes challenging when multiple potential triggers appear in the same text unit\textsuperscript{4}. Most existing approaches to event extraction decompose the task to independent classifications of events and arguments. For instance, the winner of the BioNLP’09 shared task on event extraction\textsuperscript{6} first extracts a list of candidate triggers and then determines for each pair of triggers and entities whether one is a theme of the other (with around 50% F-score).

**Coreference resolution.** The entity grouping task we explore has parallels with several related but subtly different tasks, such as coreference resolution, entity linking, and normalization. Coreference resolution determines whether two concepts are linked by an equivalence relation. For example, in the following two sentences ‘Color Doppler valve analysis during transesophageal echocardiography (TEE) can be used to …’ and ‘In patients with poor transthoracic echocardiographic images, TEE may be used to …’, the two mentions of procedures are equivalent as they refer to the same entity. A number of systems have been developed for coreference resolution in clinical texts\textsuperscript{6,7}, including those based on handcrafted rules (e.g. keywords, regular expressions, spelling correction, abbreviation expansion), supervised learning (e.g. maximum entropy classifier, support vector machines, hidden Markov model), and a mix of the two, with best-reported F-score of around 70%.

Entity linking, the task of linking each mention found in the text to a structured database such as UMLS, is done as part of UMLS concept extraction and as such is a well-studied task within the medical informatics literature\textsuperscript{10,11}. Because linking mentions back to a database implicitly groups them by the database categories, entity linking is similar to both the coreference task and the entity grouping task examined here. However, unlike these tasks, entity linking is constrained by the structure of the database, potentially leading to grouping concepts at a level inappropriate for the given task\textsuperscript{12}.

**Text summarization.** The production of conditional diagnostic guidelines across a document is one form of a text summarization task. The majority of related work in the medical informatics domain focuses on extractive summarization of electronic health records\textsuperscript{13}, where summaries are created by borrowing phrases or sentences from the original input text. In clinical summarization, normalization of words to (groups of) concepts has only recently been investigated, primarily based on well-defined ontologies\textsuperscript{14}. Our recommendation extraction pipeline built on top of clinical concept extraction sheds interesting light on identifying and aggregating similar information at a more abstract level\textsuperscript{15,16}.

**Material and Methods**

We model the production of conditional diagnostic guidelines as a pipeline of three tasks. First, each mention of a diagnostic procedure in the text is labeled as either suggesting that the procedure should be performed, suggesting that it should not be performed, or giving no recommendation one way or another. Second, we link each those mentions labeled as positive or negative recommendations with conditional statements explaining the scope of this diagnostic
recommendation. Finally, we perform a coreference task to link mentions from different sentences, producing a set of document-level recommendation statements for a given diagnostic procedure.

Data. The Medscape website provides disease-centered documents containing explanations and guidelines for the presentation, diagnosis, and treatment of these diseases. To build our dataset, we extracted the text from a set of 33 Medscape diagnostic workup pages describing cardiac ailments. Annotation was then performed to identify procedure mentions in the text and to label whether the given mention is recommending that the procedure be performed. To ease the annotation process, mentions of procedures were initially detected by simple string matching against all concepts with procedure-related semantic types (e.g., “laboratory procedure”) from the Unified Medical Language System (UMLS). Although this process provided an initial set of mentions for annotations and annotators were asked to use this as a guideline for which procedures were considered, annotators had the option to correct cases where the initial mention identification was incorrect. As a second aspect of annotation, procedure mentions were linked with conditional statements that dictated when the procedure should be undertaken. Conditional statements were represented by the head of its syntactic phrase, usually a preposition. Finally, annotators grouped together all mentions in the document that referred to the same procedure. Annotators have linguistic but not medical background. Although annotators were not medical experts, practicing clinicians were on hand to clarify any uncertainty. The brat tool was used to produce the annotations.

Figure 1 shows an example of this annotation style. The annotations in the figure combine in different ways to produce a gold standard for our three tasks. For the recommendation task, each procedure (e.g., enhanced external counterpulsation) is given a recommendation label of either unknown (no positive or negative recommendation stated in the sentence), recommended, or not recommended. For the conditional task, each trigger-procedure pair in the sentence is a candidate conditional statement, with annotators linking together true conditionals (e.g., in-EECP). No explicit example of the entity linking task is given in Figure 1. However, since the linking task compares all procedures in the document, the two procedures in Figure 1 would be checked to see if they refer to the same procedure in the given context (in this case they do not).

Overall, a total of 926 procedure mentions appeared in our dataset over a span of 2382 total sentences. Of those, 295 were recommendation statements. A total of 1103 mention-trigger pairs were present, 174 of which were marked as true conditional statements. Additionally, a small set of unannotated data from the same domain was examined for the development of features and algorithms. This data was used for development only and was not considered in training or evaluation.

Recommendation Identification. Because we wish to associate procedures with conditional recommendation statements, we perform the recommendation annotation task for each individual mention of a procedure in the text. This allows us to predict that a procedure is recommended in some instances while not recommended in others, a distinction that would be lost in document-level recommendation classification. We model the recommendation identification task as a three way (Recommended, Not Recommended, Unspecified) mention-level supervised classification task. To learn a classification model we derive features from the surrounding context in three broad categories: concept features, word features, and NLP-derived features.

Concept Features. To extract concept-based features, we first attempt to link each procedure to a UMLS concept. To do so, we use a proprietary concept extraction procedure based on identifying longest common subsequence matches between the text and candidate UMLS concepts. Although standard concept extraction procedures such as MetaMap and cTAKES exist, we chose our concept extraction procedure because internal tests suggested that it outperformed the freely available alternatives. Once concepts are identified, several features are extracted. For the concepts associated with the procedure of interest, the UMLS concept unique identifier (CUI) and its semantic and category names are retained as features. Additionally, features are produced from the CUIs of all other concepts present in the sentence. Features from concepts in the sentence were differentiated from those associated with the procedure.
concept. Finally, a Boolean feature captured whether or not any of the other concepts in the sentence were also procedures.

**Word Features.** Following previous text classification work, several feature sources were based simply on the presence of certain words in the sentence. First, a small set of both positive and negative recommendation keywords (e.g., recommend, critical, prognostic) was derived by examining a held out set of development data. One feature indicated whether any of the positive recommendation keywords were present, while another indicated the presence of negative keywords. A Boolean feature indicated whether the surrounding sentence mentioned the disease that was the theme of the document. The three words before and after the mention text were captured, as well as their relative position. Unigram and bigram features were extracted for all words in the surrounding sentence.

**NLP-derived features.** The final set of features required more linguistic interpretation. The Stanford CoreNLP toolkit (Version 3.4.1) was used to obtain a syntactic parse of the sentence and to assign part-of-speech labels. Using this information, the main verb of the sentence and any adjectives modifying the mentioned procedure were extracted as features. Positional features were extracted that indicated whether the procedure was in a list or conjunction with other procedures. Finally, the dependency parse of the sentence was used to determine if the mention was governed by a negation modifier.

**Conditional Identification.** Given a procedure mention with a positive or negative recommendation, the conditional identification task attempts to extract any part of the surrounding sentence that puts constraints on that recommendation. In order to obtain a set of candidate conditional snippets, we extract a series of trigger words that could possibly be the syntactic head of a conditional phrase. A list of possible trigger terms was generated by starting with all prepositions found in the document collection then examining development data to supplement and refine this list. Once a set of candidate triggers is identified, the task is to make a binary decision for each mention-trigger pair as to whether the phrase headed by the trigger word is a conditional statement modifying the procedure recommendation. As with recommendation identification, we model this task under a supervised learning framework.

Since many of the features used for recommendation identification potentially have discriminative value for conditional identification, the conditional identification feature vector starts by incorporating modifications of these features. This feature set is then expanded to include features capturing the relationship between the conditional phrase and the procedure and those based on the conditional phrase itself. A summary of the feature set is shown in Table 1.

**Table 1. Conditional extraction feature set.**

</tr>
</tbody>
</table>

**Entity Grouping.** In order to turn a set of conditional recommendation statements into a recommendation chart, mentions that refer to the same conceptual entity must be linked together. While linking each mention to an entry in
an existing knowledge base such as UMLS implicitly groups them, this linking is often imperfect due to differences in word form, part of speech, or granularity between what is given in the knowledge base and what is expected in the document context. For instance, while the terms echocardiogram and echocardiography each have their own UMLS concept, they will often be used interchangeably in procedure recommendation statements. Similarly, if the term echocardiography appears after the term transthoracic echocardiography in the text they may be used to refer to the same procedure, even though normally one is a subset of the other. Given this, linking to UMLS is an insufficient method for our entity grouping task, which could be seen as more similar to traditional coreference resolution. However, unlike most coreference tasks that consider pronominal instances, in this work we are only concerned with grouping explicit (non-pronominal) mentions in the text.

We developed a new algorithm that iteratively groups mentions of procedures into clusters based on their string similarity. Given two mentions of procedures: $S = <s_1, s_2, ..., s_M>$ of $M$ words, and $T = <t_1, t_2, ..., t_N>$ of $N$ words, we define their longest common prefix as $LCF(S, T) = <p_1, p_2, ..., p_L>$, where $L$ is the largest subset of words from $S$ that found a partial match in $T$, and $p_i$ is a partial match of a word $s_i \in S$ to a word in $T$. A word $s_i$ in $S$ is said to partially match a word $t_j$ in $T$, if the length of their longest common prefix $p_i$ is above the threshold: $|p_i| \geq \tau$. When $\tau = 1.0$, this reduces to finding exact matches to words of $S$. We used relatively large $\tau$ (e.g. 0.9) for recognizing words with different forms but sharing the same root and meaning. Similar to the longest common subsequence matching problem, LCF can be computed using dynamic programming in quadratic time relative to the length of the sequences. Two procedure mentions are linked together if their LCF equals either of the two, making it possible to group coarse- and fine-grained concepts such as echocardiography and transthoracic echocardiography under the same category.

Results

Although we examine the performance of each task separately, the training and evaluation of the recommendation and conditional identification tasks follow the same basic framework. In each case, the LIBSVM package (Version 3.17) was used to train a Support Vector Machine (SVM) classifier using a linear kernel. Other kernel types were examined as well, with no impact on performance. Performance was then assessed via leave-one-out cross validation. Conversely, since our entity grouping method is based on predefined rules, no model training was required, and evaluation was done directly on the entire dataset.

The results for the recommendation identification task are given in Table 2. As to our knowledge no other systems for mention-level procedure recommendation exist, we have no existing baselines for comparison. We thus compare to a bag-of-words baseline where only the unigrams and bigrams in the sentence are considered as features. As shown in the table, the proposed system is able to significantly outperform the baseline when using the entire feature set. To get a better understanding of the contribution of each features source, a feature ablation study was also conducted. As shown, removing any of the feature sources causes a loss in performance, suggesting that each feature type played a role in the prediction. However, removing NLP-based or concept-based features caused relatively modest reductions in performance. Conversely, the word-based features were shown to be most critical, as without them the classifier yielded worse than baseline performance.

For the conditional identification task, we present two views of the performance. To understand how well the classifier performs the task in a vacuum, we present the results of the task (and an associated baseline) when ground truth recommendation labels are known. However, since in a true usage scenario it is necessary to perform the recommendation identification task first, we also present overall performance numbers for a pipelined system that
performs conditional identification on the output of the recommendation identification task. Table 3 gives the results of the conditional recommendation task. Because a bag-of-words baseline would not give the classifier any information relating the procedure to the conditional, we instead chose a baseline trained on all of the word-based features given in Table 1, giving it a wider range of information. In the case where the ground truth labels are known, the learned system significantly outperforms the baseline. Similarly, the pipelined approach also outperforms the baseline, even though performing the tasks in sequence propagates the errors of the recommendation task and significantly hurts performance.

The goal of the entity grouping task is to assign each mention to one of several non-overlapping sets, making evaluation less straightforward. This is a problem common to general coreference resolution approaches, where several evaluation metrics have been proposed. In this work we adopt one of the more frequently applied evaluation metrics, b-cubed score\(^{24}\). B-cubed score calculates a local precision and recall score for each mention based on the overlap between its predicted set and the ground truth set, and then produces final precision and recall numbers by aggregating over all mentions.

Table 4 shows the results of the entity grouping task. We report only a single result for our system, as the entity grouping task in not dependent on the output of the other two tasks, leading results to be the same in both the pipelined and non-pipelined scenarios. As shown, overall entity grouping performance was good, with F-measure of 0.938. We present two baselines as a means of comparison. The first baseline presents performance when grouping was done by simple string match. To get a sense of the performance of UMLS entity linking, we ran our concept extraction procedure to perform entity linking as the second baseline. Unsurprisingly, the baseline methods performed well on instances in which the terms were the same or quite similar, but less well in cases of linguistic variation. In both cases, the baseline method produced very high precision but poor recall, and produced overall F-measure significantly worse than the proposed method.

Discussion

In this work we examined the recommendation identification, conditional linking, and entity grouping tasks separately, with the intent that they be combined into a larger diagnostic summary generation pipeline. This is consistent with many other multitask extraction scenarios, where pipelined approaches have been shown to be effective\(^{25}\). However, this pipelined approach potentially ignores interdependencies between the tasks that may be exploited to improve performance. In particular, it is clear that the conditional identification task is dependent on the output of the recommendation identification task, but it might also be the case that recommendations could be better identified if the presence of relevant conditional statements were detected. To explore this option, we attempted a pilot study in which the two tasks were combined with a Markov Logic Network\(^{26,27}\) based approach. Although we do not go into details about this approach here, ultimately the results indicated that the joint model produced results comparable but not superior to the presented pipelined approach. While this attempt at tighter task integration was unsuccessful, future work may wish to further examine methods that tie the tasks together.
Once each task has been performed, a diagnostic recommendation chart can be produced from the output. Several minor heuristics were applied to decide on the layout and presentation of the charts. The name used to label each procedure was selected from one of the ways in which it appeared in the text, with the most general name that mapped to a UMLS procedure given precedence. Procedures were ordered on the chart based on the order of their first appearance in the document. Conditional statements were similarly sorted by their original document ordering. To extract the conditional statement itself, the syntactic parse of the sentence was used to identify the largest phrase headed by the trigger term. Finally, a simple heuristic was used to determine if a procedure was generally (unconditionally) recommended. If at least two recommendation statements appeared for the procedure that were not linked to a conditional and none of these statements disagreed (i.e., recommended vs. not recommended), the procedure was marked generally recommended or generally not recommended, as applicable.

**Acute Coronary Syndrome Procedure Recommendation Chart**

**Electrocardiography (ECG)**
- Generally recommended.
- Recommended for angina.

**Chest radiography**
- Recommended in assessing cardiomegaly and pulmonary edema.

**Echocardiography**
- Generally recommended.
- Recommended in the setting of ACS.
- Recommended in defining the extent of an infarction and in assessing overall function of the left and right ventricles.
- Recommended in assessing overall function of the left and right ventricles.
- Recommended if the diagnosis is questionable.
- Not recommended in patients whose symptoms have resolved.

**Myocardial Perfusion Imaging**
- Recommended in other testing modalities.

**Angiography**
- Recommended in Myocardial Infarction.

**Coronary Angioplasty**
- Recommended for assessing obstructive CAD in patients without diabetes.

**Cardiac Catheterization**
- Recommended in defining coronary anatomy and the extent of a patient's disease.

**Figure 2.** Example automatically generated diagnostic recommendation chart. Incorrect extractions are given in gray.

Figure 2 shows an example of an automatically generated summary. As shown, in many instances the chart is able to present a concise statement about the conditions under which each procedure should be performed. While the figure illustrates that the tasks undertaken here have the potential to produce relatively clean recommendation tables, it also highlights some of the potential sources for error. First and most critically, because of the nature of the automatic generation process several of the recommendations and conditionals are incorrect. For instance, the table contains the nonsensical statement that myocardial perfusion imaging is “recommended in other testing modalities”. Because the cost of giving an incorrect recommendation is potentially severe, automatically generated summaries would need to be accompanied by human oversight in a true human usage scenario, but may still have beneficial use cases for machine interpretation. A less severe error is the extraction of statements that, while not quite incorrect, provide no extra conditional information. For instance, Figure 2 states that echocardiography is “recommended in the setting of ACS”, which gives no further conditional information in this context. Finally, we note that some additional errors arise from parsing errors, where the extracted conditional contains more or less information than the ground truth.

To get a rough understanding of the overall quality of the automatically generated summaries, we performed a small qualitative study. For each of the 33 diseases we randomly generated a recommendation chart using either the baseline, system, or gold standard methods. The generated charts were then shown to a medical resident, who examined their correctness and coherence and assigned a rating to each one on a 1 (best) to 4 scale. Results of this study suggested that the quality of the system generated charts was at least comparable to those generated by the gold
standard, with average ratings of 1.72 and 1.50, respectively. However, because of the small scale of the study, we caution that while these results suggest that the automatically generated summaries have potential, a more robust analysis would be required to fully understand the overall quality.

While the tasks undertaken in this work can be used collaboratively to produce diagnostic guideline summaries, they each have the potential to play other roles in medical text extraction. Recommendation classification can be used separately to identify procedure recommendations at a high-level, and has overlap with other information extraction tasks of interest, such as the extraction of diagnoses and findings from the electronic health record\textsuperscript{28,29}. Similarly, conditional extraction has parallels with other relation extraction tasks, such as biological event extraction\textsuperscript{30–32}, semantic relation labeling\textsuperscript{33,34}, and the identification of treatment relations\textsuperscript{35}. Finally, coreference resolution and entity linking are frequently applied to extract and link clinical terms from various sources of unstructured text, although approaches for reference text may be different than those made on clinical notes\textsuperscript{36}.

**Conclusion**

Understanding the scenarios in which a diagnostic procedure should be performed is a difficult and nuanced task, and one in which there is a potential role for NLP-based automation and guidance. In this work we examined the extraction of conditional recommendation statements, as a first look at diagnostic recommendation summarization. This was done by examining the assignment of mention-level recommendation labels, linking these mentions with conditional recommendation statements, and grouping them based on their underlying referent. Our results show that each of these tasks can be performed with above baseline accuracy, and the resulting output can be combined into concise summaries of the diagnostic procedure. While our automatically generated summaries are likely to contain more noise than those generated from gold standard human annotations, they represent a first step toward the automated extraction and understanding of the diagnostic workflow.

While the conditional summaries produced here attempt to give an overview of when procedures are appropriate, they do not impose a relative order on when each procedure should be performed. As such, the current recommendation summaries still require that some inference be performed by the clinician to choose the most appropriate test for a given scenario. While this does not necessarily diminish their usefulness to human readers, it can be a potentially problematic omission for machine interpretation. Given this, future work will focus on the expansion of this summarization framework towards a fully formed flowchart of diagnostic procedures that attempts to give a conditional roadmap to the entire diagnostic process.

Using Monte Carlo/Gaussian Based Small Area Estimates to Predict Where Medicaid Patients Reside

1Jess J. Behrens, M.Sc., 2Xuejin Wen, Ph.D, 1Satyender Goel, Ph.D., MBA, 2Jing Zhou, Ph.D, 2Lina Fu, Ph.D, 1Abel N. Kho, MD, MS

Abstract

Electronic Health Records (EHR) are rapidly becoming accepted as tools for planning and population health1,2. With the national dialogue around Medicaid expansion12, the role of EHR data has become even more important. For their potential to be fully realized and contribute to these discussions, techniques for creating accurate small area estimates is vital. As such, we examined the efficacy of developing small area estimates for Medicaid patients in two locations, Albuquerque and Chicago, by using a Monte Carlo/Gaussian technique that has worked in accurately locating registered voters in North Carolina11. The Albuquerque data, which includes patient address, will first be used to assess the accuracy of the methodology. Subsequently, it will be combined with the EHR data from Chicago to develop a regression that predicts Medicaid patients by US Block Group. We seek to create a tool that is effective in translating EHR data’s potential for population health studies.

Introduction

Electronic Health Records (EHR) are a promising data source for examining population health and for community health needs assessments1,2. For high density populations, zip codes may be used as the units for location analyses, but zip codes are widely considered to be insufficiently granular for modelling environmental/human interactions3,4,5,6,7. While geo-statistical methods exist for interpolating probable location from known points8,9,10, the literature is sparse on evaluating how accurate these techniques really are at predicting where the modeled event occurs. Understanding the accuracy of these methods, at spatial & demographic resolutions that are meaningful to health related processes, is vital for epidemiological studies based on EHRs to be successful.

We set out to evaluate the accuracy of one such technique for predicting probable patient location, a Gaussian Geo-statistical & Monte Carlo methodology that has proven effective for estimating probable voter location11. For this analysis, we selected Medicaid status as our condition of interest. We selected Medicaid status for two reasons. First, recent expansion of Medicaid status to new populations presents a controversial effect of the Affordable Care Act ripe for analyses of effects on population health12. Secondly, it represents a definite, unique indicator of patient socio-economic status that is most likely also associated with both patient health outcomes & exposure to potential health related environmental influences13,14. Thus, the goal of our study is to ensure that patient location can be accurately imputed from zip code aggregated EHR data using U.S. Block Group Census counts as a tool to weight that imputation, just as it was for voter location.

Methods

Using only registered Medicaid patients in 2 different cities (Chicago & Albuquerque), we developed small area estimates of Medicaid patients for both study areas from aggregated zip code patient counts to block group using a combination Monte Carlo/Gaussian Geo-statistical simulation technique. Chicago Medicaid patients were represented using HealthLNK EHR records. HealthLNK represents a total of 6 years (2006-2011) of de-identified & de-duplicated Electronic Health Records (EHR) obtained from 6 different sites across Chicago and are thus only a sample of the total Medicaid patients in the Chicago area16. The geo-imputation for Chicago was meant as a comparison and will be used in future steps of the project. Conversely, in Albuquerque, where we have all Medicaid records & patient address data, we compared accuracy to another study done using the same methods but on registered voters in central North Carolina. The accuracy assessment in Albuquerque will be done separately over two years (2012 & 2014), using the most recent address for each Medicaid patient in each year to represent where that patient lives.
We address matched Albuquerque Medicaid patients using ArcGIS 10.3 and subsequently aggregated by zip code. Because the methodology weights probable patient location using U.S. Census Block Group counts, Albuquerque zip code to block group geographic coincidence was established in ArcGIS using a spatial join. We imputed probable patient block group location by performing a Monte Carlo simulation that uses limited personal data (age, gender, & ethnicity) & associated US Census Block Group totals to establish the probable average number of zip code aggregated Medicaid patients that live within each associated block group. These probable Medicaid patient block group averages were distributed among associated census blocks proportionally & kriged in ArcGIS. A krig is a raster based statistical surface, similar to a digital elevation model, where the raster cells represent a probability, in this case the number of Medicaid patients living there. The resulting krig was fed into a Gaussian Geo-statistical Simulation to generate an average & standard deviation probability raster to evaluate the accuracy of the predicted average number of Medicaid patients living in each raster cell (Figure 1).

We assessed accuracy for each of the three years, separately, using the Root Mean Square Error (RMSE), Error Product, and Error Product/RMSE for each (Table 1). We compared the values for each year to the North Carolina Voter results from our prior study. RMSE is a common measure of accuracy which is calculated as the square root of the average squared error for each prediction made. Since the results here involve geography, the RMSE assesses the average number of patients that the raster has over or under predicted at every point/raster cell within the study area. It follows logically that the smaller the RMSE the better. The Error Product measures how consistent the results are. It has two separate components, which are multiplied together. The first is the percentage of checked locations used in the RMSE that fall within 3 Standard Deviations of the mean. The second is the percentage of checked raster cells with a predicted average number of Medicaid patients that is greater than the 1 standard deviation measured at that same location. The goal is to have 100% of observations comply with each of these criteria, a situation that would yield an Error Product of 1. These two measures are important because they are an indicator of the quality of the simulation as an approximation of the Medicaid patient distribution. Deviations that are far from 1 indicate that the methodology is faulty, and that the RMSE should not be trusted regardless of its magnitude. Finally, the Error Product RMSE is simply the Error Product divided by the RMSE. Since the goal for each measure is a value of 1, where an RMSE of 1 would indicate that the raster has an error of at maximum one Medicaid patient at any given point in the study area, the Error Product RMSE should also be evaluated relative to a value of one.

Results

A total of 108,308 Albuquerque Medicaid patients who had received care within the last year and who were living within 482 block groups were selected for the study. This included, by year, 27,143 Medicaid patients in 2012 & 81,165 Medicaid patients in 2014. In Chicago, 88,198 Medicaid patients were selected who fall within 217 zip codes in the Cook, DuPage, & Will County areas. These patients represent all patients in those zip codes whose final insurance status in HealthLNK was Medicaid.
Table 1 shows the results of the accuracy comparison for Albuquerque & the North Carolina Voter dataset project.

**Table 1.** RMSE, Error Product, & Error Product RMSE, Albuquerque Medicaid Patients & North Carolina Voters

Given that the number of Albuquerque Medicaid patients in each year number between around 30 to 80,000, and are represented in a Gaussian raster with a resolution less than 0.01 mi², the most appropriate comparison to the North Carolina Voter project is at both 10% & 30% in the Urban Plus study area, which has 27,125 & 81,367 total voters, respectively. As table 1 shows, the RMSE is virtually identical in both study areas, with greater variability in error at 10% than 30%, which may be caused by sampling error at these lower population levels.

The higher RMSE in Albuquerque in 2012 may also be a result of population distribution. Chicago is very densely populated near the lake, & that population drops as one moves west, toward the suburbs. While

---

**Figure 1.** Probable Average Medicaid Patients, Albuquerque & Chicago Study Areas
Albuquerque has areas that are similar in density to Chicago, these areas are much smaller. Furthermore, the population density drops at a much more rapid rate as one moves out from these areas and into the surrounding desert. These stark contrast between the population distribution in Chicago & Albuquerque can be seen in a block group map of the two study areas. As block groups increase in size, the population density decreases. The krig, which is used as a base for the Gaussian simulation, can account for much of these variations, but it may be that the stark contrast in population distribution around Albuquerque may stretch its limits.

The reason for this stems from the algorithm and mathematical methods that constitute a krig. In effect, it is the same thing as fitting a curve in traditional statistics, it’s just being applied to data that has the added complexity of being spatially explicit. As is common in non-spatial statistics, binning, or grouping, data can create a sort of bias. As such, in a normal statistical project that requires binning, much time and attention is paid to how the underlying data is broken out into its groups. This, of course, includes the problematic question of how many bins to include. With spatial data such as that found in the US Census & ACS data, the binning choices have already been made. Because those bins also have the added complexity of representing an area on the ground with a specific extent and a specific spatial relationship to all of the other bins, the bias introduced by binning is not only found in the underlying counts, but in where the boundaries for that bin have been set. In spatial analysis, the two primary types of error introduced by binning are commonly called spatial clustering and spatial trend. Kriging corrects as much as possible for these two types of bias. By removing this type of bias, we can use the Gaussian to examine the degree to which the underlying data is actually spatially clustered minus that bias. Other forms of small area estimates don’t account for these types of error and bias, making the Gaussian methodology presented here unique.

Thus, after adjusting the observations for these two data aggregation errors, the krig uses a type of machine logic to ‘fit’ a three dimensional surface to those observations. The more normally distributed, or spatially disperse, the underlying data is, the better the equation developed for the krig will fit it. That goodness of fit will lead to a lower RMSE after the Gaussian simulation is run. As the Gaussian RMSE increases, within the confines of a similar or unchanging Error Product, that increase will most likely be due to non-normally distributed, or spatially clustered, underlying data.

Discussion

In this project, we created small area estimates of Medicaid patients using the same methods applied in two distinct geographies. When visualized on a map, our estimates correlate with known areas of low socioeconomic status (SES) in both cities. Compared with a prior validation study applied to voter registration records in North Carolina, our estimates of Medicaid patient distribution generated a slightly larger RMSE at low population counts, but essentially the same. When one considers that, as a rule, population rarely distributes itself ‘normally’ in space, the fact that Medicaid status is dependent on SES & registering to vote is not indicates that it is most likely these socio-economic factors that are responsible for the additional RMSE at low population levels in 2012. Fortunately, the RMSE increase is not that much relative to the total population being simulated & the Error Product for both projects is almost identical. These facts, taken together, strongly indicate that the krig & subsequent Gaussian simulation provide a strong model for Medicaid patient location. Furthermore, the increase in RMSE, most likely due to the clustering effects of low SES, indicates that the block group aggregate average Medicaid patients will serve as a strong dependent variable for future work by our group to apply regression analysis to estimate Medicaid patient population in areas based on socio-economic factors alone.

Our group is currently studying the impact of Medicaid expansion on diabetes outcomes across ten states, half of which are non-Medicaid expansion states. Developing accurate methods to estimate Medicaid patients per block group nationally will help us identify a comparison population of patients in non-Medicaid expansion states who would have qualified for Medicaid had their states chosen to participate in the Medicaid expansion program. Accurate imputation methods enable researchers to study the impact of policies or other external shocks on clinical outcomes when data are sparse or missing.

Recognizing Question Entailment for Medical Question Answering

Asma Ben Abacha, PhD & Dina Demner-Fushman, MD, PhD
U.S. National Library of Medicine, Bethesda, MD.

Abstract

With the increasing heterogeneity and specialization of medical texts, automated question answering is becoming more and more challenging. In this context, answering a given medical question by retrieving similar questions that are already answered by human experts seems to be a promising solution. In this paper, we propose a new approach for the detection of similar questions based on Recognizing Question Entailment (RQE). In particular, we consider Frequently Asked Question (FAQs) as a valuable and widespread source of information. Our final goal is to automatically provide an existing answer if FAQ similar to a consumer health question exists. We evaluate our approach using consumer health questions received by the National Library of Medicine and FAQs collected from NIH websites. Our first results are promising and suggest the feasibility of our approach as a valuable complement to classic question answering approaches.

1 Introduction

Consumer health queries are increasing at a high rate on the World Wide Web. Recent studies from the Pew Research Center show that 59% of U.S. adults searched for health information online in 2013. In the same study, we find that 35% of U.S. adults attempted to figure out what medical condition they or someone else might have by searching online resources. Consumer health questions cover a wide range of health-related topics asked generally by non-expert persons, patients or professionals. Typical information sought by consumers can be, for instance, information about a disease (e.g. “My daughter was recently diagnosed with a CTNNB1 mutation and there are only 4 published cases. Can you tell me where I may be able to find more information”), treatments (e.g. “Do you have information on the treatment of Parkinson’s disease with the use of amino acids”) or more specific questions about drugs (e.g. “is it safe to take diclofenac when taking lisinopril or aleve or extrastrength Tylenol?”).

Many websites offer online doctor consultation services in virtual hospitals (e.g. icliniccare.com, www.icliniq.com, www.jeevom.com, www.evaidya.com, www.doctorvista.com) and propose to answer medical questions, give advice or second opinions from thousands of doctors and specialists. These services attract more and more internet users seeking easy and quick answers, as well as free consultations and privacy. Many of these resources publish freely the submitted questions and doctors’ answers. New health-dedicated forums and websites continue emerging each year; and major question-answering websites such as Quora or Yahoo! Answers include important and growing health sections.

With this multitude of information, duplicate questions are becoming more frequent, and finding the most appropriate answers becomes problematic. This issue is important for question-answering platforms as it complicates the retrieval of all information relevant to the same topic, particularly when questions similar in essence are expressed differently. Finding similar questions is also important for the users as is implied by the 2013 survey, in which 16% of the users tried to find others with the same health concerns.

Efficient automatic approaches are therefore required to detect similar questions both at search time and at question submission time. In this paper we propose a new approach for the detection of similar questions based on Recognizing Textual Entailment (RTE). RTE is an important component in Natural Language Understanding and in Question Answering. Harabagiu and Hickl argue that RTE can enable question answering systems to identify correct answers with greater precision than keyword or pattern based methods [1].

We particularly tackle the detection of a most similar Frequently Asked Question (FAQ) to a given consumer question. FAQs are both a valuable and widespread source of information. Many trusted sources, such as NIH institutes and

3 www.quora.com As of March 1 2016, 7,176,197 questions were posted to Quora.
4 answers.yahoo.com
centers, provide answers to frequently asked questions organized by topics. NIH provides FAQs for many health related problems such as Rare Diseases (Frequently Asked Questions About Rare Diseases\(^5\), or Alzheimer\(^6\)).

To test our approach in a use case, we obtained consumer health questions received by the National Library of Medicine (NLM). NLM receives hundreds of requests per day, e.g., from October 2013 to September 2014, NLM received a total of 102,622 requests, including many consumer health questions. Our final goal is to automatically provide an existing answer if an FAQ similar to a consumer health question received by NLM exists. If we can reliably identify similar questions, retrieving the corresponding answers is relatively straightforward. For example, this approach to answering health related questions is taken in the SimQ system [2].

In this paper, RTE is applied to find a frequently asked question similar to a consumer health questions in order to answer consumer health questions with the answers given to similar FAQs. As far as we know, RTE from medical questions has not been studied before for Question Answering. Our contributions can therefore be summarized in three points:

- We address and define the problem of RTE in medical questions for Question Answering.
- We construct automatically an RTE training corpus of medical questions and we study the impact of varying the size and nature of the training examples.
- We use different features for the RTE task in medical questions including classical similarity measures and semantic features related to the medical domain.

The remainder of the paper is organized as follows: Section 2 presents the background. Section 3 presents our approach for RTE in medical questions developed to retrieve existing FAQs and answers. In section 4, we present our methods to construct automatically an RTE training corpus, and to construct semi-automatically an RTE test corpus for medical questions. Our experiments and results are detailed and discussed in sections 5 and 6.

2 Background

Recognizing Textual Entailment (RTE) has been addressed by numerous works in the literature and in the framework of the PASCAL challenge \(^7\). Dagan et al. [3] present the RTE task and give an overview of the research efforts in this area. A detailed survey of RTE approaches is also presented in [4].

Several machine learning (ML) methods have been explored for RTE using different features, e.g., similarity measures [5, 6, 7]. Some efforts focused on the training corpora as they are an important factor for an efficient supervised learning system. Zanzotto and Pennacchiotti [8] proposed a method to expand the existing textual entailment corpora. They extracted from Wikipedia a large set of textual entailment pairs and used a semi-supervised machine learning method to make the extracted dataset homogeneous with the existing corpora. Other efforts tackled automatic generation of training corpora for a specific language. For instance, Marzelou et al. [9] proposed a method to create a Greek Textual Entailment Corpus that can be exploited for training or evaluating a system for RTE from Greek texts.

While textual entailment in open-domain has been extensively addressed in the literature, RTE has been less addressed for more restricted and specialized fields such as the medical domain. Adler et al. [10] presented a text exploration system, in which search results in the health-care domain can be navigated at propositional level according to textual entailment relation. Ben Abacha et al. [11] proposed a supervised learning method to RTE from medical texts. For the same purpose, they also proposed an automatic method for construction of training corpora from MEDLINE abstracts and compared the results obtained from the open-domain model, derived from the PASCAL training corpus, and the medical-domain model, derived from the automatically-constructed corpus. Their experiments showed the benefits of domain-related models and automatic corpus construction.

\(^5\)http://www.genome.gov/27531963 National Human Genome Research Institute, NIH.  
\(^6\)http://nihseniorhealth.gov/alzheimersdisease/faq/faqlist.html  
\(^7\)http://www.nist.gov/tac/2011/RTE/
One of the earliest question answering systems based on finding similar questions and re-using the existing answers was FAQ FINDER [12]. Some of the underlying assumptions about FAQs were that the information needed to determine the relevance of a (Question/Answer) QA pair can be found within the QA pair and that the question half of the QA pair is the most relevant for determining the match to a users question. Not surprisingly, much of the subsequent work was dedicated to question matching. Jeon et al.[13] showed that a retrieval model based on translation probabilities learned from a question and answer archive can recognize semantically similar questions. Duan et al. [14] proposed a language modeling using question topic and question focus for question search. An alternative approach, is to return a ranked list of QA pairs in response to a user’s question, treating finding an answer as a fielded search task, where the user’s question is treated as a query, and the items to be returned are QA pairs [15].

More recent research efforts have focused on retrieving similar consumer health questions. Wang et al. [16] developed a syntactic tree matching method to find similar questions for 0.5 million QA pairs from the Healthcare domain in Yahoo! Answers. SimQ [2] aims to retrieve similar web-based consumer health questions. The system uses syntactic and semantic features and reaches a precision of 72.2% and a recall of 78.0%. SimQ is used to complement the existing Q&A services of Netwellness and allows reducing response delay by instantly providing closely related questions and answers.

3 Recognizing Question Entailment (RQE)

A. Problem Definition

Textual Entailment (TE) is a directional relation between two text snippets called text (T) and hypothesis (H), expressing the fact that the meaning of T is contained in the meaning of H [3]. In a similar definition, the first PASCAL Recognizing Textual Entailment Challenge (2004-2005) defined the task of Recognizing Textual Entailment (RTE) as deciding, given two text fragments, whether or not the meaning of one text (H) can be inferred (entailed) from the other one (T) [17].

In our case, the (T, H) pairs refer to pairs of questions (Q1, Q2). Our goal in to retrieve answers to Q1 by retrieving entailed questions Q2 that have associated answers. Groenendijk and Stokhof (1984) define an entailment relation between two questions Q1, Q2 if every proposition giving an answer to Q1 is also giving an answer to Q2 [18]. Roberts (1996) called the first question Q1 as a superquestion and Q2 a subquestion (if we answer enough subquestions, we have the answer to the superquestion) [19]. In accordance with these definitions, we define question entailment as follows:

Question Entailment. Question A entails Question B if every answer to B is also a correct answer to A exactly (cf. Example 1) or partially (cf. Example 2).

Consumer health questions often contain heterogeneous information, e.g. information about the patient’s history. Our rule for ignoring additional information in the question is based on the assumption that it is not required to retrieve a correct answer (cf. Example 1, in which the fact that the patient has only central vision will not help retrieving information related to treatment of the disease). Here are two examples from our datasets:

- Example 1:
  - A1 (consumer health question): Hi I have retinitis pigmentosa for 3years. Im suffering from this disease. Please intoduce me any way to treat mg eyes such as stem cell ....I am 25 years old and I have only central vision. Please help me. Thank you
  - B1 (FAQ): Are there treatments for RP?
  - A1 → B1

- Example 2:

---

8http://netwellness.org/
9http://pascallin.ecs.soton.ac.uk/Challenges/RTE/
• A2 (consumer health question): Can sepsis be prevented? Can someone get this from a hospital?
• B2 (FAQ): Who gets sepsis?
• A2 → B2

A2 includes 2 questions about prevention and susceptibility. An answer to B2 (about the susceptibility to Sepsis) is considered as a partially correct answer to A2. In this case, we consider that A2 implies B2.

B. Learning Method for RQE

We propose a supervised machine learning approach to determine whether or not a question Q2 can be inferred from a question Q1. In order to extract relevant features, we first remove stop words and perform word stemming using the Porter algorithm [20] for all (Q1,Q2) training pairs.

**Lexical Features:**

We compute different similarity measures between the pre-processed questions and use their values as features:

- **Word Overlap:** we compute the word overlap as the proportion of words that appear in both Q1 and Q2 and normalize by the length of Q1.
- **Bigram:** we compute the bigram similarity between Q1 and Q2 as the total number of matched bigrams in (Q1,Q2) pair normalized by the number of Q1 bigrams.
- **Best similarity value:** the maximum similarity between five similarity measures: Levenshtein, Bigram, Jaccard, Cosine and Word Overlap.

**Semantic Features:**

**Negation:** we use NegEx [21] for identifying negation scope in Q1 and Q2.

**Medical entities:** we annotate all (Q1,Q2) pairs with medical entities using two supervised systems. The first system uses a CRF classifier trained on the i2b2 corpus [22] to recognize medical entities of 3 types: Problem, Treatment and Test [23]. These three medical categories are the most frequent and important categories in consumer questions. The second system is a meta-classifier [24] trained on four corpora: two clinical texts corpora i2b2 and SemEval [25] and two scientific abstracts corpora NCBI [26] and Berkeley [27] to recognize medical problems. In many cases, the focus of the consumer health question and the FAQ is a medical problem (e.g. questions about treatment, symptoms or medical exam). Starting from the obtained annotations, we generate the following semantic features for each question pair (Q1,Q2):

- Number of medical entities in Q1. Number of medical entities in Q2.
- Number of medical problems in Q1. Number of medical problems in Q2
- Number of medical entities in common between Q1 and Q2.
- Number of medical problems in common between Q1 and Q2.
- **Common medical problem:** binary feature indicating whether or not at least one medical problem from Q1 is mentioned in Q2.

4 Data

A. Automatic Construction of Training Data

We used the NLM collection of 4,655 clinical questions asked by family doctors [28] to construct our training corpus for RQE. An extract from this collection is presented below (Clinical question with NLM ID: NQ003094):
6 and 1/2-year-old girl. What’s causing her ear pain? She has a normal ear on exam and normal tympanogram. Is it just eustachian tube dysfunction? 

What is causing the ear pain in this child with a normal ear exam?

What would cause ear pain in a child with a normal exam?

History

Earache

Diagnosis

To obtain positive QE examples, we use the original form and the short form of the question as expressed in the collection.

original question → short form (4,655 positive examples)

To obtain the final corpus, we studied five different construction methods by varying the number and type of negative pairs, and we analyzed the impact of each construction method on the results. Each of these methods led to different training sets, described below:

Training set 1: 8,588 training pairs, containing 54.2% positive pairs. The remaining pairs (3,933) are negative examples collected by associating a random short form having at least one common keyword and at least one different keyword for each original question.

Training set 2: 17,898 training pairs, containing 26% positive pairs. The remaining pairs (13,243) are negative examples constructed as follows:

- original question → short form of random question having at least 1 different keyword and at least 1 common keyword
- original question → short form of random question having at least 1 different keyword and at least 1 common content
- original question → short form of random question having at least 1 different keyword

Training set 3: 13,918 training pairs containing 33.44% positive pairs. Two types of negative examples are considered in this set:

- original question → short form of random question having (i) at least one different keyword and at least one common keyword or (ii) at least one different <content> tag and one equal <content> tag (cf. example question above)
- original question → short form of random question having (i) at least one different keyword and at least one equal <content> tag or (ii) at least one different <content> tag and at least one equal keyword.

Training set 4: 18,573 training pairs with 25% positive pairs. Three types of negative examples (13,918 negative pairs):

- Same 2 types of negative pairs as in training set 3.
- original question → short form of random question having (at least one different CONTENT) OR (at least one different keyword)

Training set 5: 9,310 training pairs with 50% positive pairs. One type of negative examples regrouping the 2 types of Training set 3 (4,655 negative pairs):
original question \rightarrow short form of random question having (i) at least one different keyword and at least one common keyword or (ii) at least one different <content> tag and at least one equal <content> tag, or (iii) at least one different keyword and at least one equal <content> tag, or (iv) at least one different <content> tag and at least one equal keyword. Duplicated questions were removed.

The four examples below are extracted from our training corpora to better show the intuition behind these different construction procedures.

- <pair id="29" type="originalQ-shortRandQ" value="negative">
  <t> What is the cause and treatment of this old man’s stomatitis? </t>
  <h> What would cause a patient to have a low thyroxine and a high thyroid stimulating hormone when the patient is on Synthroid chronically? </h>
</pair>

- <pair id="37" type="originalQ-shortQ" value="positive">
  <t> Is melatonin good for anything? I don’t know anything about melatonin. I need to know the dose. </t>
  <h> Is melatonin good for anything? What is the dose? </h>
</pair>

- <pair id="4358" type="originalQ-shortRandQ" value="negative">
  <t> How should you work up someone who tried to give blood and has positive Hepatitis B core antibody? </t>
  <h> Why did the blood pressure go up with addition of Vasotec? (Was already on Procardia.) </h>
</pair>

- <pair id="10366" type="originalQ-shortQ" value="positive">
  <t> Young woman with acute Fifth disease (son also has it). She is not pregnant. She has increased swelling of her hands and her arms go numb and she has trouble sleeping. Wants to know what to do. </t>
  <h> What is the treatment for Fifth disease? </h>
</pair>

We evaluate the constructed training corpora in terms of Precision, Recall and F-measure in section 5.

B. Semi-automatic Construction of Test Data

For test pairs, we collected two types of test data: (i) pairs of manually validated questions from the NLM collections and (ii) pairs of questions including FAQs retrieved online with a manual search of NIH websites. We constructed the two parts of our test corpus using the following methods:

We constructed the first part using two collections of (i) 300 consumer health questions annotated with the focus of the question and (ii) 349 FAQs from NIH websites, in two steps:

1. Extracting the question pairs that have the same focus (medical problem).

Here are two examples from the first part of our test corpus:

- <pair id="6" type="Part1" value="TRUE">
  <t> No. hi my name is NAME. I’m currently working with Friends Community Center in Hollywood California and I was wondering I came across some of you healthy tip fliers for HIV/Aids treatment .at the moment we have a study going on that helps HIV positive transgender women into HIV quality care .so it would be great to have some more information on HIV/Aids treatment </t>
  <h> How is HIV/AIDS treated? </h>
</pair>

- <pair id="66" type="Part1" value="FALSE">
  <t> recovery after stroke?. what is the pattern of recovery after stroke? </t>
  <h> Is there any treatment for Stroke and Atrial Fibrillation? </h>
</pair>

For the second part, we searched online for FAQs for 116 from the remaining consumer health questions from NIH websites to construct our positive pairs. For negative pairs, we selected for each consumer health question, a random FAQ from the list of 116 found online. Here are two examples from the second part of our test corpus:

- <pair id="79" type="Part2" value="TRUE">
  <t> Help for my diagnose. I have been diagnosed with SCA3. I was wondering if MedlinePlus is able to help me with resources that I may need on my journey through this disease? If not, can you help me find an organization or association that can help me. </t>
  <h> Where can I find additional information about SCA3? </h>
</pair>

315
Our final test corpus contains 302 pairs of questions consisting of 173 negative pairs and 129 positive pairs.

5 Evaluation

In this section, we evaluate the corpus construction methods as well as several algorithms to recognize textual entailment between questions.

Table 1 presents the results in terms of Precision (P), Recall (R) and F-measure (F), obtained using different training corpora. We tested different configurations (i) by adding new types of negative pairs (e.g. training set 3 vs. training set 4) to evaluate the impact of the new example types and (ii) by regrouping types of pairs to evaluate the impact of reducing the number of negative examples (e.g. training set 3 vs. training set 5).

6 Discussion

By testing the impact of different automatic corpus construction methods to train RQE classifiers we found that increasing the number of negative examples does not always improve the results. The nature and size of the training corpus obtained by our best automatic construction method (8,588 question pairs with 54.2% of positive pairs) provided a good start for building a system for question entailment recognition that can be used as an important support to find additional answers that complement classical question-answering results.

While we obtained relatively good results in our evaluation, several challenges have still to be tackled to enhance further the performance of similarity-based approaches. If we consider the example of questions Q1 and Q2 below, they are not linked by an entailment relation even though they share three different keywords (cause, dry, mouth).

- **Q1 (Consumer health question):** treatment for dry mouth caused by necessary medicine. My provider can’t help (I asked.) I am intolerant of all the sugar alcohols such as maltitol, sorbitol, xylitol, etc. and need something for dry mouth caused by med which I have to take. Biotene products help for only about two minutes.
- **Q2 (FAQ):** What causes dry mouth?
• *Entailment*: false.

More generally, relying on number of shared keywords and medical entities provided a high recall upper bound for the recognition of question entailment, however, it did not reach very high precision due to the lack of advanced features such as the identification of the answer type (e.g. treatment in Q1) and the main semantic relations (e.g. *causes* in Q2).

7 Conclusion

In this paper, we described our approach for recognizing question entailment (RQE) in order to answer new questions using existing Question-Answer pairs. We presented an automatic method for the construction of training corpora for RQE and a semi-automatic method for the construction of a test corpus for medical questions. Our experiments confirm the feasibility of medical question entailment even with a small set of features. In future work, we plan to extend our test corpus and to include more semantic features. We also plan to study the adaptation of our training corpus consisting of doctors’ questions by including a small number of consumer health questions (e.g. questions asked by non experts, patients) and manually collected FAQs.

Hypothesis-Free Search for Connections between Birth Month and Disease Prevalence in Large, Geographically Varied Cohorts

John P. Borsi

1Explorys, an IBM Company, Cleveland, OH

Abstract

We have sought to replicate and extend the Season-wide Association Study (SeaWAS) of Boland, et al. in identifying birth month-disease associations from electronic health records (EHRs). We used methodology similar to that implemented by Boland on three geographically distinct cohorts, for a total of 11.8 million individuals derived from multiple data sources. We were able to identify eleven out of sixteen literature-supported birth month associations as compared to seven of sixteen for SeaWAS. Of the nine novel cardiovascular birth month associations discovered by SeaWAS, we were able to replicate four. None of the novel non-cardiovascular associations discovered by SeaWAS emerged as significant relations in our study. We identified thirty birth month disease associations not previously reported; of those, only six associations were validated in more than one cohort. These results suggest that differences in cohort composition and location can cause consequential variation in results of hypothesis-free searches.

Introduction

The human urge to assign importance to birth season is well-documented: astrologists have been attempting to divine human fates based on birth timing for millennia. Such endeavors were put on solid scientific footing in 1929, with the publication of a work on the connection between mental disorders such as schizophrenia and birth month. Little doubt remains that birth month does have a measurable impact on many facets of life; over 250 studies had confirmed the importance of birth season before the year 2000. Links have been established between disease prevalence and birth month for numerous conditions: allergies and rhinitis, reproductive performance, attention deficit hyperactivity disorder (ADHD), dermatitis, Crohn's disease, and otitis media, among others. Studies have also suggested connections between birth month and height, life expectancy, and life events. Potential explanations for the observed links have incorporated diverse causes such as neonatal vitamin D exposure, exposure to allergens, and the impact of social age.

In 2015, Boland et al. implemented a hypothesis-free, phenome-wide method to systematically identify associations between birth month and disease prevalence. Their work is part of a growing acceptance of using electronic health record (EHR) data to conduct retrospective studies. EHRs have been mined to better understand health care utilization of diabetic patients, detect adverse drug events, and find health care fraud. “Hypothesis-free systems,” algorithms which proceed systematically through a dataset without a priori hypotheses, have achieved success in identifying clinically relevant associations. For example, EHRs were used in conjunction with genetic data to validate associations between single nucleotide polymorphisms and specific diseases.

As the authors of SeaWAS admitted, EHR observational studies have limitations—the existence of bias in health care data is well-known and well-documented. Comparison of large-scale EHR research with gold-standard, manually curated research has demonstrated that the two can produce inconsistent results. Known examples of systemic biases in EHRs include selection bias, coding bias, and missing or inaccurate records. In addition to EHR biases, retrospective studies in general may overstate effects and be subject to confounding factors. However, EHR research has been shown to provide an approximation to traditional research and has had several successful replications of large studies.

Boland, et al.’s hypothesis-free methodology was able to confirm known disease-birth month associations, discover new associations, and find clusters of birth month dependencies among disease types. Their work was significant because it applied sophisticated statistical techniques to a large dataset to derive novel insights. However, their work was limited by the cohort to which they applied their method. The SeaWAS study investigated records of 1.7 million individuals at New York-Presbyterian/Columbia University Medical Center. Observed associations from this population may be local effects that do not generalize to a more general population.

We conducted a retrospective study to apply the SeaWAS approach to larger cohorts from different geographical regions. By simultaneously applying this methodology to three separate cohorts, we were able to discern the effect of geographical, administrative, and population-based cohort differences. The increased sample size of our cohorts...
allowed increased power in detecting birth month associations. In addition, we proposed a change to the methodology used by SeaWAS to address statistical concerns first raised by Boland, et al and tested the impacts of its implementation.

Methods
Data Preparation
The individuals of interest were derived from the Explorys platform\(^3\). Patients were separated into three cohorts based on ZIP3 codes corresponding to regions in three different states. The first cohort (C1) consisted of patients in a southern US state at approximately 31° N latitude. The second cohort (C2) was constructed of patients from a midwestern US state around 40° N. The third cohort (C3) included patients from a western US state at approximately 38° N. Each of these cohorts represents an aggregation of multiple clinical and claims data sources, grouped by patient. In order to match patients across data sources, demographic records were matched on date of birth, gender, ZIP3, and the New York State Identification and Intelligence System (NYSIIS)\(^2\) representation of the patient’s name. All records were de-identified prior to analysis and all records derived from Centers for Medicare & Medicaid Services (CMS) data were excluded from the study.

Demographic information about both the original and replication cohorts is summarized in Table 1.

Table 1. Demographic information about original and replication cohorts.

† Interquartile range

A list of diagnoses was derived from each patient’s medical history documents, problem lists, billing records, and other clinical findings. All patient records that contained an International Classification of Diseases, version 9 or version 10 (ICD-9, ICD-10) code were aggregated. Using a custom map based on the Common Data Model (CDM) mapping\(^8\) and Intelligent Medical Objects (IMO) data\(^4\), ICD concepts were converted to Systemized Nomenclature for Medicine-Clinical Terms (SNOMED) codes. The ICD to SNOMED map used in this study is not one-to-one; that is, an ICD code may map to more than one SNOMED code. In this case, all relevant SNOMED codes were recorded and included in analysis.

Statistical Methodology
For each SNOMED code with more than 1,000 distinct patients, a Pearson’s chi-squared test of independence\(^3\) was performed comparing the birth month distribution of patients with the condition to the birth month distribution of all
Boland, et al applied the Benjamini-Hochberg (BH) multiplicity correction to the p-values resulting from the chi-squared test. The BH multiplicity correction is a sequential hypothesis rejection procedure designed to control the False Discovery Rate (FDR) of independent test statistics. However, as Boland states, “Study limitations include the lack of condition independence […] potentially affecting multiplicity correction” (1051). We applied a more conservative multiplicity correction to our p-values, the sequential Holm multiplicity correction. To evaluate the impact of the change in multiplicity correction, we calculated the results using both multiplicity corrections and compared the output of the different methodologies.

**Results**

In all replication cohorts, we identified several literature-supported birth month-disease associations. We used the curated reference set of literature-supported associations from Boland, et al as a baseline to compare the results from the four cohorts. SeaWAS identified seven out of sixteen associations. Using the same multiplicity correction as the original study, the replication cohorts identified ten, eleven, and three associations at the adjusted p<.05 significance level. When considering associations only identified using the more conservative Holm correction, the replication cohorts identified nine, seven, and one of the literature-supported associations. The literature-supported associations identified in each cohort are given in Table 2.

In addition to identifying correlations from the literature, we evaluated the previously unidentified associations discovered in each cohort. Out of the sixteen new associations from SeaWAS, four of them were replicated in at least one of the replication cohorts. All of these replicated findings were cardiovascular conditions. None of the non-cardiovascular associations discovered by SeaWAS were replicated. Out of the thirty-five unique conditions identified in an Explorys cohort, eight were replicated in another cohort. A summary of these findings, broken down by multiplicity correction and cohort, is presented in Table 3. The list of conditions identified is in Appendix A.
Discussion

In this replication attempt, we considered fifty data sources in three widely separated regions. The results differed greatly between different geographic regions. The most striking difference between cohorts in different geographical areas is the relatively few associations detected in cohort C3. Cohort C1 produced almost eight times more associations than did the C3. It has been shown that the strength of a birth month-disease association depends on the latitude, but birth month effects are typically stronger in higher latitudes. It is unclear why cohort C3, which is at a higher latitude than C1, produced fewer associations. It may be due to different health care processes used in different locations, or it may be related to differences in the characteristics of the individuals in the cohort. The variation in total number of associations observed and the fact that only six out of thirty newly observed associations were statistically significant in more than one cohort suggests that differences between cohorts may be a driver of substantial variation in the results of hypothesis-free searches.

Despite the lack of associations produced in C3, we have confidence that the replication cohorts were well-suited to test the hypothesis-free search. The C1 and C2 cohorts identified more of the literature-supported associations than did SeaWAS. This indicates that the sample size and extent of data was sufficient to detect legitimate birth month associations present in the cohorts.

In all of the cohorts tested, we failed to replicate the non-cardiovascular novel associations discovered by SeaWAS. These conditions include common ailments such as bruising, nonvenomous insect bite, vomiting, and venereal disease screening. Because these conditions are not typically very serious, their inclusion in an EHR may be dependent on the completeness of documentation and may suffer from seasonal bias.

Four new associations were discovered in the replication cohorts that were statistically significant in more than one geographical: coronary arteriosclerosis, tobacco use, hypoxemia, and reversible ischemic neurologic disease (RIND). The first association, coronary arteriosclerosis, may share a mechanism with the other cardiovascular conditions identified in SeaWAS. Although tobacco use has no obvious biological connection to birth month, the connection may be cultural, related to the impact of relative social age (as in Halldner or Skirbekk). The association of hypoxemia and birth month is mostly seen in individuals younger than five, suggesting that the observed effect may be transient. We are not aware of any explanation for the observed association of RIND with birth month.

The results discussed above strongly suggest that the Holm correction is an appropriate multiplicity correction to use for this hypothesis-free search. Although the recall of the search was higher with the Benjamini-Hochberg correction, there were many more non-replicable potential false positives identified using that correction. In addition to the non-replications of SeaWAS associations, the BH correction produced non-replicated associations in the new cohorts such as constipation, diaper rash, tinnitus, and headache. There is naturally a trade-off in choosing any threshold for significance; we suggest that the Holm multiplicity correction more accurately represents the uncertainties involved in this context.

This study had several limitations that could be overcome with future work. All the cohorts considered were in the northern hemisphere and the United States. Results from different regions of the globe may reveal different cultural

or environmental impacts on birth month associations. In addition, there were several confounding factors that we were unable to control in this retrospective study; two of which, age and coding differences between data sources, are known to impact studies. Future studies should more closely examine the impact of those confounding factors on the results of hypothesis-free searches.

**Conclusion**

This study is the largest of its kind with over 11 million unique patients, and is the first to include results from geographically distinct data sources. The size and breadth of this study allowed it to identify subtle trends and associations over large populations. We identified new birth month-disease associations and showed that results from a previous hypothesis-free search may not be generalizable. We have shown that the Benjamini-Hochberg multiplicity correction may not be well suited to a hypothesis-free search with dependent test statistics and shown that the Holm multiplicity correction is a better choice. It is clear that this approach can be a powerful hypothesis generator and tool for investigating the role of seasonally dependent early developmental mechanisms in general health, but obtaining generalizable results requires evaluating different sets of data and accounting for potential biases.

**Acknowledgements**

The feedback and assistance of the Innovations Team of Explorys, an IBM company was invaluable in preparing this work. I especially wish to thank Matthew Pohlman for his support throughout the research process and Amanda Yoho and Yifan Xu for their comments on the manuscript.

Improved Veteran Access to Care through the Veteran Health Information Exchange (VHIE) Retail Immunization Coordination Project

Nathan Botts, PhD\textsuperscript{1,2}, Eric Pan, MD\textsuperscript{1,2}, Lois Olinger, MA\textsuperscript{1,2}, Margaret Donahue, MD\textsuperscript{2}, Nelson Hsing, ScD\textsuperscript{2}

\textsuperscript{1}Westat, Rockville, MD; \textsuperscript{2}US Department of Veterans Affairs, Washington, DC

Abstract

The U.S. Department of Veterans Affairs (VA) Veteran Health Information Exchange (VHIE, formerly Virtual Lifetime Electronic Record, or VLER) Retail Immunization Coordination Project established a partnership between VA and Walgreens to empower Veterans to elect to receive their immunizations at a local Walgreens, which might be located closer to their home than their nearest VA facility. Analysis of Veterans immunized at Walgreens between September 2014 and January 2015 showed that 64\% of study Veterans now traveled <5 miles to receive their immunization, 12\% of study Veterans traveled between 5 to 10 miles, and 24\% of study Veterans traveled more than 10 miles. In addition, we note that 93\% of Veterans traveled less than 54 miles, the average distance rural Veterans traveled to the nearest VA facility. We conclude that the VHIE Retail Immunization Coordination Project improved Veteran access to healthcare and discuss future directions of this effort.

Introduction

VA influenza immunization rates for enrolled Veterans aged 65 years or older are currently above national averages (e.g., in 2011/2012, VA immunization rate was 77\% as compared to 65\% for the general population according to VHA Public Health data). However, VA remains below its target objective of 90\%. Many Veterans are currently already receiving immunizations through non-VA providers (e.g., employers, health outreach fairs, other clinics) and self-report their immunization history throughout the year to VA. With immunizations available at retail providers such as Rite Aid, Walgreens, CVS, etc. growing in popularity, VA is interested in determining how the convenience of retail providers, combined with automatically entered health information through interoperability, can be used to continue to improve the completeness and accuracy of the Veteran’s electronic health record and VA’s ability to accurately measure immunization rates for the target population, while boosting immunization rates of the target population overall.

VA launched the Retail Immunization Care Coordination Program (hereafter the immunization program) in October of 2013. The immunization program was structured in three phases:

**Phase 1 (2013-2014):** View only, query (Data was manually synched up by onsite VA staff following a clinical reminder. Data was transmitted from Walgreens, but onsite staff had to populate the patient record with immunization data.) It is also structured as a pilot program limited to Veterans Integrated Service Network (VISN) 8 throughout the state of Florida.

**Phase 2 (2014+):** Immunization data are automatically populating the VA patient record in CPRS. Phase 2 also extending the immunization program to a national rollout.

**Phase 3 (TBD):** Data will be integrated with Immunization Applications.

The immunization program allowed Veteran patients the option of choosing a Walgreens retail pharmacy to get a flu shot. Walgreens is authorized to administer the influenza vaccinations to the patients who are VA health care-enrolled and who voluntarily choose to participate in the program. In addition, many Veterans have coverage through Medicare or commercial insurance.

Immunization information of Veterans is available from Walgreens locations and retrieved for VA providers to review through VLER Health and eHealth Exchange, using the existing *query and retrieve* capability of VLER Health Exchange, and incorporates standard security measures to protect patient confidentiality. Participating Veterans in the VA Retail Immunization Care Coordination Program can ensure that their VA providers have complete and accurate information about the flu shot they receive, including the date, the type of vaccination, and the lot number. Once the Veteran volunteers to participate, the vaccination record is transmitted to the patient’s VA

326
electronic health record and is available for viewing via the VLER Health Exchange. VA providers will no longer have to rely on patient self-reported immunization data or unreliable paper records.

The goals of these efforts are to improve the completeness and accuracy of the Veteran’s electronic health record and to improve VA’s ability to accurately measure immunization rates for the target population, while boosting immunization rates of the target population overall. The immunization program expects to see both administrative impacts and clinical impacts from coordinating influenza vaccination with retail pharmacies (initially Walgreens).

Administratively, the retail influenza vaccination data will improve VA clinical documentation. This will eliminate the clinical reminders shown to VA clinicians for Veterans who were already vaccinated at retail sites such as Walgreens, and reduce cognitive load and alert fatigue to clinicians. Also, this will reduce unnecessary mails and outreach to Veterans for immunization reminders and self-reports once they are immunized. There will also be administrative savings from avoiding these wasted outreach activities.

Clinically, the program will provide real time influenza vaccination data to VA, which will help focus public health efforts to target Veterans who have not been immunized, reducing reminder fatigue and waste for Veterans who were already immunized. In addition, this is expected to add a large number of influenza vaccination sites and increased convenience for Veterans.

Finally, with greater and earlier influenza vaccination, there will be healthcare utilization impacts with reduced influenza-related phone calls, outpatient visits, and admissions. Influenza laboratory testing will also be reduced.

Objective

This paper covers the initial analyses of phase 2 of the immunization project, as the scope expanded nationally. Goals for the immunization pilot include the following: increased access to vaccinations by Veterans, enhanced vaccination rates, and improved data collection. Internal analysis of the Phase 1 results suggested that the immunization project is improving Veteran access and reaching a new population of Veterans. Therefore, Phase 2 analyses focused on confirming, identifying, and quantifying the impact on Veteran access. Phase 2 analyses leveraged Geographic Information System (GIS) to analyze geographic distribution of Walgreens sites providing immunization services, existing VA facilities, and residence of affected Veteran populations. The goal is to assist VA leaders and stakeholders to visualize how the immunization project is expanding Veteran Access.

Methods

We considered all Walgreens claims submitted to VA for the months of September 2014 through March 2015. The claims were matched against VA’s master patient index to confirm Veteran eligibility using patient matching algorithms and criteria according to established VA practices. Only claims with a confirmed “match” were considered in this analysis.

For each confirmed claim, travel distance was calculated between the Veteran’s home and the Walgreens store administering the immunization. The street addresses of the Walgreens stores were provided by the Walgreens national office. Due to Veteran privacy concerns, only the Veteran’s home zip code reported on the Walgreens claim was available for analysis. Therefore, travel distances were calculated from the centroid of the Veteran’s home zip code.¹ The ArcGIS Desktop program² from the Environmental Systems Research Institute (ESRI) was used to calculate the straight-line distance from the centroid of the Veteran’s home zip code to the Walgreens location where they received their immunization. Straight-line, or Euclidean distance is the minimum distance between points.

In addition, we also retrieved the location of the VA facility the Veteran frequents, based on the Veteran’s VA records and site ID, and calculated the corresponding travel distance using the same methodology as above. For Veterans who frequents more than one VA facility, the distances to each VA were calculated, and then averaged travel distance was used for the comparison.

To estimate the travel distances saved by Veterans, we only considered situations where the choice of being immunized at Walgreens led to a reduction in travel. Since these Veterans were eligible for free immunization at VA and had already received care at VA in the past (as shown by the presence of their medical records), any Veteran who traveled further than their usual VA facility to visit a Walgreens store further away were clearly not motivated to reduce travel distances, and had elected to visit Walgreens for a different reason. We also examined each Veteran’s VA visit records to determine whether they had VA visits during the influenza season before and after their Walgreens immunization.
Results

For the seven-month period between September 2014 and March 2015, there were 8,809 confirmed claims submitted by Walgreens for immunizing Veterans. Of these 8,809 claims, 827 (9.4%) had poorly formatted zip codes (neither 5 nor 9 digits), unused zip codes, or unused Walgreens store numbers. The remaining 7,982 claims were mapped to the Veteran’s home zip code (Figure 1) and used for the following travel distance analysis. Straight-line distances were calculated for each validated claim from the centroid of the Veteran’s zip code to the specific Walgreens location and the VA facilities the Veteran frequents. A further 473 (5.3%) claims where the Walgreens site visited was further away than the Veteran’s usual VA site of care. The results are shown in Figure 2. As can be seen from Figure 2, travel distances to Walgreens for these Veterans are usually 5 miles or less, whereas travel distances to VA facilities are usually 40 miles or more. After excluding Veterans who traveled to distant Walgreens for immunizations, who were presumably not motivated by reductions in travel distances, we found that during the 2014-2015 influenza season, these Veterans avoided a total of 2,055,240 miles by traveling to a near-by Walgreens store as opposed to their usual VA facility.

![Map of Veterans by 5-Digit Zip Code](image)

**Figure 1.** Number of Veterans by 5-Digit Zip Code, September 2014 to March 2015

When these Veterans’ VA visit records were review, 55% of the Veterans had one or more visits to VA facilities between the start of the influenza season on September 1, 2014 and the day when they were immunized at Walgreens. These were missed opportunities to vaccinate Veterans earlier. Further comparison of the Walgreen visits and VA visits were graphed below in Figure 3. Seventy-six percent (76%) of Veterans immunized at Walgreens visited a VA facility after their Walgreens immunization during the 2014-2015 influenza season. However, there was an average of 45 calendar days between their Walgreens immunization and the following VA visit; this represented days of extra protection against influenza and related illnesses even when compared to the ideal case that all Veterans were immunized at their next VA visit. Of the other 24% of Veterans who did not visit a VA facility during the influenza season after their Walgreens immunization, one percent (1%, the red slice in Figure 3) did visit VA prior to their Walgreens immunization; these were lost opportunities that VA never had a chance to correct. The remaining 23% never visited a VA facility during the entire 2014-2015 influenza season. It is quite possible that these 23% of Veterans would never have been immunized without this Retail Immunization Care
Coordination program. At the very least, it is certain that VA would never receive the immunization records of these Veterans without the Retail Immunization Care Coordination program, and they will erroneously remain on the unimmunized list for VA’s population health programs.

**Figure 2.** Veteran travel distances to VA versus Walgreens

**Figure 3.** Proportions of Veterans who visited VA before or after Walgreens
Discussion

This study applied GIS analysis techniques to the immunization claims submitted by Walgreens to VA in two ways: graphic visualization of geospatial distribution, and quantitative analysis of travel distances. Each claim used for this analysis represented a confirmed Veteran whose demographic information matched closely to the records in VA’s Master Veteran Index (MVI) database. In addition, the Veterans’ VA visit records were compared against their Walgreen immunization records to examine their chronological relationships. While the study is limited by the use of the Veteran’s home zip centroid and straight-line distance, these limitations applied equally to both Walgreens and VA facilities, so the impact on the travel distances compared should be minimal, and if anything, probably resulted in a conservative, lower-bound estimates of distance traveled.

Whereas Phase 1 of the immunization program was limited to VISN 8 in the State of Florida, the claims analyzed were from Phase 2 during national deployment. Visual inspection of Figure 1 confirmed the national nature of phase 2 of the immunization program, with activities shown in every state, including Alaska and Hawaii. In addition, it should be observed that several sites appeared to have higher activities than Florida, the original pilot sites. This confirmed the success of the Phase 1 pilot, and the resulting decision to deploy the immunization program nationally.

In addition, the distances traveled by these Veterans to receive immunization at Walgreens were estimated and detailed in Figure 2. It can be seen that the great majority of Veterans (73%) traveled more than 40 miles to their usual VA facilities, the distance under which the Veteran Access, Choice, and Accountability Act of 2014 (VACAA) used to define excess travel. While this is not a strict determination of VACAA eligibility, since VACAA used nearest VA facility whereas this study used the VA facilities the Veterans frequent, it nonetheless illustrated the significant travel burden for this group of Veterans. While this study did not include a direct comparison against the distances these Veterans would travel to the nearest VA medical facilities, comparison against published literature presented a very favorable picture. In 2006, Probst and her colleagues analyzed the 2001 National Household Travel Survey (NHTS) data collected by the US Department of Transportation, and found that national average distance traveled for medical and dental care was 10.2 miles. In 2010, Jeremy Mattson reported that the median distance traveled for healthcare services is 5 miles for routine health checkups, 9 miles for chronic healthcare visits, and 5 miles for emergency care. In contrast to the travel distance to VA facilities, only 7% of Veterans traveled more than 40 miles to Walgreens, seventeen percent (17%) traveled between 10 to 40 miles, fifteen percent (15%) traveled between 5 to 10 miles, and 60% traveled less than 5 miles. Using standard IRS mileage rates of 55 cents per mile for the estimated 2,055,240 miles saved by Veterans from travelling to a near-by Walgreens store for influenza vaccination, this is a savings of $1,182,000 ($0.55/mile x 2,055,240 miles) for Veterans. This study did not attempt to determine or estimate proportion of Veterans for whom VA provided transportation, travel assistance or reimbursements, which would further increase total travel cost and VA-specific costs.

As illustrated in Figure 3, 2,051 Veterans who never visited VA during the 2014-2015 influenza season were immunized at Walgreens, in addition, 6,908 Veterans were immunized earlier than their next VA appointment, gaining 323,328 days of protection against influenza and related illnesses. Based on the estimates reported by Duncan et al. in their cost benefits model, we estimated societal savings of $663.56 and $125.24 respectively for senior vs. adult Veterans who would not have been immunized otherwise. Using the same data set from the Duncan model, we also estimated the marginal benefit of earlier immunization at $3.16/day and $0.60/day respectively for senior vs. adult Veterans. Applying these estimated for the 2,051 Veterans (759 seniors, 1292 adults) who never visited VA during the 2014-2015 influenza season resulted in estimated societal savings of $665,452 (759 x $663.56 + 1292 x $125.24) and the 323,328 day of earlier influenza protection resulted in $499,492 (119,631 senior days x $3.16/day + 203,697 adult-days x $0.60/day) estimated savings.

Tallying the three sources of Veteran, VA, and societal savings from the Retail Immunization Care Coordination program during the 2014-2015 influenza season, we found a total estimated saving of $2,346,000. This compares quite favorable to the total VA expenditure for the 2014-2015 Retail Immunization Care Coordination program of $250,000, a mere 10.6% of the estimated savings.

Conclusion

By applying GIS analysis techniques, we were able to show how Phase 2 of VA’s Retail Immunization Coordination Program with Walgreens is improving Veteran access and furthering Veteran health. We first demonstrated how
Phase 2 of the immunization program had improved Veteran access by expanding the coverage beyond Florida to cover every state in the nation. We then estimated savings of $1,182,000 for Veterans from reducing more than 2 million miles in travel. We also estimated more than $1 million savings from earlier immunization and reaching unserved Veterans. We conclude that Phase 2 of the immunization program had improved Veteran access to healthcare, and VA should continue to expand the program with other private sector partners and additional services.

Automated Detection of Privacy Sensitive Conditions in C-CDAs: Security Labeling Services at the Department of Veterans Affairs

Omar Bouhaddou, PhD², Mike Davis, MS¹, Margaret Donahue, MD¹, Anthony Mallia³, Stephanie Griffin, JD¹, Jennifer Teal, RHIA¹, Jonathan Nebeker, MD¹

Abstract
Care coordination across healthcare organizations depends upon health information exchange. Various policies and laws govern permissible exchange, particularly when the information includes privacy sensitive conditions. The Department of Veterans Affairs (VA) privacy policy has required either blanket consent or manual sensitivity review prior to exchanging any health information. The VA experience has been an expensive, administratively demanding burden on staff and Veterans alike, particularly for patients without privacy sensitive conditions. Until recently, automatic sensitivity determination has not been feasible. This paper proposes a policy-driven algorithmic approach (Security Labeling Service or SLS) to health information exchange that automatically detects the presence or absence of specific privacy sensitive conditions and then, to only require a Veteran signed consent for release when actually present. The SLS was applied successfully to a sample of real patient Consolidated-Clinical Document Architecture (C-CDA) documents. The SLS identified standard terminology codes by both parsing structured entries and analyzing textual information using Natural Language Processing (NLP).

Introduction
With increased care coordination across organizations and the need to comply with Meaningful Use requirements of the HITECH Act, more Health Information Exchanges (HIE) are happening, but providers are struggling to both share clinical information and remain in compliance with applicable privacy laws, as documented by the Office of the National Coordinator (ONC)¹. The Department of Veterans Affairs (VA) estimates that about 75% of Veterans receive part of their healthcare in the private sector and need information exchange. Title 38 U.S.C. § 7332 requires VA to obtain a signed authorization from Veterans whose health record contains one of four privacy sensitive conditions: diagnosis of HIV or sickle cell anemia, and diagnosis and treatment of drug and alcohol abuse, before disclosure to an outside entity². In the paper world, the VA Release of Information (ROI) offices manually review any request for health information, and assesses whether the information includes any privacy sensitive conditions (i.e., 7332-protected). If it does, then a signed authorization is obtained from the Veteran. If not, then the information is disclosed without patient authorization, as already permitted by the HIPAA Privacy Rule. In electronic HIE, no one is manually attending to the record sharing transaction which happens automatically over the eHealth Exchange network³ or when using the Direct Project⁴. VA’s current approach to comply with this requirement in the electronic exchange world is to always obtain a signed authorization, whether or not the information to be shared contains privacy sensitive conditions. This has been the strategy because the information disclosed is not reviewed manually and a reliable method for automatic detection of privacy sensitive conditions was not available.
While requiring that all Veterans sign an authorization is effective in meeting 38 U.S.C. § 7332 regulation, this universal opt-in model has placed an unnecessary burden on the majority of Veterans whose records do not contain these conditions and whose information could otherwise be exchanged without an authorization. Opt-In means that Veterans wishing to make their information available for exchange must actively express their privacy preferences by means of a signed written request (e.g., authorization). Over the last 5 years, the VA HIE program managed to collect 270,000 authorizations (3% of the 8.76 million actively enrolled Veterans). Today, 62% of the authorizations are collected on paper, while 38% are e-signed online. These authorizations are only valid for 5 years and 1/5 needs to be renewed each year. At this pace, to provide coverage for all enrolled Veterans, it would take 162 years! Finally, the low rate of Veterans participation contributes to the low rate of HIE transactions and missed opportunity for care coordination and outcome improvements.

This situation is not unique to VA. In addition to Title 38 U.S.C., there are many laws and regulations protecting the sharing of sensitive data, including HIPAA Privacy Rule, 42 CFR Part 2, Genetic Information Nondisclosure Act (GINA) of 2008, and many types of sensitive data, including Domestic Violence, Sexual Activity, HIV, STDs, Substance Abuse, Mental Health, Reproductive Health, VIPs, and Employees. Since reliable detection of privacy sensitive information has been considered beyond the capabilities of most HIEs, organizations tend to either adopt a universal opt-in consent model or simply do not share data from potentially sensitive categories.

This paper presents a proof of concept that challenges the current assumption. It assesses the reliability of a Security Labeling Service (SLS) that would automatically detect privacy sensitive conditions within the documents currently exchanged by VA with private sector healthcare providers. The format of these documents follows the Health Level Seven (HL7) standard Consolidated-Clinical Document Architecture (C-CDA) template, which is an XML format with a human-readable block (mostly text) and computable structured entries with coded information. The SLS complies with several HL7 standards including the Data Segmentation for Privacy. It parses coded information structured entries in C-CDAs and uses Natural Language Processing (NLP) for text blocks to distinguish records containing privacy sensitive conditions, requiring authorizations, from those that are not sensitive and do not require an authorization. The objective is to achieve effectively zero false negative (normal) results while at the same time minimizing false positive (restricted) results. The success of this proof of concept and follow-on studies could lead to substantial benefits by reducing the authorizations needed when no 7332-protected conditions exists. It would constitute a major milestone toward the ability to share millions of records automatically, increase provider adoption of HIE through less restrictive consent management for information that is not sensitive, and substantially reduce costly paperwork and burden on Veterans and VA staff.

Methods

The SLS uses a list of sensitive codes from standard terminologies (e.g., ICD-9, ICD-10, SNOMED CT) against which it compares the codes found in the C-CDAs. The codes in the C-CDAs are found either in the structured entries, as required by Meaningful Use Certification or are derived from NLP parsing of the textual information found in the narrative blocks and embedded reports in the C-CDAs. If any code found is part of the sensitive codes list, then the record is labeled ‘restricted’ and cannot be exchanged without patient authorization. If no data in the C-CDA is part of the sensitive codes list, then the record is labeled ‘normal’ and potentially could be exchanged without authorization.
Figure 1 describes the experimental design. A population study was identified from VA’s Corporate Data Warehouse (CDW) by selecting 90 patients with known privacy sensitive conditions and 30 at random (unknown). A C-CDA was generated for each patient and these C-CDAs were anonymized using a strict protocol. SLS scanned all 120 documents and produced a security label and explanations for each. A VA Release of Information (ROI) specialist reviewed the 30 ‘unknown’ documents and marked whether they were restricted or normal. The results were tabulated and analyzed by two of the authors.

Figure 1: Experimental design implemented in the SLS proof of concept.

The CDW query generated 40 for each protected condition but by the time we had generated the CCDAs (some failed to generate), we got a reduced control list of 32 HIV, 29 SCA and 32 Abuse which was 93 morbidities, but one record had two morbidities so there were 92 control records with morbidities. We also ended up with 32 unknowns.

SLS SOFTWARE DESCRIPTION
The SLS solution developed for this proof of concept is based on Health Level Seven (HL7) standards. Figure 2 below describes the SLS processing flow.

SLS parses and marks each C-CDA as normal or restricted. The SLS parsing is specific to the C-CDA Continuity of Care Document (CCD) template. The SLS scans the full document examining all structured entries for the presence of any privacy sensitive code. If one or more sensitive codes are found, then SLS documents what sensitive codes were found and what sections in the C-CDA they were found. Only if no sensitive codes are found does the SLS evoke the NLP engine to parse the text parts of the C-CDA (e.g., narrative blocks, embedded notes and reports). The NLP engine is the open source SPECIALIST NLP obtained freely from The National Library of Medicine. It parses the textual information in the C-CDA, identifies Unified Medical Language System (UMLS) codes by comparing words and word groups to UMLS concepts. The UMLS codes found are then expanded into their semantic mapping set and filtered down to the code systems that are part of the sensitivity codes list. These mapped codes are then compared to
Similarly to the code scan, the NLP scan does not stop at the first sensitive code found but parses all textual information in a C-CDA and identifies all privacy sensitive codes that exist.

**Figure 2**: SLS marks each C-CDA as restricted or normal and documents the sensitive codes found.

**Sensitivity Codes List**

This is a list of terminology codes representing the concepts of HIV, sickle cell anemia, drug and alcohol abuse in standard vocabularies, including ICD-9-CM, ICD-10-CM, HCPCS, CPT, SNOMED CT, LOINC, and RxNorm. A first draft of the sensitivity codes list was based on the publicly available SAMHSA list. VA Privacy and Health Information Management specialists refined this list by removing mental health conditions, since these are not ‘protected’ conditions within 38 U.S.C. § 7332, and by adding additional ICD-9-CM and ICD-10-CM codes missing. The list count is 3989 codes distributed across the standard coding nomenclatures as follows:

Table 1: Sensitive codes list distribution

</table>
The sensitive codes list used in this proof of concept is relatively crude. Experience with the proof of concept has taught us the critical role it plays in sensitivity and specificity of the results. In the discussion section, we provide guidelines for a more robust creation, maintenance, and governance process of this list.

**Sample VA C-CDAs**

It was determined that a sample of 120 C-CDAs would be used for the proof of concept. The count of 120 represents more a practical convenience as our objective was not statistical significance. Another practical consideration led us to divide the cases in one group of known cases (90) and another group of unknown cases (30). A query was developed and run against the VA Corporate Data Warehouse to select these cases. The 90 known cases where identified as having one of the diagnoses specifically recorded as the reason for the visit in the last 12 months: 30 HIV, 30 sickle cell anemia (SCA), and 30 drug/alcohol Abuse. We did not make an attempt to confirm whether these 90 cases were true or whether the sensitive information was found in the codes, the narrative text or both. The 30 unknown cases were selected at random. The result was a table of 120 unique patient names and index numbers, where 90 entries had a ‘1’ under HIV, SCA, or Abuse column, and 30 entries, corresponding to the unknown cases, had their columns left blank, as illustrated in Table 2, CONTROL section.

A team of volunteers generated and anonymized a C-CDA for each patient. An anonymization task (not de-identification) was deemed sufficient to minimize privacy risks during processing within the VA EHTAC lab. The team manually anonymized the C-CDA documents using an XML editor. Specific rules were developed, tested, approved, and consistently implemented to remove names, date of birth, social security number, addresses, insurance IDs and contact information from structured and unstructured information contained in the C-CDAs.

Finally, the volunteers created 30 PDF files for ROI staff review, by rendering the 30 unknown C-CDAs using the VA C-CDA style sheet.

**Metrics measured**

For each case (i.e., C-CDA), results from SLS were tabulated against known conditions and ROI assessment, as illustrated in Table 2, SLS section.

| Table 2: Illustration of results table showing sensitive conditions identified in CONTROL and detected by SLS for the sample case ‘12345’. |
|-----------------|-------------|-------------|-----------|-------------|-------------|-------------|-------------|
| **CASE**       | **HIV**    | **SCA**    | **Abuse** | **Normal** | **HIV**    | **SCA**    | **Abuse**   | **Normal** |
| 12345          | 1          |            | 0         |            | 1          |            | 1           | 0          |

For the known cases, the objective is to compare SLS to control conditions. In this case, we can estimate sensitivity as the True Positive (TP) rate which is TP / all Positives. We are also interested to measure False Negative (FN) (i.e., False Normal) and any False Positives (FP). A FP creates the need for an unnecessary patient authorization but it is not as consequential as a False Negative (FN), which could result in a breach or unauthorized disclosure. The known cases were selected because they contained at least one privacy sensitive condition (restricted). However, we don’t know whether or not they contain additional privacy sensitive conditions, which is why the other columns in Table 2, CONTROL section were left blanks. Consequently, we cannot estimate specificity or True Negative (TN) rate.

For the unknown cases, the goal is to compare the SLS against ROI assessment. To calculate the overall percent agreement we take the total number of times in which SLS and ROI agree and divide that by the total number of classifications made. Because ROI staff assessment stopped at the first privacy sensitive condition found, we cannot
assess whether the SLS over detection are true positives, unless each case is reviewed by an impartial third-party and the detected conditions confirmed or denied.

Results
The proof of concept results are not expected to be statistically significant and no final decision is projected. However, we hope it would hold enough promise to pursue a more formal scientific study, upon which policy, business, and technical implementation decisions can be made.

Table 3 shows the exact count of Known conditions and detected conditions by SLS. Table 4 shows the exact count of conditions detected by ROI staff and SLS, in the Unknown cases. In both tables, SLS seems to have detected the sensitive conditions present, but also detected a few more. Table 5 and 6 take a closer look at these results, in terms of true positives and agreements.

</tr>
</tbody>
</table>

Table 5 shows that for every known case, SLS was able to detect the existence of the known condition in the case: HIV, SCA, or Abuse. Therefore, the SLS sensitivity for known positives is 100%. Also, for all known cases (all restricted), SLS never mislabeled a case as normal. Therefore, the FN rate is 0% and this is very good news as FN is the error we wanted to eliminate. However, SLS over detected many more conditions (HIV and Abuse) per case than were known as described in the section below. True FP and TN cannot be calculated, because we don’t know the status.
of all privacy sensitive conditions in the Known cases, unless we inspect them manually. Only TP and FN rates can be estimated. Consequently, specificity cannot be estimated.

**Table 6**: SLS agreement with ROI staff on Unknown cases.

<table>

</tr>
</tbody>
</table>

In Table 6, we note again that, every time ROI staff said a case was restricted, SLS agreed (100% agreement). This means that there was no case where ROI staff identified a privacy sensitive condition but SLS mislabeled it as normal. However, SLS detected additional sensitive conditions in several cases. Despite this over detection, out of about 75% Normal (25/33) determined by ROI, SLS found about 25% (9/33). This 25% is the low estimate of the auto opt-in that SLS could clear, in other words, of the benefits of SLS. Further, the over detection can be easily corrected, as discussed below.

**SLS OVER DETECTION OF FALSE POSITIVES**

There were several cases where SLS over detected an HIV condition that, after inspection, did not confirm as a true positive. This was due to the NLP limited interpretation of questionnaires and negations. Free-text questionnaires would often include discussion about patient being offered an HIV screening and declining. In other cases, Veterans accepted HIV testing and had negative results. SLS interpreted these lab results correctly and did not label them as positive. In one case only, an HIV misdiagnosis was made and later disputed by the patient and corrected in the notes. There was no FP in the case of sickle cell anemia. In the case of alcohol/drug abuse there were many FPs. Again, many were due to NLP of questionnaires and the handling of responses. Questions on alcohol use with answers of ‘no’, ‘never’, ‘occasionally’, etc. were counted as positive. Another contributor factor to FPs was the inclusion by mistake of ‘nicotine/tobacco use’ in the sensitive codes list.

**CODES VS. NLP**

The NLP was evoked only if there were no sensitive codes found in the C-CDA structured entries. As shown in Table 7 below, NLP was used only minimally. In other words, C-CDA structured entries provided the source of truth for the large majority of cases. SLS found multiple privacy sensitive conditions per record, particularly Drug/Alcohol abuse due to its systematic inclusion in questionnaires.

**Table 7**: Use of C-CDA structured entries codes vs. NLP of textual information.

</tbody>
</table>
Because our relatively simple approach to NLP, we had many false positives. We examined what the SLS results would be without the NLP. We found that SLS would ‘miss’ 5 sensitive conditions: 3 HIV and 2 sickle cell anemia. Are these conditions really false negatives? Upon closer examination, we found explanations for each case, as described below:

- **HIV cases**: the first case was selected because of the presence of the ICD-9 code for Kaposi’s sarcoma. This code was not included in the sensitive codes list, which explains why the code search did not find it. The NLP found a lab test of ‘HIV SCREEN Ag/Ab’ with a result of ‘Nonreactive’, which it counted as positive. NLP needs to do better with textual lab test results. The second case was similar to the first, except that NLP labelled it positive because of a questionnaire item of ‘Have you tested positive to HIV? No’. The third control case had the ICD-9 code 079.51 HUMAN T-CELL LYMPHOTROPHIC VIRUS. This code was missing from the sensitive codes list, which is why a code scan could not find it. NLP found it because of the question ‘HIV Status: Unknown’.

- **Sickle cell anemia cases**: The first case was selected as a control for a reason (code) yet to be determined. The C-CDA did not include a coded entry in the problem section for sickle cell anemia. The NLP labelled it as sickle cell anemia because it found a ‘provider comment’ of ‘sickle cell trait’ associated to the non-specific code ‘Anemia (ICD-9-CM 285.9)’. In the second case, an independent review of the patient complete medical record confirmed the presence of sickle cell anemia (ICD-9 282.5) diagnosis. However, the C-CDA did not include this entry in the problem section for a reason yet to be determined. This explains why SLS code scan did not find it. However, NLP found it because of this entry in the problem list: ‘sickle cell trait (ICD-9-CM 799.9)’. ICD-9 code 799.9 is not a sensitive code because it is a generic code used to allow users to enter a free-text entry when no appropriate ICD-9 code is found in the problem list.

**Discussion**

We noted considerable improvements with successive refinements of the sensitive codes list, over the multiple runs of the SLS. Going forward, it is imperative that a more concerted effort be given to the creation, maintenance and governance of this list. This effort must bring together a governance board including clinicians, privacy, medical record coding, terminologists, security architects, interoperability specialists, and others. It would take into account that certain diagnoses are markers for others (e.g., Kaposi’s sarcoma and HIV). Some lab tests can be ordered for multiple reasons. Medications can have multiple indications and out of label use (e.g., acyclovir). Diagnoses are more specific than lab tests or medications. Finally, it would be created from existing lists, and eventually converge toward a well-defined standard terminology subset.

Also, we found one particular quality issue with the EHR data. The code ‘042.’ was associated with a diagnosis of HIV and missed by SLS in the early runs, as this code is not a valid ICD-9-CM code and was not in the sensitive codes list. The valid code is ‘042’ without the period. To address this issue quickly, we added the code ‘042.’ to the sensitive codes list. Also, we were careful with the use of spreadsheets to manage terminology codes, in particular in the case of ICD-9-CM codes because leading and trailing zeros can disappear in spreadsheets if cells are not formatted appropriately to allow for that (i.e., format as text rather than numbers).

Although the role of NLP was minimal given the extent to which VA C-CDA’s have coded data, the challenges of questionnaires and negations need to be better managed if we want to minimize false positives. We understand from experts in the NLP field that more sophisticated NLP engines address these issues and other studies have shown the benefits of combining NLP with scanning for codes to collect supplemental information. We plan to use these refined tools in the future.
The sample set was too small and not representative of the Veteran patient population to draw any conclusion from it. In the next phase of the project, we need a sample where all conditions are identified in a case so that both sensitivity and specificity of the SLS can be estimated.

Conclusion
Reliable automated detection of 38 U.S.C. § 7332 protected conditions in VA C-CDAs is possible! The SLS proof of concept was successful. Sensitivity of the detection of known cases was optimal and there were no false normal, meaning, there would be no risk of a breach because of a disclosure without authorization when required. This initial study may change the way VA handles electronic HIE disclosures in the future. However, before such a business and policy decision can be made, a larger and more rigorous study is needed. We are in the process of designing such a study that will be based on a larger sample of C-CDAs and would take place in the VA production environment, alleviating the need for anonymization. There are sophisticated commercial security labeling products, using advanced NLP and comprehensive sensitivity code lists. The objectives would be twofold: 1) confirm the reliability of the SLS performance, meaning high sensitivity and low or no false normal, and 2) estimate the percent of cases that can be reliably cleared through this automatic detection process and the benefits associated. If successful, then the VA can integrate SLS and electronic HIE. An SLS could also become a support tool for the manual ROI process. Finally, beyond Title 38 U.S.C., there are other labeling that can benefit from SLS such as VA Employees, VIP records and Meaningful Use 2016 security labeling.

Abstract

The “Box model” allows users with no particular training in informatics, or access to specialized infrastructure, operate generic cloud computing resources through a temporary URI dereferencing mechanism known as “drop-file-picker API” (“picker API” for sort). This application programming interface (API) was popularized in the web app development community by DropBox, and is now a consumer-facing feature of all major cloud computing platforms such as Box.com, Google Drive and Amazon S3. This reports describes a prototype web service application that uses picker APIs to expose a new, “cloudified”, API tailored for image analysis, without compromising the private governance of the data exposed. In order to better understand this cross-platform cloud computing landscape, we first measured the time for both transfer and traversing of large image files generated by whole slide imaging (WSI) in Digital Pathology. The verification that there is extensive interconnectivity between cloud resources let to the development of a prototype software application that exposes an image-traversing REST API to image files stored in any of the consumer-facing “boxes”. In summary, an image file can be upload/synchronized into a any cloud resource with a file picker API and the prototype service described here will expose an HTTP REST API that remains within the safety of the user’s own governance. The open source prototype is publicly available at sbu-bmi.github.io/imagebox.

Availability

The accompanying prototype application is made publicly available, fully functional, with open source, at http://sbu-bmi.github.io/imagebox. An illustrative webcasted use of this Web App is included with the project codebase at https://github.com/SBU-BMI/imagebox.

Introduction

The advantages of user-facing cloud computing are particularly hard to realise for specialized image analysis applications because of the dependence on specialized libraries and infrastructure, as is the case for the popular Open Slide platform [Goode 2013]. The challenge of presenting image analysis solutions to those that do not have those specialized resources is significantly compounded if they target large images in private stores. In other words, image informatics applications are currently dependent on specialized informatics infrastructure operated by specialized human resources. This is of course not to the demerit of the specialized
libraries themselves, such as the excellent OpenSlide, it instead reflects a missing component in the cloud computing landscape. Two of the most compelling scenarios where these challenges arise are a) when one or more regions in a whole slide image needs to be object of a specialized analysis; and b) when a private image needs to presented to a domain user that does not have access to web-facing image analysis infrastructure (which is the norm rather than the exception).

The immediate motivation for this work is to address requirements associated with the set of intense research efforts that focus on linking morphologic and molecular cancer characterizations and to make use of combined imaging and molecular signatures to substratify patient populations to predict outcome and response to treatment. A number of reports by the National Cancer Institute describe efforts being carried out by the pathology and radiology research communities to link imaging phenotypes with large-scale genomic analyses, ultimately informing personalized medicine clinical trial designs such as NCI-Match (https://clinicaltrials.gov/ct2/show/NCT02465060). Characterization of tissue morphology related phenotypes is a complex effort that requires the development and deployment of a variety of pipelines, many of which require flexible access to image sections. Accordingly, the cloud API mediator described here was developed in the context of Pathology images. However, this “cloudification” approach is equally applicable to other image analysis infrastructure scenarios such as those involving Radiology.

These challenges of commoditized and portable biomedical informatics analysis are of course not a problem exclusive of image analysis applications. Novel REST API architectures are indeed emerging to address them as a generic solution. Specifically, cloud computing infrastructure has responded with new interoperability models [ONC 2015], as illustrated by the central role of the HL7 FHIR API (https://www.hl7.org/fhir), which create novel opportunities for architecturing distributed whole slide image processing. These opportunities for RESTful interoperation are assessed in this report through the use of the accompanying webApp application prototype, which places no demands on the user beyond the client Web Browser. In other words, the functionality of the “cloudified” image traversal API it validated by a prototype Web Application. This application will seek to engage the “Box / file picker” application programming interface (API) exposed by a Box cloud resource, which have emerged to interoperate with infrastructure of a wide variety of cloud providers. Picker APIs, after successful authentication (typically using OAuth 2.0), expose temporarily dereferenceable URLs which can be picked up by cloud-based applications in order to make full use of the high connectivity that characterizes hosting data centers.

The development of high performance “slice servers” (which extract slices of different regions, at different scales, from large image files) has also advanced significantly, as illustrated by the open source IIP project (iipimage.sourceforge.net). Furthermore, the ability to approach image analysis either as a web service or as computation entirely on the client side has also been object of considerable attention. The former is typically a commercial application, such as Aperio’s ePathology product [Leica 2015], and the latter is typically an Academic exploit, such
as our own [Almeida 2012]. As a result of these advances in portable image presentation, the obstacles to a consumer-facing approach to interact with large images, wherever they may be, is now reduced to the enablement of an easily distributable programmatic interoperability mechanism.

These developments place the picker API at an interesting intersection between cloud computing and high performance slice servers. As regards Biomedical applications, this intersection has, however, been associated with lack of sufficient security and privacy to allow users such as Pathologists and translational researchers. This final obstacle to exploring cloud (HTTP REST) API implementation architecture was also removed in recent times by the adoption of HIPAA compliant practices by a number of cloud providers, such as Box.com [Box 2015], Google Drive [Google 2015], and Microsoft OneDrive [Microsoft 2015].

Methods

ImageBox WebApp

The imageBox Web App was developed entirely as a within browser application, using only the Web’s “assembly language”, JavaScript. This approach, which relies exclusively on the Web Platform (webplatform.org) and W3C open standards, leads to applications that are assembled directly in the web browser of the user, with no requirement for software download and installation, concern about native library dependencies or exposure of sensitive data to third parties. As a consequence, the imageBox Web App was developed in the public domain with open source and version control from its onset (https://github.com/SBU-BMI/imagebox). The fully functional application itself is served directly from GitHub by maintaining the application code in the “gh-pages” branch (i.e. live Web App served at sbu-bmi.github.io/imagebox). This signifies that the imageBox Web App is being delivered with versioned hosting, such that sites like https://rawgit.com can expose individual versions programatically.

TCGA images

The operation of ImageBox was tested for whole slide images of The Cancer Genome Atlas. These images were both called directly from TCGA’s public web directory, or where downloaded to private Box.com and DropBox folders. The latter served the purpose of validating the desired alignment of imageBox with the governance of private whole slide image files without compromising the content of the hosting folder (see File-picker API below and also Discussion). At the time of writing this report, the public folder with tens of thousands of TCGA images for all 30+ tumor types can be found at https://tcga-data.nci.nih.gov/tcgafiles/ftp_auth/distro_ftpusers/anonymous/tumor/<tumor-type>/bcr/nationwidechildrens.org/tissue_images/slide_images/, using the codes for <tumor-type> listed at https://tcga-data.nci.nih.gov/tcga. For example, for Glioblastoma Multiforme, the TCGA slide image folder would be at
https://tcga-data.nci.nih.gov/tcgafiles/ftp_auth/distro_ftpusers/anonymous/tumor/gbm/bcr/nationwidechildrens.org/tissue_images/slide_images. However, NCI has announced the intention of moving access to public TCGA data to the new Data Commons resource at https://gdc-portal.nci.nih.gov, so in the future the URL composition may need to be redirected to that new resource.

File-picker API

The implementation of the file-picker API mechanism varies between “Box providers” (cloud resources that expose file-picker APIs, see Introduction) even if they deliver the same final result: a uniquely dereferenceable URL. The two Boxes tested by imageBox are Box.com and DropBox. The details of their file-picker APIs can be found, respectively, at https://developers.box.com/the-box-file-picker and https://www.dropbox.com/developers/dropins/chooser/js.

Cloud-hosted imageBox slicer

This component, represented as a cloud box and labeled “imageBox” in Figure 1, uses the Jetty server (http://www.eclipse.org/jetty) to handle whole-slide microscopy images upwards of 100,000 pixels by 100,000 pixels. To enable the imageBox tiling server to access the SVS image files, the Bioformats toolbox (http://www.openmicroscopy.org/site/products/bio-formats) was used, which was developed to read and write image data between different formats with a focus on digital pathology. As detailed in the project’s documentation page, this toolbox relies on the OME-Model (http://www.openmicroscopy.org/site/support/ome-model) to slice and scale image pyramids, and is then exposed by ImageBox API. To retrieve the OME annotation of a imageBox link, add “&format=json” and the end of a slice URL, which will otherwise return a pixel map.

Results

A prototype application (see Availability) was developed to engage a image tiling server (“slice server”, see Methods) as part of a file-picking API call to private cloud storage. This application was used to measure transfer and retrieval rates for both moving the full SVS file to a well connected (cloud) slice server, and then retrieving image sub-regions at different scales. As schematized in Figure 1, this cloud-based “imageBox” resource is equipped with a basic HTTP REST API to support its operation from a variety of applications and external services. The operation of the accompanying application (Figure 2) are used to build the diagram in Figure 1 and to obtain the values in Table 1. Since the whole slide SVS image is de-referenced from a URL, the full file can come from either a public image repository such as TCGA (The Cancer Genome Atlas) or from a private Box. The prototype application uses a TCGA hosted image as a default use-case, but the user is encouraged to point it to private accounts in Box.com and DropBox (Figure 2, see also videcast link in the project github page), as well as other SVS files.
in the public domain such as TCGA’s. As noted in the application user interface (see link under Box buttons), the approach can be extended to many more Box providers using their API directly, and through commercial proxy services such as filepicker.com.

Figure 1 - ImageBox implementation architecture. At the most basic level, by exposing an image traversing API (in red), the cloud hosted imageBox server acts as a cache for an IIP slice server. That is the case when the external whole slide SVS file is hosted in a public store such as TCGA’s (see Methods). The engagement of regular file-picker APIs of cloud stores such as Box.com and DropBox is the most novel aspect of this architecture, because it allows the serving of image slices without breaching the access constraints of the original image. A user can of course only push to imageBox the files she has access, and in response will receive the unique dereferenceable identifier of the private images being sliced. Finally, the slice URLs (see Figure 2) can be used by Web Apps and other client applications: see project github page for examples of direct use of imageBox from Matlab. This implementation architecture can therefore be straightforwardly extended (dashed lines) to image analysis services.
Figure 2 - Snapshot of accompanying ImageBox Web Application at http://sbu-bmi.github.io/imagebox, used to demonstrate interoperability features on the proposed slice distribution implementation architecture (Figure 1). A videocast of its usage is available in the project home page at https://github.com/SBU-BMI/imagebox.

The ImageBox application prototype was pointed to a variety of whole slide image SVS files in Box.com and Dropbox cloud folders, as well as in public folders such as The Cancer Genome Atlas (TCGA, see Methods for folder address). The ImageBox slice server (See Methods) was in turn hosted in Amazon AWS. Although transfer rates varied, we found that between the within-cloud resource components the values are consistently above 10 MBs, and are routinely twice that much (Table 1). The slice download rates, even when the client machine was in a network equipped with generous bandwidth, did not typically exceed 1.5 MBs. The more important number, however, is the availability of individual image slices resolving significant morphological features in under a second, and while placing no storage requirements on the client application. The support for slice URL’s (Fig.2, highlighted in yellow: click on “open in new page”) has two important attributes. The first one is that they are portable, readily dereferenceable, and can be analyzed and annotated by any client application without requiring the whole image. The second critical advantage is that they do not expose the original hosting source, as can be verified by noting that the same image is rendered with different URLs when retrieved from a private Box folder by two different users, or even by the same user in two different sessions. These values and behaviors can be verified by using the accompanying ImageBox prototype in Fig 2, or by visualizing the webcast on the project github page.
Table 1 - Example transfer rates from Dropbox to the imageBox in Fig 2 (http://Nitrous.IO). As is often the case, both resources use Amazon's AWS as their backend, which implies that benchmarking was in fact performed on 10Gbs connected AWS EC2 servers for both EBS-backed system volumes, as well as, SSD-backed system volumes. The reader is encouraged to generate their own measurements by using the accompanying imageBox application (see Availability).

As discussed in the next section, the scalability of the imageBox architecture benefits from the 10-fold faster within-cloud transfer rates. However, the scalability of the proposed implementation architecture does not: the faster rates only have an effect on the availability of the first slice for a given whole slide image. The slower “first slice” reflects its use as the event that triggers transfer of the full image to the in-cloud imageBox IIP server (Fig1, “imageBox”). The retrieval of subsequent slices benefits from its ready availability in the imageBox slide server (Fig1 “ImageBox”) for retrieval by a client application (Fig 1, “WebApps” and “Web Services”). It is really in these subsequent traversals of the pre-existing image that the promise of “cloudified” scalable image analysis is realised. Case in point, pathologically relevant image features, at any scale, should be resolvable by 1,000² and surely by 2,000² image slices. It is worth noting that the image analysis operations on such slices typically exceed the 1 and 4 secs, respectively, that it takes to retrieve them. In summary, with the imageBox implementation architecture, the slice retrieval ceases to be the limiting step, which then moves to the availability of distributed computational resources. Just as important, the nature and governance of those resources is now much broader than in the conventional architecture, for example when using OpenSlide, as will be discussed below.

Discussion

Given its well deserved popularity and wide use of OpenSlide [Goode 2013], this discussion of the imageBox implementation architecture has to start there. OpenSlide’s ensemble of an efficient C-based image server and a client side dynamic zoom library established and popularised the core features of availability and scalability of a slice server architecture in general. In that regard, the work described here lays on top of those achievements rather than
representing an alternative. The innovative element advanced by imageBox is the programmatic intermediation for distributed image analysis instead of visualization. Accordingly, the emphasis was placed on a) reducing the functionality of the slice server down to the bare minimum of responding to the selection of a scale and a pixel slice, b) wrapping the slice server as a cloud hosted HTTP REST service such that c) it could be programmatically operated not only for public image’s (such as TCGA’s), but also for images privately hosted in stores equipped with file-picker APIs (“Boxes”, see Introduction).

The novel operational features of the imageBox deployment architecture are particularly clear when considering a data-driven, consumer-facing approach. As the accompanying prototype demonstrates, the user of this Web Application does not have to download or maintain any server side resource. Correspondingly, the App developer does not have access, or maintenance responsibilities, to the slice server or the storage where the data is primarily hosted. In a nutshell, the imageBox implementation architecture was designed for full decoupling between application development and application usage. Although, along the lines of QMachine [Wilkinson 2014], one could distribute in-browser image analysis using approaches such as imageJS [Almeida 2012], a more immediate choice would be to expose established image analysis applications, such as 3D Slicer [Fedorov 2012], as web services. That approach, however, passes image sections to a remote location, which may raise privacy concerns or have logistical dependencies the domain user and third party client applications cannot control.

For the reasons discussed above, the prototype deployment accompanying this report stops with the demonstration that a web application (client) is able to retrieve image slices from whole slide images hosted in a private store (making use of the file-picker/Box API) without placing any requests that the user deploys or logs into a server side resource. Furthermore, the inspection of the slice URL composition will reveal a basic HTTP REST API which can be engaged from computational environments well suited for image analysis, not only 3D Slicer [Fedorov 2012] as noted above, but also general purpose image analysis environments such as Matlab (see project github repository for examples). Given the successful delivery of a functional prototype for SVS whole slide images, we would argue that one or more cloud based imageBox slice servers would be a valuable addition as public resource for researchers developing or consuming image analysis applications. We envision that such a resource would be further developed to support a wider range of image formats, and might be configured to accept only a preset list of origins for the full image files. In any case, by removing the need to download the full images and engaging the corresponding specialized analytical libraries [Teodoro 2013] [Ali 2013] programmatically, the imageBox architecture opens the distribution of domain facing applications to any Biomedical Informatics Group able to develop them. The critical data-driven nature of this architecture is that the application code can be executed by those with access to the data, without compromise of the image privacy or any requirement to support server side components. The advantages of the resulting consumer-facing architectures go beyond the promise of commoditizing specialized image analysis operations - they are at the very core of the emergence of new data-intensive disciplines studying disease [Colen 2014] such as Computational Pathology [Louis 2015, Roth 2015]. More to the point, the imageBox mediated
analysis of large images such as whole slides, is reduced to engaging the mediation of a HTTP
REST application programming interface (API) of a cloud computing resource.

Conclusion

The imageBox implementation architecture was designed to address user-facing large image
analysis scenarios. To demonstrate the feasibility of a data-driven deployment, a web
application was developed to call whole slide images in SVS format from both public (TCGA)
and private (Box.com, DropBox) stores. This open source application is made freely available at
s bu-bmi.github.io/imagebox both to demonstrate the feasibility of the imageBox architecture,
and to offer reference for other box deployments that may emerge to balance the load of their
usage. This report argues that the cost-effective distribution achieved in this manner identifies
novel opportunities for cloud-based image analysis along a path pioneered by other domains of
application such as computational genomics.

An Extended SNOMED CT Concept Model for Observations in Molecular Genetics

James R. Campbell MD1, Geoffrey Talmon MD1, Allison Cushman-Vokoun MD PhD1, Daniel Karlsson PhD2, W. Scott Campbell PhD1

Abstract

Molecular genetics laboratory reports are multiplying and increasingly of clinical importance in diagnosis and treatment of cancer, infectious disease and managing of public health. Little of this data is structured or maintained in the EHR in format useful for decision support or research. Structured, computable reporting is limited by non-availability of a domain ontology for these data. The IHTSDO and Regenstrief Institute(RI) have been collaborating since 2008 to develop a unified concept model and ontology of observable entities – concepts which represent the results of laboratory and clinical observations. In this paper we report the progress we have made to apply that unified concept model to the structured recording of observations in clinical molecular genetic pathology including immunohistochemistry and sequence variant findings. The primary use case for deployment is the structured and coded reporting of Cancer checklist© and biomarker data as developed by the College of American Pathologists(CAP) with collaboration by the Royal College of Pathology(RCP).

Introduction

Molecular genetic pathology is a new scientific frontier exploding on the practice of clinical medicine. President Obama pushed the issue to the fore when he announced the national agenda for research into personalized medicine1. Unfortunately the extensive work in developing and managing information in genetic research has not translated into ontologies of use in support and documentation of clinical practice. Of the reference terminologies cited by the Office of the National Coordinator (ONC) as required by the US healthcare information architecture2, only LOINC3 has significant content addressing observables in molecular genetics. Unfortunately the LOINC reference terminology model applied to molecular genetics does not capture important details such as laboratory methods4 or support needs of the domain ontology that would support re-use of observational data in epidemiology, research and clinical decision making5. Diverse efforts within the informatics community to develop a clinically useful observables ontology6-11 have been informative but none have gained broad acceptance for integration into the ONC terminology architecture for the electronic health record (EHR).

Laboring behind the scenes in worldwide terminology management, harmonization efforts by the International Health terminology Standards Development Organization (IHTSDO) and Regenstrief Institute (RI)12 have been quietly working to expand the expressivity and utility of observable entities and clinical findings for use in molecular genetic structured clinical data. An observable entity is a concept with semantic overlap between LOINC and SNOMED CT (<<363787002|Observable entity|) and can best be described as a conceptual model for the results of an observation – administrative, clinical, laboratory or otherwise. Although RI has served the informatics community for years providing LOINC codes for laboratory medicine and molecular genetic pathology, the lack of a domain ontology for these concepts means that the there is no terminology support for queries of aggregation or for defining features such as methods4,5. The harmonization work underway has developed a candidate unified concept model for genetic observables but the application of that work is not intuitive. This paper reports one small part of that effort focused upon the challenging issues of genetic biomarker observations in anatomic pathology supporting diagnosis and management of cancer.

The volume and types of molecular genetic data appearing in clinical medicine is growing exponentially. CAP first published cancer report protocols (checklists)13 in 1998 defining a minimum dataset for anatomic pathologists to
report when they evaluate surgical specimens concluding a diagnosis of cancer. Currently CAP publishes 82 separate checklists for various tissue pathways. The checklists were expanded in 2013 to include tumor biomarkers which have become referent findings required for staging and planning treatment.

The number of these genetic observations – regarding either the tumor or the patient – important to outcomes in cancer treatment has grown with the science. An example we encountered while modeling the colorectal cancer check sheet was “detection of the BRAF V600E sequence variant in the resected tumor”. This genetic finding has been studied and clinically validated to predict response to certain treatments in both colorectal cancer and melanoma. Historically the clinical pathologist could only detect genetic sequence variations by analyzing extracted tumor DNA for specific mutations in single genes that code for the mutant proteins they formed. Those tests yielded limited analysis of genetic material and were expensive and time consuming. With the successful mapping of the human genome and improved technology, high throughput sequencing of human and neoplastic genomes became possible. Next generation sequencing (NGS) yields relatively rapid turn-around of much more genetic sequence data. Anatomic pathology today employs both protein and nucleotide sequence data in the diagnosis, prognostication and selection of targeted therapeutic regimens for cancer.

Primary use cases for a domain ontology of observables are query support of findings aggregated by genotypic variant, tissue of origin and histologic appearance. Query use cases implied by this expectation might include: “Find all cases of malignancies that tested positive for the BRAF p.V600E (c.1799T>A) mutation”; “Find all patients who have tested positive for genetic predisposition to breast cancer”; “Find all cases of colon cancer in which no biomarker testing was performed”

The SNOMED CT concept model\textsuperscript{14} consists of a constrained set of relationships and accompanying target value sets allowed for incorporation within a computable concept definition. Allowed relationships and value sets are specified for domains of SNOMED CT, usually individual hierarchies. A SNOMED CT concept must also have at least one supertype (IS_A) relationship linking the concept within the hierarchy and a fully specified (context free) name which is the universal term denoting the concept. Each linguistic implementation of SNOMED CT can have one primary term and as many synonyms as required. When the concept model applied to the modelled SNOMED CT content is insufficient to fully define a concept, the concept is declared as Primitive. The SNOMED CT ontology is subjected to description logic classification prior to publication as an editorial quality check and to compute the inferred relationships implied by the application of the concept model. The concept model is not complete for all segments of SNOMED CT. For years the Observable entities hierarchy (\texttt{<<363787002|Observable entity|}) has been published as a hierarchy of Primitives employing only stated supertype relationships.

The IHTSDO expects that extensions of SNOMED CT may be authored, compliant with the concept model, that represent material necessary for parochial or research needs not appropriate for the international release of SNOMED CT. In the US, the National Library of Medicine (NLM) develops and maintains the US extension to SNOMED that is required for Meaningful Use compliance by EHR vendors. The University of Nebraska maintains the Nebraska Lexicon\textsuperscript{©} extension, dependent upon the US extension, which supports terminology needs of our Epic\textsuperscript{®} implementation and terminology development we have been supporting for the community since 2004. We report in this paper our use of this terminology authoring environment to develop, test and deploy an observables ontology for molecular genetics requirements of the CAP cancer check sheets.

Concept model development

The Observables and Investigation Model Project was formed by the IHTSDO in 2008 to develop a computable concept model for the Observable entity domain and prepare a model for interoperation of content with LOINC data sets. In summer of 2015, the project convened a meeting of experts from the NLM, CAP and Health and Social Care Information Center (HSCIC) of UK to discuss details of application of the proposed concept model to the set of observables necessary to the structured reporting of cancer checklists and biomarkers. During the meeting, data elements contained in the CAP colorectal check sheet and the Royal College of Pathologists (RCP) counterpart were reviewed and analyzed for semantics. Pathologists provided expert direction regarding the clinical meaning of each
element. Terminology experts then discussed the requirements and proposed templates for consistent application of a candidate concept model for observables. The deployment model for testing from that conference is pictured in Figure 1 for an Observable entity in anatomic and molecular pathology. Each attribute for refining the meaning of a concept is shown along with the valuesets of target concepts that are supported as well as the associated cardinality of the relationship. Non-defining relationships, called qualifiers, are pictured in brown in this figure.

![Figure 1. Harmonized observable concept model](image)

Application of this model was reasonably straightforward for conventional observations in surgical pathology, requiring only model extensions of SNOMED to include 8 Properties and 4 Techniques. The Colon cancer checklist which we first modeled required 61 new observable entities for anatomic pathology.

Consensus on application of this model to observables in molecular genetic pathology could not be developed in our first three meetings and a deployment strategy was only achieved at the Montevideo meeting of the IHTSDO in fall 2015. Criticisms emerging from initial discussions included: a) excessive numbers of primitives, b) insufficient semantic granularity in genetic structures and c) failure to support both protein-based and sequence-based observations. In order to meet these challenges we proposed employing Human Genome Nomenclature Committee\textsuperscript{15} resource data in our model by map reference to uniquely define nucleotide sequence entities (genes, microsatellites and other nucleotide segments) and to support the details of sequence data observations in Variant Call Format\textsuperscript{16}. We also employed representation of numbers in our model for nucleotide references\textsuperscript{17}. We proposed that a gene locus and other sequence based data could be defined in an expanded concept model specifying the gene locus as cellular substructures, specifically nucleotide sequences. These data were further characterized using the reference naming of the Human Gene Nomenclature Committee (HGNC)\textsuperscript{15} and the genetic datasets which it cross references such as the annotated genome reference Ensembl\textsuperscript{19}. An example concept model rendition for the B-RAF proto-oncogene as we defined it is included in figure 2. This particular concept definition employs sequence address
data from the Genome Reference Consortium GRCh38 release in GenBank\textsuperscript{20}, included in our publication by reference as a map data set. The map data which is shown in tabular form as an inset includes the HGNC reference number and a REST service call which will retrieve full HGNC reference data. Human protein products of gene transcription are currently implemented as primitive concepts in the 105590001|Substance| hierarchy.

**Figure 2.** Cellular structure model for BRAF gene locus

**Figure 3.** Immunohistochemistry observable: BRAF protein expression by immunoperoxidase staining
Once the reference genetic material was fully defined in SNOMED, we extended Techniques and Properties for molecular genetic pathology procedures. Immunohistochemistry observations could then be modelled. An example of an immunoperoxidase staining analysis for BRAF protein in a surgical tumor specimen is shown in figure 3. Immunoperoxidase and nuclear sequencing techniques are much more specific than the molecular procedures currently employed in LOINC 2.54 concept definitions. Therefore the observables concepts we have modeled for CAP checklists are generally semantic children of molecular genetic observables now in LOINC.

Nucleotide sequence observables were a particularly thorny issue we faced since input from our pathologist specialists required that we be able to store observations in our research databases with complete sequence data. An industry standard for identifying sequencing results has become the Variant Call Format\textsuperscript{16}. These data files issue findings of sequence variants when compared to a reference standard genome and are typically ASCII files of a few kilobytes. The report data structures complies with the recommendations for description of sequence variants issued by the Human Genome Variant Society\textsuperscript{18}. Once again, employing numbers as SNOMED CT values allowed us to extend findings data and to deploy Has value attributes in place of Has interpretation in an extended concept model for Clinical findings. Figures 4 and 5 show the Observable entity model for sequence data of the BRAF gene locus along with a positive clinical finding for the BRAF p. V600E (c.1799T>A) mutation detected in the excised tumor.
Application of the harmonized concept model and modelling of the SNOMED CT extension concepts to the recording needs of the check sheets was the first step in preparing a completely specified structured report for CAP cancer synoptics. For each observable entity representing a ‘question’ on the form, we further organized SNOMED CT value sets of ‘answers’ that would populate the attribute-value pair of the HL7 OBX segment. For the example of “BRAF protein expression by immunoperoxidase staining in excised malignant neoplasm” presented in figure 3, we show the corresponding section of the CAP check sheet for colorectal cancer in figure 6. Included in the figure is an inset with the Observable entity concept identifier, fully specified name and the complete valueset of choices that should be selected by the pathologist in the anatomic pathology system.

Figure 6. CAP check sheet for colorectal cancer; biomarkers segment for BRAF genetic observations

Results

Our deployment use cases are the 82 cancer and tumor biomarkers checklists published by CAP and supplemented by review with the RCP. There are many repeating observations across these checklists but our experience with deployment of our model for colon cancer required expansion of the Machine Readable Concept Model21 for the SNOMED CT hierarchies of Observables, Body structure and Clinical Findings. The magnitude of the new conceptual content in our Nebraska Lexicon© extension required for colon and breast cancer is summarized in table 1. This lists the number of new concepts by hierarchy which we developed for anatomic and molecular genetic pathology. The number of primitive concepts we required for each domain is also listed. In the fourth column we have listed an exemplar concept name from the content developed within that SNOMED CT hierarchy. This work has proceeded in collaboration with NLM, RI, IHTSDO, CAP and the RCP and was published on the NLM UMLS Knowledge Sources Server for public dissemination in July 2016. The work is available to all interested parties with a UMLS license.

Conclusion

As predicted, sequencing of the human genome has led to a proliferation of innovative scientific research with application to clinical medicine. We expect that new types of clinical knowledge will create challenges for recording, managing and using the clinical data that results from that research. While a number of efforts have been reported by the informatics community\textsuperscript{3-11} to organize or develop terminology models to serve for recording of clinical genomic data, only LOINC offers substantial content within the suite of ONC US standards. Unfortunately, the LOINC model does not offer the features of a domain ontology that are desirable for best query and retrieval of clinical data.

We have presented in summary form the results of a two year collaboration with clinical and terminology standards developers which represents only a new snapshot of harmonization work between the IHTSDO and RI in process since 2008. This report focuses on Observable entities for molecular genetic observations because they represent new challenges to the application of the SNOMED CT/LOINC harmonized concept model. Such advances are a challenging but important component of a comprehensive terminology model for twenty-first century medicine. CAP cancer check sheets offer one set of important use cases for clinical ontology development because they summarize anatomic and molecular genetic observations of established relevance for practice of precision medicine.

We have deployed this model for testing and evaluation by other informatics centers and published the work in collaboration with the NLM. We expect that this will stimulate dialogue with the informatics terminology community on the ontology model we have deployed. We hope to scale the work across the rest of molecular genetic pathology observations for cancer and expand the work into microbiology and human germline genetic disease testing.

The model we present interacts and draws upon NCBI resources and ontologies supported by the Genome Reference Consortium\textsuperscript{22}. We expect that the science in this field will continue to rapidly evolve and that new concepts and observations will emerge from that research requiring documentation in the EHR. The role of ONC terminologies and, more specifically clinical ontologies, should be to faithfully record those data and provide for query and re-use for purposes of clinical decision support, research and public health. We do not however, think it the role of SNOMED CT or LOINC to secondarily reproduce GRC reference data. For that reason, HGNC defining data sets are included in the model by map reference.

Analyzing SNOMED CT’s Historical Data: Pitfalls and Possibilities

Werner Ceusters, MD¹, Jonathan P. Bona, PhD¹
¹Department of Biomedical Informatics, University at Buffalo, Buffalo, NY

Abstract
SNOMED CT’s Release Format 2 (RF2) has been announced as an improvement over its predecessor, for instance because of its more consistent and almost formal approach towards describing changes in components over different versions, as well as changes in the structure of SNOMED CT itself. We explore two sorts of changes that are only partially formalized in RF2: the relationships between associative relations and reasons for inactivations as expressed in Association Reference Sets and Attribute Value Reference Sets on the one hand, and the various patterns according to which semantic tags appearing in fully specified names change over subsequent versions with or without being related to inactivations. We propose a data conversion methodology that combines assertions about SNOMED CT components into history profiles and use elements of these profiles to build Formal Concept Analysis contexts to discover valid implications that can render implicit assumptions hidden in SNOMED CT’s structure explicit.

Introduction
SNOMED CT [1], maintained by the International Health Terminology Standards Development Organization (IHTSDO) is a large healthcare terminology built around a concept-based ontology. Concepts are classified under several hierarchies, of which most of the top classes correspond roughly to the types of entities instances of which are encountered by clinicians during their work (body parts, diseases, substances, procedures, etc.) while other top classes correspond to types instantiated by descriptive elements of the SNOMED CT knowledge representation itself, for example classes denoted by terms such as ‘inactive concept’, ‘navigational concept’, and ‘core metadata concept’ [2]. In addition to active components – ‘component’ being the umbrella term used by IHTSDO for concept or relationship or description – SNOMED CT contains also inactive components which were active in one or more prior versions but at some point have been inactivated for one or other reason. Prior to July 2011 all releases were distributed in a format now known as ‘Release Format 1 (RF1)’. Release Format 2 (RF2) was introduced in 2012 in order to (1) implement a more robust and consistent representation of versions in which changes are tracked in a uniform manner in the core files themselves; (2) introduce reference sets as a more easily extensible and maintainable replacement for the RF1 representations of subsets for specific uses such as not only mappings to other biomedical terminologies and classification systems, but also to improve RF1’s history mechanism; and (3) create an added hierarchy to represent metadata about the structure of SNOMED CT itself [3, 4 p127].

The part of SNOMED CT that describes its own history has grown considerably over the years, as witnessed, for example, by the 105,313 inactive concepts – roughly 25% of the total concept count – which are annotated by 140,390 associations to other concepts or descriptions. For 99,489 of these inactive concepts reasons for their inactivations are provided. This comes on top of the 325,893 reasons for description-inactivations related to both active and inactive concepts. This raises the question whether the totality of assertions which are about changes in SNOMED CT rather than about external reality constitutes in and of itself a valuable resource to identify patterns that would allow the detection of mistakes in assertions about external reality that have thus far not been discovered. In other words: what can we learn about SNOMED CT’s mistakes committed in the past to detect still existing mistakes and prevent new ones? This sort of quality improvement being the ultimate goal of our efforts, the work described in this paper is the first phase of this endeavor during which we explored the history information included in the RF2 distribution of the January 2016 version of SNOMED CT to identify pitfalls and possibilities that should be taken into account for the development of novel error detection methods.

Changes in SNOMED CT
The content of SNOMED CT evolves with each release. Once released, SNOMED CT components are persistent and their identifiers are not reused [4, p45]. When a component becomes inactive this is indicated by the value of the active field, a field which is present in all components. Components continue to be distributed even when they are no longer active. This allows a current release to be used to interpret data entered using an earlier release. Within RF2, all changes in components are represented in the corresponding files by adding a new row, with the same component ID, a new effective time and any necessary change in the component values. As an example, Table 1 shows that the concept ‘301381004’ with FSN ‘Discomforting present pain (finding)’ was set to active in release 20020131 and to inactive in 20080131.

Legend: RelID = Relationship identifier; Active: (1) = active, (0) = inactive. Columns irrelevant for our purposes here are not shown. For readability, Attribute and Target identifiers have been replaced by their corresponding FSN – omitting ‘(attribute)’ – in the most recent version studied (January 2016).

Table 2 shows that during the life time of that concept, it underwent considerable changes in its reported relationships to other concepts after full DL classification. Table 3 demonstrates how changes in the descriptions of concepts are similarly logged. Only one description record with the same descriptionID field is current at any point in time. The current record is the one with the most recent Effective Time before or equal to the point in time under consideration. If the active field is false (‘0’), then the description is inactive at that point in time. If it is true (‘1’), then the description is associated with the concept identified by the conceptId field (not shown in Table 3).

Legend: Active: (1) = active, (0) = inactive. Columns irrelevant for our purposes here are not shown. For readability, Description Type identifiers have been replaced by their corresponding term – omitting their semantic tag ‘(core metadata concept)’.

RF2 replaces the ‘history mechanism’ implemented in RF1 [5] by means of Historical Association Reference Sets (HARS) and Component Inactivation Reference Sets (CIRS). HARSs (Table 4) are used to indicate, for example, which deactivated concepts are in one way or another related to other active concepts, and CIRSs (Table 5) to indicate the reasons for inactivating a component – such as errors, duplication of another component, and ambiguity of meaning [4, p506]. Records that express such association are called reference set members. The primary purpose of these
reference sets is to specify which (if any) of these associations should be followed in a fashion similar to following ‘Is a (attribute)’ relations when determining whether to retrieve a record entry previously coded with a concept that has since then been inactivated. Whereas ‘same as’ and ‘replaced by’ associations can be followed unproblematically, the solution for ambiguous concepts related by ‘possibly equivalent to’ associations is less clear-cut [4, p654].

**Table 4.** Historical association reference set types in SNOMED CT (modified from [4, p509])

**Methodology**

SNOMED CT undergoes changes of various sorts with each release. Most changes are recorded explicitly in the sense that there is a formal mechanism through which changes of this type are documented in one or other component of the SNOMED CT distribution files. Some types of changes, implicit ones, lack such a formal mechanism but can be retrieved through the implementation of algorithms not documented in the SNOMED CT documentation. In this paper, we report on the evolution of activations and inactivations of component instances as examples of an explicit type of change, and on the evolution of semantic tags as an implicit type of change. Both types of changes required specific data reorganization strategies. The results of these conversions were then analyzed using Formal Concept Analysis.

**Data reorganization of activations and inactivations**

We combined the explicit assertions about (in)activations in components and history information present in CIRSS and HARSs into one format. We kept track of in which versions assertions were made – and possibly also changed – through the construction of a history profile. Such profile contains for each of the 29 versions from January 2002 to January 2016 a marker indicating whether the assertion was in that version absent (A) or present, in which case it was either active (Y) or inactivated (N). Since the very same concepts can not only appear as referenced component in one HARS member and as target component in another HARS member, but also appear in members of distinct HARSs, it was possible to compute clusters of concepts by randomly selecting a concept from a HARS member and recursively collecting all reference set members in which this concept appears with the goal of processing each associated concept in the same way until no more concepts can be found. Table 6 contains assertions that were retrieved for one such cluster composed out of 5 related concepts. By ‘assertion’, we mean anything that inside SNOMED CT is explicitly
or implicitly stated as applying to a concept. Examples of explicit assertions are the inclusion of the concept 324253001 in the 1st version (‘Y’ in first position of the history profile in row 8), the inactivation of that concept in the 3rd version (‘N’ in 3rd position, row 8) and the reactivation of it in the 5th version.

Legend: concepts in cluster with most recent FSN: 324253001: Azithromycin 200mg/5mL oral suspension (product), 375558000: Azithromycin dihydrate 200mg/5mL suspension (product), 375559008: Azithromycin dihydrate 200mg/5 mL suspension (product), 376025007: Azithromycin dihydrate 200mg/5 mL powder (product). History profile: ‘A’: absent, ‘Y’: active, ‘N’: inactive.

These assertions are explicit because there are corresponding effective time and activation status assertions in the concept table. Similarly, there is in the description table the assertion that the semantic tag of this concept was in the 1st version ‘substance’ (row 7), while ‘product’ in the 2nd version (row 6). Examples of implicit assertions are, for instance, the ones to the effect that in the 1st version there was no mention of a sameness-relation between this concept and 375559008 (row 9) nor 375948007 (row 10).

Data reorganization for the evolution of semantic tags

We computed for each concept the evolution of what in SNOMED CT is called semantic tags. Descriptions provide for each concept a Fully Specified Name (FSN) most of which ‘end with a semantic tag in parentheses and which
indicates the semantic category to which the concept belongs (e.g. clinical finding, disorder, procedure, organism, person, etc.)’ [4, p41]. It is further stated that ‘the semantic tag helps to disambiguate different concepts which may be referred to by the same commonly used word or phrase’ [4, p41]. For example, it is the semantic tag ‘morphologic abnormality’ in the FSN ‘Hematoma (morphologic abnormality)’ that disambiguates the concept to which this FSN is assigned from a second concept with FSN ‘Hematoma (disorder)’. The former is intended to be used for what ‘a pathologist sees at the tissue level’, while the latter ‘represents the clinical diagnosis that a clinician makes when they decide that a person has a “hematoma”’ [4, p41]. As can already be seen in Table 6 (rows 6 and 7) concepts can be assigned different semantic tags over time, changes which for some, as exemplified by Table 7 are quite dramatic.

Data analysis

Exploratory statistical analyses were performed to find associations, or unexpected lack thereof, between the various sorts of assertions derived from the conversions. Specifically to mention here is Formal Concept Analysis (FCA), a mathematical theory for understanding the structure of data given as a set of objects described in terms of attributes they possess, which is done by representing the data as a concept lattice [6]. Every FCA concept – we will use explicitly the term ‘FCA concept’ to distinguish it from SNOMED CT concepts – has its extent (the set of objects that fall under the FCA concept) and its intent (the set of attributes that together are necessary and sufficient for an object to be an instance of the FCA concept. In [7], for instance, attributes were defined on the basis of the normal forms of pre-coordinated SNOMED CT expressions. For our analyses here, we created FCA attributes and corresponding objects on the basis of two contexts: (1) the co-occurrence of SNOMED CT HARS and CIRS attributes as described in Table 4 and Table 5 throughout the history of SNOMED CT concepts, and (2) the evolution of semantic tags over time. While FCA concept lattice diagrams have visualizing power when applied to domains with a small number of concepts and attributes governed by a simple organizational structure, they are rather useless in case of more complex situations as the one explored here. More useful here is the computation of attribute implications where an implication asserts a certain relationship between two attribute sets which are respectively called premise and conclusion: an implication is valid in the data set if every object that has all attributes from the premise of the implication also has all attributes from its conclusion. For example, if ‘being mammal’ and ‘being vertebrate’ would be attributes used to correctly describe animals, then ‘being mammal $\rightarrow$ being vertebrate’ would be computable as being a valid implication. The set of all valid implications can be reduced to a smaller set – the Duquenne–Guigues base – from which all other implications follow semantically [8], and a set of approximate implications known as Luxenburger base [6]. The latter are valid for a specified percentage of FCA concepts; for example, for a particular zoo it could be found that 85% of the vertebrates on display are mammals. For both contexts, we assessed whether implications correspond to SNOMED CT’s editorial policies in relation to inactivations and SNOMED CT’s concept model.

Results and discussion

Concept ambiguity and possibly-equivalent-to associations

SNOMED CT’s technical implementation guide [4] contains indications that certain changes in components go hand in hand with changes in HARSs and CIRSs. For instance, from the description of what it means for an inactive concept
to be *possibly equivalent to* another concept (Table 4) one can assume that such concepts are asserted as being ambiguous in a CIRSs. We found that not to be the case for 4 concepts. On the other hand, although it is allowed for an inactivé concept to be *possibly equivalent to* only one other concept – we found 7815 of such cases – it is for many of these cases hard, if not impossible, to find out, especially algorithmically through some automated procedure, why the change has been made in this specific way. It is clear that ‘Pyogenic arthritis of lower leg (disorder)’ is ambiguous in the sense that it does not specify in which joint specifically the arthritis is located, but then the question is why it has only been associated with ‘Knee pyogenic arthritis (disorder)’. Another example is ‘Distal interphalangeal joint structure of third finger (body structure)’ which has been asserted as being *possibly equivalent to* another concept with exactly the same FSN. Inactivation because of ambiguity is stated to be ‘because it is inherently ambiguous either because of an incomplete FSN or because it has several associated terms that are not regarded as synonymous or partial synonymous’ (Table 5). Since there was nothing wrong with the FSN it must have been because of the synonyms. Indeed, inspection reveals that for the inactivated concept there is the synonym ‘Distal interphalangeal joint of third digit of forelimb’ which is not to be found in the target concept, thus removing the ambiguity of whether the concept denotes a human body part in addition to an animal body part. This reasoning, unfortunately, does not hold for ‘391651001: Gluten-free/wheat-free baguette (product)’ which was rendered ambiguous in the 5th release and made *possibly equivalent to* 407775004, a then newly introduced concept with exactly the same set of terms (Table 8). Relevant questions are (1) what motivated the SNOMED CT editor to introduce the new concept, and (2) why to use the inactivation because of ambiguity rather than because of duplication? The history mechanism is not able to provide arguments.

**Table 8. Inactivation of ‘391651001: Gluten-free/wheat-free baguette (product)’**

</tr>
</tbody>
</table>

**Duplication and same-as associations**

**Table 4 and Table 5** let us reasonably assume that when a duplicate concept is discovered, it is inactivated with the reason for inactivation being stated as ‘duplicate’ and that at the same time a *same-as* association would be created. That is indeed the case for 44,113 inactivations. Yet, we found 1449 cases where a concept is stated to be duplicate without a corresponding same-as association, and 3453 cases in which a same-as association was created without a duplicate assertion.

We also found cases in which concepts are stated to be duplicates, yet denote clearly distinct entities. The most notorious case is the one in which ‘34759008: Urethral catheter, device (physical object)’ is stated to be duplicated by 73 other concepts, each one of which denoting nevertheless a more precisely specified type of catheter, for example ‘349499005: Bard 10mL balloon 22Ch 1658 2-way all-silicone male length urethral Foley catheter’ and ‘349501002: Bard 10mL balloon 24Ch 1265LV 2-way Teflon coated male urethral Foley catheter’. Several of these catheters are nevertheless, by means of other concepts, listed as descendants of ‘34759008’.

**Mining implication and association rules for concept inactivations**

The observation that – with one exception: whenever a ‘moved to’ association is asserted in a HARS, there is a corresponding ‘moved to’ inactivation asserted in a CIRS – there are no simple consistent relationships between reasons for inactivation and associations motivated us to mine for possible relationships using Formal Concept Analysis. In our case here, we used as FCA concepts every combination of CIRS and HARS membership encountered for all (active and inactive) SNOMED CT concepts as depicted in Table 6, without, however, including history profile information. We used the uppercase characters written between brackets in the first columns of Table 4 and Table 5 – with the exception of ‘pending move’ and ‘refers-to’ which were not included in this analysis – to name our FCA concepts. For example, the FCA concept ‘DLSW’ was attached to every SNOMED CT concept for which throughout its history it was at least once stated to be duplicate (D) and limited (L), as well as associated with other concepts by means of a same-as (S) and was-a (W) association. 85 such FCA concepts were found, in total covering all 424,759 active and inactive SNOMED CT concepts.
Table 9 shows the positive Duquenne-Guigues and Luxenburger base of implications between HARS and CIRS assertions. For example, the implication ‘< 3 > ADW ==» S’ states that if a SNOMED CT concept has ever been annotated as being ambiguous, duplicate and enjoying a was-a association to some other SNOMED CT concept, then it is also the case that this concept has been annotated as having a same-as association. The ‘<3>’ indicates that this implication corresponds to 3 of the 85 FCA concepts encountered which when calculated back to SNOMED CT concepts covers only 4 cases. As another example, the implication ‘< 5 > P E ==» A R’ states that whenever a SNOMED CT concept has been asserted to be possibly equivalent to some other concept as well as being erroneous, it is also the case that that SNOMED CT concept has been annotated as being ambiguous and having been replaced by some other concept. This is the case for 5 FCA concepts which cover in total 15 SNOMED concepts.

The Luxenburger base implication ‘< 24 > P ==» A’ states that for 92% of the FCA concepts which correspond to SNOMED CT concepts that have been annotated with a possibly equivalent to association it is the case that the corresponding SNOMED CT concepts have also been annotated as being ambiguous. Similarly, ‘< 20 > E ==» R’ states that for 90% of the FCA concepts with an E-attribute, there is also an R attribute. When these two implications are assessed towards the SNOMED CT concepts to which the FCA concepts apply, then we find 18,413 SNOMED CT concepts under the 22 FCA concepts for which the P ==» A implication holds, and 1,397 SNOMED CT concepts under the 18 FCA concepts for which E ==» R holds. These counts are many magnitudes higher than the 15 SNOMED CT concepts for which P E ==» A R holds. This raises the question whether this huge discrepancy is indicative for something being wrong with all or some of the assertions made in relation to these 15 concepts. And it leads to the more general question whether the differences in counts observed between SNOMED CT concepts covered by Duquenne–Guigues implications in contrast to Luxenburger implications form the basis for a novel method of quality control that to the best of our knowledge has thus far not been applied to SNOMED CT.

</tbody>
</table>

Semantic tag evolutions

We found in total 285 patterns of the sort exemplified in Table 7 according to which SNOMED CT concepts underwent changes in the semantic tags assigned to them. A change from no semantic tag at all to a semantic tag (43 patterns) counted – under one perspective – also as a change. There were no patterns with more than 3 changes over time under either perspective. Changes in semantic tags can happen for a number of reasons. One is a change in SNOMED CT’s concept model, for instance when distinctions are made that didn’t exist in earlier versions, or different interpretations were introduced (e.g. the product / substance distinction). Such changes have a global impact on large parts of the ontology. Another reason is that concepts were in one or other way erroneous and had to be corrected. The SNOMED CT documentation states for instance that ‘only limited changes may be made to the “term” field, as defined by editorial rules’ [4, p145]. This is consistent with the view that ‘the meaning of a concept can be determined [...] from associated descriptions that include human readable terms’ [4, p87]. This editorial rule is also used as argument for not retiring the concept to which it is attached in cases where the FSN undergoes minor changes. Indeed, ‘Minor changes in the FSN are those changes that do not alter its meaning. A change to the semantic type shown in parentheses at the end of the FSN may sometimes be considered a minor change if it occurs within a single top-level hierarchy (e.g. a change from a finding tag to a disorder tag, or a change from a procedure tag to a regime/therapy tag), but a move to a completely different top-level hierarchy is regarded as a significant change to
the Concept’s meaning is prohibited" [4, p393]. It was therefore hypothesized that changes in semantic tags within the history of a concept would strongly correlate with the concept being inactive in the most recent version. A first analysis summarized in the right half of Table 10 under the perspective of ‘no tag → semantic tag’ constituting a change shows that this is indeed the case for concepts in which only one such change occurred: where the expected ratio of active versus inactive concepts is 75.2%/24.8%, the observed ratio is 28.5%/71.5%. The Cramer’s V statistic over the entire table being 0.55, suggests a strong correlation. That there are more than expected active concepts with more than one change might be explained by the corrections of mistakes made during an earlier change. However, as further inspection revealed that the majority of one-time changes were changes from no semantic tag to a semantic tag, we recalculated the matrix under this 2nd perspective (left half of Table 10) only to find out that under this perspective no conclusive association is present (Cramer V=0.09). It was also at that time that our attention was drawn to the fact that a large amount of semantic tags were assigned to the FSN of concepts that were already inactive since many earlier versions!

</table>

A second observation was that certain change patterns occur frequently within a smaller subset of semantic tags. One such subset is the one formed by the semantic tags disorder, finding, situation, morphologic abnormality, event and navigational concept. We constructed again a formal concept analysis context on the basis of 13 attributes: 2 in relation to each of the semantic tags in the subset just sketched, each such attribute reflecting whether the tag is one which occurs in a non-terminal position or a terminal position in a change pattern, and one reflecting whether the concept is active in the last version. We computed the number of SNOMED CT concepts that are described by means of this FCA context (Table 11, not showing, however, the breakdown in active/inactive concepts). This table shows, for instance, that – within this context as specified – what finally became tagged as events, where primarily tagged as findings in some earlier version, as well as to a large extent disorders, with the exception of 25 concepts that started with a semantic tag outside the subset of 6.

We also computed the corresponding Duquenne–Guigues base with the number of SNOMED CT concepts that are covered by these implications (Table 12). Although this cluster applies to 20,867 concepts, there are not many cases that are covered by the positive implications in the Duquenne–Guigues base. The implication with the largest number of FCA concepts (i.e. 4) s → A covers only 40 SNOMED CT concepts. It tells us that – within this context – all SNOMED CT concepts that had a situation in non-terminal position are active. From Table 11 we can read that 14 of
these concepts were finally tagged as findings, and 26 as navigational concepts. The low coverage of positive implications suggests that hard rigor in semantic tag change patterns is hard to come by.

**Limitation: what qualifies as semantic tags?**

The SNOMED CT documentation available from the IHTSDO webserver provides insufficient information on what the precise set of semantic tags the SNOMED CT editors are working with might be. The information that a semantic tag is that what appears at the end of a FSN between brackets [4, p41] is not reliable. Historically, FSNs didn’t have a semantic tag at all, as this was apparently introduced later as witnessed by the many changes in descriptions to that end. Parsing anything that terminates a FSN between brackets leads to many false positives in older concepts. For many of those, manual inspection is required for disambiguation. But even then it is not always obvious especially in light of the occurrence of FSNs that apparently enjoy 2 semantic tags: Figure 1 depicts all terms which we assume to be (or have been at some point) semantic tags and what they are collocated with. For example, we found 393 FSN assertions in which the semantic tag ‘body structure’ collocates with other semantic tags, i.e. ‘morphologic abnormality’ (11 occurrences), ‘surface region’ (82 occurrences) and ‘combined site’ (300 cases).

**Conclusion**

SNOMED CT has undoubtedly come a very long way since its original conception as a mere nomenclature for pathology [9, 10]. The IHTSDO has been working very hard on developing editorial and technical principles for updating SNOMED CT and on training its terminologists in applying the principles faithfully. Furthermore, the distribution format RF2 presents itself as a formidable resource to obtain a deeper insight in how SNOMED CT evolved. The exploratory analyses we have performed as part of the work described here and which are of sorts that to our best knowledge have thus far not been described in the literature, made us aware of certain possibilities, but nevertheless revealed many pitfalls in attempting to derive from SNOMED CT’s history mechanism what the before mentioned principles exactly might be, or whether they are indeed applied consistently. Whether it is the methodology proposed here itself, or a lack of, for instance, discriminatory power in the reasons for inactivation – one could even wonder why no reasons are given for the addition of new concepts –, is something that needs further to be researched. Nevertheless, it is at this stage of our work possible to formulate the following concrete recommendations towards the IHTSDO: (1) formalize the relationships between semantic tags and SNOMED CT concept hierarchies, (2) implement in the authoring environment mechanisms to prevent and detect incoherent and missing CIRS and HARS records, and (3) provide reasons for not only inactivations, but also activations, which reflect whether changes are purely internal in SNOMED CT (e.g. because of changes in the concept model) or external (changes in the covered domains).
Figure 1. Co-occurrence of candidate semantic tags in FSNs. Numbers inside nodes tally the FSNs in which the candidate semantic tag in the node collocates with another tag. Numbers along the edges tally the FSNs in which the tags in the connected nodes collocate with each other.

Abstract
Exponential surge in health care data, such as longitudinal data from electronic health records (EHR), sensor data from intensive care unit (ICU), etc., is providing new opportunities to discover meaningful data-driven characteristics and patterns of diseases. Recently, deep learning models have been employed for many computational phenotyping and healthcare prediction tasks to achieve state-of-the-art performance. However, deep models lack interpretability which is crucial for wide adoption in medical research and clinical decision-making. In this paper, we introduce a simple yet powerful knowledge-distillation approach called interpretable mimic learning, which uses gradient boosting trees to learn interpretable models and at the same time achieves strong prediction performance as deep learning models. Experiment results on Pediatric ICU dataset for acute lung injury (ALI) show that our proposed method not only outperforms state-of-the-art approaches for morality and ventilator free days prediction tasks but can also provide interpretable models to clinicians.

1 Introduction
The national push for electronic health records (EHR) has resulted in an exponential surge in volume, detail, and availability of digital health data. This offers an unprecedented opportunity to infer richer, data-driven descriptions of health and illness. Clinicians are collaborating with computer scientists to improve the state of health care services towards the goal of Personalized Healthcare. Unlike other data sources, medical/hospital data such as EHR is inherently noisy, irregularly sampled (or have missing value), and heterogeneous (data come from different sources such as lab tests, doctor's notes, monitor readings etc). These data properties make it very challenging for most existing machine learning models to discover meaningful representations or to make robust predictions. This has resulted in development of novel and sophisticated machine learning solutions. Among these methods, deep learning models (e.g., multilayer neural networks) have achieved the state-of-the-art performance on several tasks, such as computational phenotype discovery and predictive modeling.

Even though powerful, deep learning models (usually with millions of model parameters) are difficult to interpret. In today's hospitals, model interpretability is not only important but also necessary, since clinicians are increasingly relying on data-driven solutions for patient monitoring and decision-making. An interpretable predictive model is shown to result in faster adoptability among clinical staff and better quality of patient care. Decision trees, due to their ease of interpretation, have been successfully employed in the health care domain, and clinicians have embraced them for predictive tasks such as disease diagnosis. However, decision trees can easily overfit and perform poorly on large heterogeneous EHR datasets. Thus, an important question naturally arises: how can we develop novel data-driven solutions which can achieve state-of-the-art performance as deep learning models and at the same time can be easily interpreted by health care professionals and medical practitioners?

Recently, machine learning researchers have conducted preliminary work aiming to interpret the learned features from deep models. An early work investigated visualizing the hierarchical representations learned by deep networks, while a followup work explored feature generalizibility in convolutional neural networks. More recent work argued that interpreting individual units of deep models can be misleading. This line of work has shown that interpreting deep learning features is possible but the behavior of deep models may be more complex than previously believed, which motivates us to find alternative strategies to interpreting how deep model work.

In the meanwhile, recent work showed empirically that shallow neural networks are capable of achieving similar prediction performance as deep neural networks by first training a state-of-the-art deep model, and then training a shallow neural networks using predictions by the deep model as target labels. Similarly, Hinton et. al proposed an efficient knowledge distillation approach to transfer (dark) knowledge from model ensembles into a single model following the idea of model compression. Another work takes a Bayesian approach to distill knowledge from a deep neural network to a shallow neural network. Furthermore, mimic learning has also been successfully applied...
to multitask learning, reinforcement learning and speech processing applications\textsuperscript{25,26,27}. These work motivate us to explore the possibility of employing mimic learning to learn an interpretable model and at the same time achieves similar performance as a deep neural network.

In this paper, we introduce a simple yet effective knowledge-distillation approach called interpretable mimic learning, to learn interpretable models with robust prediction performance as deep learning models. Unlike standard mimic learning\textsuperscript{21}, which uses shallow neural networks or kernel methods, our interpretable mimic learning framework uses gradient boosting trees (GBT)\textsuperscript{28} to learn interpretable models from deep learning models. GBT, as an ensemble of decision trees, provides good interpretability along with strong learning capacity. We conduct extensive experiments on several deep learning architectures including feed-forward networks\textsuperscript{29} and recurrent neural networks\textsuperscript{30} for mortality and ventilator free days prediction tasks on Pediatric ICU dataset. We demonstrate that deep learning approaches achieve state-of-the-art performance compared to several machine learning methods. Moreover, we show that our interpretable mimic learning framework can maintain strong prediction performance of deep models and provide interpretable features and decision rules.

2 Background and Deep Models

In this section, we will first introduce notations and describe two state-of-the-art deep learning models, namely feed-forward neural networks and gated recurrent unit. We use these two models (and their extensions) as baselines in our experiments as well as components of the proposed interpretable mimic learning.

2.1 Notations

EHR data from ICU contains both static variables such as general descriptors (demographic information collected during admission) and temporal variables, which possibly come from different modalities, such as injury markers, ventilator settings, blood gas values, etc. We use $X$ to represent all the input variables, and a binary label $y \in \{0, 1\}$ to represent the prediction task outcome such as ICU mortality or Ventilator free days (VFD). We also use $x_t$ to denote the temporal variables observed at time $t$. Our goal is to learn an effective and interpretable function $F()$ which can be used to predict the value of $y$ given the input $X$.

2.2 Deep Learning Models

Feedforward Networks A multilayer feedforward network\textsuperscript{29} (DNN) is a neural network with multiple nonlinear layers and possibly one prediction layer on the top to solve classification task. The first layer takes the concatenation of static and flattened temporal variables as the input $X$, and the output from each layer is used as the input to the next layer. The transformation of each layer $l$ can be written as

$$X^{(l+1)} = f^{(l)}(X^{(l)}) = s^{(l)}(W^{(l)}X^{(l)} + b^{(l)})$$

where $W^{(l)}$ and $b^{(l)}$ are respectively the weight matrix and bias vector of layer $l$, and $s^{(l)}$ is a nonlinear activation function, which usually takes one of logistic sigmoid, tanh, or ReLU\textsuperscript{31}. For a feed-forward network with $L$ layers shown in Figure 1(a), the output of the top-most layer $y_{\text{fin}} = X^{(L)}$ is the prediction score, which lies in $[0, 1]$. People also usually treat the output of second top layer $X^{(L-1)}$ as the features extracted by DNN, and these features are usually helpful as inputs for other prediction models. We show the structure of DNN model in Figure 1(a). During training, we optimize the cross-entropy prediction loss between the prediction output and the true label.

Gated Recurrent Unit Recurrent neural network (RNN) models, such as Long Short Term Memory (LSTM)\textsuperscript{32} and Gated Recurrent Unit (GRU)\textsuperscript{33}, have been shown to be successful at handling complex sequence inputs and capturing long term dependencies. In this paper, we use GRU to model temporal modalities since it has a simpler architecture compared to classical LSTM and has been shown to achieve the state-of-the-art performance among all RNN models for modeling sequential data\textsuperscript{30}. The structure of GRU is shown in Figure 1(b). Let $x_t \in \mathbb{R}^P$ denotes the variables at time $t$, where $1 \leq t \leq T$. At each time $t$, GRU has a reset gate $r_t$ and an update gate $z_t$ for each of the hidden state $h_t$. The update function of GRU is shown as follows:

$$z_t = \sigma(W_z x_t + U_z h_{t-1} + b_z) \quad r_t = \sigma(W_r x_t + U_r h_{t-1} + b_r)$$

$$\tilde{h}_t = \tanh(W x_t + U(r_t \odot h_{t-1} + b)) \quad h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t$$

where matrices $W_z, W_r, W, U_z, U_r, U$ and vectors $b_z, b_r, b$ are model parameters. At time $t$, we take the hidden
states $h_t$ and treat it as the output of GRU $x_{t+1}$ at that time. As shown in Figure 1(c), we flatten the output of GRU at each time step and add another sigmoid layer on top of them to get the prediction $y_{t+1}$.

**Combinations of deep models** One limitation of GRU is that it only aims to model temporal data, while usually both static and temporal features are available in EHR data from ICU. Therefore we propose a combination model of feed-forward network (DNN) and GRU. As shown in Figure 1(d), in the combination model, we use one DNN model to take static input features and one GRU model to take temporal input features. We then add one shared layer on top, which takes the features from both GRU and DNN to make prediction, and train all the parts jointly.

## 3 Interpretable Mimic Learning

In this section, we introduce the interpretable mimic learning method, which learns interpretable models and achieves similar performance as deep learning models. The proposed approach is motivated by recent development of deep learning in machine learning research and specifically designed for the health care domain.

### 3.1 Knowledge Distillation

The main idea of knowledge distillation is to first train a large, slow, but accurate model and transfer its knowledge to a much smaller, faster, yet still accurate model. It is also known as mimic learning, which uses a complex model (i.e., deep neural network, or an ensemble of network models) as a teacher/base model to train a student/mimic model (such as a shallow neural network or a single network model). The way of distilling knowledge, a.k.a. mimicking the complex models, is to utilize the soft labels learned from the teacher/base model as the target labels while training the student/mimic model. The soft label, in contrast to the hard label from the raw data, is the real value output of the teacher model, whose value usually ranges in [0, 1]. It is worth noting that a shallow neural network model is usually not as accurate as a deep neural network model, if trained directly on the same training data. However, with the help of the soft labels from deep models, the shallow model is capable of learning the knowledge extracted by the deep model and can achieve similar or better performance.

The reasons that the mimic learning approach works well can be explained as follows: Some potential noise and error in the training data (input features or labels) may affect the training efficacy of simple models. The teacher model may eliminate some of these errors, thus making learning easier for the student model. Soft labels from the teacher model are usually more informative than the original hard label (i.e. 0/1 in classification tasks), which further improves the student model. Moreover, the mimic approach can also be treated as an implicit way of regularization on the teacher model, whose value usually ranges in [0, 1]. It is worth noting that a shallow neural network model is usually not as accurate as a deep neural network model, if trained directly on the same training data. However, with the help of the soft labels from deep models, the shallow model is capable of learning the knowledge extracted by the deep model and can achieve similar or better performance.

The reasons that the mimic learning approach works well can be explained as follows: Some potential noise and error in the training data (input features or labels) may affect the training efficacy of simple models. The teacher model may eliminate some of these errors, thus making learning easier for the student model. Soft labels from the teacher model are usually more informative than the original hard label (i.e. 0/1 in classification tasks), which further improves the student model. Moreover, the mimic approach can also be treated as an implicit way of regularization on the teacher model, which makes the student model robust and prevents it from overfitting. The parameters of the student model can be estimated by minimizing the squared loss between the soft labels from the teacher model and the predictions by the student model. That is, given a set of data $\{X_i\}$ where $i = 1, 2, \cdots, N$ as well as the soft label $y_{s,i}$ from the teacher model, we estimate the student model $F(X)$ by minimizing $\sum_{i=1}^{N} \| y_{s,i} - F(X_i) \|^2$.

While existing work on mimic learning focus on model compression (via shallow neural networks or kernel methods), they cannot lead to more interpretable models, which is important and necessary in health care applications. To address this, we introduce a simple and effective knowledge-distillation approach called interpretable mimic learning, to learn interpretable models that mimic the performance of deep learning models. The main difference of our approach from
existing mimic learning approaches is that we use Gradient Boosting Trees (GBT) instead of another neural network as the student model since GBT satisfies our requirements for both learning capacity and interpretability. In the following sections, we describe GBT and our proposed interpretable mimic learning in more details.

3.2 Gradient Boosting Trees

Gradient boosting machines\(^{28,34}\) are a method which trains an ensemble of weak learners to optimize a differentiable loss function by stages. The basic idea is that the prediction function \(F(X)\) can be approximated by a linear combination of several functions (under some assumptions), and these functions can be sought using gradient descent approaches. Gradient Boosting Trees (GBT) takes a simple classification or regression tree as weak learner, and add one weak learner to the entire model per stage. At \(m\)-th stage, assume the current model is \(F_m(X)\), then the Gradient Boosting method tries to find a weak model \(h_m(X)\) to fit the gradient of the loss function with respect to \(F_m(X)\). The coefficient \(\gamma_m\) of the stage function is computed by the line search strategy to minimize the loss. To keep gradient boosting from overfitting, a regularization method called shrinkage is usually employed, which multiplies a small learning rate \(\nu\) to the stage function in each stage. The final model with \(M\) stages can be written as:

\[
F_M(X) = \sum_{i=1}^{M} \nu \gamma_i h_i(X) + \text{const}
\]

3.3 Interpretable Mimic Learning Framework

We present two general training pipelines within our interpretable mimic learning framework, which utilize the learned feature representations or the soft labels from deep learning models to help the student model. The main difference between these two pipelines is whether to take the soft labels directly from deep learning models or from a helper classifier trained on the features from deep networks.

In Pipeline 1 (Figure 2), we directly use the predicted soft labels from deep learning models. In the first step, we train a deep learning model, which can be a simple feedforward network or GRU, given the input \(X\) and the original target \(y\) (which is either 0 or 1 for binary classification). Then, for each input sample \(X\), we obtain the soft prediction score \(y_{nn} \in [0, 1]\) from the prediction layer of the neural network. Usually, the learned soft score \(y_{nn}\) is close but not exactly the same as the original binary label \(y\). In the second step, we train a mimic Gradient boosting model, given the raw input \(X\) and the soft label \(y_{nn}\) as the model input and target, respectively. We train the mimic model to minimize the mean squared error of the output \(y_m\) to the soft label \(y_{nn}\).

In Pipeline 2 (Figure 3), we take the learned features from deep learning models instead of the prediction scores, input them to a helper classifier, and mimic the performance based on the prediction scores from the helper classifier. For each input sample \(X\), we obtain the activations \(X_{nn}\) of the highest hidden layer, which can be \(X^{(L-1)}\) from an \(L\)-layer feed forward network, or the flattened output at all time steps from GRU. These obtained activations can be considered as the extracted representations from the neural network, and we can change the its dimension by varying the size of the neural networks. We then feed \(X_{nn}\) into a helper classifier (e.g., logistic regression or support vector machines), to predict the original task \(y\), and take the soft prediction score \(y_c\) from the classifier. Finally, we train a mimic Gradient boosting model given \(X\) and \(y_c\).

In both pipelines, we apply the mimic model trained in the last step to predict the labels of testing examples.
Our interpretable mimic learning approach has several advantages. First, our proposed approach can provide models with state-of-art prediction performance. The teacher deep learning model outperforms the traditional methods, and student gradient boosting tree model is good at maintaining the performance of the teacher model by mimicking its predictions. Second, our proposed approach yields more interpretable model than the original deep learning model, which is complex to interpret due to its complex network structures and the large amount of parameters. Our student gradient boosting tree model has better interpretability than original deep model since we can study each feature's impact on prediction and, we can also obtain simple decision rules from the tree structures. Furthermore, our mimic learning approach uses the soft targets from the teacher deep learning model to avoid overfitting to the original data. Thus, our student model has better generalizations than standard decision tree methods or other models, which tend to overfit to original data.

4 Experiments

We conduct experiments on a Pediatric ICU dataset to answer the following questions: (a) How does our proposed mimic learning framework perform when compared to the state-of-the-art deep learning methods and other machine learning methods? (b) How do we interpret the models learned through the proposed mimic learning framework? In the remainder of this section, we will describe the dataset, methods, empirical results and interpretations to answer the above questions.

4.1 Dataset and Experimental Design

We conduct experiments on a Pediatric ICU dataset collected at the Children's Hospital Los Angeles. This dataset consists of health records from 398 patients with acute lung injury in the Pediatric Intensive Care Unit at Children's Hospital Los Angeles. It contains a set of 27 static features such as demographic information and admission diagnoses, and another set of 21 temporal features (recorded daily) such as monitoring features and discretized scores made by experts, for the initial 4 days of mechanical ventilation. We apply simple imputation to fill in missing values, where we take the majority value for binary variables, and empirical mean for other variables. Our choice of imputation may not be the optimal one and finding better imputation methods is another important research direction beyond the scope of this paper. For fair comparison, we used the same imputed data for evaluation of all the methods.

We perform two binary classification (prediction) tasks on this dataset: (1) Mortality (MOR): we aim to predict whether the patient dies within 60 days after admission. 20.10% of all the patients are mortality positive (i.e., patients died). (2) Ventilator Free Days (VFD): we aim to evaluate a surrogate outcome of morbidity and mortality (Ventilator free Days, of which lower value is bad), by identifying patients who survive and are on a ventilator for longer than 14 days within 28 days after admission. Since here lower VFD is bad, it is a bad outcome if the value $\leq 14$, otherwise it is a good outcome. 59.05% of all the patients have VFD $> 14$.

4.2 Methods and Implementation Details

We categorize the methods in our experiments into the following groups:

- Baseline machine learning methods which are popular in healthcare domains: Linear Support Vector Machine (SVM), Logistic Regression (LR), Decision Trees (DT) and Gradient Boosting Trees (GBT).
- Deep network models: We use deep feed-forward neural network (DNN), GRU, and the combinations of them (DNN + GRU).
- Proposed mimic learning models: For each of the deep models shown above, we test both the mimic learning pipelines, and evaluate our mimic model (GBTmimic).

We train all the baseline methods with the same input, i.e., the concatenation of the static and flattened temporal features. The DNN implementations have two hidden layers and one prediction layer. We set the size of each hidden layer twice as large as input size. For GRU, we only use the temporal features as input. The size of other models are set to be in the same scale. We apply several strategies to avoid overfitting and train robust deep learning models: We train for 250 epochs with early stopping criterion based on the loss on validation dataset. We use stochastic gradient descent (SGD) for DNN and Adam with gradient clipping for other deep learning models. We also use weight regularizer and dropout for deep learning models. Similarly, for Gradient Boosting methods, we set the maximum number of boosting stages 100, with early stopping based on the AUROC score on validation dataset. We implement all baseline methods using the scikit-learn package and all deep networks in Theano and Keras platforms.

4.3 Overall Classification Performance

Table 1 shows the prediction performance (area under receiver operating characteristic curve (AUROC) and area under precision-recall curve (AUPRC)) of all methods. The results are averaged over 5 random trials of 5-fold cross validation. We observe that for both tasks, all deep learning models perform better than baseline models. The best performance of deep learning models is achieved by the combination model, which use both DNN and GRU to handle static and temporal input variables, respectively. Our interpretable mimic approach achieves similar (or even slightly better performance) as deep models. We found that Pipeline 1 yields slightly better performance than pipeline 2. For example, Pipeline 1 and 2 obtain AUROC score of 0.7898 and 0.7670 for MOR task, and 0.7889 and 0.7799 for VFD task, respectively. Therefore, we use pipeline 1 model in the discussions in Section 4.4.

4.4 Interpretations

Next, we discuss a series of solutions to interpret Gradient Boosting trees in our mimic models, including feature importance measure, partial dependence plots and important decision rules.

4.4.1 Feature Influence

One of the most common interpretation tools for tree-based algorithms is feature importance (influence of variable). The influence of one variable \( j \) in a single tree \( T \) with \( L \) splits is based on the numbers of times when the variable is selected to split the data samples. Formally, the influence \( I_{f_j}(T) \) is defined as

\[
I_{f_j}(T) = \sum_{l=1}^{L-1} I_l^2 \mathbb{I}(S_l = j),
\]

where \( I_l^2 \) refers to the empirical squared improvement after split \( l \), and \( \mathbb{I} \) is the identity function. The importance score of GBT is defined as the average influence across all trees and normalized across all variables. Although importance score is not about how the feature is actually used in the model, it proves to be a useful metric for feature selection.

Table 2 shows the most useful features for MOR and VFD tasks, respectively, from both GBT and the best GBTmimic models. We find that some important features are shared by several models, e.g., MAP (Mean Airway Pressure) at day 1, \( \Delta PF \) (Change of PaO2/FIO2 Ratio) at day 1, etc. Besides, almost all the top features are temporal features. Among the static features, PRISM (Pediatric Risk of Mortality) score, which is developed and commonly used by doctors and medical experts, is the most useful static variable. As our mimic method outperforms original GBT significantly, it is worthwhile to investigate which features are considered as more important or less important by our method.

Figure 4 shows the individual (i.e. feature importance of a single feature) and cumulative (i.e. aggregated importance of features sorted by importance score) feature importance of the two tasks. From this figure, we observe that there is
Figure 4: Individual (with left y-axis) and cumulative (with right y-axis) feature importance for MOR (top) and VFD (bottom) tasks. x-axis: sorted features.

Figure 5: Feature importance for static features and temporal features on each day for two tasks.

no dominant feature (i.e. feature with high importance score among all features) and the most dominant feature has a importance score less than 0.05, which implies that we need more features for obtaining better predictions. We also noticed that for MOR task, we need less number of features compared to the VFD task based on the cumulative feature importance scores (Number of features when cumulative score > 0.8 is 41 for MOR and 52 for VFD).

We show the aggregated feature importance scores on different days in Figure 5. The trend of feature importance for GBTmimic methods is Day 1 > Day 0 > Day 2 > Day 3, which means early observations are more useful for both MOR and VFD prediction tasks. On the other hand, for GBT methods, the trend is Day 1 > Day 3 > Day 2 > Day 0 for both the tasks. Overall, Day-1 features are more useful across all the tasks and models.

4.4.2 Partial Dependence Plots

Visualizations provide better interpretability of our mimic models. We visualize GBTmimic by plotting the partial dependence of a specific variable or a subset of variables. The partial dependence can be treated as the approximation of the prediction function given only a set of specific variable(s). It is obtained by calculating the prediction value by marginalizing over the values of all other variables.

One-way Partial Dependence Table 2 shows the list of important features selected by our model (GBTmimic) and GBT. It is interesting to study how these features influence the model predictions. Furthermore, we can compare different mimic models by investigating the influence of the same variable in different models. Figure 6 shows one-way partial dependence scores from GBTmimic for the two tasks. The results are easy to interpret and match existing findings. For instance, our mimic model predicts a higher chance of mortality when the patient has value of PH-Day0 below 7.325. This conforms to the existing knowledge that human blood (in healthy people) stays in a very narrow pH range around 7.35 - 7.45. Base blood pH can be low because of metabolic acidosis (more negative values for base excess), or from high carbon dioxide levels (ineffective ventilation). Our findings that pH and Base excess are associated with higher mortality corroborate clinical knowledge. More useful rules from our mimic models can be found via the partial dependence plots, which provide deeper insights into the results of the deep models.

Two-way Partial Dependence In practical applications, it would be more helpful to understand the interactions between most important features. One possible way is to generate 2-dimensional partial dependence for important feature pairs. Figure 7 demonstrates the 2-way dependence scores of the top three features used in our GBTmimic model. From the left figure in Figure 7, we can see that the combination of severe metabolic acidosis (low base excess) and big reduction in PF ratio may indicate that the patients are developing multiple organ failures, which leads to mortality (area in red). However, big drop in PF ratio alone, without metabolic acidosis, is not associated with mortality (light cyan). From the middle figure, we see that low PH value from metabolic acidosis (i.e., with low base excess) may lead to mortality. However, respiratory acidosis itself may not be bad, since if pH is low but not from metabolic, the outcome is milder (green and yellow). The rightmost figure shows that a low pH with falling PF ratio is a bad sign, which probably comes from a worsening disease on day 1. But a low pH without much change in oxygenation is not important in
mortality prediction. These findings are clinically significant and has been corroborated by the doctors.

4.4.3 Top Decision Rules

Another way to evaluate our mimic methods is to compare and interpret the trees obtained from our models. Figure 8 shows two examples of the most important trees (i.e., the tree with the highest coefficient weight in the final prediction function) built by interpretable mimic learning methods for MOR and VFD tasks. Some observations from these trees are as follows: Markers of lung injury such as lung injury score (LIS), oxygenation index (OI), and ventilator markers such as Mean Airway Pressure (MAP) and PIP are the most discriminative features for the mortality task prediction, which has been reported in previous work. However, our selected trees provide more fine-grained decision rules. For example, we can study how the feature values on different admission days can impact the mortality prediction outcome. Similar observations can be made for the VFD task. We notice that the most important tree includes features, such as OI, LIS, Delta-PF, in the top features for VFD task, which again agrees well with earlier findings.

5 Summary

In this paper, we proposed a simple yet effective interpretable mimic learning method to distill knowledge from deep networks via Gradient Boosting Trees to learn interpretable models and strong prediction rules. Our preliminary experimental results show that our proposed approach can achieve state-of-the-art prediction performance on Pediatric ICU dataset, and can identify features/markers important for mortality and ventilator free days prediction tasks. For future work, we will build interactive interpretable models which can be readily used by clinicians.

Designing a Clinical Data Warehouse Architecture
to Support Quality Improvement Initiatives

Abstract

Clinical data warehouses, initially directed towards clinical research or financial analyses, are evolving
to support quality improvement efforts, and must now address the quality improvement life cycle. In
addition, data that are needed for quality improvement often do not reside in a single database, requiring
easier methods to query data across multiple disparate sources. We created a virtual data warehouse at
NewYork Presbyterian Hospital that allowed us to bring together data from several source systems
throughout the organization. We also created a framework to match the maturity of a data request in the
quality improvement life cycle to proper tools needed for each request. As projects progress in the Define,
Measure, Analyze, Improve, Control stages of quality improvement, there is a proper matching of
resources the data needs at each step. We describe the analysis and design creating a robust model for
applying clinical data warehousing to quality improvement.

Introduction

The advent of electronic health record systems led to the emergence of backend electronic data
repositories of patient and provider information. As repositories grew, clinical data warehouses were
created and optimized for retrospective analysis on patient populations. This analysis has historically been
focused on either clinical research or financial and organizational queries. As more information has been
incorporated in healthcare data warehouses, the potential for data warehouses to address other tasks have
been suggested that focus more on direct patient care improvement.¹² However, it is often unclear how to
best make use of data in warehouses for quality improvement activities. In addition, there are many tools
for accessing and analyzing data in a data warehouse, but their appropriate application can be difficult.
We present a case study of a clinical data warehouse architecture that has been implemented at Columbia
University Medical Center to focus on the appropriate and efficient use of resources for quality
improvement. We modeled our data warehouse and associated tools around a framework that follows the
various phases of quality improvement life cycle. We examine the quality improvement lifecycle used for
improving care at an academic medical center and describe how we leverage the functions of clinical data
warehouse tools according to the maturity of a particular quality improvement project. Finally, we
illustrate the application of this architecture across the breadth of quality improvement initiatives at our
institution.

Background

The Clinical Data Warehouse (CDW) at Columbia University Medical Center (CUMC) of NewYork
Presbyterian Hospital (NYP) was originally created in 1994 by the Department of Biomedical Informatics
in conjunction with the Columbia University Office of Clinical Trials to primarily support clinical
research.³ The data in the warehouse was largely populated by clinical encounter data from the home
grown WebCIS electronic health record (EHR) system backend clinical data repository (CDR).⁴ With this
information from the repository, the warehouse could allow queries of all data available in electronic form
that was typically used in the care of patients. The CDR was created as an event based transactional
database optimized for data retrieval of single patient data, while the CDW was created as an entity based
analytical database optimized for cross patient (population) based retrieval of data. As the use of the CDW grew by clinical researchers, it was soon observed that the data could be used for other purposes such as financial, administrative and, clinical quality improvement in the hospital.

Concurrently there were two important developments at NYP that affected the data warehousing approach. First, NYP organized a quality improvement organization with teams trained in process improvement throughout the organization. Quality improvement was implemented using the Six-Sigma methodology to decrease variation in organizations tasks by carefully examining facts and data in improving existing processes. The application of data to quality improvement required adjustment of the data organization in the warehouse and additional tools to provide data in different workflows related to quality improvement implementation. Second, NYP completed its migration from the legacy WebCIS EHR (which was primarily used for data access to multiple data sources that were integrated in the repository) to a commercial EHR that was implemented across the system. With this new EHR implementation and federal incentive programs came an increased focus on data entry into the EHR. This affected the data warehouse by adding a significant source of new data to the existing design.

As a result of these changes, we sought to better understand how the changes could best be addressed by adaptations to the data warehouse architecture, and to create an effective model for applying data resources to quality improvement efforts.

**Methods: Analysis of Existing Issues**

We performed four analyses to understand perceptions and factors relevant to the current data warehouse and its potential redesign. Two analyses focused on the customers of the warehouse, while two analyses focused on its structure and processes. We used a mixture of an external stakeholder analysis, key user interviews and an analysis of data requests to formulate a guide a new vision for clinical data warehousing at Columbia University Medical Center and the whole NewYork Presbyterian Hospital system.

We first performed a stakeholder analysis among 6 important stakeholders across the institution, who sponsored or facilitated projects that relied on the data that was stored with the clinical data warehouse. These individuals included leaders in the information systems and quality improvement organizations, who had a broad understanding of the data requirements for quality improvement and the need for robust systems to provide that data. They were members of a committee called the Clinical Quality and IT (CQIT) Committee, which was formed with the mission to address key NYP goals for regulatory reporting, patient safety, pay for performance measures, and quality of care delivered through the use of information technology. Along with other efforts to improve the process at the hospital through the use of information technology, they participated in an analysis to inform how the clinical data warehouse could assist in the mission of the quality improvement administrators in the institution. During prioritization via a voting mechanism, a few key themes arose that included being able to track specific safety measures, access to data for analysis, quality reporting and research, the ability to integrate data across applications for reporting purposes, and ability to extract data from clinical notes for quality purposes. The committee felt that these themes could be better addressed through two key subgroups that concentrate on excellence in data warehousing and increased use of structured documentation. The data warehousing subgroup, through a gap analysis of user needs, found that the institution required a more effective method to bring together disparate clinical data sources around NYP and required a more robust way to manage user requests for data.

Next we performed a needs analysis by interviewing key trained quality performance experts with in the institution to better understand their data needs from the warehouse. We concentrated our efforts along six key quality improvement initiatives (Table 1) set forth by NYP senior leadership, and interviewed a leader from each initiative. Our goal was to determine how information technology through data warehousing could help these specific efforts at the institution’s hospitals, and how well the needs were currently being met. Through semi-structured interviews we gathered information from these users in
regards to the maturity of the initiatives, the data needs of the initiative, IT system dependence, and challenges faced in accomplishing goals (see Table 2). The institution already had data used in monitoring these projects, however the data was manually gathered and processed into spreadsheet-based static reports.

Table 1: Quality initiatives pursued at NYP during the analysis period.

<table>
<thead>

<tr>
<td>Systems / Dependencies</td>
</tr>
</tbody>
</table>

These interviews identified a few key issues arose of why the quality improvement needs of the institution were not being met. First, frequently the data needed by quality performance experts was not available within the CDW and that the data needed for these projects was mainly found in vendor based transactional systems. Second, we found that when the data was available they still needed help in defining what their data needs really were. Third, there was no way for the data experts to query across
transactional systems with the IT tools available to them. Finally, we noted that data needs changed according to the maturity of the quality improvement project. The more mature the quality improvement strategy was the more robust IT solution had to be. Still, in each initiative there was a common thread of how data was discovered, validated, and then used to monitor a particular quality improvement marker.

We also performed an analysis of the warehouse itself to identify any structural or technical characteristics that may have been root causes of the concerns raised by the CQIT review. This analysis reviewed requirements and technical factors that were seen by the data warehouse leadership as most significant in their relationship to the CQIT concerns. This analysis identified that the primary challenges were regarding data integration. First, assembling and integrating all administrative, financial, and clinical systems in one system was an immense task. While some of the institution transactional data repositories were well understood and map to a common terminology (the Medical Entities Dictionary, or MED), other newer commercial systems were less understood, and fewer tools were available for navigating the terminology. Prospective mapping large backend vendor based clinical data repositories to a common representation in the clinical data warehouse was a very time consuming goal, beyond the resources of the data warehouse team. Ideally vendors can transfer data from their systems through HL7 messaging and interfaces to the data warehouse, however we found that this was not always well supported by external systems. On analysis of the different data repositories around the institution we found several localized experts centered around different home grown and vendor based systems. This was exacerbated further by having two different patient institutional systems between the university hospitals of Columbia and Weil Cornell. In such an environment, consumers with new data needs had to either “hunt around” for the appropriate person to help them, or would try to push all requests through whoever in the past had successfully met the data need.

The findings of the CQIT committee and the focused quality performance expert interviews further justified the need for a clinical data warehouse that served the needs of the quality improvement initiatives at the institution. Moreover, we felt it was also important to maintain and perhaps improve the capabilities that were already being supported in clinical research and administration. Therefore, we performed a process analysis of the current activities of the CDW team by reviewing requests submitted to the CDW, and collecting feedback from the CDW analysts. This review included data requests made formally through a data request submission process, and informally through requesters seeking instruction directly through CDW leaders. We identified the maturity of each data request in terms of the existing access to the data, the roles of the users of the data, and how the data were integrated with the users’ workflow. We also examined the sources of data used for the data requests, and the overall data flow from our source systems to their eventual use in our CDW. We then grouped different data uses and data sources into common types, and qualitatively identified and analyzed themes among the sources and uses.

The CDW user requests have classically focused on the clinical researchers at CPMC. More recently the analysts observed an increase in requests from administrative and quality improvement personnel at the institution. Requests differ from the classic research oriented queries in that they require more time commitment and expertise from the CDW staff. Requests ranged from one-time queries to quarterly and even daily reporting to administrative systems. They also required bringing together financial, clinical, and administrative data into one query. The CDW team was spending significant time running ad-hoc queries in a one time or recurrent fashion based on the user. Additionally almost all of the ad-hoc inquiries where done without looking to building upon previously understood data requests. The CDW looked for an infrastructure for managing repeated common requests and users that keep requesting more complex data mining efforts.

**Results: System Description and Design**

From these four analyses, we were able to identify three themes that influenced the redesign of our clinical data warehouse. These themes were 1) structural changes in our data infrastructure created different needs for data integration; 2) ad hoc queries were a foundational method for accessing data and
Data Integration

A dominant theme that emerged from the stakeholder and structural analyses was regarding the need for improved data integration to support customer needs. Because we were in an academic medical center, the data warehouse had to consider the goals and data needs of both the medical school and hospital – the medical school needs were focused more on education and research, while the hospital focus was more on patient care, clinical quality, and financial measures. The designed warehouse architecture also needed to be responsive to user requests with minimal resources. The key to this architecture was handling user requests and maintaining support for research and quality improvement projects.

As mentioned above, the main data source for the CDW was the institution’s clinical data repository, which had as its sources data from multiple ancillary systems that were interfaced to a central database, and the more recent institutional electronic health record that included computerized physician order entry and a clinical documentation system. Because the EHR was intended to replace many functions of the legacy WebCIS application and CDR, the data from the EHR were not modeled and stored in the repository, and many data sources that fed to the repository also were stored directly in the EHR (e.g., lab data). This change in the primary data source for the EDW was important for the new design, as the warehouse needed to accommodate data integration that was previously done in the repository and using the MED. Because we did not have the resources for full data integration between the systems, and the EHR data represented a new data type, we focused on the extract process to simplify access to the data and modeled or transformed the data based on need (e.g., late-binding).

For data extraction, we were able to use standardized database management tools to make the data accessible in the CDW without actually consolidating the data sources by creating a virtual clinical data warehouse. We first replicated the source application’s backend database management system in real time, using standard database replication tools. This minimized the effect on the front-end application performance by not burdening the application to feed data to our warehouse directly. We then used existing database management system integration services to link the replicated database with existing tables in the CDW. These integration services supported both ad hoc analytic queries and extracting data from EHR tables to populate data marts in the CDW. Data marts contain data that is pertinent to its area of interest and hence only contains a focused subset of the source replicated databases, and required data transformation and modeling. Based on the demand of the data needs, we could focus efforts to asynchronous ad hoc queries or have more recurring and even synchronous reporting and analysis through content optimized data marts. Different data marts could be updated at defined intervals or in real time to support online analytical processing. Database integration services for both ad hoc queries and updates to centralized data marts allowed more rapid availability of the data for requesters. We found that this approach was most effective for supporting ad hoc queries, and could be effective in building data marts to support periodic data reports.

Data Access and Ad Hoc Queries

Themes regarding access and ad hoc queries were identified primarily from the process and needs analyses. We noted that requests from our users, whether they were researchers, clinical providers, or operational analysts, were all initially performed as ad hoc queries. Even when the data were needed in a complicated report or dashboard, the data were first extracted and verified using provisional queries, to check the data definitions, availability, and quality. Research queries were generally all ad-hoc queries, with few examples of where the queries were run repeatedly at intervals. While we did provide other functions within the CDW such as generated reports and data feeds to separate applications, these
requests were enhancement requests for more robust delivery of data that was originally requested as an ad hoc preliminary query. Understanding that the data requests all started as ad hoc queries allowed us to identify a pattern of how data requests evolved, and allowed us to design around optimizing data access for ad hoc queries separately from modeling for reporting. When a query is requested on a recurrent basis, often to identify trends in indicators, data marts could then be built and extract-transform-load processes were implemented to aid in the data modeling and consolidation process (see Figure 1). This was both to increase the efficiency of the end-user data extract, and also because the data modeling was better defined for these more mature requests. Ongoing requests made by applications or analytical systems, such as our business intelligence system, were handled in a similar fashion. Data marts were created in the warehouse and either used directly by the front end systems or extracted to the system database.

![Virtual Clinical Data Warehouse Design](image)

**Figure 1. Virtual data warehouse design.**

We also found a multitude of data visualization tools and services that required different levels of information accessibility from our clinical data warehouse. After careful examination of our requests we found that they could be divided into four distinct categories based upon the frequency or urgency of data required. These categories were as follows:

1) Ad-hoc Direct SQL Queries
2) Recurring Static Reporting
3) Online Analytical Processing
4) Point of Care Registry Functions
Each of these categories provided for a predefined period of time for a new inquiry to our data warehouse tables. From an ad-hoc query that maybe done once to more timely queries required for point of care reporting, each of these categories would require data updated at predefined intervals driven by the frequency of the reporting task.

Quality Improvement Cycle

The needs and process analyses identified the changing user needs that were related to the quality improvement life cycle. The fourth lesson from the needs analysis was that data needs changed according to the project maturity in the life cycle, and the process analysis identified multiple methods for supplying data. We were able to map our categorization of data warehouse data methods to the quality improvement cycle initiatives followed at our institution. The approach followed the DMAIC framework: DEFINE, MEASURE, ANALYZE, IMPROVE and, CONTROL, each representing different stages of the quality improvement life-cycle, each with differing data needs. At the DEFINE stage the user asks what type of data is needed and if it exists. With the MEASURE stage static reporting can monitor trends in data over time in order to find a baseline level for future measurements. During the ANALYZE stage data is further looked at from different angles and viewpoints in order to find the best place for intervention to make the biggest impact. Interventions are put into place and the data is used to help care givers in making the right decisions at the point of care during the IMPROVE stage. Finally, at the CONTROL stage, process improvement is incorporated in the workflow of an organization and data driven decision making is becomes part of the standard of care.

The mapping of the data access methods to the quality improvement cycle was as follows. New projects in the DEFINE phase always started with a direct database query to establish the availability and validity of the data. As projects matured, recurring automated queries would help further define the project and identify trends over time in the MEASURE phase. Deeper analysis of the data would use more advanced online analytical processing tools to find factors that correlated with the quality improvement task at hand in the ANALYZE phase. Data-driven dashboards then can bring information from real-time data marts to clinicians at the point of care so they could monitor key variables in the IMPROVE phase. As the use of the key variables was better understood, it could be integrated into workflow of the clinicians with real time decision support in the CONTROL phase (see Table 3).

<table>

</tr>
</tbody>
</table>

While this mapping to the DMAIC cycle was critical in matching data needs to appropriate tools for quality improvement initiatives. Because of the data-intensive nature of this process, leaders of quality improvement initiatives would often approach the clinical data warehouse managers to meet their data needs. This led to consideration of how to optimize the data warehouse around quality, rather than its traditional role as a retrospective clinical research tool. The phases were not always concretely defined in the data requests; however, the task being performed by the quality expert at the time of the data warehouse inquiry typically defined the complexity of the data warehouse storage and the tools used to...
access it. It also defined our expectations of how the data needs would evolve as the quality improvement initiative matured. As a project evolved from a “define” stage to “improve” or “control” stage, requirements for data timeliness and access would increase accordingly. This further classification of user needs based upon the maturity of the quality improvement initiative created a framework for prioritization of user requests and proper data mart utilization. Using this model, the CDW team sought to create a clinical data warehouse architecture that focused on the types of data required for each stage of quality improvement in order to better serve the quality improvement efforts of NYP.

Results –Diabetes Mellitus Example

We illustrate the application of this clinical data warehouse architecture supporting the stages of the quality improvement life cycle using a quality improvement initiative concentrating on the outpatient clinic population of patients with diabetes mellitus at the Columbia University Medical Center.

Ad-hoc SQL Queries (Define): For several years healthcare providers from the NewYork-Presbyterian Ambulatory Care Network intermittently requested information from our clinical data warehouse on their patients with diabetes mellitus. Each request was done on a case by case basis and customized for a particular purpose in mind, whether it was for clinic research or administrative reporting.

Static Reporting (Measure): Starting in 2006, some of these reports became more formalized and a process for automated querying and delivery of data was setup by the clinical data warehouse staff. With the help our data warehouse staff, medical directors would monitor the patients with diabetes in their clinic population and provide reports to their physicians regarding timeliness and control of laboratory values including Hemoglobin A1C, LDL, and Microalbumin. On a quarterly basis data would be compiled and delivered via “flat file” text files to the healthcare analysts in the Ambulatory Care Network for processing and reporting. This data would ultimately be delivery to healthcare providers in a paper based document. Aggregate data would be provided on both the individual physicians and clinic locations on how goals were being met for each laboratory monitor. Physicians would also receive a registry of the patients included in their calculations with associated demographic and laboratory values.

Online Analytical Processing (Analyze): As these reports became more and more utilized, the need for more frequent reporting was evident. Much of the data manipulation needed to make such reports required a great deal of manual effort and the data would sometimes be delivered when it was already temporally unusable. Additionally as medical directors sought to use this data to manage quality improvement interventions they found it very burdensome to monitor their efforts in this way.

With the goal of having timelier reporting to healthcare providers we migrated the process of data gathering into data-marts and automated the data analysis through online analytical processing tools. From various disparate data sources we built a data-mart of diabetic patient demographics, outpatient visit history, laboratory, medication, and provider information. We then created a dynamic management reporting tool using our business intelligence system to provide timely patient and provider tracking tools used at the point of care. With this new method we were able to scale up to our users needs of more frequent reporting on clinic patients with diabetes mellitus.

Dashboards-Registries (Improve): Future improvements to clinical care in diabetes will turn to our clinical data warehouse to provide instant access to patient and provider information regarding diabetic patient care. With our architecture in place we can update data-mart content with a frequency required by user needs. As new tools such as healthcare provider dashboards and chronic disease registries are implemented to manage the population of patients with diabetes in our institution, the data warehouse can provide the platform for future expansion.

Applications (Improve): As interventions are defined to improve the care of patients with diabetes they must be integrated into the transactional electronic health record applications used in the institution. New decision support alerts and reminders can keep the patient care providers up to date on what the needs are of a particular patient.
We observed in our outpatient diabetes mellitus quality improvement initiative the maturity of the project dictated the resources needed from the clinical data warehouse and its users. By planning the proper approach and building upon prior less sophisticated reporting methods we were able to create a data-mart architecture and robust data visualization tool that exactly met the needs of our users.

**Discussion**

Using multiple analyses, we were able to identify important themes regarding our data warehouse that led to a specific redesign to support evolving needs. We used virtualization of data sources and data marts to facilitate late-binding of data models and to support ad hoc queries that were foundational to using the warehouse data. Organizing our clinical data warehouse architecture around the quality lifecycle has been an effective approach to meeting the evolving demands of a data warehouse. The fundamental architecture of our virtual clinical data warehouse and associated prioritization strategy around our data visualization tool has brought to our attention a few key findings.

First, our data warehouse prioritization strategy made effective use of our technical resources for a given project. It was imperative that the proper resources were also given to the project from our users perspective. As the maturity of the quality improvement initiative progressed, more resources were needed on the user side to ensure success of the project. While ad-hoc queries required only minimal user interaction, mature projects required greater time commitment and technical proficiency from our users. Additionally, as a project matured, higher level management skills were required of the administrative staff monitoring its progress. As our diabetes project moved from static reporting to online analytical processing, the need for project management skills was evident to coordinate the different users and technical staff for the project.

Second, as we built customized data-marts we needed to keep in mind that it was important to keep data-mart models separated from the data visualization tools. Different tools required different backend data sources. This abstraction of backend supply side and frontend demand side environments of a clinical data warehouse has been described in the University of Michigan Health System. As a project matures different tools will need to interact with the same data-mart. Keeping data-marts as generic as possible facilitates future requirements and expansions to the data model.

Third, defining projects based on maturity helped to ensure that users were provided with appropriate tools for the task. Once we identified the expected progression of a project through the quality improvement life cycle, we were able to avoid situations where we would try to extend tools of one level to different functions as the project evolved. For example, prior to the mapping against the quality improvement model, projects at a Measure stage, using reporting software, might be steered to extend the tools to different functions. We experienced discussions of how to implement reporting tools at the point of care, which would be an expensive and difficult implementation. With the understanding of project evolution, we recognized that projects were expected to evolve, and that we should migrate to the appropriate tools rather than extend the tools at one level.

Some limitations exist in the architecture of a virtual data warehouse. By relying on discretely replicating backend databases of source systems we create a delay in delivery of data to the warehouse. While our data warehouse is not formally used for transactional processes, it is feasible in our model that data be available in a synchronous manner for dashboard style point of care reporting. To solve this we would need to look more toward HL7 messaging and interfaces that would feed data directly from source systems as it is entered. We have recently begun testing of loading data directly into the CDW using HL7 messaging, which would improve the data currency.

Additionally, as with any data warehousing approach, one must be sensitive to the quality of data that is in the warehouse tables. Data can only be as good as what is available in the source systems. At every level of warehouse function, we find that data must be cleaned in order to create meaningful reports to
users. In the future we expect to create a scoring system for data points stored in our warehouse. This way one can not only provide data, but also can impart a level of integrity for data points provided.

While the analysis-derived themes and design were valuable as they were applied to the data warehouse at NewYork Presbyterian Hospital, perhaps their most significant characteristic has been their robustness beyond the institution where they were developed. Since this initial analysis, discovery and application, some of our team members have migrated to different institutions, and we have applied these findings to warehousing and analytics strategies in these other settings. In each case, these important lessons have been effective in creating local strategies for addressing the evolving user needs of clinical data, especially for quality improvement initiatives.

**Conclusion**

We found that by concentrating on the needs of our users we could establish a robust clinical data warehouse that supports the needs of quality reporting initiatives at our institution. By building a clinical data warehouse architecture to support the dynamic needs of data visualization tools available we could scale up resources as user needs required. By creating a framework for user needs based upon the maturity of quality improvement initiatives we could direct users to the proper level of data warehouse tools.

Integrative Spatial Data Analytics for Public Health Studies of New York State

Xin Chen, MS, Fusheng Wang, PhD
Stony Brook University, Stony Brook, NY

Abstract

Increased accessibility of health data made available by the government provides unique opportunity for spatial analytics with much higher resolution to discover patterns of diseases, and their correlation with spatial impact indicators. This paper demonstrated our vision of integrative spatial analytics for public health by linking the New York Cancer Mapping Dataset with datasets containing potential spatial impact indicators. We performed spatial based discovery of disease patterns and variations across New York State, and identify potential correlations between diseases and demographic, socio-economic and environmental indicators. Our methods were validated by three correlation studies: the correlation between stomach cancer and Asian race, the correlation between breast cancer and high education population, and the correlation between lung cancer and air toxics. Our work will allow public health researchers, government officials or other practitioners to adequately identify, analyze, and monitor health problems at the community or neighborhood level for New York State.

Introduction

Open data initiatives supported by the governments are providing unprecedented information about our health. New York State Cancer Mapping dataset, for example, consists the number of people diagnosed with cancer (cancer counts, 2005-2009) in small geographic areas. New York State data from Statewide Planning and Research Cooperative System (SPARCS) collects patient level detail on patient characteristics, diagnoses and treatments, services, and charges for each hospital inpatient stay and outpatient visit. Such data also provides street level location information for each patient and healthcare facility site. The improved availability of health data combined with improved geospatial analysis and spatial statistics techniques has significant potential to uncover the spatial patterns of diseases in a population and provide insight as to their causes and controls.

Integrative spatial data analytics for public health has a strong focus on locating patients and the agents of disease, studying the community and region level patterns and variations, and assessing demographic, socio-economic, and environmental factors on diseases and human health. In the past, due to limited accessibility of health outcome data, public health studies were often limited at macro scale levels such as county level or ZIP code tabulation areas (ZCTAs), and may not allow public health researchers and health officials to adequately identify most at-risk populations, analyze, and monitor health events at the community or neighborhood level.

One critical challenge for spatial epidemiology and public health research is the isolated datasets with different spatial resolutions, data formats, or data quality. The patient addresses from hospitals, for example, have to be converted into geolocations (latitude, longitude) and then get approximated into a standard geographic identifier (such as census tract or census block group IDs) to protect the privacy of human subjects. Another common issue is the problem of spatial interpolation that combines both point and areal data through the use of area-to-area, area-to-point, and point-to-point covariances. To align spatial data with different geographical granularities, we also need to either aggregate values from small areas into larger ones or vice versa.

Our goal is to integrate fine-grained open health data with a comprehensive set of spatial “exposure” data, which is ranging from levels of various environmental pollutants to the socioeconomic status of persons at risk. We focus on the spatial public health research at the community level and consolidate a variety of spatial datasets into a data warehouse system, supported by a scalable computing infrastructure for spatial data integration and spatial analytics. We take advantage of Hadoop-GIS, a MapReduce based spatial data warehouse system to perform spatial query based data integration. Integrative spatial data analytics is built on top of the integrative spatial data warehouse to support various spatial query types and analytic methods.

In this paper, we verified our methodology for integrative spatial data analytics by linking the New York Cancer Mapping Dataset (Table 1) with three categories of spatial impact indicators (Table 2) generated from representative spatial exposure data sources such as census statistics, geospatial and map data from TIGER (Topologically Integrated Geographic Encoding and Referencing), the American Community Survey (ACS) data, and air toxics data from Environmental Protection Agency (EPA). We first studied spatial distributions and clustering of the cancer risk and
spatial impact factors at the level of census block group or census tract. We then correlated the cancer risk ratios with spatially varying demographic, socio-economic, and environmental factors (Tables 3-5), using both non-spatial correlation analysis (ordinary least square regression) and spatial correlation analysis (geographically weighted regression). The results were consistent with three well-established relationships: that between stomach cancer and Asian and Hispanic race, that between breast cancer and high income and high education population, and that between lung cancer and air toxics. At last, we undertook three case studies to identify the detailed spatial trends for each of these three pairs of relationship separately (Figures 1-3).

Methods

Data Sources

Spatial Public Health Data: Cancer Incidence Data in New York State. There has long been a demand for cancer incidence data at a fine geographic resolution for use in etiologic hypothesis generation, methodological evaluation and teaching. We demonstrated our vision of integrative spatial analytics by linking the New York Cancer Mapping Dataset with a comprehensive set of spatial impact indicators from representative spatial exposure data sources such as census and TIGER data, the ACS data, and air toxics data from EPA.

The cancer data set consists of observed counts for 23 anatomic sites of cancer at the neighborhood scale, diagnosed between 2005 and 2009 (Table 1). The data include 524,503 diagnoses of cancer distributed across 13,823 Census block groups with an average population of about 1,400. A census block group is an area containing about 1,000 to 2,000 people as defined by the US Census. Cancer data are reported for a five-year time period because the number of cases in single years can vary dramatically, particularly for outside metropolitan areas.

Besides the observed counts of diagnosed cancers, expected counts are also calculated using the indirect standardization method, adjusted for sex and 5-year age groups up to 85+, using the 2010 census counts for New York State. The data set thus contains both observed counts and expected counts per census block group for each of the 23 cancer sites.

Spatial Exposure Data. We linked three categories of spatial impact indicators to the cancer incidence data using both non-spatial correlation analysis and spatial correlation analysis as shown in Table 2. 1) For demographic indicators, we examined the population proportion for different groups of individuals based on self-identified race and ethnicity, including Asian, Hispanic, White, Black, Pacific Islander, and American Indian. 2) For socio-economic indicators, we examined the number of persons per household, the proportion of poverty population and the population with less than high school education. 3) For environmental indicators, we examined 10 most frequently found air toxics with national average cancer risk greater than one in a million.

The demographic indicators here were generated from the 2010 United States Census and the socio-economic indicators were from the 2006-2010 American Community Survey. The environmental indicators for New York State were generated from Environmental Protection Agency (EPA) National-scale Air Toxins Assessment. As the EPA air toxics data were at census tract level, we aggregated lung cancer counts per census block group into the counts per census tract.

Analyses

Relative Risk (RR). We calculated RR through dividing observed counts by expected counts per census block group for different cancer categories (Table 1). The RR estimates provide useful information about how common cancer incidence in a specific location is as compared to the global baseline.

Spatial Clustering. To test whether there is spatial autocorrelation of the cancer RR, we used Moran’s I (Tables 1 and 2). Moran’s I is a widely used global cluster test, which determines the degree of clustering or dispersion within a data set. The resulting values may range from 1 (perfect correlation), 0 (complete spatial randomness) to -1 (perfect dispersed). For the cancer incidence data, a positive spatial autocorrelation means that the areas with high cancer RR are close to other areas with high cancer RR.

To assess colocation (= spatial correlation) between cancer incidence and each of the spatial impact indicators, we calculated the bivariate Moran’s I for each spatial impact indicator with the cancer RR (Tables 3 and 4). Such bivariate measure of spatial autocorrelation relates the value of a cancer RR at a location to that of a spatial indicator at neighboring locations, as a straightforward generalization of the concept of spatial autocorrelation. This measure of spatial autocorrelation shows the association between cancer incidence at a given location and the local indicator value in neighboring area. The Moran’s I index and the bivariate Moran’s I index were conducted in GeoDa (v 1.6.7).
In addition to observed and expected counts, the New York Cancer Mapping Dataset also includes an indicator variable used to highlight block groups with unusually high or low cancer incidence, as determined using the spatial scan statistic. The spatial scan statistic is a local cluster test, which detects local clusters with statistically significant elevated or deficit risk of diseases. A block group is defined as a high incidence area if 1) it was included in the most likely high incident rate cluster detected by the spatial scan statistic, or 2) it was included in a non-overlapping secondary cluster, and 3) the observed rate was at least 50% higher than the expected rate. A block group was defined as a low incident area in the same manner.

**Spatial Regression.** To identify potential correlations between diseases and spatial impact indicators, we assessed both non-spatial and spatial correlation. Ordinary least square regression analyses (OLS) was used to determine non-spatial correlation between cancer RR and each of the spatial impact indicators. We then used Geographically Weighted Regression (GWR) to assess the spatial trends of relevant indicators at a local level.

OLS is a linear regression method that closely fits a function by minimizing the sum of squared errors. To determine potential candidate indicators, we evaluated several possible indicator combinations that form a properly specified OLS regression model. GWR is a local form of linear regression used to model spatially varying relationships. To evaluate the correlation between cancer incidence and spatial impact indicators accounting for data in surrounding areas, we conducted GWR with a selected indicator combination based on OLS results. Specifically, a fixed kernel type function was used to calculate the GWR regression coefficients. The extent of the kernel is determined using the Akaike Information Criterion (AICc). The OLS, GWR and resulting choropleth maps (Figures 1-3) were conducted in ArcGIS (v 10.3).

Results

In this section, we verified our methodology for integrative spatial analytics by linking cancer incidence data (Table 1) with three categories of spatial impact indicators from spatial exposure data (Table 2). The results were consistent with three well-established relationships: the correlation between stomach cancer and Asian race, the correlation between breast cancer and high education population, and the correlation between lung cancer and air toxics. Our results also included detailed spatial trends between cancer RR and spatial impact indicators through three case studies.

** The air toxics data from EPA are at the level of census tract.

Linking Spatial Impact indicators to Health Events

We first modeled all demographic and socio-economic indicators into OLS for both stomach cancer and breast cancer, and then excluded White population for stomach cancer and Black population for breast cancer due to the redundancy issue among different indicators. For the OLS results of stomach cancer RR, we included all indicators except the White population proportion. For the OLS results of breast cancer RR, we included all indicators except the Black population proportion.

Based on OLS results, we then tried different indicator combinations for GWR model and further excluded several indicators due to the global or local multicollinearity issue. As shown in Table 3, we separately chose 5 indicators for GWR model with stomach cancer RR and 3 indicators for GWR model with breast cancer RR. For lung cancer RR (Table 4), 6 out of the 10 air toxics were included in the final OLS model and the 3 air toxics related to lung cancer were included in the final GWR model in the same manner.

The proportion of Asian population was most strongly correlated with stomach cancer RR (Table 3). Among the other significant indicators, the proportions of Black, Hispanic, poverty, and low education population all positively...
influenced stomach cancer RR. Such finding is consistent with the high stomach cancer rates found among Asian-Americans\(^3\).

* Significant at 1% confidence interval

Among socio-economic indicators, the proportion of low education population most strongly correlated with breast cancer RR (Table 3). The proportions of different ethnicity groups all negatively influenced breast cancer RR, except the White population proportion. Such findings confirmed the risk factors of higher socio-economic status (SES), race and ethnicity for female breast cancer\(^9\). High SES, which is most often defined by high income and/or high education level, has been linked to an increased risk of breast cancer. This increased risk is not due to the higher SES itself, but rather to differences in risk factors found in women of different education and income levels. For example, compared to women of lower SES, women of higher SES are more likely to 1) have their first child at a later age, 2) have fewer children, 3) use menopausal hormone therapy, 4) use birth control pills, and 5) drink alcohol\(^9\). Since many of these behaviors tend to occur in combination as part of broader lifestyle patterns, the high education can be considered as a direct risk factor for breast cancer.

Most indicators that were significantly correlated with stomach and breast cancer (based on OLS coefficients) also displayed significant colocation relationships (based on bivariate Moran’s I index). However, the bivariate Moran’s I index (spatial correlation) was generally lower than OLS coefficient value (non-spatial correlation), indicating that such correlation was only partly determined by location.

For lung cancer, we examined the 10 most frequently found air toxics with national average cancer risk greater than one in a million (Table 4). The cancer types associated with the air toxics were also listed. We included several air toxics that affected nose cancer, leukemia, and adrenal tumors other than lung cancer for comparison purpose. Among the significant OLS coefficient results, all 3 air toxics related to lung cancer (arsenic, chromium VI, and PAHPOM) were positively correlated with lung cancer. For the air toxics not related to lung cancer, their relationship to lung cancer RR displayed certain randomness. For example, while the carbon tetrachloride (related to adrenal tumors) had the largest positive coefficient value, tetrachloroethylene (related to liver cancer) had a negative coefficient value.

The colocation relationship (Bivariate Moran’s I Index) also displayed inconsistent results as compared to OLS model. For example, while arsenic and chromium VI were positively correlated to lung cancer according to the significantly positive coefficient value, their bivariate Moran’s I indexes were negative which indicated negative spatial correlation.

** The lung cancer RR and the cancer risk due to 10 air toxics are at the level of census tract.

Among the 3 air toxics related to lung cancer, only PAHPOM had consistent positive correlation relationship with lung cancer. We then chose PAHPOM in the following case study for spatial trend of GWR coefficient.

The model comparison results were shown in Table 5. The GWR was the overall best-fitting regression model in terms of adjusted R-squared as well as the goodness-of-fit AICc statistic. The adjusted R-squared value represented the percentage of local deviance explained. In general, the higher the R-squared, the better the model fits your data. In terms of the AICc statistic, the model with the lowest AICc value is the model with the best fit. Based on this criterion, GWR regression had a slightly better fit than the OLS regression. For lung cancer, the adjusted R-squared increased from 0.18 (OLS as a non-spatial model) to 0.25 (GWR as a spatial model), which suggests a stronger correlation when information from the surrounding areas was taken into account in the spatial regression model.

</table>

Most GWR coefficients fluctuated widely across the research area and exceeded the confidence intervals found in the OLS regression (Tables 3 and 4), indicating a more or less varying relation between cancer RR and spatial indicators across research area. In the following section, we then had a closer examination for the spatial trends of local coefficients through case studies.

**Case Study 1: Stomach Cancer RR and Demographic Indicators**

For stomach cancer RR, the local coefficients of Asian population proportion varied across New York State and were mostly positive (84.4%), indicating a positive association for most part of New York state (Figure 1). The positive association was strongest in the southwest and northeast corner of upper state.
The association also displayed strong regional and intra-urban differences. All the elevated clusters were located at the New York City where the Asian proportion generally had a positive impact. The deficit stomach cancer clusters (with green boundary in Figure 1), on the other hand, mainly appeared at the rural area (areas with line fill symbol in Figure 1) and the coefficient values had a strong local differences within the cluster boundaries.

![Coefficient of Asian Population Proportion for Stomach Cancer RR](image)

**Figure 1.** The choropleth map that visualizes Geographically Weighted Regression (GWR) local coefficient of Asian population for stomach cancer Relative Risk (RR).

**Case Study 2: Breast Cancer RR and Socio-economic Indicators**

As shown in Figure 2 for breast cancer RR, the local coefficients of low education proportion were overall negative (98.6%), indicating that lower education was associated with a lower breast cancer risk. The small portion of positive coefficient was mainly located at the adjacent area between Brooklyn and Queens Boroughs in New York City.

Most of the highlighted clusters, either elevated clusters or deficit clusters, were located at urban areas in the downstate New York. While all the elevated clusters were located at three urban areas throughout the New York state, all the deficit clusters gathered in the New York City area.

**Case Study 3: Lung Cancer RR and Environmental Indicators**

As shown in Figure 3 for lung cancer, the coefficient values of PAHPOM were mostly positive throughout the New York State, which is consistent with the well-established relationship between PAHPOM and lung cancer. One exception was the area of long island where had an overall negative correlation to PAHPOM.
In general, areas with higher than expected lung cancer incidence (elevated clusters) were located in upstate New York and areas with lower than expected incidence (deficit clusters) were located in downstate New York. The only exception was the area of Long Island where two elevated clusters were located.

Most of the highlighted clusters, either elevated clusters or deficit clusters, were located at urban areas, with a small portion of elevated clusters appeared at the rural areas. Such inconsistent relationships may require further research for the potential driving factors.

Figure 2. The choropleth map that visualizes Geographically Weighted Regression (GWR) local coefficient of low education population proportion for breast cancer Relative Risk (RR).

Discussion

This study linked the New York Cancer Mapping Dataset with spatial exposure data sources, thus supporting spatial correlation analyses that draw consistent results with previous work about cancer risks in relation to spatially varying risk factors. In addition, we provided three case studies that mapped the varying values of the local coefficient with improved resolution, which is useful for refined evaluation into spatial trends between cancer risk and spatial indicators.

While our ultimate goal is to provide integrative spatial analytics at fine grained spatial resolution, for this initial work, we focused on the analysis of cancer counts, without patient level demographic details such as gender, age or age ranges, race and ethnicity groups. While the expected case counts capture certain demographic structure of the
population, it does not satisfy age-specific or race-specific analysis\textsuperscript{9}. The data also lack temporal information such as patient admission or discharge date for discovery of temporal patterns.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure3.png}
\caption{The choropleth map that visualizes Geographically Weighted Regression (GWR) local coefficient of PAHPOM for lung cancer Relative Risk (RR).}
\end{figure}

In our future work, we will take advantage of data from New York Statewide Planning and Research Cooperative System (SPARCS), which comes with fine grained spatial information. SPARCS data comes with patient level details on patient characteristics, diagnoses and treatments, services, and charges for each hospital inpatient stay and outpatient\textsuperscript{2}. Such data also provide street level location information for each patient and healthcare facility site.

After geocoding and de-identifying addresses into census block group identifiers, our framework for integrative spatial data analytics will provide spatial queries based on coordinates or boundaries, thus linking and integrating the health records with spatial exposure data at multiple resolutions. We will first provide multi-dimensional analysis by grouping patients according to their demographic or socio-economic attributes. We will then study potential spatial clusters of disease distributions and correlations between disease risk and spatial impact factors. For example, we are interested in exploring potential hotspots of Hepatitis C or potential environment and weather factors that may have correlations with asthma.

Conclusions

Vast amounts of spatial big data are being increasingly generated and provided in the public health domain. Integrating multiple sources of spatial big data could provide new insights and create new forms of value at much higher spatial
resolutions to support community or neighborhood level public health studies. In this paper, we present our initial work on integrative spatial data analytics combining cancer incidence data in New York State, Census data and air toxics data. We focus on three representative case studies: correlation between stomach cancer and ethnicity groups, correlation between breast cancer and high education population, and correlation between lung cancer and air toxics. Our results not only are consistent with traditional studies, but also provide much refined results with improved spatial resolution. Our methods are generic and will be applied to New York State SPARCS data in the future.

Abstract

Smartphones are ubiquitous, but it is unknown what physiological functions can be monitored at clinical quality. Pulmonary function is a standard measure of health status for cardiopulmonary patients. We have shown phone sensors can accurately measure walking patterns. Here we show that improved classification models can accurately measure pulmonary function, with sole inputs being sensor data from carried phones. Twenty-four cardiopulmonary patients performed six minute walk tests in pulmonary rehabilitation at a regional hospital. They carried smartphones running custom software recording phone motion. For every patient, every ten-second interval was correctly computed. The trained model perfectly computed the GOLD level 1/2/3, which is a standard categorization of pulmonary function as measured by spirometry. These results are encouraging towards field trials with passive monitors always running in the background. We expect patients can simply carry their phones during daily living, while supporting automatic computation of pulmonary function for health monitoring.

Keywords: knowledge representation and information modeling, mobile health (patients), chronic care management (clinicians).

Introduction

A revolution in health monitoring is coming, due to widespread mobile devices. Individual measurement can generate population cohorts of similar patients with similar status, so treatments can be effectively and efficiently targeted towards all groups\textsuperscript{1}.

Mobile phones are nearly ubiquitous in the United States, with the Pew Internet Project showing 91\% ownership in May 2013, including 56\% with smartphones. Even seniors over 65 years of age have 76\% penetration of mobile phones\textsuperscript{2}. Since hundreds of millions of patients are already carrying phones, the opportunity appears for passive monitoring without adherence difficulties. We seek clinically valid physiological measures, vital signs which can be accurately monitored with smart phones.

Of the many measures that could be measured, the most important for diagnostic purposes are functional status. This is particularly true of cardiopulmonary disease, the major cause for chronic conditions in senior patients. As the patients age, their hearts and lungs slow down, and are not able to keep up with the demands. The physiological tests and measures clearly demonstrate their response to activity demand, e.g. as a patient walks, they slow down or move unsteadily when their heart and lungs cannot provide sufficient oxygen delivery to match increased exertion.

Pulmonary function is measured with a medical device called a spirometer. The patient breathes into this device, and the amount of air respired is recorded. The volume of air exhaled has been calibrated to provide standard measures of pulmonary function as discussed below. We show that a classification model can perfectly compute pulmonary function. In testing with cardiopulmonary patients, we further show that adequate inputs are the motion sensors already contained in ordinary smartphones. Simply carrying phones in daily living can measure health status.

For chronic heart and lung conditions, walk tests are widely used to assess the severity of the disease, including measures with accelerometer sensors\textsuperscript{3,4}. The Six-Minute Walk Test (6MWT) is a standard assessment\textsuperscript{5} for Chronic Obstructive Pulmonary Disease (COPD) and Congestive Heart Failure (CHF), which affects tens of millions of patients. A 6MWT measures the distance walked in six minutes back and forth over a fixed length walk way.
Normal gait requires many systems, including strength, sensation, and coordination, function in an integrated fashion, so abnormal gait is a diagnostic of many conditions\(^6\). Note that gait is the total walking pattern, the complete body motion, including swaying as well as stepping. So effective motion analysis must include more features than merely step counting, with adequate models.

Previously, we used the 6MWT to show motion features can be measured with smart phones carried by chronic patients, as sole input to a trained model that accurately predicts computes gait speed\(^7\) and oxygen saturation\(^8\), among other physiological measures for health status of chronic conditions. This study extends these results to computing pulmonary function, based on characteristic motions of health status. We also developed a phone app called MoveSense, and showed that it can record walking using phone sensors with similar accuracy to medical devices and higher accuracy than fitness devices\(^9\). This is true while running on the least expensive smart phones, such as the LG Optimus Zone, which now cost less than the portable fitness devices, such as the FitBit Flex.

**Subjects and Data Collection**

We recruited twenty-seven pulmonary patients at NorthShore University Health System, under IRB approval start November 2014. All chronic patients going through pulmonary rehabilitation in Respiratory Therapy in Evanston Hospital are now offered the option of participating in our study. Such patients are given our provided smartphones for recording their motion during a standard six-minute walk test during each visit, carried in a fanny pack. The six-minute walk tests are performed on a thirty-meter straight walkway in hospital corridor, with cones at the terminals. The patient walks back and forth on the walkway under the supervision of nurses for six minutes and the distance is recorded. The patient is permitted to stop and rest anytime, although the clock keeps going. Our software does not include this stationary data. All six-minute walk tests follow the ATS guidelines in a completely standard way\(^5\).

Pulmonary function tests are performed with a spirometer in clinical conditions\(^10\). In obstructive diseases, such as COPD, the ratio of forced expiratory volume in one second (FEV\(_1\)) as compared to an age, gender, race, and height adjusted expected value is used as a sufficient indicator to measure severity level of the disease, called predicted FEV\(_1\)% . The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines a standard for cardiopulmonary severity levels based on the predicted FEV\(_1\)% values\(^11\). There are four GOLD stages: GOLD 1 (mild), GOLD 2 (moderate), GOLD 3 (severe) and GOLD 4 (more severe). In this study, we have two GOLD 1 patients (predicted FEV\(_1\)% \(\geq 80\)), thirteen GOLD 2 patients (predicted FEV\(_1\)%: 50-79) and nine GOLD 3 patients (predicted FEV\(_1\)%: 30-49). GOLD 4 patients (predicted FEV\(_1\)% <30) typically cannot complete walk tests.

The demographic information for each group is shown in Table 1. There were two patients, Patients 12 and 24, who did not have pulmonary function tests in the record, so we eliminated these in our dataset. Patient 2 did not perform a six-minute walk test, which means there is no eligible walk data collected for this patient. This leaves twenty-four patients with walking data eligible for analysis with the models.

**Table 1.** Demographic information of each group of patients by GOLD levels. Age, height and weight are in average (minimum - maximum) format. These demographics plus gender are used to adjust the model.

Our phone app MoveSense was installed on the smartphones (a high-end Samsung Galaxy S5 and a low-end LG Optimus Zone2) for motion data collection. Our previous hardware experiment showed that the accelerometer in high-end and low-end smartphones are identical for human motion capturing, and both of them have comparable high quality as a medical accelerometer\(^8\). We take all data collected with the high-end smartphone for analysis and keep the low-end smartphone data for backup. Due to technical failure of the high-end phone, we use the data from low-end phone for three 6MWT sessions: the second session of Patient 5 and the first and the second session of Patient 16. We recorded the approximate starting time of each 6MWT session, and we let the patients stand still for seconds right before and after the 6MWT so that a pure six-minute walk can be easily extracted. The phone sensor data is downloaded into an archival database and correlated with patient medical data from the Epic EMR system.
Methodology

We established a model for GOLD stage classification. The model input is the raw three-dimensional acceleration collected by carried smartphones, and the output is a class of GOLD stage from 1 to 4 for each patient.

Preprocessing

MoveSense collects and processes the raw sensor data to extract qualified walking data. In six-minute walk test, subjects are allowed to rest during the walk test, so we must clean the dataset to detect if the patient is walking or stationary mode. We introduce a classification algorithm based on standard deviation analysis\(^\text{12}\).

We calculate the magnitude of the raw acceleration data to compress 3D signals into 1D signals, then split the signal of each session into ten-second length samples with five-second sliding window\(^\text{7}\). Rather than a static threshold of standard deviation, the classification algorithm dynamically assigns standard deviation threshold for each session by reading the whole signal thread beforehand in one-second intervals. The algorithm can detect walking or stationary mode for six-minute walk test, see Figure 1. When the standard deviation threshold is set, each one-second walking has a binary decision for walking/not-walking. Then for all ten-second samples, if the ratio of walking is larger than 0.7, we select this sample as an eligible sample based on training sets.

Feature Selection

After preprocessing, we have obtained good walking data for each patient. We compute input features for training the model by feature selection approach (FSA)\(^\text{7}\). Feature selection approach (FSA) is based on empirical knowledge. A primary parameter to measure gait is the cadence, which is the number of strides within a unit of time\(^\text{13}\). We calculated cadence by counting steps in each ten-second interval\(^\text{4}\) and dividing by length of sample.

Related studies in motion tracking by wearable devices extract a series of features from raw acceleration data\(^\text{15,16,17}\). We selected eight sufficient spatio-temporal gait parameters in both time and frequency domain. In the time domain, we selected mean and standard deviation of acceleration to describe the general distribution of the acceleration sample. In addition, mean crossing rate (MCR), root mean square (RMS), autocorrelation coefficient (AC) and coefficient of variance (CV) were calculated from time-series acceleration data. The mean crossing rate (MCR) represents the ratio of above and below acceleration. The root mean square (RMS) is a statistical measure on the variation of signal magnitude. The autocorrelation coefficient (AC) measures periodical similarity in time domain. The coefficient of variance (CV) is a normalized measure for dispersion of discrete samples. In the frequency domain, we computed the peak frequency (PF) and Shannon entropy. The peak frequency (PF) represents the frequency of peak magnitude in spectrum. Shannon entropy is an expected value of the information in the signal\(^\text{18}\).

Besides the cadence and spatio-temporal gait parameters, demographic information must also be considered in model training, just as a spirometer uses it to adjust the raw values from patient respiration. Unlike selecting demographic cohort and training models by cohort in our previous research\(^\text{7}\), we keep the four basic demographic parameters: age and sex, height and weight as factors in the input feature vector. With such input feature vector, we train universal models which ideally can be applied on general population. Overall, for each ten-second sample, the input feature vector \(x\) contains thirteen independent features -- covering stepping, moving, and demographics.

![Figure 1](image-url)
Model Training

Support vector machines (SVM) are a class of machine learning algorithms, widely used in learning classification models. We apply RBFSVM, the SVM with radial basis function kernel, to train the model for GOLD classification. SVM allows classification by remapping multi-dimensional vector $\vec{x}$ into a higher dimensional space and determining a hyperplane or a set of hyperplanes that separate different classes. The hyperplanes optimize the separation between data points in the given space, yielding the classification Equation (1). SVM classification requires a training set to find the variables $\alpha_i$ to determine $f(x)$ with a given kernel function and given inputs.

$$f(x) = \sum_{i=1}^{N} \alpha_i \cdot K(x_i, x)$$

From Equation (1) we know that different kernel functions affect the overall performance of the trained model, previously we applied simple linear kernel in model training and obtain the technical baseline. In this study we applied RBFSVM, using the radial basis function kernel to train the SVM model, as Equation (2). We set the hyper-parameter $\gamma = \frac{1}{D}$, based on the number of dimensions in training samples. $x_i$ and $x_j$ are two arbitrary sample vectors in the training set. In our dataset patient’s status are labeled as one of the three GOLD stages (GOLD 1, GOLD 2 and GOLD 3). One-against-all strategy is applied to train this three-class classification model. The tolerance of termination criterion is set as 0.001 and the insensitive-loss variable $\xi$ is set as 0.1.

$$K(x_i, x_j) = \exp\left(-\gamma \left\|x_i - x_j\right\|^2\right), \quad \gamma = \frac{1}{D}$$

Model Validation

Since patients only take pulmonary function tests during the initial walk test (6MWT1) but not for the following test (6MWT2, 6MWT3), we only know the FEV1% predicted values for their first 6MWT session. We label samples during the first 6MWT with corresponding GOLD stages. Thus the dataset is partially labeled. We then select all labeled samples to form the training set. To avoid over-fitting, 10-fold cross validation is applied for self-validating the classification model. That is, randomly split the training set into ten parts, and each time select one out of the ten subsets as the test set and the other nine to train the model. After ten folds of model training and testing, we obtain predicted results of all samples in the dataset with a model trained by other samples from the same cohorts.

Voting Status with Thresholding

A classification model obtains GOLD stages for each ten-second walking samples. However, each six-minute walk test contains multiple ten-second walking samples, up to 37 if no stopping during the test. For cardiopulmonary patients, the severity will not change within a single walk test. But a walking sample may be affected by other factors and lead to false classification. Majority voting is robust rule to obtain single decision from multiple samples. Majority voting worked in our previous studies so we apply to obtain predicted GOLD stages for each patient. Based on empirical observations, we apply a strict threshold of 85% to accept the voting, which means only when the majority group gets more than 85% of the votes, the decision will be accepted. Otherwise, if none of the groups obtains higher than 85% votes, we mark the status as pending and clinically analyze the risk of this walking session.

Results

The dataset contains 1204 ten-second walking samples (39 six-minute walk tests) from 24 different patients, including 769 labeled samples from the first 6MWT session of each patient. We train classification models only using all labeled samples. Ten-fold cross validation is applied to self-validate the model. We then utilize the trained model to predict all unlabeled samples.

Evaluating the model

Besides the RBFSVM model, we train a classification model as in our previous study, which applies SVM with linear kernel as baseline. The results are shown in Table 2. The overall accuracy of the RBFSVM model is 98.60% (100% for GOLD 1, 99.28% for GOLD 2 and 98.37% for GOLD 3). While the overall accuracy of the linear SVM model is 86.35% (100% for GOLD 1, 88.31% for GOLD 2 and 82.02% for GOLD 3). The RBFSVM model significantly improves classification accuracy for GOLD 2 and GOLD 3 samples from 82% to 98%.
Table 2. Self-validation results for RBFSVM model and linear SVM model. We compare the accuracy of classification, which is all correct classified samples divided by the total number of samples. This is by ten-second interval, not by patient. See Figure 2 for patient-level results.

Figure 2. Evaluation of GOLD classification for labeled 6MWT sessions. The bar-plot shows the portion of predicted GOLD stages for all labeled walking samples of each patient. Except for Patient 7, 9 and 17, all other patients are 100% correctly predicted within every interval. After voting, all patients are predicted as their actual GOLD stages.

After obtaining the classification results for ten-second samples, majority voting is applied for categorizing each patient into a target GOLD stage. We perfectly categorize all patients into the corresponding GOLD stages summarized from their FEV1% predicted values, shown in Figure 2.

Classifying Unlabeled Samples

We train a universal classification model with all 769 labeled samples and apply this model to classify all unlabeled samples. There are 435 unlabeled samples from thirteen unique 6MWT sessions from ten patients, where three patients have third 6MWT sessions (5,16,21). Two out of the thirteen walking sessions are classified differently.
from the patients’ first labeled 6MWT session. For Patient 1, the second 6MWT session is 100% predicted as GOLD 2 while the first 6MWT shows the patient is in GOLD 3, as the FEV1 indicates with spirometry. For Patient 16, the second 6MWT session is 68.97% predicted as GOLD 2 and 31.03% predicted as GOLD 3, while the first 6MWT session of this patient is labeled as GOLD 3, as the FEV1 indicates with spirometry. Referring to the rule of voting with thresholding, none of the predicted GOLD states reaches the 85% threshold so the second session of this patient is in pending status. Patient 16 also has a third 6MWT, which is 10.34% predicted as GOLD 1, 3.45% predicted as GOLD 2 and 86.21% predicted as GOLD 3. So the third session of Patient 16 is decided as GOLD 3, the same as the first session. For all other patients, the classifications of the unlabeled 6MWT sessions are 100% identical to their first 6MWT sessions for all intervals. The GOLD classification for each 6MWT session is shown in Figure 3.

**Figure 3.** Evaluation of GOLD classification for unlabeled 6MWT sessions. The bar-plot shows the portion of predicted GOLD stages (PGOLD 1, PGOLD 2, PGOLD 3) for all unlabeled walking samples of each patient. Except for Patient 1 Session 2, Patient 16 Session 2 and Session 3, all other patients are 100% predicted as the GOLD stages they are labeled by the initial 6MWT session (Session 1).

### Sufficient Walk Length for Accurate Classification

The main results above show that the classification model yields high accuracy when the model is trained with full six-minute walk for each patient session. Additionally, we analyze the effect of walk length in training progress to classification accuracy of the model. We randomly select different lengths of walking in the 6MWT session for each patient, from 30 seconds to six minutes (30s, 40s, 50s, 1min, 2min, 4min, 6min). We train and evaluate the model on the selected walking periods using the same strategy as above to obtain the predicting accuracy for each length. The result is shown in Figure 4. When the walk length is 120 seconds (two minutes), the predicting accuracy has reached 100% and remains there through the full six minutes. Note it is nearly perfect after just one-minute. So we assume a two-minute good walking for each patient is sufficient to train a classification model for detecting GOLD status. Here “good walking” refers to the steady pattern, as during a walk test, where high accuracy of the model is achieved, since the patient changes speeds reflecting their pulmonary function.
Figure 4. Classification Accuracy with Different Walk Length in Training. The accuracy in ten-fold cross validation reaches ~100% after two-minute (120-second) length.

Discussion

High Accuracy Classification on Labeled Walking Sessions

There were twenty-four patients participating in at least the first six-minute walk test session. The model does perfect computation for their pulmonary function. That is all patients are categorized into the correct GOLD stage. In this case the pulmonary function tests are performed the same day as the six-minute walk test, so we assume all patients’ predicted FEV1% represents their current severity of respiratory limitation when we collect their motion data and the phone motion could fairly match the lung function. Figure 2 summarizes this perfect computation of health status for pulmonary function.

In more detail, for twenty-one patients, all their ten-second walking samples are identically predicted, and correctly reflect the patient’s GOLD stage. This indicates spatio-temporal motion reflects more stable information than the one-dimensional walking speed. Patient may speed up or slow down during the six-minute walk test, but the spatio-temporal motion will always yield the correct health status, by measuring stability deviation of walking movements. Based on this outcome, we assume that six-minute walk tests are not necessary for detecting health status of cardiopulmonary patients. Instead, if we can find any good walking sessions that are identical to the walking during the six-minute walk test, spatio-temporal motion data from such walking session can be used to compute GOLD status. As Figure 4 shows, our model only needs 2 minutes of good walking for perfect computation.

For three patients, not all ten-second samples are classified correctly, including Patient 7, Patient 9 and Patient 17. For Patient 9, one ten-second sample out of thirty-three eligible samples gets false classification, while for Patient 17, one ten-second sample out of twenty-five eligible samples gets false classification. These can be simple statistical error so we can ignore them. For Patient 7, five samples out of thirty-seven eligible samples get false classification, which takes 13.5% of the overall classification classifying GOLD 2 for a patient measured as GOLD 3. So voting with 85% threshold would still predict correct status compared to spirometry that measures FEV1%.

In addition, for Patient 7, the spirometry measurement was 5 months earlier than the 6MWT, whereas nearly all other patients had their PFT within 1 month. This delay could lead to false classification, due to change in clinical status. For this patient, they also had a medication change to begin COPD inhalers during this period, so we expect an improved status with better pulmonary function. Thus there is a clinical explanation for lower model inaccuracy.

Identical Classification on Unlabeled Following Walking Sessions

From medical literature, six-minute walk distance (6MWD) is considered as a gold standard for diagnosis of COPD severity and other cardiopulmonary health status, but it is more accurate for severe COPD than moderate or mild COPD. In our experiment, ten patients performed at least two six-minute walk test sessions, as shown in Figure 3, usually spaced several weeks apart. We compare their initial 6MWDs and following 6MWDs, shown in the Bland-Altman plot in Figure 5.
There are 13 sessions, since 3 patients also did a session 3, but only 11 points since we eliminate 2 because no actual 6MWD recorded (Patient 5 Session 3 and Patient 16 Session 3). The initial 6MWDs are in average of 310.8m (±95.16m) and the following 6MWDs are in average of 367.1m (±106.5m). Generally, the patients walked further (had greater 6MWD) in later sessions, as expected for rehabilitation patients.

Our analysis indicates that 6MWD is not sufficient for measuring COPD severity levels, certainly compared to pulmonary function for cardiopulmonary patients. In our dataset, the GOLD 2 and GOLD 3 patients are not well distinguished by 6MWD. The 6MWD of GOLD 3 patients can be as high as 350 meters but the 6MWD of GOLD 2 patients can be below 250 meters. Note the variation between two different 6MWDs of a patient becomes larger when the distance is shorter, e.g. the second 6MWD of one GOLD 3 patient (Patient 23) is 150 meters longer than the initial 6MWD, even though performed just twenty days after he began the rehabilitation process.

Our classification model again had high accuracy, since such variation on total distance does not affect the stability of patients' motion pattern. Eight out of ten patients are detected strictly as the same GOLD status for their second or third 6MWT sessions. All of the ten-second walking samples of their following 6MWT sessions are identical to their original GOLD status, even for Patient 23, the one with the largest variation of 6MWDs. This “unfair” 8 of 10 model accuracy for later sessions compared to the initial GOLD status is shown in Figure 3.

The two patients who are not correctly classified at subsequent sessions are Patient 1 and Patient 16. For Patient 1, GOLD 2 is classified at the subsequent session but the PFT measure indicates GOLD 3. Patient 1 had a clinical diagnosis of both COPD and CHF when he was enrolled in cardiac rehabilitation. His medication regimen for CHF was adjusted at the start of his rehabilitation program and his motion was noted to improve, likely from better control of his CHF, so in fact this “unfair” comparison of initial GOLD status to improved GOLD status with the model may be measuring actual improvement rather than model inaccuracy. Congestive Heart Failure is less closely correlated to pulmonary function than Chronic Obstructive Pulmonary Disease, limiting the usefulness of GOLD criteria for defining the severity of functional limitation in CHF. The second 6MWD of Patient 1 is 72.5 meters longer than the initial 6MWD.

Monitoring Severity Change Longitudinally

Patient 16 had diagnosis of sarcoidosis, which is a lung disease that has variable effects on pulmonary function. Sarcoidosis cannot be well categorized by disease severity based upon GOLD criteria, as the physiologic limitations are less clearly correlated with predicted FEV1%, as in COPD. However, this patient was measured for pulmonary function via spirometry for FEV1 indicating GOLD 3, which was correctly classified in Session 1.

Patient 16 performed three 6MWT sessions at different visits, among which the second session was about one month later than the initial session and the third session is about five month away from the initial session, which is beyond the three-month rehab period. In Session 2, there was mixed classification of 2/3 intervals indicating GOLD 2 and 1/3 indicating GOLD 3. The patient was likely within transition between status levels, due to rehabilitation progress. During Session 3, not only was it much later, but there was a clinical note that the patient had suffered a significant illness which was the reason to return to rehabilitation. This session was the only true mixture, with some classifications of GOLD 1/2/3, although 86% of the intervals indicated GOLD 3 once again. So the lung
physiological function likely worsened and the patient regressed back to the original status level. Our model would have predicted this correctly, if the threshold mentioned earlier of 85% was implemented. Thus there is clinical evidence that our model can predict changes in pulmonary function.

**Conclusion**

In this study, we expand our previous results into accurate computation of pulmonary function with universal models. This requires utilizing demographic features with better training sets (ATS standard) and better statistical models (RBF-SVM), which utilize characteristic motions in addition to step counting. Every patient now has correct modeling of GOLD level, even sample by sample (10 seconds) not only walktest by walktest (6 minutes). Measuring motion is a potential solution for passive monitoring, which distinguishes this work from the phone applications measuring pulmonary functions with the microphone. A passive monitor has compliance advantages over active phone applications. That is, the patient simply uses their personal phone as usual during daily activities, no special actions or special experts are necessary. The microphone “spirometer” also has adherence difficulty, the patient must breathe properly into the proper place, also a difficulty with a medical spirometer.

The trained model is providing perfect computation of pulmonary function category (classifying GOLD stage). This is especially true for the first session with pulmonary patients, where spirometry has just measured the pulmonary function so the pulmonary function value can be directly compared to the motion value. For senior patients undergoing pulmonary rehabilitation, respiration and motion are closely correlated. This is why the classification is so accurate, especially in the hospital setting with monitored walk test. The result is encouraging, so we shall be relaxing environmental constraints on our measurements in forthcoming studies, moving closer to daily activities in the real world of cardiopulmonary patients. Under expanded IRB, we now allow selected patients to bring smart phones home from rehab, to measure their motions and predict their pulmonary functions during daily activities.

The home trials are more complex than the hospital trials thus far. The patient will be doing many different activities throughout the day, while the periods when they are carrying their phones could all be potentially recorded by a passive monitor that is always running. The passive monitor phone app used in the home is a re-implementation of the active monitor used in the clinic, which only records when the phone is in steady motion and only archives when the patient is good walking. Since the models have high accuracy during walk tests, we are developing software for activity recognition. This is a well-studied problem in computer science, for using motion sensors to detect which activity a person is performing. General activity recognition is hard, but our problem is a specialized version of that. The recognition filter in the phone app need only detect good walking, when the body motion is similar to a walk test. This paper reports on initial progress of autodetecting stopping during walktests. Since the amount of walking needed for accurate computation is very small, only 1 or 2 minutes per session, the filter can be tuned up, for high precision only during periods when there is definite measurement of good walking.

We are optimistic that full-scale clinical trials are possible to compute health status for cardiopulmonary patients. They need only carry their own phones and do some limited good walking during the day when the passive monitor is recording unobtrusively. Since the cheapest smartphones can accurately support this computation, large-scale population measurement can become an everyday reality for health systems.

Abstract

Chemoprevention with antiestrogens could decrease the incidence of invasive breast cancer but uptake has been low among high-risk women in the United States. We have designed a web-based patient-facing decision aid, called RealRisks, to inform high-risk women about the risks and benefits of chemoprevention and facilitate shared decision-making with their primary care provider. We conducted two rounds of usability testing to determine how subjects engaged with and understood the information in RealRisks. A total of 7 English-speaking and 4 Spanish-speaking subjects completed testing. Using surveys, think-aloud protocols, and subject recordings, we identified several themes relating to the usability of RealRisks, specifically in the content, ease of use, and navigability of the application. By conducting studies in two languages with a diverse multi-ethnic population, we were able to implement interface changes to make RealRisks accessible to users with varying health literacy and acculturation.

Introduction

Breast cancer is the most commonly diagnosed and second deadliest cancer among women in the United States.1,2 Based upon randomized controlled trials, chemoprevention with antiestrogens, specifically tamoxifen, raloxifene, anastrozole, and exemestane, can reduce the incidence of breast cancer among high-risk women by 30-70%.3–6 It is estimated that at least 15% of women in the United States meet high-risk criteria for breast cancer, defined as a 5-year risk greater than 1.67% or a lifetime risk greater than 20%, according to the Gail model.7 However, of these women fewer than 5% who are offered chemoprevention therapy reported taking the medication.8 While this low uptake is partially attributed to concerns about side effects, lack of knowledge about chemoprevention among both patients and primary care providers (PCPs) is another a major contributor to low uptake.9

Recognizing and making decisions about health can be a difficult task for patients, particularly when there are multiple options for care and patient preferences are not well defined.10 The United States Preventive Services Task Force (USPSTF) recommends that physicians engage in shared decision-making with patients regarding chemoprevention and screening for breast cancer.11 Studies have indicated that patient decision aids (PtDAs) are an important part of influencing a woman’s decision to seek certain types of treatment for breast cancer.12 PtDAs for considering breast cancer screening options and prevention strategies have been developed to assist women with assessing their risk and making informed choices about their health.13–17 While PtDAs for screening were successful in reducing over-screening rates, chemoprevention uptake among high-risk women exposed to a PtDA on breast cancer chemoprevention remained low up to 3 months after use.15–17 PtDAs that provide information that is tailored to the risk status of the patient tend to be more efficacious than those that do not.10

We have developed an innovative web-based PtDA, RealRisks, to provide high-risk women with more information about breast cancer chemoprevention. RealRisks is designed to improve users’ accuracy of risk perception while presenting them with information about breast cancer risk and chemoprevention options that can be tailored to their preferred method of receiving health information. The PtDA offers users the ability to input personal information in order to engage with modules that reflect the prevention options that are available for women with the same risk level. Patients who complete RealRisks are provided with an action plan for discussing prevention options with their PCP. RealRisks is designed to be used in conjunction with the Breast cancer risk NAVigation (BNAV) tool, a clinical decision support tool for PCPs that is integrated into the electronic health record.18 Together RealRisks and
BNAV provide comprehensive information to high-risk women and their PCPs in order to promote shared decision-making about chemoprevention.

We previously conducted focus groups and participatory workshops with an early prototype of RealRisks, which specifically targets women from diverse racial/ethnic and educational backgrounds. In particular, we demonstrated that after exposure to RealRisks, women with low or high numeracy levels had improved breast cancer risk perceptions and the majority found the tool useful and easy to use.19 The aim of this study was to assess the usability of a more advanced prototype of RealRisks, which is available in English and Spanish, by evaluating issues related to the design, content, and user engagement of the PtDA. We sought to make improvements to the application that would make RealRisks understandable to multi-ethnic women with a broad range of health literacy and acculturation levels.

Methods

Participants and Recruitment

Participants in the study were recruited from a database of women who had undergone routine screening mammography and previously consented to be contacted for future research. Participants were contacted by telephone and offered morning and afternoon sessions to partake in usability testing. Subjects who indicated that they were unable to use a computer or had serious issues relating to reading a computer screen were not eligible for the study.

We initially recruited 5 English-speaking subjects for the first round of usability testing. For the second round of testing, we recruited 2 English-speaking and 4 Spanish-speaking subjects after changes were made to the program. The literature has shown that conducting usability testing with at least 5 subjects will usually identify upwards of 80% of design issues, and that 10 subjects will identify a minimum of 82% of usability concerns before becoming repetitive.20,21 In total, 11 subjects participated in the usability testing for RealRisks. All subjects signed written informed consent and the study was approved by the Institutional Review Board at the Columbia University Medical Center (CUMC).

The RealRisks Decision Aid

The RealRisks PtDA is tailored to provide personalized information about chemoprevention to high-risk women in both English and Spanish. The PtDA contains 6 modules that provide various information about risk assessment and chemoprevention (Figure 1). Each module includes a comic following a fictional character, Rose, who discusses breast cancer risk with family, friends, and health care providers (the light narrative), a series of informational slides (the dense narrative), and interactive games (Figure 2). For example, the first module introduces users to the concept of risk through a “clicking” game that demonstrates the 5-year and lifetime breast cancer risk for an average 50-year old woman using a pictograph with 100 clickable women (Figure 4). This experience-based risk interface asks players to continue to click (e.g., sample from a population of women) to better learn the meaning of a given pre-set probability (i.e., 12 out of 100 or 12% of women will develop breast cancer in their lifetime) and has been previously shown to improve risk perception in high and low numeracy women.19,22 The second module outlines various risk factors for breast cancer and prompts the participant to calculate their Gail risk score and allows users to revisit the previous risk game using their personal risk for breast cancer. The third module asks users to input their family tree, with special attention to family members with a history of cancer. The fourth and fifth modules are tailored to the woman’s level of breast cancer risk and includes preference elicitation games (Figure 3). Module four gives information about BRCA genetic testing, whereas module five describes different breast cancer chemoprevention options. Preference elicitation is done through the use of scales that allow users to rate how important the risk of developing breast cancer, risk of side effects with chemoprevention, and various personal factors are to their decision about taking chemoprevention. The sixth module opens for all participants and provides information about lifestyle behaviors than can lower the risk for breast cancer. Completing all six modules generates an action plan that includes all of their inputted information that can be printed and shared with their PCP during their next clinic visit. A copy of the action plan is also provided to the PCP through the electronic health record via the BNAV tool. RealRisks is designed to be accessible on a computer, tablet, or smartphone. Development of the risk clicking game and other components of RealRisks have been addressed in previous studies.18,19
Usability Testing

Usability studies were conducted in English and Spanish by pairs of researchers who took on the role of moderator and observer and were bilingual for the Spanish-speaking participants. The moderator was tasked with receiving consent from the study subjects, orienting the subject to the PtDA, and providing guidance and assistance as the participant completed the study. The observer used Morae Observer software to view a livestream of the subject and code the usability study in real time on a separate laptop. This livestream captured the audio and visual image of each subject, as well as non-verbal reactions. The moderator was positioned across from the subject, while the observer was in a corner of the study room. All usability studies took place at CUMC.
Participants consented to be audio and video recorded. Prior to beginning the usability testing, subjects were asked to complete a short survey to indicate their familiarity with computer and web-based technology and validated measures of acculturation and health literacy. Study subjects were then introduced to the RealRisks platform and instructed to create an account using predetermined patient profiles and scenarios. These preset profiles included simulated health information that would activate both the genetic testing and chemoprevention eligibility modules without requiring subjects to disclose their personal medical history to the research team. Participants were then asked to complete the six RealRisks modules in any order they desired and follow a think-aloud protocol as they moved through the PtDA. In this protocol, subjects voiced their feelings and intentions about chemoprevention, the design of the application, and their understanding of the information as it was presented to them. When subjects ceased thinking aloud as they used the PtDA, they were prompted by the Moderator with questions relating to the section of the application they were on. The most frequently used prompts included “how are you feeling about the information on this page”, “what are you currently thinking about”, and “why did you decide to move to that section”. Prompting was not necessary for the majority of study subjects. The moderator did not interact with the participant beyond prompting and answering direct questions regarding the application.

Each usability study lasted approximately two hours or until the subject completed the entire RealRisks PtDA. The PtDA was considered completed once a subject had gone through all six modules of RealRisks and viewed their action plan. At the end of the testing period, all subjects were asked to complete the System Usability Scale (SUS), a validated 10-item questionnaire used to determine the usability of a software. The results of the SUS were used to determine the current usability status of RealRisks.

Data Collection and Analysis

Morae Recorder, Observer, and Manager software version 3.3.4 (Techsmith Corporation, Okemos, MI) was used for all usability recording and analysis. Morae software allows for the creation of usability study templates to be created with Tasks and Markers for ease of coding. Markers were used to label points in the video such as “error”, “participant prompted”, and “observation”. Tasks were used to identify when subjects had completed activities in RealRisks, such as “created an account”, “finished module 1”, and “viewed action plan”. All participant recordings were coded by two researchers – the first being the Observer and the second being an additional researcher involved in the study, usually the Moderator. The first round of coding was done in real time, while the second occurred immediately after the study.

Qualitative coding was used to identify themes regarding the design, content, and user engagement with RealRisks. Recurring issues brought up by participants were sorted into whether they related to the dashboard, light narrative, dense narrative, games, or action plan. SUS scores were calculated using the standard methodology described by Brooke. The results of the usability studies were used by the research team to identify opportunities to improve RealRisks. Feedback given to the programming team was used to update RealRisks prior to implementation of the tool among high-risk women.

Results

Participants

For the first round of usability studies, a total of 5 English-speaking subjects were enrolled. Of these subjects, 1 had difficulty with reading some information on the screen because she forgot her glasses – this subject was given assistance by the moderator to read the screen. In the second round of usability studies, 2 were English-speaking subjects and 4 were Spanish-speaking subjects. A total of 11 subjects took part in the two rounds of usability testing for RealRisks. Our sample population was relatively diverse, in terms of education level, race and ethnicity, health literacy and acculturation (Table 1). The English-speaking group had a higher median health literacy than the Spanish-speaking group, however, in both cohorts health literacy ranged from low to high. The English-speaking group was more acculturated than the Spanish-speaking group. Two subjects spoke a language other than English or Spanish – the one subject who identified her additional language spoke Amharic.

All subjects owned a mobile phone, and 9 owned a smart phone. All but 3 subjects owned a computer of some type, although at least 1 of these subjects indicated that she had a computer in the house but was not the owner. Of the 11 subjects, 10 had access to the internet in their home.

Theme Identification

Usability themes were grouped into Content, Ease of Use, and Navigation, which were used to identify potential usability problems that could be addressed by improving RealRisks. All themes were marked as being concerned with the dashboard, light narrative, dense narrative, games, or action plan. Major recurring themes and corresponding changes are described in Table 2.

Table 2. Themes identified and addressed during the usability studies.

Content Issues

Most problems arose in the dense narrative and during the genetic testing and chemoprevention preference elicitation games. Two subjects were vocal about their distaste for the light narrative, indicating that they thought the comics were “speaking down” or “not something I would read”. However, subjects who aligned more closely with the target population identified the cartoon figure of Rose as being “like me” and performing actions that were in line with what they would do in real life. Based on this feedback that some users prefer the light narrative whereas others dense, RealRisks was updated so that end users can complete either the light and/or dense narrative sections to trigger the creation of the action plan based upon their preferences for cognitive load.

Certain sections in the dense narrative were frequently confusing to subjects. Slides in depicting the growth of breast cancer cells was described as hard to understand and several subjects either asked the moderator for further information or described frustration with the use of technical words like “hyperplasia” or “atypia.” These concerns were addressed by improving the picture of breast cancer growth on this slide and using layman’s definitions in the rollovers on the slide. Similarly, use of the metric system on some slides was difficult to understand for at least two subjects. The dense narrative was edited to include measures in imperial units. A body mass index (BMI) chart that appears in the lifestyle factors module was difficult to read for subjects, with one staring at it for a period of time and expressing confusion at what she was looking at. This chart will be amended in future versions of the PtDA.

The most major content issue occurred with the preference elicitation games in modules 4 and 5 and overlapped significantly with ease of use. These games were designed to allow subjects to consider a variety of factors that may influence their decision-making about genetic testing or chemoprevention. In the original version of RealRisks, subjects were presented with a set of scales for genetic testing and each type of chemoprevention. Users would drag different factors onto the scale to indicate whether they considered it a positive or negative factor. The purpose of this activity was to elicit and visualize the user’s preferences. Content issues with this game included confusion over the purpose, lack of clarity regarding how the scale was weighted, and an inability of the scale to capture preferences outside of clinical factors such as “reduced risk of breast cancer” and “increased risk of endometrial cancer”. These concerns were addressed by completely redesigning the game to make the scale more intuitive. The changes included embedding the sliders directly into the page and allowing the scales to move with each slider. A Likert-type scale and color was also added to each slider. Examples of new nonclinical preference factors added to the game include “taking control of my health”, “don’t trust medications”, and “availability of social support”. A comparison of the before and after of this interactive game for chemoprevention can be seen in Figure 3.

Figure 3. Comparison of the original (left) and updated (right) versions of the preference elicitation scales for chemoprevention

Users were also confused about the purpose and structure of the action plan at the end of RealRisks. Original versions of the action plan did not specify explicitly that it was to be shared with her health care provider, and the layout of the page made it difficult to read. These issues were addressed by including more information about the purpose of the action plan and restructuring the page to be easier to comprehend.
Ease of Use Issues

Ease of use concerns were the most frequently brought up usability issue with RealRisks, but were generally minor to fix. These concerns primarily related to how easy it was to use some of the features of the games. In regards to the preference elicitation scales, there were issues with the sensitivity of the scales and the drag and drop functionality. We amended the tool to have all options preloaded, so subjects would not have to drag individual boxes (Figure 3).

For the risk assessment games, users were asked to click on a pictograph of 100 figures to identify one with breast cancer, which is a novel experience-based format for conveying risk information to those with low numeracy. Participants stated that the game took too long to complete and that it wasn’t clear how they were supposed to move on from the game (Figure 4). These issues were amended by shortening the number of clicks necessary to identify a breast cancer patient, improving the feedback for when a person was clicked, and adding a pop-up window to automatically find the patient after a certain number of clicks. Another issue with the clicking game that was brought up by both English and Spanish-speaking subjects was that the different rounds of the game were difficult to tell apart. Explanations of the risk of breast cancer appear in a yellow box to the right of the game, however, some participants found it confusing that the 5-year risk game was not further differentiated from the lifetime risk game. This concern was addressed by expanding the instructions and clearly labeling the two games.

Figure 4. The RealRisks “clicking game” used to visually demonstrate breast cancer risk

Some participants voiced difficulty with reading all of the information on the dense narrative screen – either it hurt their eyes or they would prefer to listen to the material. RealRisks was designed to include an audio option, and this feature was added in English and Spanish. Another ease of use issue occurred with the family tree in the family history module. In this game, subjects are asked to create a family tree by inputting information about their family. However, the final product did not include an index for what different shapes, colors, and lines meant, therefore, a legend was added to the family tree.

Navigation Issues

Navigation concerns were a minor recurring concern among study participants. Subjects generally chose to follow through the modules in order and found the process of moving through RealRisks to be intuitive. One recurring issue relating to navigation was confusion regarding where in the application the subject was supposed to go next. After completing a module, subjects would be brought back to the main screen with no indication of which module was meant to be next. This was addressed by improving the performance of a “checkbox” feature, that indicated to the subjects which items they had completed. When users start RealRisks, they are briefly guided through the features of the PtDA by a series of on-screen instruction boxes. One recommendation that was brought up by older English and Spanish-speaking subjects was the desire for some sort of tutorial to help guide participants through the rest of the PtDA. Another suggestion was to turn the introductory guide into a video to better explain the features of RealRisks. These recommendations will be implemented in a future version of the PtDA.
System Usability Scale Scoring

Every participant completed the SUS questionnaire at the end of the usability study. Scores varied appreciably between English and Spanish-speaking subjects. English-speaking users gave RealRisks a median score of 80.00 (range, 55.00-95.00), while Spanish-speaking users gave the application a median score of 66.30 (range, 55.00-75.00). The mean score between the two groups was 72.00. An empirical review of SUS scores has indicated that a SUS score between 65 and 70 is considered “ok” or “high marginal”, while a score above 70 is considered to be “good” or “acceptable” usability for a web-based application. This would indicate the need for further analysis and improvement of the RealRisks application based on the feedback we received from Spanish-speaking users.

Discussion

The aim of this series of usability studies was to evaluate RealRisks in order to better tailor the patient decision aid (PtDA) to women at high-risk for breast cancer, particularly multi-ethnic women with a broad range of health and computer literacy. By conducting studies in both English and Spanish, we were able to identify several issues across three themes that reduced the usability of the application for our target population. This study illustrates the importance of usability testing in creating culturally relevant and targeted PtDAs, particularly for web-based tools designed to be used by diverse populations with varying health literacy and acculturation.

Uptake of antiestrogens for chemoprevention remains low, in large part due to patients and providers viewing the risk of side effects as disproportionately higher than the potential benefits of breast cancer risk reduction. The literature supports that inaccurate perception of risk may lead women to overestimate their own breast cancer risk or the risk of side effects for chemoprevention agents. Thus, one of the goals in designing RealRisks and the corresponding usability studies was to improve the accuracy of users’ perception of risk. The “clicking” games, designed to help users explore pre-set probabilities, were developed based on previous research on risk perception but were not adequately describing risk to study participants in the format they were presented. By updating the feedback and explanations for these games, we were able to improve the application for all users.

Another key feature that differentiates RealRisks from other chemoprevention PtDAs is the use of preference elicitation games to engage users in making decisions based on their personal preferences. In the original version of RealRisks, users found these games difficult to use and reported confusion about their purpose. By redesigning the tool as a series of sliding scales, users are now able to adjust their preferences towards various aspects of genetic testing or chemoprevention in order to make more informed decisions. Furthermore, by adding more options to the scales, users are empowered to make decisions based on clinical and non-clinical factors, such as how chemoprevention will impact their family. By including the preference scales in the final action plan, users will be able to review their personal preferences towards chemoprevention with their family and primary care provider (PCP).

In our study, Spanish and English-speaking participants voiced similar concerns, and differences tended to arise based on health literacy and numeracy rather than acculturation. Spanish-speaking participants rated the PtDA as somewhat less useful based upon the SUS. Research on breast cancer decision-making among low-literacy Hispanic women, such as those targeted by RealRisks, has found that this population tends to report poorer decision outcomes when using a PtDA. PtDAs for this population tend to be more effective when they are culturally appropriate and better integrate clinicians and family members into the decision-making process. RealRisks is designed to provide women with an action plan that they can discuss later with their PCP and family members to facilitate decision-making about chemoprevention. Furthermore, RealRisks will be integrated into clinic workflow with the BNAV tool for providers. In an ongoing pilot study with 50 patient-provider dyads and an upcoming randomized controlled trial of RealRisks for high-risk women and BNAV for PCPs, we will assess shared decision-making when both patients and providers are primed prior to the clinical encounter with these decision support tools.

Strengths and limitations

There were several strengths to our usability studies. We achieved a sufficient sample size to identify at least 80% of usability concerns with RealRisks. The recurrence of certain themes in later studies indicated that we reached the saturation point of usability testing. Features that were problematic during the first iteration of tests, such as the preference elicitation scales, were viewed as more usable in the second round. Usability testing was conducted in
both English and Spanish in order to address concerns relevant to the multi-ethnic population that the PtDA was designed for. Furthermore, the population included in the study was diverse and represented a broad range of ages, ethnicities, and acculturation levels. The majority of problems for English-speaking subjects were also found by Spanish-speaking users, indicating that there may be similarities in how both populations view PtDAs, despite differences in acculturation and health literacy.

Limitations in our study were primarily due to the structure of RealRisks and usability testing in general. The web-based format of the PtDA restricted the inclusion of women who were computer illiterate or unable to read a computer screen. Additionally, the think-aloud protocol was difficult for older participants to understand and utilize and necessitated frequent prompting by the study moderator. While think-aloud protocols are standard for usability testing, there is some evidence that using concurrent think-aloud methodology might decrease user engagement during studies. While our sample was diverse, recruitment was limited to women who were able to come in for testing during work hours and thus may not have fully captured usability issues that would impact all populations that use RealRisks. Finally, the time limit placed on each usability study meant that some subjects were unable to complete the entire PtDA in a single sitting. Participants were guided towards relevant sections when time was low, and therefore certain problems may have been missed by users who skipped modules.

Conclusion

In conducting usability studies for the RealRisks decision aid, our team was able to identify several key issues that informed the design of the tool for our target population of low-literacy, multi-ethnic women. Our study is unique in that it incorporated the suggestions and feedback of a very diverse population of potential users and found that concerns were similar between English and Spanish-speaking participants but that differences arose based on health literacy and numeracy. Users reported moderate to high satisfaction with the overall usability of the tool, and future changes will be made to address concerns specific to Hispanic users. Future usability studies of web-based PtDAs should take into account the computer literacy, acculturation, and health literacy of participants when testing in order to develop tools which are accessible to diverse populations.

ABSTRACT

Standardization of clinical data element (CDE) definitions is foundational to track, interpret, and analyze patient states, populations, and costs across providers, settings and time – critical activities to achieve the Triple Aim: improving the experience of care, improving the health of populations, and reducing per capita healthcare costs. We defined and implemented two analytical methods to prioritize and refine CDE definitions within electronic health records (EHRs), taking into account resource restrictions to carry out the analysis and configuration changes: 1) analysis of downstream data needs to identify high priority clinical topics, and 2) gap analysis of EHR CDEs when compared to reference models for the same clinical topics. We present use cases for six clinical topics. Pain Assessment and Skin Alteration Assessment were topics with the highest regulatory and non-regulatory downstream data needs and with significant gaps across documentation artifacts in our system, confirming that these topics should be refined first.

Introduction

Standardization of clinical data definitions for use in a learning health system is a critical foundation to achieve the Healthcare Triple Aim: 1) Improving the experience of care, 2) Improving the health of populations, and 3) Reducing per capita costs of health care.\textsuperscript{1} Improving the experience of care requires effective coordination across people, time, and settings, but is effectively enabled only with consistent data to track patient states. Improving the health of populations is dependent on common data definitions to group similar patients across sites and providers, enabling the identification and tracking of patient need and outcome patterns. Reducing per capita costs of health care requires reliable comparisons of clinical data across settings, health professionals, and research databases, particularly considering the need to understand relationships between cost, care complexity, and patient outcomes.

Prospective clinical data collection, even if performed efficiently, is not substantially useful if it is not “reliable” (i.e. collected using inconsistent data definitions), and/or not “computable” (i.e. collected using nonstandard formats and values). Unfortunately, consistent and standards-based data definitions for EHR clinical documentation do not naturally emerge, even within the same clinical information system, without proper clinical governance and technical oversight.\textsuperscript{2}

Background

Definition of standardized data sets for clinical documentation, often operationally known as Minimum Data Sets, have been used to enable effective clinical data analytics, such as nursing care and management across hospitals, and clinical assessment of all residents in Medicare or Medicaid certified nursing homes.\textsuperscript{3–8} The Nursing Minimum Data Set and Nursing Management Minimum Data Sets have been added to LOINC\textsuperscript{9,10}, an internationally adopted standard terminology. Standard terminologies help ensure that discrete clinical data elements (CDEs) can be aggregated and compared across patients, providers, and care delivery sites. Standardized data sets also identify the specific collection of CDEs necessary to represent a given clinical domain or topic. Each collection of CDEs can be simply characterized as a “reference model,” or more appropriately as a “detailed clinical model”.\textsuperscript{11–13} A few publically available sources provide ready-to-use clinical reference models, or sometimes preliminary examples that can inform the development of new models for a given clinical topic.\textsuperscript{14–19}

At our organization we leverage these terminology and model resources to refine existing clinical data reference models, or to develop new models, always seeking a direct application to our commercially available EHR.\textsuperscript{20} We have developed a process to validate reference models based on pre-defined best practices and consensus of interprofessional subject matter experts (SMEs).\textsuperscript{21} The central deliverable of our process is a reference model that can be effectively implemented using our EHR, ensuring consistent data capture and documentation across settings, professions, and purposes.
Detailed and consistent data capture within commercially available EHRs is critical to building a learning health system. While the need for consistent data is widely recognized, the required methods and scope definition, particularly the specific steps for identifying EHR data collection tools (e.g. forms and flowsheets) that need refinement and alignment with available standards, remain unclear to many stakeholders and organizations. Critical initiatives are in process, such as the S&I Framework Structured Data Capture Initiative and HL7 Clinical Information Modeling Initiative (CIMI). However, individual organizations are overwhelmed with the effort required to refine CDE definitions within their EHRs and may ask “where do we start?” or “do we have enough resources to complete the work?”.

To help organizations answer these questions, we have defined practical analytic methods to: 1) identify priorities for the definition of clinical data reference models and, 2) identify and resolve gaps between existing EHR data collection tools and validated reference models. These methods can be applied within and across EHR systems as a systematic and rigorous path to align data definitions within and, eventually, across healthcare organizations.

Methods

We previously published a description of a process for governance and refinement of structured data elements. In that publication we outlined a 10-step approach that: 1) identifies clinical topics, 2) creates draft reference models for clinical topics, 3) identifies downstream data needs for clinical topics, 4) prioritizes clinical topics, 5) validates reference models for clinical topics, 6) perform gap analysis of EHR CDEs compared against reference model, 7) communicates validated reference models across project members, 8) requests revisions to EHR CDEs based on gap analysis, 9) evaluates usage of reference models across project, and 10) monitors for new evidence requiring revisions to reference model.

In this paper we focus on a more detailed description of the metrics and analytical processes involved in the scoring of downstream data needs to prioritize clinical topics and, the process to identify gaps when EHR documentation artifacts are compared against reference models. Figure 1 illustrates how these criteria combine to help prioritize and direct EHR refinement. We view steps 3, 4, and 6 as the most critical steps from an organizational perspective, since these steps provide a rigorous and repeatable method to identify refinement priorities in the context of limited resources. A detailed description of steps 3, 4, and 6 is not included in our prior publication.

Figure 1. Criteria to Prioritize Clinical Topic Refinement

Downstream data needs

The analysis of downstream data needs begins with an environmental scan for the following types of needs related to the identified clinical topic: 1) regulatory, 2) billing, 3) reporting (via automated extracts), 4) clinical decision support (CDS), 5) reporting (via manual chart review), 6) quality initiatives, 7) past data usage statistics, 8) order sets, 9) plans of care, 10) institutional protocols, and 11) literature (published evidence). The environmental scan may require input from SMEs, such as hospital quality and compliance experts. Since the aim of this analysis is to identify high priority topics, an extensive and exhaustive environmental scan is not always necessary. This approach purposefully exploits the underlying assumption that important downstream data needs are readily and efficiently identified during brief interactions with SMEs and from relatively simple online searches. In exploiting that assumption, the usefulness of this method is tied to expedience and analytical rigor, as well as repeatability for comparisons between topics.

Data needs are categorized in two tiers: “direct data needs” (Tier 1) and “indirect data needs” (Tier 2). A direct data need is defined as requiring a process of automated reuse for data filed within a structured CDE, such as electronic Clinical Quality Measures (eCQMs) to Centers for Medicare and Medicaid Services (CMS) programs. An indirect data need is defined as not requiring a process of automated reuse for data filed within a structured CDE. Rather, an indirect data need may be fulfilled using manual chart review processes, such as chart extraction (e.g., quality initiatives), or in the course of clinical care (e.g., reference to protocols). Each identified data need counts as ‘1’ and is applied to the appropriate data need category (see Table 1).

Usage data is also an important variable in our model. During the transition phase while implementing a new EHR at our organization, we used usage statistics from our legacy EHR systems in our model. Six months after our new
EHR was implemented, we switched to usage statistics from our new EHR system. The usage data statistic is a simple rate of use per month and needs to be normalized for comparison with the other data need counts (which in our experience are typically in single digits). Based on an analysis of the counts of usage per month from our legacy systems for our initial set of clinical topics, we determined a cutoff range of 1,000 data points per month for any CDE to indicate high usage. CDEs that had less than 1,000 data points per month received a score of 0.5, topics with greater than or equal to 1,000 data points per month received a score of 1, and CDEs with no usage per month received a zero. The specific cutoff range and additional scores in the instance of particularly high usage (e.g., score of 2 for 2,000-2,999 data points/month, score 3 for > 3,000 data points per month etc.) may be modified per organization based on typical usage rates taking into account number of EHR users and patient encounters.

The downstream data need ‘count’ for each data need category and the weighted values from Table 1 are applied to the formula in Figure 2 below. The key requirement for this formula was that any topic with regulatory data needs should have a higher score than any topic without any regulatory data needs. In order to accomplish that, the first term in the formula is a regulatory term that includes a factor of the signum function applied to the count of the regulatory data sources. In the event that there are no regulatory data needs, this factor, hence the first term, has a value of zero so that the score value is simply equal to the rest of the formula, which is the nonregulatory part of the score. If there are any regulatory data needs, then the first term has a value which is greater than one and less than two. This property of the first term being greater than one is needed in order to exceed the value of the rest of the formula, or the nonregulatory component, which has a value greater than or equal to zero and less than one. This situation guarantees that a topic with even a single regulatory data need has a higher score than a topic with no regulatory data needs, even if such a topic has many nonregulatory data needs. The inverse square root function was chosen for the formula for more even scaling than an exponential or simple inverse function would allow, so that differences among topics could be better pronounced and visually distinguishable. It was also desired that the formula for this score gracefully scale with added data needs and across topics having different numbers of data needs. Using the inverse square root function in this way allows for this in order to confine the score value to a finite range, rather than allowing an unbounded score value as the number of data sources increases.

Using results from this formula we produce a scorecard summarizing Tier 1 data needs that can be easily disseminated among stakeholders. Regulatory data needs are given the highest weight due to their significance for healthcare institutions. The formula results in a weighted score between 0 and 3. Scores in the range of 0-1 indicate there is a non-regulatory data need only; scores in the range of 1-2 indicate there is a regulatory data need; and scores in the range of 2-3 indicate there are regulatory and non-regulatory downstream data needs. These scores are used to rank topics by their identified downstream data needs.

\]

Figure 2. Formula to calculate weighted Downstream Data Need Score per Clinical Topic
Gap analysis of EHR Clinical Data Elements compared against Reference Model

The development of reference models loses significance if the subsequent implementation of those models within an EHR system becomes too onerous and is deferred for a later date when implementation resources are available. The purposes of quantifying the gap between current state and the reference model are: 1) to estimate the effort required to close the gap for particular documentation artifacts, 2) to rank the documentation artifacts that should be prioritized for refinement based on estimated effort, and 3) to achieve reliability in alignment with the reference model across documentation artifacts.

Table 2. Calibration Metrics for Gap Analysis

</table>
Table 2 outlines our adaption of the MUC-5 (Fifth Message Understanding Conference) Evaluation Metrics, which were originally used to express error rates as part of a scoring system for template instances produced by information extraction systems when compared to manual extraction by humans. Each documentation artifact being evaluated is compared to the reference model by assigning to each CDE one of the following codes: match, partial match, conflicting, extra, or missing. Next, the four metrics are calculated for each documentation artifact: total mismatch, undergeneration, overgeneration, substitution. Each score is on a scale of 0 to 100, with higher scores for greater discrepancies. The total mismatch score is useful for a gross estimate and ranking of the effort required for aligning documentation artifacts with the reference model. The undergeneration score identifies CDEs that are not included on documentation artifacts. The substitution score identifies CDEs from the reference model that are inconsistently implemented in EHR documentation artifacts. This score is useful to identify changes that are slightly more complex than fixing undergeneration scores by simply adding new CDEs, but likely can be completed without further SME input. The overgeneration score identifies CDEs that may be irrelevant to the clinical topic, i.e. truly spurious, and that require additional review by SMEs for possible inclusion.

We view these metrics as useful to compare any reference model (i.e. set of standardized CDEs) to existing clinical documentation artifacts to identify gaps and work toward alignment. These metrics are also useful to directly estimate the level of effort, time, and expertise to align current documentation artifacts to the reference model and can be useful for readiness assessments at sites with limited resources (see Table 3). For example, based on estimates provided by analysts that implement changes to documentation artifacts in our EHR system, we can use the above described results to calculate the total amount of time required to make the necessary changes, including relevant EHR configuration details that might increase the complexity of the change.

Results

Downstream Data Needs

We display our results of the downstream data analyses for 6 clinical topics: 1) Pain assessment, 2) Skin Alteration assessment, 3) Lung assessment, 4) Mental Status assessment, 5) Gait assessment, and 6) Living Situation
assessment (see Figure 3). We also present the detailed ScoreCard for the two highest priority clinical topics: Pain assessment (see Table 4) and Skin Alteration assessment (see Table 5). The clinical topic Pain Assessment resulted in the highest weighted score for downstream data needs with a score of 2.76 out of 3. Skin Alteration Assessment was the second highest weighted score at 2.70 out of 3.0. Lung Exam, Mental Status, Gait, and Living Situation assessments were 2.56, 2.48, 2.42, and 2.2, respectively.

These results demonstrate that all six topics include regulatory requirements, indicating they are all high priority topics, and can be ranked in order of highest priority. The weighted score allowed for continuous updates to the score and ranking of these high priority topics as new needs were identified. For example, our initial list of topics did not include mental status assessment and lung assessment, but as usage data from our EHR became available, these two topics were identified as frequently documented and added to the analysis. This approach allows for an iterative process to identify and analyze downstream data needs with continuous updating of the prioritized list for selection of the next topic to devote resources for refinement.

### Calculation of Gap Analyses of EHR and EDC Compared Against Reference Model

We present the gap analyses for CDEs from each reference model that were identified by SMEs as important to be present on all clinical documentation artifacts in our EHR. We found that the total mismatch rate ranged from 26% to 82% for Pain Assessment CDEs on documentation artifacts. In comparison, the total mismatch rate ranged from 58% to 98% for Skin Alteration Assessment CDEs. Based on these calibration metrics and resources available a threshold should be selected and refinement efforts targeted at any CDEs above that threshold (higher scores = greater discrepancies). For example, we could establish a threshold of 60% for our data set. The undergeneration rate for the CDE ‘Pain Location Qualifier’ was 64% and the substitution rate was 67% across documentation artifacts analyzed. These rates were based on 20 documentation artifacts in which the CDE ‘Pain Location Qualifier’ was missing and 11 documentation artifacts in which the CDE ‘Pain Location Qualifier’ was a partial match. We can calculate (based on Table 3) that the 20 missing CDEs require a total of 100 minutes of EHR configuration (5 minutes/CDE), 0 hours for SME review, and 200 minutes for unit testing (10 minutes/CDE). The 11 partial match CDEs require 275 minutes (25 minutes/CDE), 1-2.5 hours for SME review, and 550 minutes for unit testing (50 min/CDE). Therefore to optimize the clinical data capture of the CDE ‘Pain Location Qualifier’ throughout our EHR will require a total of about 20 hours of effort. These estimates are intended to be realistic with time allotted for troubleshooting and team communication as needed.

Figure 5. Mismatch of Clinical Data Elements in Documentation Artifacts Compared to Skin Reference Model
Discussion

Refinement of EHR CDEs and documentation artifacts is a continuous process that requires consistent effort, yet is often delayed due to a lack of resources, competing deadlines, and difficulty identifying “where to start”. We found that analyzing downstream data needs at the clinical topic level, and calibrating how well documentation artifacts for that topic matched CDEs from a validated reference model was an effective and productive exercise to initiate and direct refinement efforts for our EHR. This approach is both rigorous and flexible. The metrics provide rigorous comparisons while the ranking and selection of clinical topics and CDEs in which to focus our efforts can consider contextual organization factors such as available resources, strategic quality and safety initiatives, and usage statistics. We believe this approach is useful for topic prioritization and re-prioritization as priorities shift. For example, ‘Pain Assessment’ may be shifting in priority and/or management approach due the Opioid Epidemic.

One of the strengths of the downstream data scoring system is that the scoring is performed at the individual CDE level to identify priorities within clinical topics. The clinical topics serve to scope and group the work to catch inconsistencies in CDE definitions within the context of that topic. For example, inconsistencies may not be detected if only the CDEs that address regulatory requirements were selected for analysis and refinement. For example, a Pain Assessment Scale may appropriately capture data to meet a regulatory need; however, if the other CDEs on that documentation artifact are inconsistently defined it will be challenging for an organization to use sets of data from that documentation artifact in a useful way, besides meeting that isolated regulatory requirement.

To our knowledge, this is the first publication to propose a prescribed, rigorous process and metrics to use for prioritizing work to optimize EHR structured CDEs. We believe the initial time investment required to conduct these analytic activities is realistic and is particularly critical for organizations with limited resources. As expected, we found a high rate of mismatch between a number of CDEs from the reference models and their implementation on EHR documentation artifacts. We used these metrics to highlight which CDEs have the greatest need for alignment with EHR documentation artifacts and the resources required to achieve that alignment. As one example, we quantified that 20 hours of resources was required to optimize one CDE throughout the EHR system. These estimates assume that work is conducted to refine only one CDE at a time. In the instances when refinements can be scaled (a set of CDEs can be refined on one or more documentation artifacts together) there is likely a decrease in total resources required. From a governance perspective, the ability to quantify the resources needed to refine a constrained set of high priority clinical topics is important for organizations hoping to realize a return on investment from the interoperability and data analytics capability of their EHR implementation. The priorities and estimates that result from our analytics can be used to prioritize refinement work to fit allotted resource hours or to request resource hours based on refinement work that is a high priority for an organization.

Limitations

This work has been performed at one integrated health care system during, and immediately after, implementation of a vendor-based enterprise-wide EHR. These metrics and processes should be applied at other institutions to understand how to best apply and integrate them across different operational clinical informatics governance structure and resources. Evaluation of the use of these metrics and processes is needed to quantify their added value in the context of enabling analytics and secondary use of structured data as well as prioritizing work and resources. Finally, the work described is limited by the topics identified and the scope of those topic areas. Topic identification could be enhanced through mining or Natural Language Processing of EHR data for topic areas that are highly used.

Conclusion

Refinement of CDE definitions on documentation artifacts across an enterprise EHR system can be an overwhelming task. We propose a set of metrics that can prioritize and direct this work as part of continuous refinement activities and alignment of EHR data. We presented use cases of high priority topics. In the use cases presented, we found high rates of mismatch between CDEs from our validated reference models and documentation artifacts, indicating the need to move forward with refinement of these artifacts. EHR refinement is an iterative process that requires insightful expertise and motivated individuals. These metrics can illuminate priorities and gaps to focus efforts. We believe these analytical steps are practical and generalizable across organizations and should be shared as a critical collaborative step toward continuous EHR refinement and alignment.

Abstract

Mosquito-borne diseases account for multiple public health challenges in our modern world. The international health community has seen a number of mosquito-borne diseases come to the forefront in recent years, including West Nile virus, Chikungunya virus, and currently, Zika virus. Predicting the spread of mosquito-borne disease can aid early decision support for when and how to employ public health interventions within a community; however, accurate and fast predictions, months into the future, are difficult to achieve in urgent scenarios, particularly when little information is known about infection rates. New sources of information including social media have been proposed to accelerate the development of predictive models of disease progression. In this research, we adapted a previously described model for the spread of mosquito-borne disease using open intelligence sources. The novel implementation of a mixed-model for mosquito-borne disease was capable of being executed in minimal runtime. The results indicate that this model yields fast and relevant results with acceptable margins of error.

Introduction

In August 2014, in response to the rising threat of the Chikungunya virus in 47 Pan-American countries, the United States Defense Advanced Research Projects Agency (DARPA) announced its “Forecasting Chikungunya” Challenge, supported by Innocentive.com1. The goal of this challenge was to gather researchers, analysts, and interested parties to investigate and predict how the Chikungunya virus (CHIKV) would impact populations in 55 countries with relatively untested immunities, such as the United States2. Strategies for preventing the spread of Chikungunya on an individual level typically include avoiding travel to emergent areas, wearing clothing that covers extremities and exposed skin, using mosquito nets for beds, and of course, the usage of repellent3. Public health officials can encourage prevention as well by distributing mosquito nets, spraying densely mosquito-populated areas, and while notifying the public at large of methods for prevention. However, with CHIKV threatening the estimated 950 million individuals currently living in Pan-American countries, it is helpful to determine where the virus may hit hardest in tandem with, if not before, implementation of prevention strategies. There are a number of epidemiological strategies for modeling the spread of mosquito-borne diseases such as dengue fever4, malaria5, and yellow fever6. In 2012, Ruiz-Moreno et al. introduced a combined climate and epidemiological model for predicting the spread of Chikungunya virus in the United States via the Aedes mosquito, finding that climate-based changes could be used to classify regions of the United States according to epidemic risk7. In this model, Ruiz-Moreno et al. incorporated parameters for mosquito and human population density, temperature, and initial infection rates to forecast the potential peak of CHIKV with enough accuracy to recommend potential areas for targeted public health interventions, should the need arise.

To address DARPA’s call for methods to forecast the spread of CHIKV, we have implemented and modified Ruiz-Moreno’s model to extend it for use in any country or region, but specifically implemented it for Pan-American countries. The model was implemented for the months of September 2014 to February 2015, as per DARPA’s solicitation. This model takes as input total country population (N), land area (km²), mosquito population (M), temperature (C) and number of infected individuals (I). The population and area variables can easily be computed using available online resources (described further in Methods) and mostly remain constant, so the model largely depends on the current temperature (also easily found online, but frequency of change is according to the user), the mosquito population (estimated) and the number of infected individuals. In the Methods section, we describe how
we are able to collect these parameters using publicly available data and calculate or infer other parameters required to run the model. We have implemented the model using the R programming language to discern the rise in infected individuals, per country, on a weekly basis.

Methods

To forecast the number of cases infected with Chikungunya Virus (CHIKV) across the Americas, we modified the model proposed by Ruiz-Moreno et al\(^7\). The modified model, which we will informally identify as our SEIRM model, uses ordinary differential equations to simulate the dynamics of mosquito-borne infections in human populations. In particular, the human population is divided into susceptible (S), exposed (E), infected (I), and recovered (R) individuals. The mosquito population is also subdivided into immature eggs, larvae, eggs under diapause, and mature susceptible, exposed and infected. Parameters related to the life-cycle of the *Aedes* mosquito were taken from the literature, as reported in Ruiz-Moreno et al\(^7\). All of the data sources described below used for the forecasts are freely available and readily accessible.

Data Sources

The main data sources used included information from news reports gathered via an automated news information system (solely from HealthMap.org), weather data, and population and country size data. The model requires the following initial conditions: 1) the number of susceptible, exposed, infected, and recovered individuals in a given country; 2) the size of the mosquito population. The number of infected cases per country was extracted from HealthMap (www.HealthMap.org), an automated system that monitors information sources on outbreaks\(^8\). The rationale behind choosing HealthMap is that it provides almost instantaneous reports at a local level, as opposed to more traditional surveillance systems that may be lagging behind in their reports. This information can be filtered by species, disease, dates, and location; the data collected particularly for CHIKV was reported as it happened and not on a regular interval (i.e. a country was only reported to have cases on HealthMap if cases were found that day, week, or month). HealthMap was the main source for CHIKV infection numbers, but it does have some disadvantages. In some cases, HealthMap provides case numbers for entire countries and cities within those countries; the numbers provided for major cities might be contained within the country level estimate. To account for this, only numbers counted for entire countries were considered for this project. A second issue is that in some cases numbers were reported based on data mined from news reports, resulting in inaccurate reports on HealthMap. For example, in an article that may have stated “Experts believe cases could reach up to 100,000 in Chile,” HealthMap may report 100,000 cases for Chile when the actual number of cases would be much lower. This is an issue that seems to have been resolved on the website but was present in the early stages of the project. Some countries never had reported numbers of cases, or in the case of the Caribbean Islands, numbers were reported in groups (i.e. “St. Bart’s, St. Vincent, and St. Kitts collectively have X amount of cases.”) Finally, due to inconsistency of CHIKV reporting, there could be a long absence of reported cases for any given country and then a week where new numbers were reported everyday; the question remained which number to be used. As a result of these issues, we adopted the following guidelines for collecting CHIKV infection numbers from HealthMap:

1. For a given month, if a country reported infected cases on CHIKV, the *most recent* number of cases was recorded for our forecast (even if this number was not the highest possible).
2. If there was a large deviation from previous numbers (for example, one case reported in August and then 50,000 cases reported in September), the articles were manually investigated for their veracity – the *most recent* number with the most likely cases reported was recorded for use in the forecast.
3. Only numbers reported for countries were used; numbers for individual cities contained within eligible Pan-American Health Organization (PAHO) countries were ignored.
4. If a country had no cases reported for that time interval, a Google News search for the country’s name and chikungunya (i.e. “Anguilla chikungunya”) was performed to validate that no cases had been reported. If an article was found where some cases had been reported, it was individually evaluated for reliability and if it was deemed a reputable source, that number was recorded. If this scenario occurred, the source of the number recorded was also recorded.
5. If no change had been reported from month to month for a country via HealthMap and no reputable new source was found via a Google News search, the initial number of infected was not changed.
6. For each country at each forecast, we have recorded whether the number of infected cases came from HealthMap or a news article found via Google News search.

The CHIKV numbers were recorded as described above via HealthMap and other sources were used for each country as the initial number of *Infected*. To estimate the other initial values (*Susceptible, Exposed, Recovered*), the
total population was found for each country via Google search (i.e. “Anguilla population”) and recorded using the following approach. Given a list of $C = \{c_1, c_2, \ldots, c_N\}$ countries provided, a Google search for each country in $C$ was performed using the search term “$c_i$ population” where $c_i$ represents the current country in $C$. This search was done manually as less than 100 countries were being studied and to use an API would require more time and work than just searching manually. For country population, Google provides not only a list of search results in the form of hyperlinks, but also a “definitive” population based off the last major formal census of the region as the top result. This is the number that was used to determine the total country population – the definitive population stored by Google’s “Map Data” resource. The values for remaining compartmental populations of a country (Susceptible, Exposed, and Recovered) were estimated using the following simple equations (chosen arbitrarily to reflect reasonable and conservative estimates):

Given the Country population ($P$) and Infected Population ($I$):

$$\text{Recovered (R)} = I \times 0.75$$
$$\text{Susceptible (S)} = (P - I - R) \times 0.9$$
$$\text{Exposed (E)} = (P - I - R) \times 0.01$$

Initially, the Exposed population was set to $(P-I-R) \times 0.1$ to ensure that $S+E+I+R = P$. However, in our model this resulted in a very large number of persons becoming infected and was felt to inaccurately describe a realistic scenario of exposed persons. As such, in October forecasts and further, a new Exposed equation was adopted and each country was held to the condition that $S+E+I+R < P$.

To estimate the size of the mosquito populations at a per-country level, we used mosquito density data reported by Eiras and Resende for Brazilian municipalities\(^9\), and the surface area of each country. Although the estimates are necessarily only approximations, we found a change in predictive power over simply using a fixed number of mosquitoes for each country.

The average monthly temperature (AMT) in Celsius was collected for each country for every month from 2001 to 2010. Latitude, longitude, and temperature data was downloaded from the following website provided by The Centre of Climatic Research, University of Delaware\(^10\). The Google maps API was used to convert the latitude and longitude information to its respective country name. Temperature data for a country was calculated as the average of temperature readings from all the points in that country. For each month from 2001 to 2010, the AMT was averaged to get a single value for input into the model. As such, for every forecast, the input parameters for weather changed according to the average of all AMTs for that country in that month from 2001 to 2010.

**Model Implementation:**

The aforementioned modified Ruiz-Moreno model was implemented in R using the `deSolve()` library and an array of inputs and parameters described below. Equations that have been modified from the Ruiz-Moreno manuscript are highlighted in bold and described in a comment; many of these modifications are very small. All involve removing a density-dependent parameter specified in the original paper that was defined only for certain US cities (Miami, Atlanta, and New York) and these parameters could not be effectively estimated for duplication in our model. Very brief pseudocode of the model can be found below. The code for the model can be found at https://github.com/katecooperOMA/Chikungunya.

```r
/***Begin model***/
1 Load library deSolve and other requirements
2 /***Load inputs by user***/
3 initials = {
4   country = user input
5   S = user input #Susceptible
6   E = user input #Exposed
7   I = user input #Infected
8   R = user input #Recovered
9   G = user input #Mosquito population by country size
10  temp = user input #Average AMT for country during current month
11 }
12 /***Load Hard Parameters by Ruiz-Moreno***/
13 parameters = { Adult mosquito population, symptomatic/asymptomatic ratio, etc.  }
14
15 /***Load Soft parameters by Ruiz-Moreno #See [7]for full definitions***/
16 parameters = { mosquito egg mortality, larval mortality, incubation period, etc.}
17 population = S+E+I+R
```
19 \( dT = \text{sequence 1 to 4 by 1/7} \)  \# define the time interval desired
20 \text{SEIRM}\_function = |
21 \quad \text{define changes in mosquito populations (adult, larval), compartmental populations}
22 \quad \text{population} = S+E+I+R
23 \quad \text{der}<-\text{c}(dS, dE, dI, dR, dG, dD, dL, dAs, dAe, dAi) \quad \# \text{der is a function of deSolve library}
24 \}
25
26 \text{simulation}<-\text{as.data.frame}(\text{lsovda}(\text{initials}, dT, \text{SEIRM}\_\text{function}, \text{parameters}))
27 \text{output results}

For each forecast, the inputs (S, E, I, R, G, country name, and temperature) were collected and ran using a small Perl wrapper that iteratively ran each command in a designated folder where outputs and error logs, if any, were collected. The model gives S, E, I, and R predictions for 21 weeks after the initial values but only the Infected numbers are recorded. Because the country temperature input changed from month to month, the model was run for every month remaining in the forecast. For example, for the December 1 forecast, the model was run three times: once for December, once for January, and once for February. The output of December’s forecast, then, became the input for January’s forecast, i.e., if the number of infected cases for the last week of December was predicted to be 30, then 30 was used as the initial value of Infected for the January iteration of the December forecast. Similarly, the last week of the January forecast then became the initial value for the February model iteration. This was structured according to the DARPA Forecasting Chikungunya Challenge guidelines.

A number of parameters used in our model were held steady at every iteration; these included: the adult mosquito population, the number of eggs per mosquito per day, the rate of symptomatic to asymptomatic individuals, the biting rate of the mosquito, the infective period, the probability of both human-to-mosquito and mosquito-to-human transmission, the density dependent factor for reproduction and density function, and the natural and disease-induced mortality rates. The numbers are estimates and were taken from Ruiz-Moreno et al. and after discussion, it was determined that none of these parameters had enough evidence to warrant their change in our model in its early stages. Other constant parameters included were country population and area/size.

Saint Martin and Sint Maarten were counted as two separate countries.

Results

Real-world Performance. The ability to effectively display the results of simulations is particularly important in this domain, where several different scenarios might have to be explored and interpreted by professionals with diverse backgrounds and expertise. Our model generates an easily interpretable time-dependent chart, illustrating the number of predicted susceptible, infected, and recovered cases over a given time range.

In Figure 1, we documented our forecasts for all months (September, October, November, December, January, and February) compared to Historical PAHO data in Haiti. For example, our September forecast for Haiti predicted a slow rise to around ~30,000 infected cases reported by February (Figure 1); by the time the October forecast came due, HealthMap had reported several cases in Haiti and future predictions reflected this update. With a population

![Figure 1. Our forecasts for Haiti compared to Historical PAHO data (HIST)](image-url)
around 103 million, the number of cases in Haiti was predicted to represent around 90,000 or 0.87% of the population. This prediction model also applies well to smaller countries. A similar data plot is shown below for Montserrat (Figure 2), which has a population of around 5,900 individuals. Our initial predictions for September and October predicted a rise to approximately 100 or 120 infected individuals by February; in the final week of December, Montserrat reported an increase in cases from 6 (first reported in Week 42) to 119 (reported in Week 52). However, with few to no cases reported by HealthMap in December or January and a change in temperature, our December, January, and February forecasts assumed a low initial Infected value and a slow climb in the number of cases. Still, at 119 cases, this represents about 2% of Montserrat’s total population.

St. Bart’s (Figure 3) is an example of a case where nothing was being reported specifically for the country in the news or on HealthMap itself; occasionally it would be included in a count for a group of countries, but being a small island with a small population, this country did not manifest itself in the news often. As a result, our forecasts predicted a slow rise in the number of cases (compared to the actual number of cases reported); when these predictions did not reflect the HealthMap/news data released in the next month, the slow rise in cases was simply pushed back by the model to the next month.

For countries where the mosquito population is not regularly be exposed to CHIKV, such as the United States or Canada, our initial forecasts predicted far too many cases because numbers for exposure and mosquito populations were not modified (Figure 4). However, once the temperatures in these countries dropped, our predictions became (slightly) more accurate.

Suriname (shown in Figure 5) is an example of a country where we are not yet quite sure how well our predictions have come out; as of the time of this manuscript they had not reported their CHIKV cases since Week 44. All indicators suggest that while we had a few differences in the severity of infectiousness trend, this prediction may be one that is more accurate than others. Further, we can also potentially display the number of cases on a geographic map over time, a type of representation that is particularly useful to track the spread of the disease and the effects of containment measures in specific areas.

Sensitivity Analysis. It is difficult to perform accurate sensitivity or uncertainty analysis on our model due to incomplete and inconsistent PAHO reporting. However, we have completed some tests to investigate how much our forecast would deviate by modifying temperature, mosquito population, and number of infected for the most populous country (United States at 313 million), the least populous country (Saba at 1,824), the median country for population (Guadeloupe at 17 million) and the average country for population (Chile at 405,739). We ran our forecast for 22 weeks based on our input data for February 2015 for each of these countries, and identified three major areas of modification to investigate: (1) change in the original input temperature (+ or -20C), (2) change in mosquito population (+ or – 50% of the February input mosquito population), and (3) change in the number of infected (increases of 10%, 20%, and 30% of the February input of infected cases). The results of these iterations are below.
Saba: the smallest PAHO country by population (Figure 6). The number of infected for Saba was only distinctly affected by the temperature – it would appear based on the curves for both an 20C increase and decrease in temperature that the ideal temperature for CHIKV spread would be around the current average temperature there, 27.2C. However, the forecast shown assumes this temperature remains the same for the next 20 weeks – this would not be the case in a real world situation. Changes in mosquito population and number of infected have minimal effect on the outcome of the 22 week forecast, with mosquito population having a 22 week range of ~25–45 infected and number of infected forecasts all having a 22-week prediction of ~35 infected.

Figure 3. Our forecasts for St. Bart’s compared to Historical PAHO data (HIST)

Figure 4. (Left) All forecasts for the United States and (Right) the December, January, and February forecasts for the United States

Figure 5. Our forecasts for Suriname compared to Historical PAHO data (HIST)
Chile: the average PAHO country by population (Figure 7). None of the forecasts for Chile were distinctly affected by any change in parameter. A change in temperature resulted in a 22-week prediction range of 5966 infected (20°C decrease) to 7158 for a 20°C increase, a difference of only 1192. A change in mosquito population resulted in a range

Figure 6. Modified Forecasts for Saba. Top left: Forecasts for original Feb. 2015, or with a + or -20°C input modification. Top right: Forecasts for original Feb. 2015, or with a + or -50% mosquito population. Bottom: Forecasts for original Feb. 2015, or with a + 10%, 20%, or 30% population increase.

Figure 7. Modified Forecasts for Chile. Top left: Forecasts for original Feb. 2015, or with a + or -20°C input modification. Top right: Forecasts for original Feb. 2015, or with a + or -50% mosquito population. Bottom: Forecasts for original Feb. 2015, or with a + 10%, 20%, or 30% population increase.

Chile: the average PAHO country by population (Figure 7). None of the forecasts for Chile were distinctly affected by any change in parameter. A change in temperature resulted in a 22-week prediction range of 5966 infected (20°C decrease) to 7158 for a 20°C increase, a difference of only 1192. A change in mosquito population resulted in a range
of 6222 to 7990 infected for a 50% decrease and a 50% increase respectively. The increase in number of infected resulted in a predicted range of 7208 (10% increase) to 7360 infected (30% increase).

Guadalupe: the median PAHO country by population (Figure 8). None of the forecasts for Guadaloupe were
distinctly affected by any change in parameter; in fact, two of the modifications (temperature and mosquito population change) had almost no impact on predicted number of infected at all. A change in temperature resulted in a 22-week prediction range of 1,101 infected (20°C decrease) to 1,093 for a 20°C increase, a difference of only 8. A change in mosquito population resulted in a range of 1,097 to 1,112 infected for a 50% decrease and a 50% increase respectively. The increase in number of infected resulted in a predicted range of 1,203 (10% increase) to 1,402 infected (30% increase).

United States: the largest PAHO country by population (Figure 9). The forecasts for the United States were the most affected by any changes both temperature and mosquito population. A change in temperature resulted in a 22-week prediction range of 9,333 infected (20°C decrease) to double that at 18,556 for a 20°C increase. However, the original February forecast inputs were very similar in range to the 20°C decrease in temperature, suggesting that the 20°C increase or decrease signaled a change in mortality for mosquito populations, thus affecting the number of infected. A change in mosquito population resulted in a range of 5,992 to 11,048 infected for a 50% decrease and a 50% increase respectively. The increase in number of infected resulted in a predicted range of 8,574 (10% increase) to 8,470 infected (30% increase).

These results suggest that our model is potentially at its best when dealing with populations in the average or median range, but can also perform on very small and very large populations. The biggest changes observed were between the parameter modifications in the United States, the largest PAHO country by population. Compared to the forecasts of Guadaloupe (with a population of 17 million), this suggests that a threshold for integrity of the model as it sits currently may lie somewhere between 17 and 300 million population. All of this, of course, is speculative at best – more rigorous robustness testing with accurate PAHO data would better reveal the strength and predictive power of the model.

Applicability. The SEIR model that was used for our predictions can be easily applied to other mosquito-borne diseases such as Malaria, West Nile, dengue fever, Congo-Crimean hemorrhagic fever, or yellow fever. Depending on the type of disease, parameters related to the infectivity of the agent and to the life cycle of the vector would have to be suitably chosen, but the general structure of the model does not require major changes. This extends to diseases transmitted via other vectors such as ticks to humans and animals alike; the main dependencies of the model lie in initial values, population, temperature, and area of a country or district. Of course, the model can be modified. In fact, related SIR (Susceptible, Infected, Recovered) models have been successfully used in the past to model the spread of dengue fever and other borne infectious diseases [4][5]. This could, then, theoretically be applied to other diseases such as Ebola or measles, with relatively small changes.

Computational Resources. The model does not require specialized hardware, and can run on a desktop computer or laptop. It is implemented in the widely used R language, which is freely available for Windows, Mac OS X, and Linux platforms. A simulation takes approximately 15-30 seconds for all countries on a Late 2013 MacBook Pro with 2.4 GHz Intel processor running OS X 10.9.3.

The model is general in its implementation, and can be easily adapted to accept data sources that are different from the ones that were used for this research. For example, instead of news reports from HealthMap the model could use surveillance data or other sources containing the incidence of new cases. Furthermore, all of the data collection and processing can be scripted and automatically run at certain intervals without user interaction.

Conclusion

Our modified Ruiz-Moreno model is a simple and easily interpretable approach that uses freely available data. The datasets used as input are reliable, ranging from very high confidence (population and country area/size) to moderately reliable (HealthMap data and news reports). The model runs very quickly (under 1 minute) on most laptop computers equipped with the R statistical suite and the essential libraries discussed previously. Additionally, our model is discriminatory – it remains free of extraneous variables and data by depends largely on initial values, temperature, population and land area to determine rates of infection. More variables can be added as they are deemed important by public health authorities. The contribution of this research is a novel implementation of a mixed model for -borne disease that executes in minimal (<5 minute) runtime using only publicly available information.

Abstract

Sudden Unexpected Death in Epilepsy (SUDEP) is the leading mode of epilepsy-related death. The Center for SUDEP Research (CSR) is an NINDS-funded Center Without Wall’s initiative aimed at prospectively creating a comprehensive clinical research resource for SUDEP. This resource consists of a growing set of data and biological samples of a statistically significant cohort of patients at an elevated risk, best represented by the Epilepsy Monitoring Unit (EMU) patient population. The Informatics and Data Analytics Core (IDAC) of CSR has developed a state-of-the-art informatics infrastructure, to integrate patient data captured in multiple EMU’s at a greatly accelerated pace. Data quality assurance is a priority of IDAC. This paper reports our approach, Ontology-guided Data Curation for Multisite Clinical Research Data Integration (ODaCCI), to address the challenging task of centralized data curation while new data is continuously generated and integrated from distributed sites. ODaCCI leverages the Epilepsy and Seizure Ontology not only for upstream data capture, but also for supporting a range of quality assurance tasks such as data quality monitoring, data update, and data reports. Between October 2014 and February 2016, ODaCCI has integrated phenotypic and electroencephalogram signal data of 629 patients from 7 clinical sites, while supporting continuous and asynchronous data quality enhancement over time.

1 Introduction

Data errors in research databases are prevalent. They include inaccurate interpretation of data in the initial documents and incorrect data entry into databases [1]. Data quality (DQ) in clinical research is a fundamental topic because it impacts the subsequent decisions and conclusions [2, 3]. Researchers have shown that electronic health records (EHR) often contain errors that may affect research results [4]. However, the process of data quality auditing and improvement is challenging because of multimodality, the lack of provenance information, the lack of coordinated versioning and updates, and the time and effort needed.

Data quality assurance is a unique, acute challenge for prospective, multi-site studies such as the National Institute for Neurological Disorders and Stroke (NINDS) funded Center Without Wall’s initiative called the Center for SUDEP Research (CSR [5]). The CSR is a collaboration of 14 institutions, bringing together scientists and physicians to investigate and identify the molecular and structural brain abnormalities underlying SUDEP. The potential discoveries could then be utilized to identify features that could predict and identify patients at risk of SUDEP. Clinical phenotype, electroencephalogram (EEG), imaging and other data are prospectively collected from CSR patients in multiple participating Epilepsy Monitoring Units (EMUs). As the EMUs capturing multi-modal patient data, such data are de-identified and integrated into the CSR central data repository. Data correction and update at the source is less feasible than in the central data repository, sometimes because of the lack of resources, other times because of the lack of specific knowledge about a domain at an individual site. The Informatics and Data Analytics Core (IDAC) of CSR adopted a strategy to perform centralized data curation, by reviewing and cross-referencing linked physiological data such as video-EEGs to enhance data quality.

The paper introduces an ontology-guided approach to support the IDAC data curation strategy, called ODaCCI, by integrating curation and reporting interfaces into the CSR data integration pipeline. A collection of 95 common data elements were identified by CSR domain experts as the main curation targets. ODaCCI consists of an epilepsy domain ontology-guided, web-based, data curation interface to support data auditing, error correction, and data entry, with an interactive reporting interface for auditing the completeness of the types of data uploaded from multiple sites. A total of 629 patients’ data sets have been integrated from 7 clinical sites from October 2014 to February 2016. Among them, 393 are from University Hospitals of Cleveland (UH), 65 from New York University (NYU), 11 from
University of California, Los Angeles (UCLA), 54 from Northwestern University (NW), 44 from Thomas Jefferson University (TJU), 56 from University College London (UCL), and 6 from University of Iowa (UIowa). ODaCCI supports continuous and asynchronous quality improvement while data has been ingested and integrated from multiple clinical sites.

2 Background

2.1 Center for SUDEP Research (CSR)

Epilepsy is the most common serious neurological disorder, affecting 65 million people worldwide [6]. Sudden Unexpected Death in Epilepsy (SUDEP) is one of the leading modes of epilepsy-related death. More than 1 out of 1,000 epilepsy patients die from SUDEP each year [7, 8]. However, the mechanism causing SUDEP is not well understood [5]. CSR is an ongoing NINDS-funded Center Without Walls initiative for Collaborative Research in the Epilepsies [9], to accelerate the understanding of SUDEP by bringing together extensive expertise from 14 institutions across United States and Europe. Due to the low annual incidence of SUDEP (∼1%), cross-institution data sharing are required to collect SUDEP/near-SUDEP data of sufficient statistical significance. This is the mission of CSR, with the goal of recruiting at least 2,500 cases from EMUs in the participating clinical sites to support prospective recruitment and identify possible risks for SUDEP.

2.2 CSR Data Integration Challenges

Major challenges to the CSR data integration include, but are not limited to, the following:

- **Data heterogeneity.** Phenotypic data were captured in disparate formats (e.g., EHR, PDF documents) in different clinical sites. The integration of heterogeneous data is the most critical issue in a multisite research setting.

- **Data access restriction.** This involves the protection of privacy for patients data. Researchers from one site should not have access to the protected health information (PHI) of the patients from other sites (e.g., patient name, date of birth) without additional IRB review and agreement.

- **Multimodal data linkage.** Phenotypic data and electrophysiological signal data recorded in different devices need to be properly linked.

- **Data quality.** Quality data is essential for use in clinical research [10]. However, in a multisite research effort, inconsistent codings are often seen across different clinical sites. It is unavoidable that unintended erroneous input may happen during the manual data entry process. Missing data is another major issue.

2.3 Related Efforts to CSR Data Integration

To minimize the potential format heterogeneity, a uniform electronic data capturing system, called OPIC (Ontology-driven Patient Information Capture system) [13], has been adapted and enhanced to prospectively capture patient phenotypic data for CSR. To avoid inconsistent coding, an enhanced version of OPIC has incorporated standardized coding for terms in the Epilepsy and Seizure Ontology (EpSO) [12]. In addition, automatic data validity checks (e.g., data must conform to an expected format) have been implemented to ensure better data quality at the data entry stage. The enhanced OPIC has been deployed as a Virtual Machine (VM) image in the clinical sites. These OPIC instances operate behind hospital firewalls.

To address the data access challenge, a central CSR data repository has been built to integrate and store de-identified patient data from multiple sites. A data de-identification module has been implemented in OPIC to remove PHI information before integrating into the central repository. To ensure patient-level record linkage without revealing PHI, a distributed study identifier generation algorithm has been implemented in OPIC using randomized n-gram hashing [11]. At the moment patient record is initially created, a unique study identifier is automatically generated to facilitate the data de-identification and linkage of multi-modal data.

2.4 CSR Data Quality Assurance

Although certain data quality assurance measures have been incorporated in the enhanced OPIC (e.g., data validity check, standardized coding), inconsistencies may still exist due to unintended manual input or misinterpretation of observations from electrophysiological signals. Review, auditing, and curation of the acquired data in the central
repository by CSR domain experts are necessary for ensuring data quality. Inconsistencies found by observing and analyzing electrophysiological signal data will also be used to help curate phenotypic data. Moreover, since patient data is prospectively collected and continuously growing, the central data repository needs to incorporate both incoming data from each individual site as well as curated data by CSR domain experts. Therefore, there is a unique need of a streamlined data integration and curation workflow to facilitate the CSR data integration and quality assurance framework. This paper introduces ODaCCI to address this need.

3 Methods

Figure 1: CSR phenotypic data integration and curation workflow.

3.1 Data Integration and Curation Workflow

Figure 1 shows the overall architecture of ODaCCI, for integrating and curating patient phenotypic data from an individual site to the CSR central repository. Initially, the patient phenotype data is entered into the OPIC system with identifiable information at each individual site. Such phenotypic data includes patient demographics, history, medications, diagnosis, epileptogenic zone, seizure semiology, and EEG findings. Then, automatic de-identification by OPIC and manual de-identification by study personnel are performed to produce de-identified data, which is transferred to the CSR central repository through SSH File Transfer Protocol (SFTP) on a weekly basis. The de-identified data for a single clinical site are then imported to a standalone MySQL database in the central repository, which is interfaced with the web-based data curation system for a domain expert to perform auditing and curation. The curated data is saved in a separate MySQL database that only contains curated data. The rationale for separating the curated data from the original integrated data is to accommodate both the continuously acquired data from the source clinical site and the existing curated data in the central CSR repository. Moreover, when integrating new data into the central de-identified database, the curated data in the separate database will replace certain original data that are not curated from the source.

3.2 ODaCCI: Ontology-guided Web-based Data Curation System

In this subsection, we focus on introducing each of the following components in ODaCCI:

- **Common data elements (CDEs)**, which are data elements that are common to all the individual clinical sites.
- **Ontology-based vocabulary**, which serves as the main knowledge source for possible values of domain-specific data elements, and plays an important role in dynamic generation of web-based curation widget and MySQL statement to interacting with the backend database.
- **CDE to data source mappings**, which link common data elements to actual tables and columns in the backend databases from different sources. Such mappings not only drive the rendering of the backend data in the web
interface for curation, but also facilitate the translation of content captured in the web interface to MySQL statements to be executed in the backend database.

- **Dynamic generation of data curation widget**, which provides a systematic way to generate web-based curation widgets for different types of data elements.
- **Dynamic generation of MySQL statements**, which automatically translates the curation result obtained from the web-based widgets to backend MySQL statements.
- **Data auditing measures**, which provide intuitive and interactive web-based reporting interfaces for domain experts to perform data auditing and curation.

### 3.2.1 Common Data Elements (CDEs)

A set of common data elements from all the data sources were selected by epilepsy domain experts for data integration. Selected epilepsy patient phenotypes include age, gender, epileptogenic zone, etiology, semiology, epileptiform discharge, drug, transection, body mass index, sleep position, smoking, and bleeding. Table 1 shows a partial list of common data elements organized in sections. For example, **DEMOGRAPHIC** section includes data elements **Age** and **Gender**; and **CLASSIFICATION OF PAROXYSMAL EPISODES** section consists of **Epileptogenic zone**, **Etiology**, **Semiology**, **Nonepileptic semiology**, and **Lateralizing sign**.

</table>

The value set (i.e., set of possible values or responses) of a common data element determines the type of the common data element. Types of common data elements include **boolean**, **categorical**, **numerical**, and **ontological**. A data element is called **ontological** if its value set originates from a vocabulary of ontological terms organized as a hierarchy. For both categorical and ontological data elements, their possible values are coded using integers to support effective data capture and retrieval. For instance,

- **boolean**: **Transection** is boolean with value set \{0, 1\} (0 means no and 1 means yes);
- **categorical**: **Gender** is categorical with value set \{1, 2\} (1 means male and 2 means female);
- **numerical**: **Body mass index** is numerical;
- **ontological**: **Semiology** is ontological with value set \{1, 2, \ldots, 51\} (1 means Aura, 2 means Autonomic Seizure, and 51 means Hypnopompic Seizure). The hierarchical view of the value set can be found in Figure 2 (middle).
A common data element may have properties such as modifier (see the last column in Table 1). For example, *Semiology* has two properties: modifier and only during admission. Semiology modifier may be Generalized, Bilateral asymmetric, or Left or Right Axial/Proximal/Distal/Head/Face/Arm/Hand/Leg/Foot. The value of only during admission may be Yes or No. These common data elements as well as their specifications form a common data dictionary managed in a Common Separated Values (CSV) file.

### 3.2.2 Ontology-based Vocabulary

We leverage the Epilepsy and Seizure Ontology (EpSO) [12] as the vocabulary to construct value sets for ontological data elements. For each ontological data element, its value set consists of all the direct and indirect subtypes of a class in the EpSO. For instance, in EpSO, *Epileptogenic Zone* (left in Figure 2) has seven subtypes: *Anterior Head Regions, Generalized, Hemisphere, Multi Focal, Posterior Head Regions, Unknown, and Unlocalizable*. And *Hemisphere* further has subtypes including *Central, Cingulate, Frontal, and Occipital*. For such ontological terms in EpSO, the data capturing system OPIC [13] has dedicated integer codes. Therefore, we use the same standardized codes for data curation in order to seamlessly integrate continuously collected data and curated data.

![Ontology-based vocabulary](image)

Figure 2: Ontology-based vocabulary for *Epileptogenic Zone, Semiology, and Drug*.

### 3.2.3 CDE to Data Source Mappings

Since the data capturing system OPIC has been distributively deployed and continuously operating at each clinical site, disparate sites may have different versions of OPIC, thus the data schemas in the de-identified data sources may not always be the same. Therefore, for each site, the common data elements in the common data dictionary are mapped to source data tables and columns if applicable. For example, for each data source containing patient phenotype *Epileptogenic Zone*, the common data element *Epileptogenic Zone* is mapped to the column “epileptogenic_zone_id” in the table “classification_zones,” and its property *Modifier* is mapped to the column “modifier” in the same table. Such mapping information is maintained in CSV files for each data source.

### 3.2.4 Dynamic Generation of Data Curation Widget

To facilitate manual curation of patient phenotypic data by domain experts, we developed a web-based data curation interface driven by the common data elements and their mappings to data sources. When a user triggers an event to edit or curate a common data element, an interactive dialogue (see Figure 3) is dynamically generated based on the type and properties of the data element as follows.

- If the type is boolean, then a dropdown option of *Yes* and *No* is provided for selection.
- If the type is categorical, then a dropdown list containing the value set of the data element is provided.
- If the type is numerical, then a text box is displayed for editing.
If the type is ontological, then a multi-level dropdown list is rendered according to the ontology-based vocabulary corresponding to the data element. For instance, clicking the “Add Semiology” button inside the interactive dialogue (arrow (a) in Figure 3) first triggers the display of all the direct subtypes of Semiology; clicking one of these subtypes “Aura” further renders its direct subtypes (arrow (b) in Figure 3); clicking the subtype Autonomic Aura further drills down to its direct subtypes (arrow (c) in Figure 3). In addition, the Modifier property of Semiology can be updated by clicking the icon after its value (arrow (d) in Figure 3).

Moreover, the default values for the data elements in the interactive dialogues are automatically populated from the data source. Therefore, the values that do not need curation are kept intact.

The web-based curation interface was implemented using an agile web development environment called Ruby on Rails (RoR) [18] with a MySQL backend database. The integrated and curated data sets are also stored in MySQL databases, which are separate from the main RoR application database. The specifications for the common data elements and ontology-based vocabularies in CSV files are imported into the application database to drive the web interface.

### 3.2.5 Dynamic Generation of MySQL Statement

The common data elements and their mappings to data sources not only drive the rendering of web-based curation interface, but also play an important role in the dynamic generation of MySQL statements for saving the interactive edits provided by domain experts. For each type of common data elements, a general template of MySQL statement is predefined and used for generating the actual MySQL statement for data curation. For example, the general template for an ontological common data element is predefined as:

\[
\text{INSERT INTO } \text{<mapping.table>} \left( \text{id}, \text{<mapping.column>}, \text{<property_1>}, \ldots, \text{<property_n>} \right) \\
\text{VALUES } \left( \text{id_value}, \text{<cde_value>}, \text{<property_1_value>}, \ldots, \text{<property_n_value>} \right);
\]

where <mapping.table> and <mapping.column> represent the data source table and column to which the cde is mapped, and <property_i> represents the i-th property of the cde. All the variables in the angle brackets can be replaced by real values to generate the actual MySQL statement. For instance, in Figure 3, the first record for the ontological common data element Semiology has the following values for the variables in the template:

- <mapping.table>: seizure_type_semiologies
- <id_value>: ‘TSXP606170783305’
- <property_1>: modifier
- <property_1_value>: ‘Left Arm’
- <property_2>: only_during_admission
- <property_2_value>: NULL

Replacing the variables in the template with real values results in the following MySQL statement:

\[
\text{INSERT INTO seizure_type_semiologies(} \text{id, seizure_type_semiologies, modifier, only_during_admission)} \\
\text{VALUES (‘TSXP606170783305’, 40, ‘Left Arm’, NULL)};
\]
3.2.6 Data Auditing Measures

Since CSR prospectively collects patient data from multiple sites, it is important to have data auditing measures to audit the quality of data being integrated. We adapt two commonly used data quality measures, completeness and consistency, to facilitate the CSR data integration and curation process (refer to [20] for a review of data quality measures). We audit the data completeness according to the types of data (phenotype and EEG signal) and common data elements, respectively. To perform auditing for types of data, the completeness is determined by whether both phenotypical and EEG signal data for a patient have been uploaded. For this, we develop an interactive reporting interface for CSR data manager to audit the uploading status of phenotypical and EEG signal data from individual clinical sites to the CSR central repository. To perform auditing for each common data element, the completeness is calculated or measured by the number of patient visits with actual data for the common data element divided by the total number of patient visits. Note that one patient may have multiple patient visits.

Moreover, we monitor coding consistencies for categorical and ontological common data elements, which is calculated by the number of valid values for the common data element divided by the total number of its actual values (i.e., the percentage of the valid coding values among all the actual values). For numeric common data elements, we use representation consistency, which is obtained by the number of numeric values divided by the total number of its actual values (i.e., the percentage of the valid numeric values among all the actual values).

4 Results

The CSR data integration pipeline and web-based data curation system have been implemented and deployed at https://medcis.case.edu/medcis. A collection of 95 common data elements were identified by CSR domain experts. A total of 629 patients have been recruited from seven clinical sites from October 2014 to February 2016. Among them, 393 are from UH, 65 from NYU, 11 from UCLA, 54 from NW, 44 from TJU, 56 from UCL, and 6 from UIowa. These numbers were generated in the reporting interface shown in Figure 5 (the numbers in the parentheses after the site names). The EEG signal data associated with these recruited patients exceeded 7TB. Since CSR is an ongoing effort, more patient data will be integrated and curated.

4.1 Web-based Data Curation Interface

Figure 4 presents a screenshot of the web-based curation interface for the section CLASSIFICATION OF PAROXYSMAL EPISODES. Clicking the “Edit” button for a common data element such as Semiology will trigger an interactive...
dialogue for a curation widget (see the red arrow in Figure 4). Clicking the “Update” button when the curation is done will save the curation result to the backend database and reflect the updated result in the web interface. Such web-based data curation widgets not only provide domain experts or data curators an intuitive interface to review and correct data, but also ensure the quality of the corrected data by strictly conforming to the standardized codings used for data capturing in OPIC. The CSR domain experts have been actively using the data curation interface to correct unintended errors and inconsistencies found between patient phenotypic information and EEG signal data.

4.2 Data Auditing Measures

Figure 5 shows the interactive reporting interface for auditing the completeness of the types of data uploaded from multiple sites. Domain experts can configure the report results by choosing sites of interest and the upload status of different types of data for each patient (EEG denotes the EEG signal data, PDF denotes the phenotypic data in PDF report). The returned results also include the number of visits for each patient (or Study ID). The customized reports can be exported to CSV files for the data manager in the CSR central repository to track down the types of missing data for each site and each patient.

Table 2 shows the data completeness of 10 common data elements by different sites and in total dated to February 2016. Age, Gender, and Drug achieved over 90% completeness. For Age, a total of 97.76% data completeness was obtained considering all sites. Individually, UH achieved 97.6% (487/499), NYU and UCLA got 100%, NW got 96.3%; but TJU, UCL, and UIowa only had 0% completeness for Age. The reason of 0% completeness for these three sites is that the OPIC instances deployed in these sites are not up-to-date, which is a common issue for multisite data integration or federated query (referred as data release cycle synchronicity in [19]). The most up-to-date percentages will be immediately available after the OPIC instances are updated.

For data consistency, all categorial and ontological data elements achieved 100% coding consistency, which demonstrates the effectiveness of using standardized codings for data capturing and integration. In addition, all numeric data elements achieved 100% representation consistency. Such data quality measures have been incorporated into the curation system in real time to facilitate data integration and curation.

5 Discussion

This paper presented ODaCCCI, an ontology-guided data curation system for supporting multisite data integration in CSR. It is adaptable to other multisite clinical data integration and curation workflows because of its general design
Table 2: Data completeness in terms of 10 common data elements for multiple sites up to February 2016.

</table>

of defining common data elements and ontology-based vocabularies, and dynamic generation of web-based curation widget and dynamic interaction with backend databases.

For CSR, common data elements show different data completeness for disparate sites (Table 2). Since it is at the early stage of patient recruitment and data collection, values for certain data elements may still be missing from the source sites. Realtime data auditing from the CSR central curation system enables the center data curators to monitor the data entry process for each site, so that they can make data entry suggestions to each site for data elements with low completeness.

A limitation of ODaCCI is that it currently does not automatically handle the case that different sites may have data about the same patient. This is because OPIC instances are distributively deployed in multiple sites and cannot check potential duplicated patient information across different sites. Manual effort is needed to identify and resolve duplicated cases. Another limitation is that the web-based user interface has not been formally evaluated by end users. We plan to perform a usability evaluation of the web-based data curation interface and data auditing interface.

**Related Work.** Several related research efforts have been focused on multisite clinical research data integration and sharing. For instance, the Shared Health Research Information Network (SHRINE [21, 22]) was developed as a general clinical data integration system with federated query that could aggregate patient observations from multiple hospitals. It has been implemented for multisite studies of autism co-morbidity, colorectal cancer, diabetes, and others. SHRINE’s core ontologies include ICD-9-CM for diagnoses, RxNorm for medications, and LOINC for lab tests. The Human Studies Database Project (HSDB [23, 24]) has developed an informatics infrastructure for federated access and query of human studies databases. HSDB also developed the Ontology of Clinical Research (OCRe) to facilitate the data sharing. Similar to SHRINE and HSDB, ODaCCI uses a domain ontology to facilitate data integration.

There are also work on data quality assessment (DQA) of multisite clinical data. In [3], a “fit-for-use” conceptual model was proposed for DQA with a process model for conducting multisite DQA based on EHR data. In [25], DQA was performed based on EHR data from multiple student health centers in the College Health Surveillance Network. In [26], DQA was focused on Haiti’s national electronic medical record (EMR) systems, with an interactive “DQ dashboard” developed for quality improvement. Distinct from these studies [3, 21, 22, 23, 24, 25, 26], which focused on either multisite data integration or DQA, ODaCCI handles both multisite data integration and DQA. In addition, our web-based data curation system enables correction of data errors after data has been integrated concurrently.

**6 Conclusion**

This paper presented ODaCCI, an ontology-guided data curation system to address the data quality assurance needs for ongoing multisite clinical research data integration in the Center for SUDEP research. Phenotypic data and EEG signal data of 629 patients have been acquired and integrated from seven clinical sites between October 2014 and February 2016. Different types of data auditing measures have been incorporated in real time to help the CSR domain
experts with their curation work. ODaCCI supports continuous and asynchronous data quality improvements while data has been ingested and integrated from multiple clinical sites.

Abstract

Medical data is routinely collected, stored and recorded across different institutions and in a range of different formats. Semantic harmonization is the process of collating this data into a singular consistent logical view, with many approaches to harmonizing both possible and valid. The broad scope of possibilities for undertaking semantic harmonization do lead however to the development of bespoke and ad-hoc systems; this is particularly the case when it comes to cohort data, the format of which is often specific to a cohort’s area of focus. Guided by work we have undertaken in developing the ‘EMIF Knowledge Object Library’, a semantic harmonization framework underpinning the collation of pan-European Alzheimer’s cohort data, we have developed a set of nine generic guiding principles for developing semantic harmonization frameworks, the application of which will establish a solid base for constructing similar frameworks.

Introduction

The quantity, quality and prevalence of digitally represented medical data available for research world-wide is now such that a tipping point has been reached in terms of the ability of that data to inform novel and innovative methods of research¹. This so called ‘Big Data’ revolution, where the volume of data available is such that previously unobtainable research results are obtainable will inevitably inform medical research practice moving forwards². That data is universally available in digital form does not however mean that it is available and represented in the same form – data sets large enough to catalyze novel research will inevitably come from a myriad of sources³. These sources, at least in the present, can and will draw from a large number of potential methods of representing data. As such, drawing data from multiple sources and combining it into a form upon which research can be conducted will require a process of either combining data into a single representation or explicitly mapping and translating between items of knowledge from the various sources⁴.

Semantic harmonization then is the process of combining multiple sources and representations of data into a form where items of data share meaning⁵. Harmonized data imparts the ability of allowing single given questions to be asked and answered across the data as a whole, without need to modify or adapt queries for a given data source, invaluable as a tool for researchers. The process of harmonizing data is far from trivial though. The technical undertaking of specifying a representation for capturing harmonized knowledge, the person-effort of specifying domain specific mappings between instances of data and the fact that for any given items of knowledge from within the same domain there may not be a universally agreed translation between them combine to make the task of harmonizing data, even for relatively specialized and small domains of knowledge, onerous if not impossible. Regardless of the feasibility of successfully harmonization any given data sets, undertaking the process and building a framework for semantic harmonization is a common and perhaps inevitable part of projects leveraging ‘Big’ medical data⁶.

Given that the implementation of some form semantic harmonization framework will necessarily form part of a project that utilizes medical data from across multiple sources, it seems natural to ask the question as to what common frameworks are available for enabling these harmonization processes? In answering this question we will draw a distinction between a method of harmonization and a framework for harmonizing data. A harmonization method is the underlying technical or logical means of specifying knowledge or mapping between items of knowledge, Formalisms such as ontological representations and their related reasoning mechanisms⁷, or openEHR archetypes⁸ would qualify as harmonization methods. It is uncommon and perhaps unwise for projects dealing with semantic harmonization to go down the path of specifying novel underlying representation formats. A harmonization framework on the other hand would be the overarching infrastructure for enabling harmonization and utilizing its
results as well as the specific choice of how to use a chosen harmonization method. While systems such as I2B2 would fall into the category of harmonization frameworks it is still often necessary to develop novel frameworks for capturing data, particularly where the domain the data is being drawn from is focused or specialized. One such area would be that of cohort data. The collection of cohort data in a particular disease area will often focus on items or forms of knowledge specific to that area and the representation and capturing of that knowledge may require methods and formalisms unique to the domain in question.

Regardless, the development of frameworks for enabling semantic harmonization, particularly given the ongoing development of the field of ‘Big Data’ research in the medical informatics space, will continue. Each such system will be different; they will take varying approaches to how to harmonize data and how to enable the use of that data. We believe however that there should be a set of core principles that underlie the development of any such system. Key to these principles are features that inform the separation of concerns in the representation of knowledge and approaches to the stratification of knowledge. These are outlined following a description of the project that informed the development of these principles.

The EMIF Knowledge Object Library

The European Medical Informatics Framework (EMIF) is a large-scale collaboration between academic research institutions, small and medium sized companies and members of the European Federation of Pharmaceutical Industries and Associations (EFPIA), part of the Innovative Medicines Initiative (IMI). It aims to develop a suite of tools for enabling the reuse and linkage of healthcare data from across Europe. Specific use cases within EMIF are drawn from the participation of data cohorts from the Alzheimer’s and Metabolics spaces. It is with a focus on the Alzheimer’s space that we have produced the EMIF Knowledge Object Library (EKOL). This is a system for capturing both specific local knowledge from Alzheimer’s disease patient cohorts and mapping this knowledge into a global representation that allows the combination of data from multiple cohorts into a single representation, giving researchers the ability to launch research queries against this unified view of the data. Data recorded by the participating cohorts is universally represented in individualized data schemas and the majority of the data is coded with reference to local vocabularies, when formally coded at all. This led to the need for a system that dealt very explicitly with local data in a form unique to its source, but local data that in turn generally referred to the same set of global concepts.

One practical outcome of this work was the application of the Knowledge Object Library as the underlying mechanism used to capture, process and provide data for the EMIF ‘Participant Selection Tool’ (PST). The PST is a web based tool that presents researchers with a list of approximately 20 core criteria present in the majority of EMIF AD cohorts (covering items such as participant age, diagnosis and mental state examination scores), showing counts of patients per cohort that have records covering those items of data. It then allows researchers to select logical combinations of these criteria and their values and dynamically adjusting the count of patients that match the selected criteria. So, for example, we could select ‘Patients over 50 with a diagnosis of Mild Cognitive Impairment OR Patients over 60 with a diagnosis of Alzheimer’s Disease’ and be presented with an updated count of the number of patients across the EMIF cohorts that match this selection. An illustrative screenshot of the PST is shown in figure 1. The PST is part of a wider tool-chain that ultimately allows for the specification of research studies and the export of associated harmonized data for use by researchers. The information presented by the PST comes from data harmonized using the EKOL harmonization framework.

As part of the process of specifying, designing and developing the EKOL system we explicitly drew out and developed a set of principles for designing semantic harmonization frameworks. These were developed through a combination of analysis of user requirements, an iterated agile approach to the development of the associated software which allowed for philosophical design decisions to be rapidly tested and potentially rejected in real-world settings and analysis of existing systems. These principles, outlined in the next section, both informed the development of the EKOL framework and directed the specification and design and application of the Participant Selection Tool.
The successful harmonization of data for use within the PST and its deployment as a tool for research offer an empirical justification that the principles we explicated during the development of the EKOL framework at least offer the beginnings of a generalizable approach to the design and development of similar systems. These principles are outlined below.

**Principles of Semantic Harmonization**

Our work in the development of EKOL has lead to the formulation of the following set of generic guiding principles for developing frameworks for semantic harmonization. Given the range of ways in which knowledge can be defined, represented and captured, we use the generic term *knowledge object* to describe a singular representation of an item of knowledge, independent of the underlying formalism for capturing that item of knowledge. In this generic sense it is the representation of knowledge objects combined with the ability to the system to capture and specify them that underlies the functionality of any semantic harmonization system.

The nine points, presented below, when taken together are designed to guide the development of frameworks for supporting and enabling the semantic harmonization of medical data from multiple sources.

1. **Separate technical from semantic harmonization.**

Data can be stored in many different file formats or databases. The ability to access and process available data is clearly an essential prerequisite to being able to semantically harmonize that data. We refer to the process of transforming data into the same technical storage implementation or transferring it to a system that can be queried by the same standard query engine as *technical harmonization*. The process of making all the data available on compatible platforms is a technical problem and should be separated from the semantic harmonization of the data, which is a data content problem - *technical harmonization is not semantic harmonization*

As such:
- A technical connector to the local data source should be developed only once.
- Technical upload scripts or tools should not be impacted by a change in semantics, such as a change in a vocabulary.
- Conversely, changes or additions to technical harmonization infrastructure or process should not impact semantic modelling or representation.

2. **Distribute ownership of local and global knowledge objects.**

In general, it is the role and responsibility of a subject matter expert to specify how variables need to be harmonized semantically. Semantics encapsulate meaning and ultimately it is only a subject matter expert, particularly in the medical domain, who can specify such meaning. However, knowledge of how variables and data can be utilized, particularly for research, may fall within another domain of knowledge, such as that of the researcher, whose knowledge and expertise, whilst complimentary to the domain expert, is not necessarily the same. They should be able to describe the variables they require and, if applicable, how normalization or harmonization should be performed. Variables that are used for data analysis are the global representations of knowledge. They are defined independently of any data source. Knowledge of measurement protocols and local variables – how variables are measured and what they really represent – are, on the other hand, available only at the data source. It is therefore the responsibility of the data source custodian to describe these variables semantically and create a local representation of knowledge for each variable they want to make available.

Bridging the gap between local knowledge, as described by local experts, and global knowledge, as requested by researchers, is a joint responsibility and effort and is part of the workflow of a semantic harmonisation process. As such:

- Ownership of local and global representations of knowledge objects should be distributed according to the location of expertise.
- Explicit distinction should be made between what is local knowledge and what is global.
- It should be possible to build up and maintain a library of global knowledge objects over time – both global and local concepts should be extensible.
- Global knowledge should make only generic reference to local knowledge, but local knowledge should be grounded in terms of global concepts.

3. **Separate vocabulary from structure.**

Data integration in the medical field is often achieved by the use of common vocabularies or taxonomies. Examples of well-known taxonomies are SNOMED-CT\(^\text{[12]}\) or the NCI thesaurus\(^\text{[13]}\). CDISC\(^\text{[14]}\) also specifies vocabularies that need to be used for naming variables or for standardizing values for those variables used commonly in clinical research.

Similar to the distinction we have drawn between technical and semantic harmonization, we will also highlight a distinction between the act of specifying a vocabulary for grounding the meaning of items of knowledge via explicit reference to vocabularies and the act of structuring items of knowledge such that their internal relationships carry meaning. Whilst structure is often present to varying degrees within formal medical vocabularies and this structure can be leveraged in the formalization of semantic harmonization frameworks, drawing a conceptual distinction between vocabulary and structure can avoid a system relying on the tacit knowledge carried in language to derive its full utility. When the meaning of knowledge is externalized a system can no longer manipulate that knowledge and utility is lost.

So, the concept of vocabularies should be incorporated into the underlying representation of knowledge, since without any reference back to the real world the ultimate meaning of the semantics of knowledge is lost. However, a knowledge object should be a general construct that gets its definition from a link to a vocabulary term, rather than begin inferred from its structure.
As such:

- Knowledge representation structures should be generic, with terminology details and dependencies separated by reference to vocabularies
- Knowledge representations should retain meaning across vocabularies, and maintain meaning and structure in the absence of a vocabulary
- The addition of new vocabularies should be possible with zero, or minimal, change to the structure of global knowledge representation

4. **Re-use standard vocabularies where possible.**

Following on from point 3, we note that many medical vocabularies exist today and a semantic harmonization framework should re-use what is available. This both removes the need to maintain vocabularies and, given the ability to take on board new vocabularies or extend existing ones. The design of a novel semantic harmonization framework does not necessitate the design of a novel vocabulary, these are separate (though clearly related) areas of research, and should not be conflated.

As such:

- Existing vocabularies should always be used in the first instance
- Where there is a need to define new terms not available in a public vocabulary there should be mechanisms in place to accommodate this.
- Such mechanisms should be used sparingly

5. **Use declarative mappings.**

Domain experts are generally better at describing the logic of a mapping between knowledge objects, rather than describing the control flow of the computation of that mapping. Given the need to capture knowledge from domain experts, rule based rather than computation-based systems are better. A domain expert, assuming the role knowledge author, needs to be presented with a mechanism for capturing rich and complex domain knowledge. Declarative rule based systems are best suited for this purpose.

As such:

- Mappings between knowledge objects should be described using rules.
- Mapping rules need to be unambiguous and executable and as such expressed in a formal language
- Such rules should still be simple enough to explain in plain language to other domain experts for verification.

6. **Code isolation.**

The use of rules to specify mappings has the added benefit that a rule can be specified as a stand-alone object, independent of other mapping rules. This contrasts to scripts or other representations of computational flow, where changes to the code can have an impact on code statements further down the control flow. A rule for specifying knowledge should encapsulate a single concept and should be as limited as possible in scope. With this approach rules can be replaced or amended without affecting other rules within the system and the effort of authoring and maintaining rules can be distributed and scaled.

As such:

- A given mapping rule should be assigned to or linked with a single knowledge object
- A rule should contain the instructions on how to calculate a given knowledge object only from upstream knowledge objects
- The scope of rule should be limited solely to the knowledge object it describes and the upstream knowledge objects it is derived from – it should be unaware of any other variables of knowledge objects.
- The impact of changing any given rule on the global structure of knowledge should be minimised.

7. **Enable integrated security and provenance.**

Semantic harmonisation more often than not will need to occur across data sources where the ownership of data (in terms of access control) differs between sources. It is essential that the data custodian for a given data source can control access to the data source variables or local knowledge objects, even when data is ultimately queried at the level of the global knowledge objects. Access to a local knowledge object should be propagated through the dependency graph to global knowledge objects. A knowledge representation system should have constructs in place that can handle this propagation.

Access to data can be restricted based on a number of dimensions:

- **Users**: access is restricted to certain users or research teams, based on the description of their scientific use case.
- **Variables**: the researchers should only have access to the data they need to answer the research question. To avoid having to set permissions on each variable, data source custodians can group variables (as is done for example in CDISC domains) or provide access to the complete data source.
- **Patients**: data source custodians could allow access to data of a subset of patients only, based on inclusion or exclusion criteria or on legal restrictions.
- **Time**: access to source data can be limited in time.
- **Permission level**: access could be granted to the patient-level data or to aggregated knowledge objects only. At the level of the outflow tools it could be restricted to pre-defined reports or could allow custom queries on the data.

As such:

- Items should be grouped as much as possible in order to minimize administrative complexity (for instance users can be grouped in teams, institutions, capability groups etc.)
- In the context of describing security variables should be grouped in domains or by data type (e.g. clinical data vs. high dimensional data).
- Patients should be grouped and categorized by originating data source
- Derived instance values corresponding to knowledge objects should always reference source data instances from which they have been derived, allowing full traceability of every derived value (data provenance).
- The data source of a derived value should be inferable directly from the mapping rules.

8. **Separate WHAT is measured from HOW the measurement is done.**

When mapping data from different data sources we clearly need to make sure that variables that are mapped to a common global knowledge object are compatible, i.e. that they measure the same thing. Using terms of the Ontology for Biomedical Investigations (OBI)\(^\text{15}\), they need to share the same “quality” that “inheres in” instances of the same “material entity”. If there were no measurement errors (instruments have infinite accuracy), variables that measure the same quality in the same material entity could directly be pooled.

However, the actual measured value is also determined by the measurement protocol and the accuracy of the instruments used. Compatibility of protocols or normalization of values (to factor out the effect of the protocol) is use case dependent. The scientist analysing the data needs to decide if data measured using different protocols can be pooled. Whilst it is not necessarily the case the full details of a given measurement protocol should be modelled,
we recommend specifying the independent variables of a protocol using vocabularies so they become comparable between data sources. Figure 2 gives a graphical overview.

![Diagram]

**Figure 2.** Compatibility of measurement variables depends on what is being measured and on how the measurement was performed (the protocol).

The knowledge object representation should be able to capture the “quality” and “material entity” for the variable it models, but should also capture as many of the protocol’s independent variables as deemed useful. Independent variables can be used as filters at query time, or be retrieved as additional information to the actual measurement value. They can also be moved into the “quality” to make the knowledge object more specific.

A typical example would be a knowledge object for hippocampal volume. The “quality” in this example is “volume”. The “material entity” is the hippocampus (e.g. bilateral). But there are many independent variables in the measurement protocol, such as the type of scanner, manufacturer of the scanner, image acquisition sequence, field strength, segmentation algorithm, digital brain atlas used etc. We could also define a knowledge object for “hippocampal volume as measured on 1.5T MRI using Freesurfer cross-sectional”, which would fix some of the independent variables. Such a knowledge object would measurements of different data sources more comparable but decreases the number of data sources that can deliver the data represented by the knowledge object.

As such:

- A knowledge representation should always distinguish what is measured from how it is measured
- This principle should be applied to measured observations both for continuous and categorical variables, textual information and other coded observations.

9. **Balance generic versus specific descriptions.**

The range of possible variables that can be captured by knowledge objects is very large. For clinical data common use cases at least cover all the domains described in the CDISC SDTM standard. CDISC models each domain differently and specifies columns that are common to (most) domains, but also lists columns that are domain specific. Most CDISC domains specify one column per variable to record measurement values (pivoted data format). The demographics domain, for example, has a separate column for Age, Sex, Race etc. But some domains use one column to record the test that was performed and another for the measured value (unpivoted data format). The lab domain, for example, uses the column LBTEST for the laboratory test name and LBORRES for the (original) measured value. Other common data models such as OMOP take a more general approach and store all clinical observations in a single database table (Observation). Patient related information, however, is also stored in tables such as Person or Condition_occurrence.
Choosing specific data structures for different types of variables can customize the information that is recorded. A generic data structure may have difficulty recording domain specific details. However, storing information across different tables and columns can result in domain dependent models.

There is no clear guideline on what the optimum generality level of a data model should be. The structure of a knowledge object tries to be sufficiently general to be able to capture the anticipated types of data and its metadata, but over-generalization has the drawback of a possible loss of domain dependent detail.

This challenge is equally recognised in the development of semantic interoperability sources such as detailed clinical models for healthcare information exchange. Discussions about how to balance generic versus very specific clinical models are currently ongoing within the Clinical Information Modeling Initiative (CIMI). There is a complementary ongoing debate about the level of detail and completeness that models (and knowledge objects) should aim to specify: should one aim for large very comprehensive representations or smaller fragments that may be combined in different ways.

This final principal is in a sense necessarily vague: in developing a semantic harmonization framework, the representation of knowledge into which data is harmonized needs to be generic enough to harness the benefits of simplicity without losing the ability to capture domain specific structure that can come from a bespoke knowledge representation structure.

As such:

- The design of a knowledge representation scheme for semantic harmonization should be as generic as possible.
- Specificity of representation should only occur where the representation of that knowledge cannot be generalised, i.e. where there are features of the representation not shared by any other objects in the general knowledge representation scheme.

Discussion

Systems or frameworks for harmonizing knowledge from multiple heterogeneous data sources must, where knowledge is being explicitly represented, be designed around that representation of knowledge. In this sense it is crucial that a clear, principled approach to the design of those systems, particularly when it comes to the stratification, specification and codification of knowledge, is taken. In this paper we have outlined a set of guiding principles that we believe when followed will lead to the design of frameworks for semantic harmonization that are robust, future proof and able to capture the full richness of knowledge within a given domain.

The nine principles outlined above can be applied en masse or adopted piecemeal, and conflicting views or implementations are inevitable. We do believe however that to a large extent the nine principles express a clarification of common design philosophy rather than a dictation of choice of approach. The value in outlining the set of principles comes from their explication rather than from the authors having made binary choices on behalf of others.

The focus of the principles outlined here focus specifically on areas of semantic harmonization that address aspects of conceptual modeling as opposed to value modeling (in terms of the ISO 11179 MDR standard at the data element concept rather than data element value level). This focus stemmed primarily from the emphasis of this work being driven by the need to harmonize cohort data, where we found that the primary differences between data sources lay in the structuring rather than the value of measurements and results. Adaptation or revision of these principles to account more for value driven harmonization efforts could be an important extension of this work.

We have drawn a distinction in this work between both between methods and frameworks of harmonization and between technical and semantic harmonization and believe that the field as a whole would benefit from applying further similar analysis to the structure of the field itself and particularly application development within it. The field of software development has benefited immensely from a rich and varied analysis of the types of approaches that can be taken to software development itself, leading to myriad approaches to the ‘art’ of the field. We believe that the area of semantic harmonization would benefit similarly from a similar reflective approach being taken.

A K-Reversible Approach to Model Clinical Trajectories

Filip J. Dabek, MSc¹, Jesus J. Caban, PhD¹
¹National Intrepid Center of Excellence, Walter Reed National Military Medical Center, Bethesda, MD

Abstract

A clinical trajectory can be defined as the path followed by patients between an initial health state \( s_i \) such as being healthy to another state \( s_j \) such as being diagnosed with a specific clinical condition. Being able to identify the common trajectories that a group of patients take can benefit clinicians at identifying the current state of patient and potentially provide early treatment to avoid going towards specific paths. In this paper we present our approach that enables a clinical dataset of patient encounters to be clustered into groups of similarity and run through our algorithm which produces an automaton displaying the most common trajectories taken by patients. Furthermore, we explore a dataset of patients that have experienced mild traumatic brain injuries (mTBI) to show that our approach is effective at clustering and identifying common trajectories for patients that develop headaches, sleep, and post traumatic stress disorder (PTSD) post concussion.

Introduction

A clinical trajectory can be defined as the path followed by patients between an initial health state \( s_i \) such as being healthy to another state \( s_j \) such as being diagnosed with a specific clinical condition. Commonly clinicians review a patient’s medical history to better put the medical findings within the context of the patient. While collecting and reviewing medical history is essential to providing personalized treatment, current clinical decision support systems are not effective at aggregating and understanding how a group of patients go from state \( s_i \) to another state \( s_j \). Therefore, being able to identify the common trajectories that a group of patients take can benefit clinicians at identifying the current state for a particular patient and potentially providing early treatment to avoid going towards some specific paths. Despite the significant amount of longitudinal information that Electronic Health Records (EHRs) include related to patients’ clinical encounters, determining the most frequent clinical trajectories followed by a given group of patients is still a challenging task. Often within a given cohort of patients, a group of patients take similar paths to a certain disease while others take a vastly different path. Due to the increased interest in understanding how a patient’s condition will develop over time, understanding these varying paths can benefit healthcare by providing physicians and patients crucial information in preparation for the future. Clinical trajectories possess the power of providing physicians and patients with a visual representation that can easily be understood and analyzed. They have the potential to uncover hidden information in data that could not be seen otherwise. With these goals in mind, in this paper we present a framework for creating meaningful clinical trajectories using longitudinal clinical data. First we describe the challenges faced by researchers in using clinical data, next we describe some of the previous work, then we present our approach to cluster patients and to build a condensed model that can be analyzed, followed by discussing how we’ve applied our approach to a large clinical dataset, and finally we conclude the paper and describe some of the future work.

Healthcare data has been predicted to exceed 25,000 petabytes in 2020 compared to 500 petabytes in 2012, an increase by a multiplier of 50¹. With this rise in the amount of available big data in healthcare, there exists an opportunity to apply machine learning techniques on a large scale to identify key information in patient trends. Understanding what causes patient deaths, what is effective at improving a patient’s life, and how a population of patients end up in a certain diagnosis are just a few examples of the insightful analytics that can be discovered in this data.

However, even though there are many points of information that are desired to be studied, the vast amount of data provided along with the many different types of patients poses extreme challenges to researchers. Not only are efficient algorithms and powerful systems required to extract and perform computations, but understanding the wide variety of patients is key in identifying breakthroughs in healthcare research to assist future patients. It may be easy for a physician to analyze one individual patient to understand their medical history, but at a large scale of data it is not feasible to analyze each patient individually in an attempt to get an overall view of the population. The amount of time it would take to analyze, with more data being added by the minute, would not provide tangible benefits for the short term. Therefore, methods that attempt to combine similar patients and produce a model of the patient population...
will prove to be effective at providing physicians with a condensed representation of the population in order to assist in preventative care and supporting future patients that will undergo similar conditions.

**Background**

Research in the area of clustering big data has proposed methods in which an ensemble model of statistics information and word sense information is used to cluster documents, a framework in which the popular k-means algorithm applied to a weighted linear co-association matrix to cluster biomedical data consisting of text and images, and applying data clustering algorithms to the problem of big data. All of these approaches have shown the benefit that clustering has: the power to be able to identify groupings in data that otherwise could not be found with alternate methods.

In the clinical realm, approaches to understanding the clinical trajectory of a patient, by means of clustering, have focused on a specific disease with the intention of being able to predict whether a new patient will develop a similar diagnosis or not. In the realm of PTSD patients, Bryant et al. studied the long-term trajectory of PTSD patients over 6 years and classified them in chronic, recovery, worsening/recovery, worsening, and resilient groupings. The study found that analyzing patients over time provides a more accurate means to identifying and predicting PTSD rather than relying on hospital admission analysis. A similar study analyzed patients 12 months after a burn and also found four different trajectories for patients with PTSD. In addition, it was found that the risk factors differed between trajectories indicating that each group possessed similar traits which could be used in clinical practice. Another study concentrated on children after an accidental, but traumatic, injury in which they developed Post Traumatic Stress Symptoms (PTSS). In this study the researchers utilized group-based trajectory modeling to identify patterns of PTSS and found three distinct trajectory groups where pre-injury risk factors were predictive of the corresponding group. With this information the researchers concluded that identification of distinct trajectory groups can help understand the course from traumatic injury to PTSS and the necessary treatment for a child. Gotz et al. utilized patient similarity metrics to visually analyze patient clusters. In addition, various Bayesian and mathematical models have been utilized to build disease models and cluster patients, but lack the ability to provide a simple visualization of disease trajectory. Furthermore, several Harvard researchers have shown their ability to classifying and predicting long-term medication adherence using group-based trajectory models. All of these studies alike indicate that patients’ trajectories can be grouped together to find a common path and give clinicians an insight into the expected diagnosis path and optimal treatment.

**Approach**

For our approach we attempted to classify the patients into their respective groups, based on the trajectory that they underwent, followed by representing each group’s trajectory with the most common paths highlighted in a visual manner using automata. Below we will outline the steps taken for each aspect of our approach.

**Clustering**

With the knowledge that not all patients are the same and that patients take varying, but similar paths, we used the popular clustering algorithm, k-means clustering, to identify the various groups. The k-means algorithm takes a set of feature vectors and a value of k which it then attempts to find k unique groups using a distance metric, in this case the Euclidean distance.

Our first attempt at clustering the patients was to associate each diagnosis with an integer and thus create a feature vector of the diagnoses in order. However, because patients have varying number of diagnoses and k-means requires uniform length, the algorithm ultimately clustered the patients based on the length of their original trajectory. With this we had to find an alternate method that did not discriminate between the patients based on their varying trajectory length. Using our previous work in which we predicted patient outcomes based on their medical history, from Electronic Health Records (EHR) data, we created a sparse matrix representation of each patient which we will briefly describe next.

To create meaningful input for the k-means algorithm, first the encounters / diagnosis tuples were transformed into a sparse matrix where each row was a diagnosis and each column corresponded to a different time point.

With the sparse matrix defined, we used the Bayesian Information Criterion (BIC) and the elbow criterion method.
to identify the optimal number of $k$ as this method identifies the point at which additional clusters would result in overfitting.

**Model Automata**

In an attempt to design a model to estimate the common trajectory followed by most patients from their initial injury to the first diagnosis of PTSD, we model the longitudinal clinical encounters as an automata and employ grammar induction algorithms to minimize the complexity of large automata. This approach allows us to simultaneously consider the path of N patients and minimize the graph into a single automaton that represents the common path. In order to understand our approach, we will first give a brief overview of automata.

Automata are self-operating machines that consist of states and transitions, where the input is compared against the transitions in order to move between states in the machine. Two forms of machines exist in finite automata: deterministic (DFA) and non-deterministic (NFA). For a given state and input symbol, deterministic machines only have one possible transition, whereas non-deterministic machines can have multiple transitions.

Using the two forms of automata, nondeterministic (NFA) and deterministic (DFA), will allow us to visualize the trajectory of patients over time. Both of these approaches represent the data in a unique way allowing for us to evaluate different aspects of the trajectories. It should be noted that both the NFA's and DFA's were run through a simple minimization algorithm that reduced the number of nodes for each individual patient trajectory. For example, a patient that followed the path of: \texttt{A -E1 -E2 -E3 -B -E4 -C -E5 -C -A} would be reduced to: \texttt{A -E1 -E2 -E3 -E4 -E6 -E5 -A}, as can be seen in Figure 1.

The first approach, using an NFA, treats each diagnosis as an individual node and stacks into a column representing an encounter. An example of a single patient’s NFA can be seen in Figure 2 where “f” corresponds to a Concussion, “P” corresponds to PTSD, “D” corresponds to Depression, and “E” corresponds to a diagnosis related to Speech. In this example we can see that the patient was diagnosed with P, D, and f in their first encounter, followed by P and D in their second encounter, etc. Representing a patient as an NFA allows us to understand the change in the number of diagnoses over time and represent the concept that a patient can take the path from any disease in a single encounter to any disease in the next.

The second approach, using a DFA, represents each encounter as a node with the diagnoses acting as paths leading into the node. This representation is shown for the previously presented patient in Figure 3, where the automaton looks to be smaller due to the lesser amount of nodes. This DFA approach will allow us to utilize a grammar induction algorithm for identifying a common trajectory amongst a group of patients.

Furthermore, both of these approaches can be augmented by placing a scale for the amount of days between encounters in order to understand the timeframe of the patient’s encounters better. The previous patient’s NFA and DFA were modified to display the amount of days between encounters in Figure 4.
Figure 3: A DFA representing six encounters corresponding to the path followed by a particular patient between his/her first concussion to PTSD.

Figure 4: Patient’s DFA (Top) and NFA (Bottom) with a timeline of days between encounters in the first row of each automaton. The timeline represents the number of days between mTBI and PTSD, which is 24 days in this patient’s case.

Using the previously demonstrated NFA and DFA’s of a patient’s trajectory, we applied a grammar induction algorithm to the automata with the goal of identifying the most common paths that a group of patients take within their trajectories. The specific algorithm that we chose was the K-Reversible algorithm as it treats all input as being equal, compared to other algorithms such as Gold’s Algorithm that requires positive and negative data.

Merging

A prefix tree acceptor (PTA) is a tree-like DFA built from a learning sample of strings $P = p_1, p_2, ..., p_n$ by converting all of the prefixes $p_i$ in the sample $P$ into states $Q = q_1, q_2, ..., q_n$, and constructing the smallest DFA that is a tree and consistent with the learning sample\textsuperscript{10}. For example, given a sample string set $P = aa, aba, bba$ it can be converted into a set of states $Q = q_1, q_2, ..., q_7$ as illustrated in Figure 5a.

One of the basic operations that can be performed on a PTA is a merging operation, which takes two states $(q_i, q_j)$ from an automaton and merges them into a single state\textsuperscript{16}. An example of the merging algorithm is shown in Figure 5b. The algorithm takes in two states, $q_i$ and $q_j$, that are to be merged together and then takes everything that points into $q_j$ and makes it point into $q_i$. In addition, everything that $q_j$ points to is now made to originate from $q_i$. This removes all of the transitions into and out of $q_j$ and transfers them to $q_i$, allowing the algorithm to now remove $q_j$ from the finite state machine.

Algorithms such as Gold’s Algorithm\textsuperscript{17}, RPNI\textsuperscript{18}, and K-Reversible\textsuperscript{16} start from a PTA and perform operations on it to try and create a DFA that recognizes the target language. By using these algorithms, we can input an automaton of clinical trajectories that will be merged leaving behind the most common paths taken by patients.

Minimizing the Automata

The specific algorithm that we chose was the K-Reversible Grammars Algorithm\textsuperscript{16,19} as it treats all input as being equal, compared to other algorithms such as Gold’s Algorithm that requires positive and negative data.

Figure 5: (a) Example of prefix tree acceptor built from strings $P = aa, aba, bba$. (b) Example of merging states $q_1$ and $q_2$. 

463
The K-Reversible Algorithm is classified as a look-ahead language that takes into account a length \( k \) sub-sequence of diagnoses at a time. This means that the algorithm starts at a state and looks backwards for up to \( k \) states, combining the diagnoses on the backwards path into a sequence. Subsequently, two states can be compared by contrasting their sequences of \( k \) length diagnoses. An example of this is shown in Figure 6, where states \( p \) and \( q \) are similar for \( k = 0 \) as “a” equals “a”, but for \( k = 1 \) or \( k = 2 \) they are not similar as “ad” does not equal “ab” and “adc” does not equal “abc”.

This K-Reversible algorithm was ultimately chosen for its ability to merge similar states based on a length \( k \) sequence of diagnoses as similar sequences of diagnoses can potentially lead to the same condition in a patient.

Breaking down the K-Reversible Algorithm, there are three cases that need to be considered. The first case looks for a state, \( p \), that has two identical transitions to two different states, \( q \) and \( q' \). Once this case has been matched then the states \( q \) and \( q' \) are merged together. This is shown in Figure 7a. The second case of the algorithm looks for two final states, \( q \) and \( q' \), that have identical paths leading into them of length \( k \), and merges them together. This is shown in Figure 7b. Continuing on with the algorithm, the subsequent states, \( p \) and \( p' \), are also merged. The third case of the algorithm looks for a state \( p \) that has two identical transitions leading into it from two different states, \( q \) and \( q' \), that also have an identical path leading into them of length \( k \). Once again, \( q \) and \( q' \) are merged together by this case. This is shown in Figure 7c.

Algorithm Modifications
We found that the three cases of the K-Reversible algorithm did not achieve an optimal automaton, through visual inspection, such that:

1. similar, but not identical, paths were not merged
2. duplicate paths were not removed
3. a patient’s path was merged with itself

With these flaws present, we modified the algorithm by adding three cases in addition to the original three cases.

First Modification The K-Reversible algorithm strictly considers paths without taking into account that two distinct paths may in fact be the same despite a difference in order of diagnoses. For example, there could be a state \( q \) that has paths of \([b, a]\) and \([a, b]\) leading into it, as shown in Figure 8a. In these types of occurrences, we assumed that the ordering of the diagnoses does not matter as both paths lead to the same state of the patient. This property of
the algorithm required a modification, accomplished by reordering the less probable path to be equivalent to the more probable path. Upon reordering and running the algorithm further, it will eventually merge these two paths into one.

**Second Modification** The second modification to the K-Reversible Algorithm was to remove identical paths to the same state, that was generally caused by the first modification. During the minimization of the grammar, the algorithm would cause there to be two states, p and q, where more than one path went from p to q with the same value as the transition. Therefore, by merging these paths, the grammar would be minimized to the furthest extent. An example of this modification is provided in Figure 8b, where the duplicate path of ‘a’ is merged into one single path.

**Third Modification** The third modification to the algorithm was with the goal of not allowing the algorithm to merge a patient’s trajectory into itself. What this means is that instead of treating a patient’s trajectory as one entire path, the algorithm would attempt to alter the trajectory to be minimal, resulting in only one node and the patient not being represented accurately. We therefore modified the algorithm to track the patient ID’s at each node and did not allow two nodes to be merged if the intersection of the ID’s contained a patient. This ultimately forced the algorithm to ensure that the diagnosis trajectory of each patient was treated as an individual sequence.

**Fourth Modification** Due to the large size of automata that can result from running the algorithm on an extensive dataset and due to the nature of clinical encounters: in that patients can take many varying, unique paths which cannot be merged together, it can become difficult to understand the common trajectories on a large automaton. This limitation in understanding resulted in us making one final modification which involved pruning the resulting automata to only consider the most probable/most taken paths. During the execution of the K-Reversible algorithm, we kept a count of the number of patients that took each path. Then, once the algorithm finished running we used the patient counts to compute the probability of each path being taken from a node, thus leaving us with a patient count and probability at each path. Using these two metrics, we were able to set varying probability and count cut-offs such that the resulting automaton would only include paths that were above the cut-off. This allowed for the size of the automaton to be reduced as can be seen in the next section.

With these modifications made to the algorithm we will explore, in the next section, the automata that result from running our modified algorithm on longitudinal clinical data.

**Application Domain**

For our results we will explore a dataset available to us centered around the application domain of patients that experience a concussion or a mild traumatic brain injury (mTBI) and the long term affects associated with this injury. Specifically, we will be looking at patients that develop diagnoses related to either headaches, sleep, and/or PTSD post concussion.

**TBI Data**

A concussion is a poorly understood mild traumatic brain injury (mTBI) that can alter the way the brain functions. During the last decade a significant amount of attention has been given to the acquisition of clinical data from patients suffering mTBI and psychological health (PH) problems after a concussion. The increased awareness has been in part driven by the Department of Defense (DoD), the National Football League (NFL), and many other government and private organizations that have been leading different efforts to raise awareness about the short- and long-term effects of concussions.

A traumatic brain injury (TBI) is defined and indicated by “Any period of loss of or a decreased level of consciousness, Any loss of memory for events immediately before or after the injury, Any alteration in mental state at the time of the injury, Neurological deficits that may or may not be transient, or intracranial lesion following the traumatic event”20. In the United States alone, an estimated 1.7 million TBIs occur each year, leading to more than 1.3 million emergency room visits, a quarter million hospitalizations, and 52 thousand deaths21. The leading causes of TBIs are falls, physical assault/injury, and motor vehicle accidents. In the U. S. Military, over 307,000 cases of TBI have been diagnosed since 2000, 80% of which were in a non-deployed setting22.

Patients who have been screened positive with mTBI are at an increased risk of psychological problems that can have a significant impact in the recovery time. Early detection of psychological conditions such as PTSD following a concussion might improve the overall outcome of a patient and could potentially reduce the cost associated with
treatment.

Dataset

The original dataset consisted of EHR data for 98,342 mTBI patients. The data was filtered to only include patients with more than thirty days of data and no history of moderate or severe TBI. The resulting subsets of 89,840 patients had 5.3 million TBI-related clinical encounters and 8.7 million clinical diagnoses. In this study, a TBI-related encounter was defined as a visit to the doctor regardless of inpatient/outpatient where the patient is treated with one or more of the conditions that are commonly known to be related to concussions such as behavioral disorder, sleep problems, cognitive deficiencies, and audiology complaints. Note that only TBI-related encounters were taken into consideration. The patients under consideration had an average of 59 encounters.

To build our model the dataset was defined to be $P = \{P_1, P_2, \ldots, P_n\}$ where $P$ is a set containing each patient $P_i$ had an associated sequence of encounters $E_i \in \{E_1, E_2, \ldots, E_m\}$ representing unique clinical appointments or hospital visits. Each encounter $E_i$ had an associated set of diagnoses represented by $D \in \{D_1, D_2, \ldots, D_k\}$. To build the sparse matrix representation, as was described in Section , for clustering we set the splitting diagnosis as the first mTBI event and the timeframe of the matrix to be $T = \langle(-60, -30], (-30, 0], [0, 30)\rangle$, where $(-30, 0]$ represents $t_{-30} \rightarrow t_{-1}$ (i.e. 30 days prior to a concussion not including the day of the concussion). The reason for choosing this timeframe was that in our previous work we found that 30 day intervals best capture the critical information of patients and that the first thirty days post concussion are crucial in differentiating between patients.

Figure 9: Example of an automaton, before running through the modified K-Reversible algorithm built from 20 patients that had a concussion (f) and a diagnosis of headaches (H), sleep (S), and/or PTSD (P) with more than 15 days between. For our results, we will be analyzing the trajectory that patients took to develop diagnoses of headaches, sleep, and/or PTSD post concussion, with a minimum of at least 15 days between the concussion and diagnoses being required. We will only be using patients that have enough data to cover the time intervals defined previously, which amounts to 6,473 patients. For generating the automata, we will only be using the first 5,000 patients as any number larger than that requires substantial processing power which is beyond the scope of this paper.

Results

With our dataset defined, we set out to apply the approach that we previously defined in order to construct and analyze a model of the clinical trajectories that patients undergo post concussion to headaches, sleep, and PTSD.

First, we built an automaton consisting of 5,000 patients and ran it against our modified K-Reversible algorithm to identify the usefulness of our algorithm. Figure 9 shows an example of an automaton of 20 patients before being input to our algorithm. In this Figure it can be seen that understanding the similarities and differences between patients is near impossible and this difficulty would grow even more as the number of patients would increase. In Figure 10 we see the computed trajectory for all patients that experience a concussion and end up with a diagnosis of either headache, sleep, and/or PTSD. Analyzing this computed automaton, Figure 10, compared to the initial automaton, Figure 9, reveals that it is much easier to understand the path that most patients take. It should be noted that for the automaton in Figure 10, as with the rest of the computed automata that we will show, we set the line thickness of each transition to be equivalent to the probability of getting the specified diagnosis from that state. These varying thicknesses allow for a viewer to understand the flow of patients visually.

Next, breaking down the trajectories for each individual diagnosis we see headaches in Figure 12a, sleep in Figure
Figure 10: Automaton of all patients developing a diagnosis of headaches (H), sleep (S), and/or PTSD (P) post concussion (f).

Figure 11: Automata of all patients post concussion developing a diagnosis of (a) headaches, (b) sleep, and (c) PTSD.

To understand how the patients can be broken down we input our patients into the k-means clustering algorithm, as defined in the Clustering section of the Approach, to identify the various groups of patients and ran it for $2 \leq k \leq 30$. Using $k$ versus the BIC and the elbow method we found a value of 5 to be the most optimal for splitting the patients into clusters. With this value of 5 for $k$ the number of patients in each group varied, with the counts being: 2543, 95, 820, 3002, and 138 respectively. With the patients clustered into 5 groups, we now would be able to analyze the automata for each group and identify the various trajectories taken.

Using these defined patient clusters, we analyzed the five groups for patients that experienced a diagnosis of headache, sleep, and/or PTSD post concussion. We see the four of the five groups in Figure 12.

In these figures we are able to see the various paths that patients took to these diagnoses and from this we are able to characterize the groups as such:

- **Group 1** Early diagnosis, but long history of encounters afterwards.
- **Group 2** Early diagnosis, encounters, followed by late diagnoses.
- **Group 3** Early diagnoses, followed by a long history of encounters (similar to Group 1).
Figure 12: The first four groups of patients (a, b, c, d respectively) developing a diagnosis of headaches (H), sleep (S), and/or PTSD (P) post concussion (f).

- **Group 4** Early diagnoses and a short length of encounters with high probabilities.
- **Group 5** Early diagnosis, breaks, followed by late diagnoses with a short length of encounters.

With these five groups of encounters we are able to see that we can identify the varying, but most common trajectories that patients take in their diagnoses of headaches, sleep, and/or PTSD post concussion. This information could be passed along to clinicians in the TBI discipline so that they could gain insights that they could not otherwise discover.

**Conclusion**

In this paper we have defined our approach that enables a clinical dataset of patient encounters to be clustered into groups of similarity, represented as NFA’s and DFA’s that include a timeline indicating the number of days between each encounter, and finally run through our modified K-Reversible algorithm to produce automata that display the most common trajectories taken by patients. In our results we applied our approach to an extensive clinical dataset of 89,840 patients that were diagnosed with headache, sleep, and/or PTSD post concussion and showed that with our clustering and grammar induction algorithms we are able to produce trajectories that clearly show the path that each cluster of patients take. With this information we were able to identify and characterize the five different groups of patients that existed in our dataset and with this information we have shown that our approach is effective at clustering and visually representing the clinical trajectory of patients. We anticipate that the automata that we have generated will assist clinicians in understanding the path that their patients take and then being able to provide early treatment to help patients avoid going down specific paths.

Abstract

In this work we present our efforts in building a model able to forecast patients' changes in clinical conditions when repeated measurements are available. In this case the available risk calculators are typically not applicable. We propose a Hierarchical Bayesian Logistic Regression model, which allows taking into account individual and population variability in model parameters estimate. The model is used to predict metabolic control and its variation in type 2 diabetes mellitus. In particular we have analyzed a population of more than 1000 Italian type 2 diabetic patients, collected within the European project Mosaic. The results obtained in terms of Matthews Correlation Coefficient are significantly better than the ones gathered with standard logistic regression model, based on data pooling.

Introduction

Predictive models may play an important role in guiding interventions during monitoring of chronic diseases. However, such models, in particular risk calculators, are often learned from data sets coming from studies based on specific experimental designs and on patients with specific population characteristics that do not (fully) apply to the clinical group of interest. Moreover, the availability of monitoring measurements is typically not considered when building models, as well as the presence of important dynamic factors, such as delivery of drugs and/or lifestyle changes. As a result, the clinical utility of many risk calculators is strongly limited by model calibration drift (due to the different background characteristics of patients and to the different treatment approaches) and by model inadequacy (due to the lack of dynamic information).

In this paper we present an approach to learn predictive models able to take into account both the characteristics of the specific population at hand and the presence of repeated monitoring measurements about the same patients, including changing clinical conditions. In particular we propose to use Hierarchical Bayesian Logistic Regression models, which allow learning individual models borrowing strengths from data coming from all patients thanks to a suitable population model. Our approach is applied to a relevant clinical and social problem, the prediction of metabolic control in Type 2 DM (T2DM) patients; models are learned on the basis of a 10 years retrospective data collection gathered within the EU project MOSAIC.

A related approach can be found in ¹: they tested how fast HbA1c (Glycated Hemoglobin) changes after a change in glucose-lowering medication¹ within a 2-week cohort study. The described analysis has implications for whether routine HbA1c testing intervals before 12 weeks could inform diabetes medication adjustments. In ² authors evaluated the presence of factors associated with HbA1c control over 4 years in an observational cohort study of T2DM patients (CREDIT study) starting insulin therapy. They found that poor glycemic control over the 4 years was mainly modulated by the HbA1c values measured before starting therapy after adjusting for informative covariates (BMI – Body Mass Index, age, diabetes duration, glucose-lowering drugs, basal insulin alone, higher insulin dose and female sex).

Background

Diabetes and the MOSAIC project

Diabetes Mellitus (DM) is a chronic metabolic disorder which encompasses a range of metabolic diseases that share the phenotype of hyperglycemia over a prolonged time¹. Type 2 Diabetes Mellitus (T2DM), also referred to as non-insulin dependent diabetes or adult-onset diabetes, is the most common form of DM, encompassing at least 90% of all cases ². It refers to a heterogeneous group of disorders characterized by variable degrees of insulin resistance (reduced tissue responses to insulin) and insulin deficiency (inadequate insulin secretion for glucose load) ³. T2DM results from the interaction between a genetic predisposition and behavioral and environmental risk factors ⁴. The risk of developing T2DM increases with age, obesity, and lack of physical activity. It occurs more frequently in
individuals with hypertension or dyslipidemia and its frequency varies in different ethnic subgroups. It is often associated with strong familial, likely genetic, predisposition; however, the genetics of this form of diabetes are complex and not clearly defined.

The prevalence of DM in the worldwide population has risen dramatically over the past 2 decades, with 382 million patients diagnosed with diabetes in 2013. Based on current trends, the International Diabetes Federation estimates that by 2030 there will be about 550 million people suffering from DM, making it a leading cause of morbidity and mortality.

The metabolic dysregulation associated with DM causes secondary pathophysiologic alterations in multiple organ systems. There is strong evidence that chronic hyperglycemia plays a causative role in the pathogenesis of diabetic vascular complications. However, the mechanism by which it leads to such diverse cellular and organ dysfunction is still unknown, though several theories have been proposed. The association between increased levels of glycated hemoglobin (Hba1c), which is the reference parameter to measure average plasma glucose concentration over prolonged periods of time, and a higher risk of developing complications has been shown by landmark studies such as the Diabetes Control and Complications Trial (DCCT) in Type One DM patients and the United Kingdom Prospective Diabetes Study (UKPDS) and the Kumamoto study in T2DM patients. The findings of these studies emphasized the importance of intensive glycemic control in all forms of DM and of early diagnosis and strict blood pressure control in T2DM to prevent the adverse effects of the complications of diabetes. A recent study carried on the Italian population suggests that Hba1c variability affects nephropathy more than its average value, thus highlighting the importance of stability of metabolic control in the prevention of microvascular complication.

These recent findings made clear that it is important to retrieve more evidence from longitudinal studies, and to estimate how the variations in glycemic control are affected by heterogeneous factors.

MOSAIC (Models and simulation techniques for discovering diabetes influence factors) is an EU-funded project carried out within the 7th Framework Program, including partners from Italy, Spain, Finland and Greece. The project is devoted to: i) the development of mathematical models and algorithms that can enhance the current tools and standards for the diagnosis of T2DM. Impaired Glucose Tolerance (IGT) and Impaired Fasting Glucose (IFG); ii) improve the characterization of patients suffering from those metabolic disorders and iii) help in evaluating the risk of developing T2DM and its related complications. The final aim of the project is to deploy tools that may contribute to improve the control of the disease evolution, including the prevention of complications, by defining suitable clinical and lifestyle interventions.

One of the main tasks of MOSAIC is to exploit data mining techniques to better understand the mechanisms underlying the progression of diabetes through the analysis of individual patient histories, temporal events and behavioral factors.

Multiple clinical databases at the European level have been made available to the MOSAIC consortium as a result of the activities carried on by its members in previous projects and studies. These data have been exploited for the development of prediction models incorporating information related to environmental and clinical factors including physical, metabolic, phenotypic and lifestyle variables. The objectives of these models are the identification of relevant clinical pathways in patients’ histories and the stratification of the population for the risk of developing T2DM and its related complications. The aim is to integrate them in current decision support systems to enhance decision making in clinical care.

The dataset collected in the Italian Pavia area within the MOSAIC project includes data of 1020 T2DM patients and retrieved from two sources: the hospital Fondazione Salvatore Maugeri (FSM), which collects the clinical data related to the routine clinical activities, and the local public health agency (Agenzia Sanitaria Locale, ASL), which collects process data for administrative and organizational purposes. The integration of these two data sources provides a complete view of the clinical histories of the diabetic patients enrolled in the study. Variables considered in the analysis include demographic data (age, gender, diabetes duration), clinical data from the integrated FSM and ASL dataset (body mass index, glycated hemoglobin, smoking habit, lipid profile and systolic blood pressure) and administrative data collected by the ASL (drug purchases). Durations of the follow-ups of the patients included in our dataset are shown in Figure 1 and range from 1 to 18 years, with a mode of 5 years.

Risk calculators

Within the MOSAIC project, we initially studied the problem of selecting suitable calculators of the risk of complications to be used in our patient group. A score for cardiovascular risk was available, the validated Progetto
Cuore score\textsuperscript{16}. Such score, derived from the Framingham study\textsuperscript{17}, has been adapted to the Italian population. However, FSM treats patients with metabolic control instability and patients suffering from cardiac diseases. For this reason, in the FSM Hospital dataset, microvascular complications have a larger number of cases developed after the first visit as compared to macrovascular ones. Moreover, patients usually start to be treated by FSM (and their data collected) after the disease onset. Given the very nature of the data available in Pavia, we could not find any microvascular risk model that was applicable without a consistent calibration drift.

We therefore decided to build predictive models based on data collected at the first visit for microvascular complications: Retinopathy, Nephropathy and Neuropathy. We considered three prediction horizons: 3, 5, and 7 years from the first visit, and we applied standard modeling strategies, including logistic regression and Naive Bayes. After feature selection and model validation, we selected the models with the best overall performances. As an example, the variables included in the 5 years models were: HbA1c, for all the models; Time from T2DM Diagnosis and Hypertension for Retinopathy; Body Mass Index (BMI), Gender, Hypertension and Smoking habit for Nephropathy; Gender, Age, Time from T2DM Diagnosis, BMI for Neuropathy models.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{Follow-up durations.}
\end{figure}

The outline of the above described analyses follows a cross-sectional approach and the risk calculators could be particularly useful when employed during the first visit, to suggest to the clinicians those patients that might need particular attention. They are suitable for the prediction of chronic complications onset. However, these models cannot be used when monitoring patients during their disease progression, especially when the goal is to predict variations in complication risk biomarkers, like Hba1c, during consecutive follow-ups.

As already discussed in previous works\textsuperscript{18–20} another limit in deploying traditional risk calculators for patients monitoring is to cope with external and internal heterogeneity, where external heterogeneity is the one represented by the differences among patients within a population, and internal heterogeneity is the one produced by variations in single patient’s state over time. Various methods\textsuperscript{21,22} have been proposed to overcome these heterogeneity effects, while considering the irregular structure of medical datasets. In the following we will present a Bayesian hierarchical model, able to deal with both kinds of heterogeneity.

\section*{Methods}

\textit{Hierarchical Bayesian Logistic Regression models}

Hierarchical Bayesian Logistic Regression models are of peculiar interest when data are characterized by repeated measures, i.e. follow-up, by units of observation, i.e. patients. In this case two models are jointly applied: one model is used for within-unit analysis, dealing with internal heterogeneity, and another model for across-units analysis, dealing with external heterogeneity. The Bayes theorem is used to integrate the two models and to properly account for the uncertainty in the data, allowing individual learning by borrowing strengths from population data\textsuperscript{23}.
Given $h=1, \ldots, N$ patients, and $i=1, \ldots, n_h$ measurements available on the $h$-th patient, collected on a feature vector $x$ of $m$ “monitoring” variables, and on an outcome binary measure $y$, the probability that the outcome occurs (say metabolic control worsening) is described by the logistic model:

$$P(y_{hi} = 1|x_{hi}) = \frac{\exp (x^t_{hi}\beta_h)}{1 + \exp (x^t_{hi}\beta_h)}$$

The parameter vector of the $h$-th patient, $\beta_h$, is assumed to be a stochastic variable described by a “population” linear model:

$$\beta_h \sim N(\Delta^t z_h, V_{\beta})$$

where $N(\ldots)$ is the Gaussian p.d.f., $z_h$ is a vector of $s$ “static” covariates, such as sex, $\Delta$ is a $s \times m$ matrix of population parameters that associates static and monitoring variables and $V$, is a $m \times m$ covariance matrix.

In order to perform Bayesian inference from the data, the population parameters are typically provided with a suitable prior choice. In our case, we will consider:

$$\text{vec}(\Delta|V_{\beta}) \sim N(\text{vec}(\overline{\Delta}), V_{\beta} \otimes A^{-1})$$

$$V_{\beta} \sim IW(v, V)$$

where vec(.) is the vector representation of the elements of a matrix, $A$ is a suitable prior precision matrix of size $s \times s$, $\otimes$ is the Kronecker product, $IW$ is the Inverse Wishart distribution, and the prior hyperparameters ($\overline{\Delta}, A, v, V$) are typically selected to generate diffuse priors.

The estimate of such models is usually performed by resorting to Markov Chain Monte Carlo (MCMC) methods. Instead of deriving the analytic form of the posterior distribution, the idea behind the MCMC approach is to create a Markov chain able to generate draws from the posterior distribution of the model parameters. These Monte Carlo draws are then used to calculate statistics of interest such as parameter estimates and confidence intervals. Despite the idea behind MCMC methods is simple, its implementation requires the derivations of the appropriate (conditional) distributions in order to produce the draws. Many tools exist to efficiently implement MCMC strategies. In our case, the Hierarchical Bayes logit model is implemented in the R environment (www.r-project.org) package called bayesM24. The bayesM package includes the rhierBinLogit function, which implements an MCMC algorithm for hierarchical binary logits with a normal heterogeneity distribution. This is a hybrid sampler with a Random-Walk Metropolis step for unit-level logit parameters25.

Data pre-processing

HbA1c was originally expressed in mmol/mol and it was converted into % by the following formula: HbA1c % = (0.0915 x HbA1c mmol/mol) + 2.15. Missing values for continuous variables (body mass index, systolic blood pressure, total cholesterol and triglycerides) were imputed by the k-Nearest Neighbor (k-NN) method, using the knnImputation function implemented in the R package called DMwR. Missing values for smoking status were imputed assuming that patients do not change their smoking habit during their follow up period, otherwise by the most frequent value observed in the dataset (for patients for which the smoking status was missing at any visit). Continuous variables were then discretized into three intervals according to the 33th and 66th percentiles of their distribution and recoded as dummy variables. Male gender was recoded as “1” while females as “0”, since the expected risk of diabetes complication is expected to be increased in men. Similarly, smoking status was recoded using dummy variables with “never-smoker” being the category at lower risk, while “ex-smoker” and “current-smoker” at intermediate and high-risk respectively.

Patients were excluded if being characterized by less than 3 follow-up visits. Single visits were excluded if not followed by at least one visits within a time frame of 12 months. Figure 2 shows the distribution of time spans between follow-ups in the population.

The dependent variable of the analysis was defined as an observed increase in terms of HbA1c % $\geq 0.5$ within a time frame of 12 months from each visit. The presence of the increase was coded as “1”, “0” otherwise. Demographical and behavioral characteristics (Gender, Age at follow-up visit, Time between follow-up visit and Time from T2DM diagnosis, Smoking habit), clinical measurements (HbA1c, BMI, Triglycerides, Systolic Blood Pressure (SBP), Total Cholesterol) and presence of pharmacological treatments (Insulin, other Anti-Diabetic treatments) were considered as independent variables to be included in the analysis.

---

1 The output is the covariance block matrix for vec(A) of size $m \times s \times m \times s$. 
Figure 2. Time between follow-up, in months.

Data deriving from the first three visits available for each patient were used to train the model. At the first iteration, predictions were performed on data deriving from the 4th visit and the event to predict was the occurrence of an increase in terms of HbA1c % of at least 0.5 with respect to HbA1c % measured at 4th visit in a time-frame of 12 months. To be noted, only a fraction of the whole cohort has data for more than 3 visits, thus the prediction is performed on a subset of subjects. At the second iteration, measurements deriving from the 4th visit were included in the training set and the prediction was performed on data from the 5th interval and so on until the 6th iteration (prediction on visit number 9). Figure 3 provides a graphical representation of the analysis schema.

Figure 3. Analysis schema. Example of analysis involving three patients with a number of visits ranging from 4 to 5. Blue and red rectangles correspond to visits included in the training set and test set respectively. Grey rectangles
correspond to visits not considered at the specific iteration. At the first iteration data from the first 3 visits were used to train the model that was tested on data deriving from the 4th visit (all 3 subjects had information about HbA1c % for at least one year starting from the 4th visit). At the second iteration, data from the 4th visit was included in the training set: once learned, the model was tested on data from the 5th visit (only patient A and C had information about HbA1c % for at least one year starting from the 5th visit).

The same analysis schema was performed in parallel by logistic regression (glm function with logit link in the R package stats). The deriving regression coefficients were used to estimate the probability of the outcome on unseen data.

The probabilities estimated by the Hierarchical Bayesian model and by logistic regression were binarized using the probability of increase in terms of HbA1c % ≥ 0.5 characterizing the training data. Once the number of true positive (TP), true negative (TN), false positive (FP) and false negative (FN) classifications were estimated, models performances were quantified and compared in terms of Matthew’s Correlation Coefficient that is the most appropriate metrics to be considered in presence of unbalanced dependent variables.

\[
MCC = \frac{TP \times TN - FP \times FN}{\sqrt{(TP + FP) \times (TN + FN) \times (TP + FN) \times (TN + FP)}}
\]

**Results**

**Cohort characteristics**

A total number of 684 T2D patients (401 males, 283 females) meeting the inclusion criteria were analyzed, with a median number of 10 visits (min = 3 – max = 52). Table 1 describes the general characteristics of the analyzed cohort at the first and last visits considered.

Table 2. Regression coefficients. Each column represents a static variable, each row a different time-varying variable and corresponding intervals defined by the 33th and 66th percentiles of the distribution (the lowest interval was used reported since it was considered as the baseline).

Individual-level regression coefficients learned on the training sets were used to estimate the probability of experiencing an increase in terms of HbA1c % ≥ 0.5 within a time frame of 12 months from each visit. Table 3 reports the total number of patients and corresponding frequency of events in each training set and test set considered, according to the analysis schema in Figure 3. Regarding the computational complexity of the method, the algorithm took an average time of 14.83 ± 0.14 minutes to fit each model (computer characteristics: iMac, 4GB RAM), for a total computational time of 88.89 minutes for performing the whole analysis (six models were fitted). Logistic regression was also applied, as a term of comparison. Results are reported in Table 3 and show that the MCC reached by Hierarchical Bayesian Model was always higher than MCC obtained by logistic regression on the same data except for the prediction after the 9th visit (t-test p-value <0.05).

Table 3. Dependent variable's distribution on the training and test sets and discriminative performances on the test set. Learned on data from visit # (training set) = visits used to train the model and defining the training set; Prediction on data from visit # (test set) = visit on which the model was tested and defining the test set; Training set: n. patients, mean n. visits = number of patients defining each training set and average number of visits; Test set: n. events/ n. tot patients (%) = number of patients experiencing an increase in terms of HbA1c % ≥ 0.5 within a time frame of 12 months from the visit considered as test set / number of patients observed during the visit considered as test set; MCC Hierarchical Bayesian Model = Matthew’s Correlation coefficient reached by the Hierarchical Naïve Bayesian Model in discriminating patients experiencing an increase in terms of HbA1c % ≥ 0.5 within a time frame of 12 months from the visit considered as test set from those who did not experienced such increase; MCC Logistic Regression.
Logistic Regression Model = Matthew’s Correlation coefficient reached by the Logistic Regression Model in discriminating patients experiencing an increase in terms of HbA1c % ≥ 0.5 within a time frame of 12 months from the visit considered as test set from those who did not experienced such increase.

Conclusion

A challenging problem of clinical data mining is to derive predictive models able to be tailored to both the specific clinical center and to the single patients’ characteristics, i.e. to take into account external and internal heterogeneity. This is crucial when monitoring chronic patients, where repeated measurements are available on a potentially large cohort of subjects. In order to deal with this problem, we have proposed a method based on a Hierarchical Bayesian logistic regression approach, which is able to suitably take into account individual information when the individual model parameters are estimated, while exploiting the data of other patients thanks to a population model. When applied to the problem of predicting variations in HbA1c between two consecutive visits of T2DM patients, the model proved to outperform standard logistic regression modeling based on data pooling. The approach seems therefore promising to deal with this class of problems, which turn out to be very common in the clinical context. Although one of the limitations of the obtained results is related to the choice of a definite population, coming from a single hospital in Italy, where patients show specific characteristics. For this reason, the obtained model may not be generalized well to other patient populations. Moreover, the method itself has two potential drawbacks. First, parameters estimate relies on MCMC methods. This makes the estimation strategy inefficient and not easily scalable when very large data sets are available. Second, the model assumes that the measurements are exchangeable, i.e. time is not explicitly modeled in the individual measurements. In the future we will work on improving both aspects; first in trying different estimation strategies, such as variational methods; second, we will consider autoregressive structures when modeling dynamic features.

Abstract

Medication non-adherence is a pressing concern among seniors, leading to a lower quality of life and higher healthcare costs. While mobile applications provide a viable medium for medication management, their utility can be limited without tackling the specific needs of seniors and facilitating the active involvement of care providers. To address these limitations, we are developing a tablet-based application designed specifically for seniors to track their medications and a web portal for their care providers to track medication adherence. In collaboration with a local Aging in Place program, we conducted a three-month study with sixteen participants from an independent living facility. Our study found that the application helped participants to effectively track their medications and improved their sense of well-being. Our findings highlight the importance of catering to the needs of seniors and of involving care providers in this process, with specific recommendations for the development of future medication management applications.

Introduction

Seniors take on average about seven medications per day, representing the highest number of prescribed medications and the most complex medical regime compared to any age group. While this complexity is a natural response to chronic disease conditions that are increasingly prevalent as one ages, it also brings with it a higher risk of medication non-adherence. Medication non-adherence increases from an average of approximately 20% for patients taking one medication daily to over 50% for those taking medications four times per day. It not only results in unalleviated disease conditions, but can also lead to an increased risk of comorbidities and longer hospital stays. Ultimately, it is responsible for approximately 125,000 deaths per year at an annual cost of roughly $100 billion.

Mobile applications have been proposed as promising tools for mitigating some of the challenges of medication non-adherence by providing seniors with tracking, organizational, and reminder supports. Unfortunately, there are several reasons why such applications continue to have limited impact on the aging population. The most pronounced problem is that the vast majority of these applications are designed for technologically savvy individuals, fundamentally limiting their use by a senior population that is often slow to adopt new technology. Further, despite the integral role that communication between patients and care providers plays in providing healthcare workers with the root causes of non-adherence, these applications generally have very limited ability—and often no ability—to connect the patient with care providers. These factors severely limit the practical use of these applications by seniors.

We are developing eSeniorCare, a comprehensive system targeting quality of life, comprising both a tablet application and a web portal. While the application has an extensive set of functions, in this paper we focus specifically on the application’s medication adherence component. This component assists seniors in tracking their medications by providing reminders for when medication is due and by recording the intake of medications. It also provides a communication mechanism with the care provider. The web portal helps care provider teams to communicate with seniors about missed medications, changes, and refills. By building the system around these components, eSeniorCare has been carefully designed with the features needed to empower seniors to take charge of their medication management and to enable care providers to support the medication adherence of their patients.

To investigate the impact of eSeniorCare on medication adherence, we conducted a pilot study of the system at a local independent living facility catering to a low-income senior population. The care provider team at this facility consists of a nurse and Resident Life Health Administrator (who we collectively refer to as RLHA) under the supervision of Memorial Hospital of South Bend (part of Beacon Health System). We present the design, development, and evaluation of the system’s medication management component to investigate two main research questions (RQ1 and RQ2) and an exploratory research question (RQ3):

• RQ1: How do the participants use the application to track their medications?
• RQ2: How does the application impact participants’ quality of life, specifically as it pertains to health?
• RQ3: What influence does the application have on participants’ knowledge of their medication regimes?

Related Work

There are various methods for measuring medication adherence. Some of the methods measure adherence directly, while others attempt to infer adherence through indirect (proxy) indicators. Direct methods include measurements that determine drug metabolites, biomarkers or additionally applied marker molecules in biological fluids (e.g., plasma and urine), and direct observation therapy. While these methods can provide fairly accurate measurements of adherence, they are not scalable, incur high costs, and tend to be labor intensive. Indirect methods include electronic pill box cap monitoring, pill counts, self-reporting, and pharmacy refill systems. While these indirect methods are fairly inexpensive, their reliability depends on the individual’s responses. For example, an individual can open the electronic pillbox for a medication despite not physically taking it, thereby providing an overestimation of adherence.

The increasing popularity of smartphones has led to the development of mobile applications for medication management. These applications typically provide reminders for when a medication is due, information on medication dosage history, and medication refill alerts. While some of these applications have been developed without a focus on any particular condition, many have been developed to cater to chronic disease conditions such as hypertension, diabetes, and asthma. The potential of these mobile applications to address the challenges of medication management has been encouraging, with several studies demonstrating that they can be effective in improving medication adherence.

Despite their potential, very few mobile applications have been developed for or targeted at seniors. One such application, ALICE, provides medication reminders and can send messages to the care providers in the case of non-response to these reminders. However, almost none of these applications track the medications taken as needed (PRN) and many provide no or non-real-time information regarding missed medications. Further, few of these applications support a direct connection between the patient and care provider. As a result, unlike eSeniorCare, these applications do not enable intervention by the care provider in the case of medication non-adherence. We have also designed eSeniorCare with several features practically useful for medication management, such as care provider follow-up in case of missed medications and PRN intake, that are missing from currently available mobile applications.

Application Design

We are developing a tablet-based Android application called eSeniorCare that focuses specifically on the components of quality of life for seniors. In this section, we provide an overview of the features provided by the application’s medication management component, as illustrated in Figure 1(a).

Medication Reminders. For each participant, eSeniorCare automatically generates reminders for all prescribed medications based on the prescription data that is queried from the encrypted local database (Figure 1(b)). A reminder is scheduled five minutes before the prescribed dosage time. For each medication due at the dosage time, the reminder screen displays the following information: (a) medication name, (b) dosage information (i.e., quantity and unit), (c) associated treatment condition, (d) audio icon to speak out the medication’s name, (e) image of the medication, and (f) a checkbox that the user must check to confirm intake. If the checkbox associated with any medication is not checked, the user is asked to validate the response. The user can also view a magnified version of the image of the pill.

Medication History. For each participant, all current and previously prescribed medications are listed, along with a status—active, dosage modified, or discontinued—for each medication. This feature can help participants improve communication with their physicians.

Current Medications. The application provides participants with comprehensive information about their current medications, along with the frequency and dosage of each medication and the corresponding treatment condition. The purpose of this feature is to empower the participants in maintaining an aggregated list of prescribed medications, which may be used as a quick reference for the patient or clinician during medical visits.

PRN. Pro re nata (PRN) medications are taken whenever the need arises. All PRNs are listed here, along with corresponding disease diagnoses, and dosage directions. Due to their potential impact on patient health, the inclusion of PRN medications is an important feature that has traditionally been absent from mobile health applications.
Medication Taken. The participants may respond to a medication reminder even after it has disappeared by tapping the “Taken” button, as shown in Figure 1(b). The participant is then presented with a list of dosage times before the current system time for which responses have not yet been entered. If a participant selects a particular dosage time, he or she is presented with the appropriate medication reminder. This feature is typically unavailable in the mobile health applications.

Medication Change. A participant can inform the RLHA to a change in his or her medication by clicking this button. The RLHA receives information on the medication change via the web portal. The RLHA then follows up on this information by updating the participant’s medication information.

RLHA Portal for Monitoring Adherence. A participant’s response or non-response to the reminders is reported to the RLHAs via the web portal, allowing the RLHA to follow up with the participant to resolve any issues and to provide appropriate motivation. To validate the participant responses for medication reminders, we implemented the “Refill Medications” button that provides a list of the refillable medications. They can pick the ones for which they require a refill. We calculate an estimate of the refill date for each refillable medication based on the initial pill count and the dosage. If the requested date does not match the estimated refill date, the RLHA is notified through the portal.

Missed medication is marked “Not Taken”; otherwise, it is marked “Taken”. In order to track the workflow of a missed medication and for ease of maintenance, we added a status field. When no action has been taken by the RLHA, the status is “Unread”. After the RLHA has followed up with the participant, the status is changed to “Resolved” and a reason is entered for the missed medication. The RLHA may use the portal to create new users, populate and maintain their medication profiles.

Offline Usage. Our study site has Wi-Fi connectivity that is limited to the core of the building and community areas. As a result, the majority of the participants did not have Wi-Fi connectivity in their apartments. To account for the intermittent connectivity, the tablet application has a local database—located in the tablet’s encrypted internal memory—that enables the desired offline functioning of the application. The application is only required to connect to Wi-Fi once a day for synchronization with the remote server.

Methods

We conducted a study of eSeniorCare in collaboration with the Aging in Place (AiP) program designed by the Community Health Enhancement (CHE) vision of the Memorial Hospital of South Bend. The program operates in several local independent living facilities with a mixed-income senior population, and aims to positively impact wellness and quality of life for its participants while they are living in their current home settings. As part of this aim, AiP is actively interested in the development of a low-cost solution to help its participants improve adherence to their medication regimens.

Overview: We held an interest meeting with residents at the facility to introduce the purpose of the study and requirements of participation. We only accepted residents who were cognitively intact, determined by the St. Louis University Mental Status Exam (SLUMS), a 30-point screening questionnaire that tests for orientation, memory, attention, and executive functions; fluent in English; and had good vision. Finally, participation was restricted to individuals with at least one chronic condition and one actively prescribed medication.

Each resident who qualified for the study, based on the selection criteria described above, was given an encrypted, password-protected 7-inch Samsung Galaxy Tab 2 tablet device. Participants were expected to carry the device with them at all times and to manage their medications as reasonably directed by the device. Those who participated for the full duration of the study were permitted to keep the tablet.

Participants. We recruited sixteen participants with an average age of 66 years (SD = 9.2). Five participants were male and eleven were female. Twelve participants identified themselves as African American/Black, three as non-Hispanic White, and one as other. One participant was married, six were divorced, two were widowed, two were separated, and five never married. One participant was employed, one was looking for work, seven were retired, and four indicated that they could not work. Two participants had between 9th and 11th grade education, four had completed high school, eight had 1–3 years of technical school, one was a college graduate, and one had an advanced degree. The number of medications per participant ranged from 1 to 13, with an average of 6–7 medications.

Study Design. We conducted the study over a period three months to evaluate the RQ1, RQ2, and RQ3. The participants were required to respond to the medication reminders, report PRN intake, and report changes in medication. To familiarize participants with the application, one-on-one training with the application was provided at the beginning of the study. The RLHA were instructed to access the web portal on alternate days to track the medication responses. In the case of missed medication, a registered nurse followed up with the participant and took appropriate action.

Evaluation Metrics. To answer our research questions, we used the following information:

- Medication Usage Logs (MUL): Participant responses to medication reminders, reported changes to prescribed medication, and incidences of PRN were recorded in a database.
- Medication Adherence Questionnaire (MAQ): A questionnaire designed based on the Brief Medical Questionnaire (BMQ) for measuring medication adherence. Studies have shown that if a patient is better aware of her or his medications and diseases, then he or she will have an improved adherence to his or her medication regimen. We administered a paper-based MAQ both at the beginning and at the end of the study. Table 1 provides an outline of the questionnaire. The questions in MAQ are tailored to the prescription information provided by the participants. The response(s) for each question are matched with the prescription information.
- Final Feedback Questionnaire (FFQ): A 38-point post-study feedback questionnaire for evaluating the usability of the application and the effectiveness of the study. Sample questions are included in Table 2. The questionnaire was administered both on paper and online at the end of the study.
- SF12v2: A 12-item health survey provided by Quality Metric to measure the general health (physical and mental) of an individual and health-related quality of life, and well-validated for the aging population. It measures the health status in eight functional domains: bodily pain, physical function, role physical, role emotional, mental health, vitality, social function, and general health. These domains are further collapsed into a physical component summary (PCS) and a mental component summary (MCS). The survey was administered on paper at the beginning and end of the study.

For each segment, the value denotes the number of participants with the response, while its length denotes the proportion.

Results

In this section, we provide details of the results from our study of eSeniorCare. Our results come from information gathered by tracking how participants used the application over the course of the study, as well as from questionnaires, administered at the beginning of the study and at its conclusion.

RQ1: How do participants use eSeniorCare to track their medications?

A majority of the participants \((n = 12)\) initially faced difficulties in maneuvering the touch screen (sensitivity, pointing, and dragging) and with the tablet itself due to a lack of technological fluency and unfamiliarity with the tablet. Several hour-long group workshops and one-on-one training sessions helped familiarize participants with the technology and application. To help overcome usability challenges with the touchscreen, we provided each participant with a stylus. We also provided printed manuals for eSeniorCare application. These activities were substantial in helping to foster user engagement, with participants expressing a strong desire for the study to continue as it approached its conclusion.

The FFQ included several questions to assess how participants used the application to track their medications. All but one of the participants reported that the application showed the correct medications (Table 2, Q6). We note that one participant also made a considerable number of changes to his or her medication list, so it could be a function of that artifact. Around 50% of the participants reported that they showed the application to their physician (Table 2, Q5). More than 65% of the participants reported that they felt the application helped them to manage their medications (Table 2, Q4), and about 50% of the participants reported that they felt the application made them more aware of their health (Table 2, Q1).

Medication Reminders. We used the MUL to define a rating system for tracking the frequency of medication responses for each participant. A rating of 1 was given if the participant acknowledged a medication reminder. The maximum possible daily rating for the participant is then equal to the number of times per day that a medication is due to be taken. We calculated the weekly rating as the sum of the participant’s daily ratings for a week divided by the sum of the participant’s maximum possible daily rating for a week (thus taking into account the variation in the number of daily reminders among the participants). We averaged the weekly rating to obtain the average weekly rating (AWR).

To identify similar usage patterns among participants, we performed \(k\)-medoids clustering on the participants’
weekly ratings, using the measure of silhouette width to evaluate the number of clusters. Based on the maximum average silhouette width, we discovered three distinguishable clusters of participants, illustrated in Figure 2(a). The majority of the participants (n = 7) had moderate usage, shown in Figure 2(b), with AWR ranging from 0.52 to 0.73. The remaining participants were split between low-usage ratings (n = 5), shown in Figure 2(c), with AWR less than 0.28, and high-usage ratings (n = 4), shown in Figure 2(d) with AWR greater than 0.93.

To determine whether the ratings (usage patterns) given by participants grouped into different clusters is statistically significantly different, we performed a one-way ANOVA test on the AWR for the clusters. The extremely low p-value for the AWR of different clusters (Table 3: AWR) indicates that the ratings are statistically significant different. There is also a statistically significant difference in the AWR for different clusters when all of the demographic factors (gender, race, education, employment status, and marital status) are considered as variables in the model (Table 3: DWR). To identify differences between specific groups, we use the post-hoc Tukey-Kramer method (Table 3: AWR right side), which shows that there is a statistically significant difference in the AWR between several pairs of groups.

Note: AWR: Medication Average Weekly Rating; DWR: Medication Average Weekly Rating by Demographics; MAQ: Medication Adherence Questionnaire. Low, Medium, and High refer to the groups shown in Figure 2. * Significant at a 95% confidence level. † Formatted as: score (degrees of freedom). ‡ Formatted as: mean difference (p-value).

RLHA Interaction. Table 4 shows the percentage of medication alerts to which each participant responded, and the number of days over which these responses occurred. A low response percentage was observed for two participants, namely 1 and 13. Participant 1 had only one medication listed as a daily medication, but was advised by his or her physician to take it as needed. Participant 13 had a considerable number of changes to his or her medication list, making it difficult to finalize the list. Table 4 shows the count of medications that were reported “Taken” and “Not Taken” for each participant over the study span. The most common reason cited for missed medications was “did not want to take” (28%), followed by “took but didn’t enter” (17%) and “discontinued” (15%). The RLHA followed up with the participants in case of any missed medications, and medication change. Only 37.5% of the participants would prefer to enter their own medications (Table 2: Q7). All of the participants appreciated this follow-up and felt that their best interest is being looked after.

PRN Intake. We found that eight participants had at least one PRN medication listed during the study phase. For those with at least one PRN medication, the number of PRN medications ranged from 1 to 5, with a median of 5. We also found that five participants tracked their PRN medications at least once over the study period; two of these participants tracked their PRN medications exactly 1 time, two tracked 5 times, and one tracked 69 times. Of the participants who did not track even once during the study phase, one had only a single medication listed and did not receive any confirmation from the physician regarding medication intake.

RQ2: How does eSeniorCare impact participants’ health-related quality of life?

SF12v2 was completed by nine participants. The majority of these participants belonged to the medium-usage group, as defined above. We used the missing data estimation supplied by the SF12v2 scoring software to estimate scores for the remaining participants. A majority of the participants (56.25%) had a post-study physical health score (PCS) score greater than or equal to that at the beginning of the study. We also observed a decrease in mental health score (MCS) for the same proportion of participants at the end of the study. We note, however, that about 50% of the
Figure 2. Cluster analysis based on participants’ weekly ratings. (a) Illustrates the average silhouette width (Y-axis) as a function of the number of clusters (X-axis); the blue point (n = 3) represents the natural number of clusters determined by the silhouette width. Based on the usage patterns, we call these clusters: low-, medium-, and high-usage clusters. (b)(c)(d) Illustrate the weekly ratings for participants of the low-, medium-, and high-usage clusters, respectively; for each plot, the X-axis is the week and the Y-axis is the weekly rating for each of the cluster’s participants, with each line representing a participant.

* Calculated based on the number of days in the second phase (89 days).

participants reported PCS higher than the U.S. norm for their age category, both at the beginning and end of the study. To examine the relationship between post-study scores and medication component usage (WR), we developed a linear regression model with the post-study SF12v2 component score as the dependent variable and the pre-study SF12v2 scores and cluster number (high, medium and low rating groups) as independent variables, while controlling for demographic variables (age, education and race), other components of the application, and tablet use. We observed a strong relationship between the post-study and pre-study scores (Table 3: PCS and MCS). However, we did not observe a notable relationship between post-study scores and WR (Table 3: PCSWR and MCSWR). This may be due to the short duration of the study, the weather conditions (winter), and the small sample size. Further, we did not take into account the impact of chronic conditions on the scores.

RQ3: What influence does eSeniorCare have on participants’ knowledge of their medication regimes?

To explore the influence of eSeniorCare on a participant’s knowledge of their medications, we examined each participant’s responses to the questions in the MAQ. For each correct response to a question, we gave the participant 1 point. We then calculated each participant’s MAQ score as the total number of points he or she earned divided by the maximum possible points for that participant.
There was an increase in MAQ scores for 50% of the participants, while 19% showed a decrease. The remaining 31% of the participants showed no change in their scores because they obtained maximum or nearly maximum scores for both pre- and post-study questionnaires. To determine whether the difference between the pre- and post-study MAQ scores is statistical significantly different, we performed a paired t-test ($t$-statistic: $-1.03; p$-value: 0.317). We did not find any statistically significant difference. We further examined the relationship between MAQ scores and the clusters assigned based on weekly ratings via a one-way ANOVA test (Table 3, MAQ). We did not observe any statistically significant relationship between the change in MAQ scores and weekly ratings.

Discussion

The main objective of our study was to evaluate the design and impact of the medication adherence component of eSeniorCare on the participant’s health-related quality of life and explore the impact on their knowledge of medications. As a part of three-month-long study, the participants (seniors aged 55 years or older) used a tablet-based application to record their medication intake. The RLHA used a web-portal to track missed medications, changes in medications, and refill alerts reported by the participants through the application. All of the participants completed the study.

From our clustering illustrated in Figure 2 we found that the majority of participants ($n = 11$) used the medication component to track their medications, with most of the participants ($n = 13$) reporting higher (or maximum) MAQ scores at the end of the study than at the beginning. The majority of participants ($n = 10$) also reported higher physical health SF12v2 scores. However we found that, after controlling for demographic factors, the medication component usage (technology) did not have an impact on these scores. This accords with prior studies that have investigated the impact of computer use on quality of life. That said, we did observe a significant change in the post-study scores compared to the pre-study scores, even after controlling for age, gender, education and race.

From our ANOVA tests shown in Table 3 we found that the majority of the participants had an increase in MAQ scores at the end of the study, though the improvement in the MAQ scores for the participants at the end of the study was not statistically significant. We note, however, that the majority of the participants already had almost perfect scores at the beginning of the study, resulting in a very small margin of potential improvement for most of the participants.

For tracking medication adherence, we relied on each participant’s self-reported responses. As there is no gold standard in tracking adherence, a combination of methods is instead recommended. We thus implemented a secondary method of tracking medication adherence via a “Refill Medications” function. During the study phase, however, most of the participants did not use this functionality. This may be because most of the participants had already obtained 90-day refills for their medications, thus obviating the need to use the refill functionality throughout the duration of the study.

Recommendations for future work. We believe that our study provides a foundation for further development of integrated technological solutions for seniors. We also believe that the benefits of these solutions can and should go beyond the seniors themselves, as they can also help care providers and clinicians by providing them with a direct connection for monitoring medication adherence and connecting with their patient pool on health and wellness. Based on our findings, we provide the following recommendations for the development of mobile applications for medication management, and particularly for those oriented to low-income aging populations:

- The application should function appropriately with intermittent Internet connectivity. We found that limited access to Wi-Fi was a major obstacle for the deployment of our application. To use the available connectivity efficiently, we specifically recommend periodically synchronizing locally stored data with a remote server. The care provider should be able to track the last synchronization date for each participant for tracking medication adherence to overcome the challenges with limited to no internet connectivity in a low-income, independent living facility.
- The application should be accompanied by a companion web portal, accessible to a care provider. The portal should provide information on missed medications, refill alerts, and medication changes so that the care provider can take appropriate action. We found that participants were grateful for follow-ups by their care provider team.
- The companion web portal should have functionality for the creation and maintenance of medication profiles for the users. We found that the complex medical regimen maintained by many seniors frequently makes medication entry directly via the application difficult. Further, to expedite this process, the application could be integrated with health information exchanges (HIEs) with necessary safety and privacy measures.
- The participants should be able to send to and receive messages from RLHA using the application as we found this communication to be a key factor for using eSeniorCare.
**Limitations.** While our current study was informative in impact as well as needs assessment, we do believe that having a larger sample pool over a longer time period can help strengthen the findings and conclusions drawn from the study. However, this is an important first step in developing an application that is integrative of the senior participants and their care provider team, demonstrating its strengths and weaknesses, and laying the foundation for partnering with independent living facilities for longer-duration studies. A further limitation is that we only address unintentional medication non-adherence, as our medication tracking relied on self-reporting; this is an area of ongoing research. It should be further noted that other features of the application aside from those actively investigated may have also contributed to the positive findings of our study.

**Conclusion**

We presented *eSeniorCare*, a health and wellness system focused specifically on improving senior care and quality of life. By analyzing participant information collected both through this system and through surveys, we found that *eSeniorCare* provides an intersection of technology and relationship building that can help seniors to effectively track their medications. We observed that the participants became more aware of their medications and were more likely to use them as prescribed. We also discovered that the role of RLHAs—providing personal support and medication tracking—is crucial to this improvement. Based on our findings, we also provide a series of suggestions for future developers to improve the design of their own medical management applications. Through an easy-to-use application and web portal, *eSeniorCare* empowers seniors to take charge of their medication management and places them in the center of a system of support, representing an important step toward improving senior care and quality of life.

Investigating Delays in Updates to Infusion Pump Drug Limit Libraries

Poching C. DeLaurentis, Ph.D.1, Kang-Yu Hsu, M.S.1,2, Ana Isabel De la Hoz Armenta1,3, Yuval Bitan, Ph.D.4

Abstract
Interoperability is a major challenge in current healthcare systems. It brings big hope for data exchange, but also raises some concern about patient safety. We study the wireless updating of modern infusion pumps and demonstrate the possible flaws in this process. Through analyzing data on drug limit libraries (DLL) versions in one hospital we could identify the delays in distributing DLL updates and the impact these delays might have on patient safety. We found that 31% of all started infusions had used outdated DLL versions, and 22.6% of all alerts were triggered by outdated DLLs. These findings suggest that clinical and operational stakeholders in healthcare systems must address the unreliable interoperability of medical technologies such as seen on infusion pumps. The impact of information inconsistency across healthcare systems might result in use error which would impair patient safety.

Introduction
Medical devices’ advancement in automation and interoperability is playing a significant role in the way they are integrated into the drug delivery system. In order to make all component synchronized in the integrated system, which includes the human operator and the medical devices, it is important to have very reliable communications between all of them. Devices that are not synchronized may cause inconsistency (or, from the operator’s viewpoint, operational failure) which in turn might translate into use errors and distrust of the technology. Such distrust likely would lead to low adoption rate of using the technology and also undesired workarounds1, 2.

Infusion pumps are among the technologies that have advanced interoperability in the clinical setting. Modern infusion pumps models have built-in dose error reduction systems (DERS) and drug limit libraries (DLL) that can alert users when a drug is programmed outside of the preset limits, and they have shown to be effective in reducing potential infusion errors3. These functions were designed as a safety feature that should ease and standardize the way clinicians program the infusion pump. Moreover, hospitals often make changes to drug limits to reflect evolving clinical needs, and, thus, would publish new versions of DLL from time to time. Such updates on DLL are done wirelessly nowadays without the need to perform updates of the DLL file on each individual pump manually with a cable. Ideally, in order to standardize clinical workflow and avoid confusion, all infusion pumps in the hospital should have the same version of the DLL especially with such wireless automation.

Objective
The objective of this study is to raise clinicians’ awareness of the issue of inefficient infusion pump DLL updates, and what the impact may be. The problem of delayed updates on pumps may have been known by some but not so much about its magnitude, its impact on drug limit compliance and the potential risk of patient harm4, 5. Following the authors’ prior descriptive work on the issue of long update delays of DLL in several hospital systems using merely infusion alert data5, we took a step further to collect pump status and all infusion detail reports in addition to the alert data from one of our collaborating hospitals. By cross checking the numbers in each of these different types of report, we would also be able to discover in-depth the spread and impact of such issue on infusion drug alerts, potential patient harm and its contribution to nursing workarounds.

Materials and Methods
Data
The data for this analysis came from three infusion pump data sources. One is drug alert data from the Infusion Pump Informatics (IPI) System maintained and supported by the Regenstrief Center for Healthcare Engineering (RCHE) at Purdue University6. Another is the pump status report which can be generated by a vendor pump management software. The other data source is the detailed all infusion report, available through the vendor analytics software tool,
which contains each infusion start of the dates of interest, with or without triggering drug alerts or alarms. Each report
type is explained as follows.

Infusion Pump Alert Data. All IPI community member hospitals share pump alert data by periodically uploading them
to the IPI System on CatalyzeCare, a Hubzero©-based cyber infrastructure. An infusion alert happens when a
programmed value violates the preset limits for the drug and its clinical use, and the clinician can decide to accept the
alert by cancelling or reprogramming the infusion or override the alert. As of late 2015, the system contained more
than 21 million infusion pump drug alerts from more than 120 hospitals across the U.S. Even though the IPI data
contains alert data from multiple pump manufacturers, we focused our analyses using data from one of them. Each
line of alert includes detailed information such as drug name, profile name, drug limit library version used, infusion
type, programmed value, drug limit violated, time stamp of infusion attempt, etc.

Pump Status Reports. Pump status reports are available through the vendor provided pump management software tool
which is different from the analytics suite. A pump status report is a snapshot of all the pumps in the network. For
each pump it details the location (facility), model, pump serial number, activated DLL (i.e., the version all pumps
should be using at the moment), DLL version on the very pump, any pending DLL version on the pump (i.e.,
downloaded DLL file but yet to be installed), last communication time stamp (between the pump and the server) and
profile last observed.

All Infusion Detail Reports. As the name suggested, all infusion relevant events are included in an all infusion detail
report, such as infusion started, restarted, stopped, paused, alerted, resolved, time stamp, whether or not the event is
under guardrails system, type of infusion (continuous, bolus, etc.), actual infusion duration seconds, programmed
duration seconds, volume to be infused, dosage, and infusion rate, etc. An infusion delivery is actually composed of a
sequence of infusion events which share the same infusion ID. As show in the report, usually an infusion
administration starts with an “infusion started” event and ends with an “infusion stopped”. In summary, the all infusion
report lists information regarding when an infusion event happened, for what purposes it happened, how the infusion
was programmed (using basic mode or with guardrails), and the detailed infusion settings. This allows us to study not
only the infusion alerts generated by various DLL versions but also the bigger picture of all infusion starts that did not
generated any alert.

Methods

We used the alert data of an inner-city hospital of 315 beds in the Midwest from July 1st to September 18th, 2015 and
the DLL version information indicated in each alert to show how many and which DLL versions exist in the infusion
drug alert. There were 680+ pumps (i.e., the main units with memory) in the facility. We also collected the hospital’s
pump status reports and all infusion detail reports for the same period of time. Since the pump status report is a
snapshot of each pump’s status in the fleet, we requested that the pharmacist in charge to send one to us daily if at all
possible in order for us to keep track of the status change of each pump and the patterns of the changes. Our partner
hospital had three DLL updates during that period of time. Note that an update cycle is defined as the time from the
first day of a new published version of DLL to the day before the publication of the next DLL version. We then
classified, on that specific reporting day, each pump as “current” or “outdated” by comparing the DLL version on
each pump with the activated DLL version. We further examined the severity of the DLL update problem in all
infusions recorded in the all infusion detail reports.

Results and Discussion

DLL Update Rate by Alerts

Figure 1 illustrates the phenomenon that alerts could be generated by outdated DLL versions. Each color represents
the alerts trigger by a DLL version, and each column is a day. In this hospital, alerts were seen to be generated by
seven different DLL versions within an 80-day window. As the figure shows, once a DLL update is pushed out to the
pumps, alerts by the new version started to happen (as a new color starts to show in the bars). However, the more
troubling is the fact that some alerts were still being triggered by updated DLL versions as their colors bleed into more
recent days. Should the drug limit settings be different in the new versus the old DLL versions, clinicians may be
getting false alerts (i.e., those that should not have happened) or missing alerts (i.e., those that should have happened).
Figure 1. Percentage of alerts by DLL versions.

DLL Update Rate by Pump Status Reports

We tracked each individual pumps and their status using the pump status reports. Figure 2 shows the distribution of the DLL versions on each day of the reporting. Each time a new color appears in the vertical bars it indicates that a new DLL version has been released and has been installed on some of the pumps. However, as shown in the figure, more and more colors show up in the bars as time goes. It means that the number of DLL versions kept increasing every time a new one is released, i.e., the old versions never got replaced on some pumps during this period of time.
Figure 2. The number of pumps (shown) of each DLL version. The length of each color on the bar indicates the percentage of such version found on that day.

We further showed the effect of the pumps using outdated DLL versions by combining the alert counts and the status of each of the pumps on these days. Figure 3 shows the correlation of the m: the diamond markers are percentages of pumps with outdated DLL based on pump status reports, and the square markers are the percentages of alerts generated by outdated DLLs. Naturally, the more pumps with outdated DLL versions the more alerts would be generated by outdated DLLs especially shortly after a new version of DLL was published and pushed out to all pumps in the network. If the probability of alert generated per pump and the utilization of pumps be equal on all, these two percentages should remain very close to each other on any given day. One possible explanation of the gaps between the diamond and square markers on some days may be that some pumps were not being used as often as other were. In other words, it is reasonable to speculate that some pumps were used and/or turned over much more often thus they were provided more opportunities to get updated and be generating alerts. More analysis is needed for us to understand this phenomenon better.
Impact of Using an Outdate DLL Version on the Pump

We extracted all events of infusion started from the all infusion detail reports during this period of time and investigated how many of started infusions were on pumps with outdated DLL versions. The results were further categorized by infusion type (Table 1). It shows that on average almost one third of all infusions started with an outdated DLL version, and, among all infusion types, bolus infusions had the largest incident rate (44%). The results here also indicate that over 30% of all attempts of infusion starts were at risk of not equipped with the most up-to-date version of the DLL on the pump. Recall the DLL analysis on infusion drug alerts seen earlier in this section, the results of infusion started events showed us that drug alerts do only represent a small portion of all that might have been “risky” infusions.

Conclusion

In this study we exhibited and verified long delays of infusion pump drug limit library updates using multiple data sources from one hospital including pump drug alerts, pump status reports, and all infusion detail reports, all available through vendor provided software tools. In this specific case study of one hospital we saw that on average more than 50% of the pumps were using outdated DLL on reporting days, 31% of all started infusions had used outdated DLL versions and 22.6% of all alerts were triggered by outdated DLLs. This has great implication of potential inconsistency
of pump response to the operator, and the possibility of patient harm due to incorrect drug limit settings (such as when an error made in the DLL was not able to be corrected in time for patient care). Outdated DLL triggered false alerts may cause confusion of the nursing staff and attribute to alert/alarm fatigue problem well known in the healthcare setting while missed alerts may allow inappropriate infusions to be administered. It is also very likely that a nurse would choose to use “basic mode” of infusion, i.e., electing not to apply drug limit settings to the infusion, when s/he cannot find the drug due to not having the most up-to-date DLL on the pump. Such workaround or deviation from the best practice of using the limit settings (i.e., noncompliance), is highly undesirable because of its potential to cause patient harm should a programming error occurs.

Our analyses provided different ways that a hospital can utilize pump informatics to track the effectiveness of pump updates and monitor their progression and impact. We believe it is crucial in ensuring consistency in nursing workflow, thus reducing unnecessarily workarounds, and most importantly, patient safety in hospital care. Our future work will include more in-depth analyses on missed or false alerts due to outdated DLLs.

Evaluation of a Digital Companion for Older Adults with Mild Cognitive Impairment

George Demiris, PhD, FACMI¹, Hilaire J. Thompson, RN, PhD, FAAN¹, Amanda Lazar, PhD², Shih-Yin Lin¹
¹University of Washington, Seattle, WA, USA; ²Northwestern University, Evanston, IL, USA

Abstract

Study Objective: The purpose of this study was to examine the feasibility of a digital companion system used by older adults with mild cognitive impairment (MCI). We utilized a commercially available system that is comprehensive in its functionalities (including conversation ability, use of pictures and other media, and reminders) to explore the system’s impact on older adults’ social interactions, anxiety, depressive symptoms, and acceptance of the system.

Study Design: We conducted a three-month mixed methods evaluation study of the digital companion.

Results: Ten female community-dwelling older adults (average age 78.3 years) participated in the study. Overall, participants utilized the tool regularly and appreciated its presence and their interactions. Participants scored higher at the end of the study in cognition and social support scales, and lower in presence of depressive symptoms.

Conclusion: Findings indicate the feasibility of a digital companion for people with MCI and inform the need for additional research.

Introduction

In recent years, various information and communication technology (ICT) applications have been developed in order to engage older adults with cognitive impairments in entertainment or reminiscence therapy or to simply provide a forum for interactive and tailored engagement. The types of applications available can be grouped into those that mitigate specific impairments of their target users, such as motor impairments or memory deficits, and those that take advantage of and aim to maximize continuing abilities. Technology has been used accommodate motor impairments and aid interaction through commercially available gaming devices, touch screens, and prototype devices. The MINWii videogame employed a Wii remote as an input device to accommodate motor impairments of users who might not otherwise be able to play the game.¹ ¹ Shik, Yue, and Tang (2009) used headphones and amplifiers to accommodate hearing impairments and projectors to magnify photographs to accommodate vision impairments.³ Other systems may gather, for example, materials from the users’ daily activities using technology, such as GPS, cameras, and audio recorders, to compensate for memory deficits).⁴ Tools have been designed to alleviate caregiver strain originating from the need to repeatedly provide details to help someone with dementia recall facts about events during casual reminiscence.⁵ Yamagami and colleagues used a video at the beginning of a session with the ICT to remind participants how to use tools. The participants then showed staff how to use these tools, reversing the roles of staff as helper to resident as helper. By using a video instead of having staff instruct the residents, this role reversal was possible.⁷

Certain skills, such as sensory awareness, musical responsiveness, and emotional memory, have been labeled “continuing abilities” in dementia, as they are thought to persist after others have been compromised by the disease.⁸ Sensory awareness is the response to various forms of stimuli (e.g., visual, audio, tactile). Musical responsiveness refers to the strong responses people with dementia can have to music. Emotional memory refers to the ability to experience rich emotions. Technology is commonly used to encourage and draw out these continuing abilities. Such
as through the display of movies, photographs, and audio that elicit sensory or emotional responses. Many systems that promote reminiscence with people with dementia use technology solely for this purpose. Media are used as triggers to prompt a positive response in the form of interactions or improved mood. Reminiscence systems that focus on emotional memory appeal to something personally relevant to the individual user. This ranges from materials that are personal only in that they are from the general era in which one grew up to artifacts related to individual interests or even objects that belonged to the individual.

ICT tools that integrate one or more of the functionalities described above can provide an integrated system that is meant to not only engage older adults in specific activities and tasks but also create an opportunity to address social isolation and loneliness. The effects of loneliness and social isolation are well documented for older adults; a recent meta-analysis of 148 longitudinal studies reported a 50% reduction in the likelihood of mortality over a period of 7.5 years for individuals with strong social relationships. Social isolation is negatively associated with health status and health-related quality of life of older people with effects magnified among older adults with dementia. ICT applications that address loneliness and social isolation often have anthropomorphic or animal features in order to generate a likeness to a friend or pet, and are referred to as digital companions. An older adult can interact with such a digital companion both at pre-programmed times (for example, when reminders or other messages are sent) as well as at the discretion of the user. Conversations can range from simple exchange of messages to sophisticated discussions depending on the system’s features and the level of machine learning algorithms, artificial intelligence or human response involved at the other end.

Digital companion tools are also referred to as Embodied Conversational Agents (ECAs). ECAs interact with users through verbal and non-verbal behavior cues such as prosody (pacing and intonation) and hand movements. A small number of studies have emerged examining the use of digital companions or ECAs. Bickmore et al. (2013) created a virtual laboratory to study users’ reactions. Elderly participants interacted with an ECA acting as an exercise coach. Results showed that users who interacted with an ECA that used variable dialogue exercised significantly more than those interacting with an ECA with non-variable dialogue. Vardoulakis et al. also investigated the use of an agent to provide social support and wellness counseling for older adults. A system was constructed that allowed research assistants to control an ECA placed in an older adult’s home in real time. Qualitative analysis of the interactions identified multiple topics that older adults liked discussing with the agent and general design principles towards building future companion agents for older adults.

While these studies have introduced insight into the potential of digital companion tools, the vast majority of them have been tested within laboratory settings, where older adults were unable to interact with the system over a long period in a naturalistic setting, or only tested with one user only. Furthermore, these studies are not longitudinal and for the most part rely on assessment of the system when it is used once or for a limited number of times. Finally, most of these digital companions either provided simply opportunity for conversation, or focused on one aspect of interaction by showing pictures or other media or served a single purpose (for example, exercise coaching or reminding of upcoming events and medication).

The purpose of this study is to examine the feasibility of digital companion systems in real world settings used by older adults with mild cognitive impairment in their natural environment and for a longer period of time. For this purpose we utilized a system that is comprehensive in its functionalities (including conversation ability, use of pictures and other media, and reminders) to explore the system’s impact on older adults’ social interactions, anxiety and depressive symptoms, and participants’ acceptance of the system.

Methods

We conducted a three-month mixed methods evaluation study of an existing commercially available digital companionship device. We recruited community-dwelling older adults.

Recruitment

Older adults were recruited through 1) posted flyers (at sites such as hospitals, memory clinics, day health programs, memory care groups and retirement communities with permission of those sites); 2) flyers sent to people in memory groups with the permission of memory group leaders; 3) word of mouth and snowball sampling; and 4) with the
permission of memory group and day health program leaders, we approach participants directly and told them about the study using language similar to that on the flyers. Older adults interested in participating contacted a member of the research team. We utilized a phone screening form that also included the administration of the Memory Impairment Screen-Telephone (MIS-T) instrument, a phone based instrument to screen for cognitive impairment in older adults. The maximum score is 8. If an older adult scored 6 or below, this indicated the possible presence of cognitive impairment, and then a member of the research team met with them to assess them further for eligibility. Additional eligibility criteria for older adults included: 1) be able to see and hear well enough to interact with the device to some degree (as assessed by researcher), and 2) reside in the Seattle metropolitan area. Participants were excluded if they were 1) unwilling to be audio recorded 2) unable to speak English. Family members were identified by older adults who agreed to be in the study. If an older adult chose to identify a family member to participate in the study, a member of the research team contacted them to provide information about the study and recruit them if they were eligible and interested. Interested and eligible persons were provided with information about study procedures, risks and benefits and asked to explain their understanding back to the research staff. All study participants provided written informed consent.

Intervention
The virtual pet companion is displayed on a tablet as part of the GeriJoy service provided by a company called “care.coach.” It interacts with the older adult through voice and expression. It stays plugged in to a dock by the older adult’s bedside or other preferred location in their residence. On the other end of the device is a trained staff member of a 24/7 call center who listens to the older adult and types responses that are then converted to audible speech. Thus, the “pet” is fully controlled by a human who uses both scripted text and unscripted spontaneous exchange for all the interactive sessions with the end user. The call center staff summarize their interactions with the older adult and send a log to a family caregiver. The caregiver can also send pictures to the device to share with the older adult (see Figure 1). In this study, we provided older adults with the option to share this log with a family member, but it was not automatically transmitted to anybody besides the research team. The device allows the human on the other side of the tablet to see the older adult in their room (when the pet is “awake,” signified by its eyes being open) to determine if the older adult is interested in engaging in conversation and to add a dimension to the interaction. In this study, we allowed the older adult to opt-in to having this video feature. This application supports all functionalities of ICT tools for dementia and MCI described earlier, namely addressing cognitive deficits by providing reminders and prompts (based on a pre-defined script that is used by the call center), use of pictures and multimedia to facilitate sensory awareness and memory support and it furthermore facilitates interactive communication ranging from small talk to any topic of concern to the older adult.

Study Procedures
Older adults were given a digital companionship device to use for three months. Semi-structured interviews were conducted at baseline, midpoint, and three months. The following instruments were administered at baseline and three months:

-Montreal Cognitive Assessment (MoCA): A 10 minute test covering 8 domains to screen for cognitive impairment in older adults. Higher scores indicate better cognitive function. Scores can be used to rate cognitive impairment as mild, moderate, or severe. The sensitivity and specificity of the MoCA for detecting early dementia are 100% and 87% respectively.17
- **MOS Social Support Survey (MOS-SS):** A 19-question test to measure social support. The instrument has been tested extensively for reliability (with Cronbach’s Alpha greater than 0.91) and construct validity. There are four subscales to the MOS-SS: Emotional/Informational Support, Tangible Support, Affectionate Support and Positive Social Interaction. Each of the subscales are scored 0-100 with a higher score indicating more support.

- **Patient Health Questionnaire PHQ-9:** A 9-question test to measure depressive symptom severity. This tool is extensively tested for reliability and validity including in use with older adults with MCI and early dementia. A higher score indicates more depressive symptoms.

- **Generalized Anxiety Disorder GAD-7:** A 7-question test to measure overall anxiety (general anxiety disorder. This instrument has been found to have high levels of reliability, criterion, construct factorial and procedural validity (Spitzer, Kroenke, Williams, & Loewe, 2006). A higher score indicates higher levels of anxiety.

The following instrument was administered at 3 months only:

- **Comfort from Digital Companion Animals Scale:** An 11-item questionnaire to assess participants’ attachment to the digital companion, which was modified from Zasloff’s Companion Animals Scale.

### Results

A total of ten older adults participated in the study. All participants were female and their average age was 78.3 years. Eight of the ten participants completed all study procedures. Two withdrew before the midpoint interview. One of the participants who withdrew from the study had more advanced cognitive impairment and felt it was too difficult for her to trouble shoot on her own when the device was not working (e.g. not being able to connect to the internet, the device not charging properly, etc); the other participant who withdrew from the study had a hard time getting the device to work for a few days (mainly due to issues with her new Wi-Fi) and felt that she needed a deeper level of interpersonal connection than what the digital companion was able to offer. Only one of the participants chose to invite a family member to participate in the study.

Table 1 summarizes demographics and baseline use of technology. Table 2 compares survey responses at baseline and at study exit. Although there were not enough participants in this pilot study to do robust statistical analyses, we did assess change from baseline in each of the instruments, noting reduced depressive symptoms. There was an increase noted in both the MoCA and the MOS-SS, with the largest benefit seen, not surprisingly, in the positive social interaction subscale. There was a small increase in anxiety at study exit. We explored the association between change in anxiety and attachment to the digital companion (recognizing that such a sub-analysis is weakened by our small sample size). Interestingly, those with higher attachment to the pet had baseline GAD of 3.75, increasing to 5 at end while those with lower attachment (not very/not attached) actually had a decrease on the GAD from 1.75 to 0.75. Table 3 includes the level of attachment that participants had at study exit.

Table 3. Participant Responses at Study Exit pertaining to the digital pet. Data are reported as mean (SD) unless noted.

| Table 3. Participant Responses at Study Exit pertaining to the digital pet. Data are reported as mean (SD) unless noted. |
|---|---|
| Comfort from Digital Companion Animals Scale | Post-Test (n=8) |
| | 27.8 (7.9) |
| How attached were you to this digital pet? | |
| Very attached | 25% |
| Attached | 25% |
| Not very attached | 37.5% |
| Not attached | 12.5% |

At baseline, participants expressed interest and curiosity as to how their interactions with the digital companion would evolve over time. As one participant stated “it’s just an adventure; like, I like going to the secret film festival because we don’t know ahead of time what movies we’re going to see.” Another participant stated “I will have something to look forward to play with to do, something with each day.” When asked why they agreed to participate, few participants indicated they were curious and wanted to try new things out, others talked about helping out with research projects that can help future generations and one participant specifically mentioned the inability to have and maintain a real pet as the reason: “I am very sorry that I don’t have a pet here because I’ve always had pets. They’re an integral part of the way I relate to life.”

In the exit interviews, participants overall discussed being satisfied with the digital companion and having enjoyed their interactions. When asked to identify system strengths, participants talked about having a remote friend who is always available and ready to talk when one is lonely, the significance of the reminders that the digital companion would provide (for medication adherence or dietary restrictions) and the ease of mind that a remote “friend” provides by “checking on you regularly and asking if things are ok when [the pet] hears a strange noise or sees something strange.” One participant also appreciated the visual communication whenever the digital companion would show pictures or little hearts: “I would have it right next to my chair, the hearts would go. When people would come, they’d say, “What’s that?” I said, “Those are just little love notes. [chuckles].” Another participant also showed appreciation for times when the pet would use pictures to entertain the participant: “He found a birdbath with some crows in it on Google. He was always very good-very sensitive to what I was trying to do.”

One weakness identified by participants was the fact that the interaction was strictly verbal or visual. As one participant pointed out “I wish it was something you can hug, that you can touch, like a real cat or dog.” While numerous participants commented that the communication was at few times problematic with the pet either having a limited vocabulary, being repetitive in its questions, not remembering details of previous conversations or asking questions at inappropriate times (e.g., when the participant was taking a nap or watching TV), other participants commented on the sensitivity that the “pet” showed as a conversation partner in engaging only in conversation topics that participants wanted to discuss at a given time.

**Conclusion**

Our study findings indicate the feasibility of a digital companion tool for older adults with MCI. Overall, participants utilized the tool regularly and reported appreciating its presence and the time they interacted with it. Participants scored higher at the end of the study in their assessment of cognition and social support and lower in presence of depressive symptoms. Anxiety overall was higher at the end of the study, but upon closer investigation, anxiety increased for those who felt attachment to the digital pet (potentially because they had to give up their digital companion).

This is an exploratory feasibility study with a small sample size and no control or comparison group, which clearly limits the generalizability of our findings and does not allow for identification of confounding factors or natural trends. Additionally, participants were selected from only one geographic region. The sample had limited diversity.
in terms of race and ethnicity and no diversity in terms of gender, as all participants were female. Additionally, only one participant chose a family member to participate with them in the study. This may be due to privacy concerns or a perception that participating in the study may become burdensome to family members. The feasibility of family involvement needs to be further investigated. The system was deployed for three months for each participant, and while this time frame is the longest documented for these types of systems, it may still be too short to fully examine adherence to the intervention. In spite of these study limitations, our findings highlight the potential of digital tools to provide companionship, reminders, and potentially health behavior coaching for older adults with MCI. Future studies need to be based on experimental design and include a control group in order to understand potential confounding factors and natural trends, and should furthermore address how the use of such a tool affects clinical outcomes as well as ways to meaningfully engage family members or other stakeholders. Design considerations need to be assessed to determine the extent to which such a tool meets older adults’ preferences and needs. Finally, ethical considerations around attachment to a digital tool and unintended consequences in cases where the tool is no longer functional or available need to be explored.

Abstract

Clinical decision support (CDS) knowledge, embedded over time in mature medical systems, presents an interesting and complex opportunity for information organization, maintenance, and reuse. To have a holistic view of all decision support requires an in-depth understanding of each clinical system as well as expert knowledge of the latest evidence. This approach to clinical decision support presents an opportunity to unify and externalize the knowledge within rules-based decision support. Driven by an institutional need to prioritize decision support content for migration to new clinical systems, the Center for Knowledge Management and Health Information Technology teams applied their unique expertise to extract content from individual systems, organize it through a single extensible schema, and present it for discovery and reuse through a newly created Clinical Support Knowledge Acquisition and Archival Tool (CS-KAAT). CS-KAAT can build and maintain the underlying knowledge infrastructure needed by clinical systems.

Introduction

Vanderbilt University Medical Center’s (VUMC) long history of innovation in biomedical informatics has led to the creation of unique and increasingly complex clinical decision support (CDS) over multiple decades. These CDS resources are embedded in the many information systems within the institution at the point of care. This paper presents VUMC’s efforts to externalize this varied content in a systematized manner, leading to the creation of a comprehensive CDS schema and knowledge acquisition and archival tool.

At VUMC, CDS is tightly integrated with the system in which it is implemented. Horizon Expert Orders (HEO), the computerized physician order entry (CPOE) system originally developed at Vanderbilt as WizOrder,¹ presents CDS ranging from allergy checking and drug-drug interactions to discharge instructions and complex protocols. Within HEO, CDS is written in a locally-developed scripting language called Vanderbilt Generalizable Rules (VGR) that allows user screens to be overridden with simple display templates and HTML files.²⁻⁴ Within StarPanel,⁵ Vanderbilt’s electronic health record (EHR) system, built-in CDS visually presents relevant information derived from the patient’s data. These display resources are called Indicators⁶ because they rapidly indicate critical information about the patient. Indicators are created by professional developers in the high-level programming language Perl. Other systems such as the outpatient order entry system, VOOM, similarly integrate unique CDS directly into the system with which providers interact. This approach has led to the implementation of CDS through diverse languages and mechanisms.

Support for Horizon Clinicals, the suite of clinical systems¹ used by VUMC which includes HEO, HED (the inpatient nurse documentation system), AdminRx (the barcoded medications administration system), and HMM (the pharmacy management system) will be discontinued. In light of this, VUMC leadership created the Clinical Systems 2.0 initiative⁷ to replace the clinical systems with a new suite of products. The part of this institution-wide effort presented in this paper is focused on transitioning select CDS content knowledge from the current systems and implementations to representations that retain clinical significance and intent and can be implemented in the new clinical systems. The Center for Knowledge Management (CKM) team was approached directly by the Chief Informatics Officer and asked to apply its unique set of skills towards this project in March 2015.

The CKM team at VUMC aids in supporting the information-strata of the organization through innovative processes of knowledge acquisition and organization for the purposes of archiving and reuse. As such, the CKM team is well

504
situated to work on this project given our close linkage to biomedical informatics and our expertise with metadata schema development, long standing provision of actionable evidence in the clinical setting, relational database and interface creation, content curation, and extraction and identification of linkages between disparate information sources.9,10

Preliminary meetings with leadership, CDS content creators, and stakeholders further demonstrated both the scope of the institution’s need and that CKM’s skills could easily, and immediately, be directed towards managing the existing content. For example, as evidence has been a critical part of creating and updating CDS resources, the CKM team recognized the opportunity to extend and update this evidence alongside the executable content. Further, production databases hold both content that is currently used and content that had been intentionally deactivated, presenting an opportunity for archiving and future retrieval. Additionally, the meetings further aided CKM in fostering collaboration with HealthIT’s Knowledge Engineering team at VUMC. The knowledge engineers, using their relationship with clinicians and end-users of CDS content, helped shape the approach the CKM team used to refine tool development, and eventually, content validation. The meeting outcomes, along with CKM’s long history of expert evidence provision in complex environments,11 made ongoing content maintenance another key goal for the project.

Implementation Background and Methods

Synthesizing the institutional need, the preliminary data we gathered from meeting with experts and stakeholders, and our own skills, we arrived at the following goals for a unified approach to managing knowledge around clinical decision support: extract content and medical context from application-specific representations, preserve complexity, identify and update evidence to support current practice, enable cross-system search for the discovery of previously obscured linkages, validate content, and aid in the process of making decisions on active versus archival retention. These goals would be tested over the entirety of active content from two types of CDS: VGRs and Indicators. The rationale behind this implementation was dictated by our goals and the relevant literature.

Our first and most critical goal was to extract content directly from the multiple applications in which it was created and represent it in a unified way. As this initiative was started well in advance of new clinical systems being implemented, VUMC did not have a replacement suite of systems selected, and it became a major design goal to keep the extracted knowledge system-agnostic. We therefore focused first on standardization efforts such as Arden Syntax, Knowledge Artifacts, and GELLO that show the value of representing CDS in a generic way using a consistent schema. In Arden Syntax, basic descriptions of content are standardized, while data to support the logic are kept entirely application-specific, which means the decision support must be mapped to each application to be reused.12 Knowledge Artifacts solve this challenge through an XML representation of logic using the Virtual Medical Record (VMR) domain analysis model of the HL7’s Reference Information Model (RIM) to promote interchange and interoperability.13,14 GELLO likewise uses the RIM to enumerate all possible data types and type extensions.15 The CKM team conducted a thorough literature search of CDS standards, schemas, taxonomies, ontologies, and development methods and considered the aforementioned standards as ways of creating implementation-independent representations of the CDS resources at scale, while allowing for extensibility to meet evolving needs.

Another goal of the CKM team’s effort was to facilitate unambiguous human understanding of complex rules while ensuring ease of use. Local CDS that implements a protocol or guideline is complicated, and to allow users to truly understand that protocol we had to correctly capture all of its intricacies. The Clinical Decision Support Consortium created a model for representing guidelines that uses multiple layers of increasing complexity from text to semi-structured, structured, and executable,16 similar in nature to the multiple representation formats of DeGeL.17 This allows consumers of the representation to pick the level that best suits their needs, potentially increasing use.16 CKM similarly chose to create a tiered approach that allows both complexity and simplicity depending on user preference.

A chief concern of the CKM team was enabling discoverability of resources in as many ways as possible. As we were starting from a collection of software artifacts, some understanding of methods from software reuse were beneficial to our efforts. Software reuse is a software engineering concept that starts from a piece of code that provides an important function and creates a searchable abstraction. The goal of this process is that useful snippets of code can be reused as much as possible, saving future development time. While not quite the same as our goal of recreating rather than reusing these resources, software reuse provides four key components of reusability: abstraction, concise description, specificity enough to distinguish between descriptions, and a clear understanding of...
relationships to other artifacts. Further, software reuse literature describes eight classical methods of abstraction that can fulfill these needs, whether for reuse or adaption.

Other work in biomedical informatics has further described the content and context of decision support beyond standards. Decision support taxonomies in the literature describe the functions decision support can provide, based on empirical observation. Greene presented a general schema based on purpose and design. This body of work provided context for thinking about discoverability specific to CDS.

It was important to the team to automatically extract as much as possible from the existing disparate systems and present the resulting information in a single repository for users to find and view CDS. Sittig et al. defined four tools needed to effectively manage clinical knowledge: an external repository of clinical content, a collaborative space to develop content, a terminology control tool, and a mechanism for end users to provide feedback. Our focus was on creating this external repository through iterative feature development based on stakeholder requirements.

Finally, it was critical to identify clinical owners, validate our work, and prioritize the CDS content to move into the new systems. Validation and decision-making on CDS prioritization was provided by the Knowledge Engineering team in partnership with clinical content owners. Further, the first step in validation was ensuring the schema was robust through testing across a varied set of highly used and logically separate resources as a representative sample. Reference documentation was used to aid in application of the schema to each clinical system. Knowledge Engineering team members were also encouraged to contribute to populating any content fields that their expertise could provide.

This intervention took place within the clinical systems of VUMC’s tertiary-care teaching hospitals, which serve middle Tennessee and the surrounding areas, as well as inpatient and outpatient facilities, all of which use StarPanel as the EHR.

Results
In all, the CKM team extracted 1024 Indicators (965 active; 59 inactive), 3147 VGRs (1671;1476), 1875 display templates (945;930), and 1951 HTML pages (705;1246) for representation in our in-house created web-based tool. This tool (Figure 1), named the Clinical Support Knowledge Acquisition and Archival Tool (CS-KAAT), allows all the above knowledge to be viewed and edited. CS-KAAT uses a MySQL database with a PHP front end. Access is restricted by login, and user role enables various functions from access to editing specific fields. Codified information is collected automatically via scripting and validated by human agents. If the automatically extracted data needs to be modified, the new values for that field are clearly marked as edited, allowing end users to differentiate which party to trust for the accuracy of the information. Changes to production databases are captured periodically and automated content extraction and manual reconciliation are performed on all new or modified resources to ensure that content in CS-KAAT remains current with production systems.

Figure 1. Clinical Support Knowledge Acquisition and Archival Tool (CS-KAAT).
Our schema provides 70 elements informed by multiple literature sources and modified to fully describe CDS content at VUMC. Content is described along central facets with controlled vocabularies that enable comparison. This method of software abstraction allows high precision and recall, while providing transparent and easily understood access to users.\textsuperscript{19} The schema driving CS-KAAT can be divided into important components – for instance, divisions taken from the high-level concepts of the GEM model\textsuperscript{27} – to present the elements (Figure 2). Identity elements uniquely identify a resource. Developer elements are the names and roles of people involved in the creation of a resource, and Testing elements identify editorial oversight and modifications. Purpose elements define the reasons a resource was implemented. Intended Audience elements identify the clinicians impacted by a resource, while Target Population elements delineate patients affected by the resource. Knowledge Components elements store the knowledge from applicable evidence, local practice, and implemented logic and display. Finally, Revision Plan elements ensure currency of the resources.

The schema applies to decision support of any type by mapping the features of that particular type of content to the appropriate schema elements. Mapping to each system allowed us to see that the schema element ‘Category of Intervention’ would receive the same value for all Indicators, but individual VGRs could have values for this element different from each other. From this realization, schema elements are mapped to the most appropriate of four levels to fully describe the CDS resource: system, group, resource, or resource part.
System-level elements apply equally to each resource from the same system. For example, the ‘Locus of Control’ is “system” and ‘Rights’ are “Copyright VUMC” for every VGR, and are therefore applied once to the entire system.

Within CS-KAAT, all users are able to create a generic group and can include any resource as members of their newly created group. This allows users to collocate resources for specific interests or needs, without restriction, and retrieve those resources easily (e.g., all resources associated with a clinical intervention or a workflow process). Group elements enable the user to describe the reasons for collocation and create multiple levels of specificity for this description. Elements that apply to these groups are ‘Description,’ ‘Date of Next Review,’ and ‘Visualization’.

The resource level denotes each distinctly named CDS resource. Elements around creation and maintenance are naturally applied here.

Critical points of interest, called events, were identified and parsed from each resource to create the resource part level. Events currently used are listed below (Table 1). ‘Logic’ and ‘Patient Type’ elements are captured around these events.

**Table 1. Events within clinical decision support rules.**

Each event is assigned a human-readable explanation of the logical condition that must be true for the event to execute. Additionally, each event has a unique identifier that is used to link events together. Finally, the value of the event is captured; for example, the specific file being loaded or the parameters of an order being modified are extracted from the source code.

Events are not tied to logical blocks, but are the points at which a resource affects the environment outside of itself, such as executing a program or interacting with a user or a different clinical system. It is common that several events will happen due to the same condition being true, or may be alternatives where a user will only be affected by one event from a set. For example, selecting to order Esmolol Infusion in a cardiac step-down unit requires electrophysiologist approval. Providing this approval places the order in the queue to be signed, logs the approving physician’s name, and emails a pharmacist. Each of these actions takes point in a different block of code: in fact, in two different files. Our interest in these operationally interconnected events is that they were all triggered by one action and that we may decide they should all happen together in the future system regardless of how many steps it currently takes to achieve that function. The loose structure of events therefore allows us to extract the clinical content and medical context of each event from the application’s execution requirements. In the VGR system, each CDS resource has several events, ranging from 3 to over 300, due to the needs of the HEO system for presenting alternatives to the clinician and providing real-time response without the delay of querying underlying databases after each selection. By defining clinically and operationally significant events rather than the blocks of code that exist now, future CDS implementations are not bound by past technological requirements.

In linking specific events to one another, only sequences have been preserved explicitly. Sequence is captured by human coders by expanding on all possible sets of events that generate all the data within that event’s condition and value. Alternatives in this sequence are allowed through a simple description logic that supports unions and intersections. Alternatives have been captured only implicitly, allowing future representations to reorder content or take pieces from resources if desired. Events are linked through backward chaining sequences, allowing the user to understand what prior data had to exist to make the current event possible. Together, all these individual data points
allow for robust visualization of highly connected networks that create a comprehensive picture (Figure 3) from initial states to ultimate possible outcomes.

**Figure 3.** Generic protocol visualization.
Red, blue, green, and black boxes represent events. Arrows indicate the direction of relationships. White boxes note conditions that must be fulfilled.

Controlled vocabularies come from taxonomies around decision support if possible, and local taxonomies if necessary. Specifically, ‘Category of Intervention,’ ‘Locus of Control,’ ‘Clinical Task,’ and ‘Method of Application’ come from taxonomies. For ‘Clinical Venue’ and ‘Patient Type,’ we had to create our own local taxonomy based on the values used in the local systems. Location data are inherently administrative and not able to be standardized across institutions, and grouping patients into similar types is also based entirely on local needs. To fully capture these elements, therefore, we started from the data definitions within our systems rather than an external source. This allows us to understand whether the current functionality can be exactly recreated or must be modified to work in a new system.

In any system allowing multiple users to create displays for different needs, there will be variability in interface design. Systematically capturing these techniques involved manual effort in both cultivating a controlled vocabulary and applying it. Display techniques captured in the ‘Category of Intervention’ element illustrate the evolution of a local controlled vocabulary. Each HTML page and display template overrides the common HEO interface and is manually coded. This has led to many different displays for clinicians that employ various tactics to present information effectively. The front-end tools taxonomy of Wright et al.\(^24\) provided a foundation, as front-end effects are often displayed in addition to executing – displaying a medication order sentence before placing that order, for example. Focusing only on information display, we removed several elements of the taxonomy that were purely functional and added new vocabulary elements for display techniques not presented in the taxonomy, such as ‘drug name/brand name display’. We also created controlled terms of general design techniques for successfully engaging
users with clinical systems from the human-computer interaction review of Horsky et al.29 By applying taxonomies of CDS design, we enable users to analyze different designs in a rigorous manner and reuse successful features, an idea presented as a potential benefit of taxonomies in Greenes.25 The exact moment in the clinical workflow that CDS is triggered is one aspect (‘Implementation Point’) captured in a taxonomy that allows users to compare differences between content initiated when an orderable is requested and content initiated after all orders are placed.

Scripting allows for the automation of some of the above tasks. Events were parsed from source code by exploiting the syntax of the underlying programming language and using regular expressions to extract and identify each event type. Based on the events present in a resource and the relationships to other resources found, the ‘Initializes,’ ‘Initialized By,’ ‘Related Orderable,’ and ‘Implementation Point’ elements were automatically inferred. System-level fields were automatically populated and passed to all resources within that system. Finally, elements that could be factually stated without ambiguity were also automated – ‘Revision,’ ‘Full Title,’ ‘Short Title,’ ‘Hover Description,’ ‘Filetype,’ and ‘Dependencies’.

Evidence is preserved in a separate workflow from the CDS it informs, as evidence around a concept can affect more than one resource. This conceptual grouping is an extension of the generic grouping feature. For example, clopidogrel metabolization is affected by genetic variation in the CYP2C19 gene. Furthermore, the evidence supporting differentiation in clopidogrel dosing by CYP2C19 variation is not simply one resource, but a collection of external resources, local evaluation of evidence quality and impact, and potentially even local practice constraints. Therefore, this concept of evidence-based practice regarding clopidogrel metabolization is the logical unit at which to maintain the evidence and local decisions on usefulness of the evidence. Attaching this concept to each resource that requires it (five resources in the current systems to perform additional decision support recommending alternative treatment for intermediate and hypo-metabolizers, and flag patients’ charts a predetermined color for those who have a recorded drug-genome interaction) allows us to periodically evaluate whether the evidence supporting this concept has changed and whether all our current decision support involving this concept is ideal.

Validity of all resources is ensured in three steps. First, the metadata for each resource is checked for accuracy by automated and manual processes. An automated check requires valid data for controlled fields, and accepts the links between specific events only if they are structurally possible between the two resources. Two manual checks, one by a CKM information scientist and one by a knowledge engineer, ensure that the human-readable logic and other event and resource-level fields are correct. Second, the resource is thoroughly tested in the production environment to determine it is still working correctly. Third, in order to determine what content is important to carry forward, a team of knowledge engineers is continuing to assess the clinical relevance of each resource by reviewing usage data, working closely with subject matter experts and system developers. At each of these points, documentation and resolution of any errors becomes part of ongoing content maintenance tasks. A companion document was created for each clinical system to provide the team with up to date information and examples of how each element should be correctly applied.

Discussion

Despite the many benefits of having CDS tightly coupled with the executing applications, this approach does require “the author to be familiar with not only the clinical domain but also with the syntax and features of the programming language.”28 For an outsider to a system to understand its decision support content required additional training in that system, even with clinical expertise and experience creating other decision support content. The VGRs were designed as a way to allow clinical experts to learn a simplified functional language rather than the programming language of HEO,4 but this benefit only applies to the single system. Ordersets are generated through a user-friendly tool that masks the programming complexities that enable each to work in the HEO application,29 but again this tool only assists in orderset creation and maintenance. We have successfully described content from two very distinct systems in a common format. Our project has shown it is possible to represent all decision support content in a consistent manner, within one single system. Each type of decision support being system-specific does require authors and editors to learn those respective tools, but content can be considered outside of the narrow bounds of the application through CS-KAAT.

In the guidelines modeling literature,16, 17 work is conducted from a textual representation to an executable one to allow different interested parties access points to the model. The CKM team worked in the opposite direction, from executables to semi-structured representation, to similarly create access points and enable flexibility to transition decision support to any number of potential systems. Multiple layers of abstraction allow end users to view content as complexly or simply as they desire. At the highest level, there is a basic description or a visual grouping. Below
In each of the above aspects, existing standards did not fully meet our needs. Our literature review and focus on discoverability highlighted several important descriptive facets that are not included in existing standards. Therefore, to fully meet our goals, it was important to adapt our schema with taxonomies extending standards. The guiding process for adding elements to the schema was to present a use case for each element to provide information that could not come from any existing element. This focus on institutional need led us to view each source as a potential contributor to the schema. With different needs, these extensions into literature-derived elements and local vocabularies will be different. For any institution interested in establishing a similar process, this has averaged 6.5 FTE equivalent effort. Given the diversity and complexity of the work, completing knowledge extraction and transformation for one named CDS resource has ranged from ten minutes to two days.

Separating the review processes for evidence and content allows flexibility in involving the appropriate parties for each step in the maintenance process. Knowledge management information scientists, who have extensive experience providing evidence, are well positioned to ensure that the latest evidence is provided to the content specialist and developers creating CDS resources. Then, clinicians can provide local context on best evidence to determine to create, modify, or retire CDS resources. This is anticipated to relieve some of the burden of engaging with CDS content for maintenance decisions. Consistent, externalized evidence provision also provides the institution the ability to more effectively integrate evidence with CDS at the point of care by making each relevant citation a focal point of the model, one that is purposefully saved and maintained. Finally, CS-KAAT provides the institution with a robust citation repository that is up to date, expertly curated, and has institution-wide scope.

CS-KAAT has made data dependencies traceable across systems. To illustrate the revelations that our tool has provided, we can follow an orderable from order creation in HEO to patient evaluation in StarPanel. A user initiates an order which is flagged to trigger a VGR when it is requested. From there, a series of VGRs eventually ends with the correct order being placed. After passing through an interface that links the different operational systems from the CPOE to the pharmacy system, data about the successful filling of this order are again sent through this generic interface engine to the medical record. An intermediate database duplicates information about the order of interest and distributes that information to the patient’s chart via an Indicator. The VGR and Indicator in this example are clearly related, but this information was obscured by the complex relationship between the two CDS resources. Because our schema has a facet for related orderables, the relationship is clearly seen at the semi-structured level and directly searchable. Additionally, the application of UMLS keywords to each of the records allows for files to be linked by concept, something that was also previously unavailable to users. Similarly, each facet gives users of CS-KAAT the powerful capability to understand connections and associations that previously only a few developers had.

Validation efforts enforced adherence to the schema. In each area where scripting was used for content extraction, users were able to manually override the harvested value. Periodic review of these overrides led to editing the scripts, making data collection more authoritative. We found that the compiler for the VGR local scripting language allowed slight variations to syntax, for example, and adjusted our extraction scripts to capture these. While these scripts are only useful in parsing knowledge from the current versions of local systems, this method both saved time for our team members and provides trusted content to end users. For data that could not be extracted automatically, validation by at least two people other than the documenter provides another level of assurance to end users that the content of CS-KAAT is trusted.

This was a significant effort that required many people to contribute different skill sets and to approach the work with a great deal of collaboration. The work at Partners and Intermountain Healthcare demonstrate that this is an extensive process, fraught with difficulty.\textsuperscript{31} It has been successful at VUMC through two key human features of our work: flexibility and communication. Our schema went through many early iterations, and as workflows changed, both the team and the CS-KAAT adapted to evolving needs. The CKM team provided support for each other and interchanged roles to assist in completing different portions of the work. Communication between teams and with stakeholders has allowed progress to be measured and created buy-in. For example, the user interface has been improved after first-time users from Knowledge Engineering provided usability feedback.

The separation of clinical content from application is critical to the long-term usefulness and maintenance of CDS.\textsuperscript{3} While there are knowledge editors for certain CDS types,\textsuperscript{30} these useful and highly used tools do not have institution-wide scope, a situation described as typical of most institutions today.\textsuperscript{31} CS-KAAT demonstrates an effective means
for separating clinical content from native applications, and further makes important steps towards an institution-wide knowledge editor through a unified acquisition and archival tool.

Future Work

The content within CS-KAAT will continue to be used to prioritize CDS for the new clinical systems, and as the new technical requirements of continued clinical needs are defined will be remixed to meet those requirements. The CKM team is focused on continued enhancements to the tool to enrich lifecycle support and enable retention of collaborative documentation for future use. As CS-KAAT has proven to be effective in the realization of our stated goals, the team will continue collaboration with Knowledge Engineering and others within the HealthIT group to incorporate CDS resources from other systems with the ultimate goal of representing all CDS content that affects care at VUMC. Further, the team is exploring various tactics for displaying evidence underlying CDS to clinicians at the point of care to enhance usefulness of decision support systems while retaining clinical user satisfaction.

Conclusion

VUMC has externalized decision support content from multiple sources in a consistent schema. Descriptive facets from decision support standards, as well as empirical taxonomies and controlled vocabularies, create many new ways for users to find and evaluate content. This understanding is supported through a focus on human-readable descriptions and multiple levels of representational complexity. In all, this flexible structure positions the medical center to effectively maintain the entirety of its decision support at the institutional level and continue to develop new methods of effectively supporting clinical care.

Acknowledgements

The authors would like to acknowledge the dedication of the CKM team members who have made this project a success: Mallory Blasingame and Jing Su. Additionally, we would like to thank all of the members of the Knowledge Engineering team, including Tina French, Shari Just, Sylinda Littlejohn, Janos Mathe, Michael McLemore, Lorraine Patterson, Debbie Preston, Audra Rosbeny, and Charlie Valdez, for their collaboration and contributions.

Abstract

Clinical practice varies among physicians in ways that could lead to variation in what is documented in a patient’s electronic health records (EHR) and act as a source of bias to predictive model performance that is independent of patient health status. We used EHR encounter note data on 5,187 primary care patients 50 to 85 years of age selected for a separate case-control study covering 144 unique primary care physicians (PCPs). A validated text extractor tool was used to identify mentions of Framingham heart failure signs and symptoms (FHFSS) from the notes. Hierarchical clustering analyses were performed on the encounter note data for finding subgroups of PCPs with distinct FHFSS documentation behaviors. Three distinct PCP groups were identified that differed in the rate of documenting assertions and denials of mentions. Physician subgroup differences were not explained by patient disease burden, medication use, or other factors related to health.

Introduction

The widespread adoption of electronic health records (EHR) by US health care providers [1] is motivating a rapid growth in the use of predictive models to guide clinical decisions [2], to identify patients at high risk of future events (e.g., 30-day readmission) [3], and to detect disease early [4], among other applications. Copious longitudinal structured and unstructured data are captured by EHRs to characterize the patient’s demographic (e.g., age, sex, address), health and treatment status, diagnoses, lab test results, and medication orders. As much as 80% of the EHR data is thought to be in unstructured form [5]. To effectively use EHR data it is important to understand how the data comes to be.

Physicians are the dominant sources of the data captured in EHR. However, physicians vary substantially and systematically in their clinical practices [6] resulting in variation in what is ordered, diagnosed, and documented for each patient, in medication prescribing and in preferences for the intensity of practice. Such physician practice styles are not idiosyncratic. Rather, practice style is known to be directly or indirectly influenced by medical school training, regional practice standards, local practice standards, and performance incentives, among other factors. However, most of these clinical practice differences are independent of the underlying health status of the patient or other characteristics of patients such as demographics or prior genetic predisposition to the disease.

These “practice phenotype” differences can significantly influence the quality of both structured and unstructured data in the EHR and act as a source of potential bias for any downstream analysis of EHR data. To build accurate computational models, we need to detect and normalize for such variances in physician behavior. However, previous studies have largely focused on differences in physicians’ practices using structured EHR data to characterize diagnostic practice [6], regional practice pattern and standards [7], expertise, prior educational and training background of doctors [8], and the patient’s treatment plan [9]. Differences may be identifiable by a limited number of practice phenotypes. Prior studies indicate that patient utilization phenotypes can be identified from structured data that are strongly influenced by provider preferences [10]. But, documentation in unstructured data has not been examined for such patterns.

In this study, we aim to explore whether there are practice phenotypes that characterize differences among physicians in how information gets into the unstructured EHR data. To test the phenotype hypothesis we use physicians’ notes to determine whether there are practice phenotypes in the documentation of Framingham heart failure signs and symptoms (FHFSS). FHFSS are frequently documented in progress notes by PCPs, often years before HF diagnosis
We describe a systematic framework, based on a clustering approach, for characterizing the practice phenotype of PCPs using a large scale unstructured EHR data.

**Methods**

We focused on FHFSS to explore variations because physicians routinely document the presence or absence of the symptoms among older primary care patients independent of HF diagnosis. There are a number of challenges in extracting FHFSS from clinical notes that are actually related to practice phenotype. First, FHFSS are often documented in clinical notes much earlier than the clinical diagnosis of HF, which means that tracking the clinical notes longitudinally throughout the patient’s medical history is needed. Second, a physician’s practice might be affected by other confounding factors such as the patient’s age, sex, prior medical history, other co-morbidities and the physician’s expertise. Such confounding factors have to be removed in order to obtain an unbiased estimate of the actual practice phenotype defined by documentation behavior of FHFSS.

We carefully performed the study design and cohort selection to remove the effects of confounding factors during the feature extraction from clinical notes. A previously validated natural language processing (NLP) tool [12] was used for extracting FHFSS from clinical notes. For convenience, we used a large well characterized sample of primary care patients selected as controls for a prior nested case control study of heart failure [4]. We focused on the control group of patients to avoid any potential practice behaviors that might be a result of disease onset rather than actual practice phenotype of physicians. We were interested in broadly testing the hypothesis of physician documentation phenotypes in a representative sample of patients and not in a sample that was defined by any specific disease. Details of the patient sample and data source are summarized below along with the feature construction and analytic methods. This study was approved by the Geisinger Institutional Review Board.

**Study Design, Population, Setting, Source of Data**

Longitudinal EHR data were obtained on patients, 50 to 85 years of age, from the Geisinger Clinic, a multispecialty group practice that provides care to approximately 400,000 residents in central and northeastern Pennsylvania. EpicCare EHR was installed at Geisinger before 2001.

A total of 1684 incident HF cases among Geisinger primary care patients were identified over the time period from 2003 to 2010 [4, 13, 14]. Up to 10 eligible primary care clinic-, sex-, and age-matched (in 5-year age intervals) controls were selected for each incident HF case for a total of 13,525 Geisinger control patients. Primary care patients were
eligible as controls if they had no HF diagnosis up to the one year post-HF diagnosis of the corresponding HF case. Control subjects were required to have their first office encounter within one year of the incident HF patient’s first office visit and have ≥1 office encounters 30 days before or any time after the case’s HF diagnosis date to ensure similar duration of observations among cases and controls. Nine or 10 controls were identified for 49% of the Geisinger cases; 1.5% of Geisinger cases had only 1 to 2 controls.

The primary care physician (PCP) was the unit of analysis and patient data were nested within each physician. Patient data were assigned to the physician who was the designated primary care provider as documented in the EHR. Assignment of patients to a PCP is documented in an EHR structured field. Note that different encounters of the same patients might correspond to different PCPs, if that patient utilized care from multiple providers. In that case, we mapped each patient to the unique PCP who treated that patient for the longest period of time. Of the total 13,525 patients, 11,268 were explicitly assigned to a PCP.

The EHR data used for this study were selected from the time period in controls that was 12 to 36 months before the incident diagnosis of HF in the corresponding matched case. This time period prior to the diagnosis of HF of the matched case is denoted as the “observation window” (Figure 1). Patients were excluded if: 1) they did not have an encounter note in the 12-36 month observation window (this observation window retained the largest amount of patient data as described elsewhere [4]); 2) if the coverage duration period (i.e., total time span covering patient encounters with the PCP that are within the observation window) for the patient was less than or equal to 180 days; and 3) if a patient had a substantial number of documented chronic diseases during the observation window. This last step was used to minimize documentation variation among physicians that could be explained by patient’s comorbidities other than disease burden. We considered 1148 ICD-9 diagnosis codes coming from three different types such as Chronic Disease (200 codes), Cardiometabolic Chronic Disease (743 codes) and Chronic Episodic Disease (214 codes) with only 9 codes being common between the first two categories. Most of the patients have very low chronic conditions as shown in Figure 2. Therefore, we only kept patient with at most five (out of 1148 codes) chronic conditions to retain maximum number of samples. The first two criteria of the observation windows of 12 to 36 months and the minimum coverage of 6 months led to 6862 patients in total, while imposing all three criteria reduced the samples to 5,187 qualified control samples to 144 PCPs in total. The data used for analysis was confined to this subgroup of PCPs.

![Figure 2: Qualified patient distribution based on the frequency of chronic diseases from three different types: Chronic Disease (200 ICD-9 diagnosis codes), Cardiometabolic Chronic Disease (743 codes) and Chronic Episodic Disease (214). 284 out of 5351 patients (5%) had no chronic disease. Majority of patients (34%) had only two out of 1148 diagnosis codes.](image)

**Unstructured Data Extraction from Longitudinal EHR Patient Data**

We used physician encounter note data to extract mentions of FHFSS. The FHFSS were originally published in 1971 [15] and are often a focus of encounter documentation when physicians assess a patient’s cardiovascular health. A
hybrid natural language processing (NLP) tool called PredMED [12] was used to identify mentions of FHFSS within the notes and to label notes according to whether, at the encounter level, each FHFSS was asserted or denied. PredMED achieves an F-score of 0.910 for mention extraction and an F-score of 0.932 for encounter labeling. Among the 17 FHFSS described in [15], 15 were deemed clinically relevant based on prior work [4, 12] and given the known frequency of documentation (Table 1). PredMED extracted mentions of these 15 FHFSS, along with modifiers that indicated the assertion (presence) or denial (absence) of each condition [except Tachycardia and WeightLoss, for which only assertion was extracted]. The resulting 28 FHFSS were used as features, for further analysis of PCP documentation.

PredMED was applied to all progress notes that were created in the 24-month observation window. Summary statistics were derived for each patient by counting of number of FHFSS mentions in the observation window. Moreover, the counts were normalized for the total timespan of all encounters and the total number of encounters within the observation window (Figure 1). This resulted in a feature vector for each patient containing the fraction of total encounters per year that contains a FHFSS mention. In a next step, this patient level information was summarized into the physician level information. Specifically, the averages of all these FHFSS fractions of all the patients belonging to a particular physician was used to build the final feature vector for each physician.

**Statistical Analysis**

For analysis, each physician is represented as a feature vector of 28 FHFSS. We used unsupervised clustering to determine if there were natural groupings of the physicians. Clustering algorithms use a distance metric for computing the similarity between two sample points. For this analysis, we used Euclidean distance as the distance metric, since the features are represented as fractions of total encounters and normalized by the span of duration of care.

We explored several agglomerative hierarchical clustering analysis (HCA) techniques [16] to determine if natural groupings were identifiable. These techniques are easier to interpret than other clustering approaches such as agglomerative and density based clusterings [16]. For example, the hierarchy generated by HCA provides relationships among different samples and the obtained physician groups, which will be useful to characterize the physician groups. Among various versions of HCA techniques, we used the Ward based algorithm due to its inclination of finding globular clusters similar to K-Means, while preserving the hierarchy of the obtained clusters [16].

Next, we compared the physician groups against each other to characterize the different documentation behaviors of each cluster. We used several descriptive statistics and visualizations to facilitate interpretation. For example, principal component analysis (PCA) [17] was performed to visualize the identified clusters. Also, the mean documentation behaviors of each FHFSS was compared among the clusters using statistical t-tests.

### Table 1: 28 Framingham heart failure signs and symptoms (FHFSS) extracted from text notes using the PredMED text analysis tool. The mean, median and standard deviation of the fraction of encounters where each of these 28 features was reported by PCPs is shown.

Results

Summary statistics were generated for each of the FHFSS. Table 1 contains the mean, median and standard deviation of the fraction of encounters where each of these 28 features was reported by PCPs. Overall, there are many more encounters with denials of the signs and symptoms than with assertions. A few of the signs and symptoms (e.g., AnkleEdema, DOExertion, Rales-denial, S3Gallop-denial) are relatively frequent. Several signs and symptoms (e.g., ICV Pressure, APEdema, WeightLoss) are very rare.

Some basic descriptive statistics regarding the patients and physicians assigned to each of these three clusters are given in Table 2. Cluster 1 and cluster 2 were larger than cluster 3 in terms of number of patients and PCPs, but no significant differences were observed among the clusters in terms of coverage days, average age, gender, and comorbid chronic diseases. In this analysis, we used three categories of chronic diseases: “Chronic Disease”, “Cardiometabolic Chronic Disease” and “Chronic Episodic Disease”.

Figure 4: Scatter plot of the first and second PCA components show reasonable separation of the three PCP clusters.
Clustering Results as Groupings of Physician’s Behavior:

Based on HCA analyses, the PCPs were clustered into 3 groups with distinct documentation behaviors. We explored several values for the possible number of clusters (k), however k=3 produced more natural groupings obtained from the HCA dendrogram (Figure 3).

Analyzing the Behaviors of Physicians in Three Clusters:

We performed a principal component analysis (PCA) of the FHFSS features to assess the discriminatory power of the three clusters as shown in Figure 4. The first and second PCA components are represented by the horizontal and vertical axis, respectively. The three clusters have reasonable separation in the lower dimensional feature space.

We also analysed the average frequencies of FHFSS mentions in the three clusters. In Figure 5, we plot the contribution of each FHFSS to the each of the three clusters by taking the mean of count frequencies of all samples belonging to each cluster. Note that this figure is normalized by z-score for each FHFSS. All FHFSS except assertion of ICVPPressure varied among the three clusters to some extent. Overall, cluster 1 has the highest FHFSS counts whereas cluster 3 has the lowest. Cluster 2 contains medium counts of FHFSS.

![Figure 5. Mean FHFSS counts of each of the 28 FHFSS symptoms for the three clusters. (Darker shade means higher counts of FHFSS in the corresponding cluster).](image-url)
Contrasting the Behaviors of Physicians among Three Clusters:

We also looked for the specific practice variations of the physicians of each cluster by comparing them with other clusters in terms of the FHFSS frequencies. Figure 6 contains the individual fraction of visits for each of the 28 FHFSS. In addition, the right three columns of each of the two panels contain the pairwise comparison of the three clusters to assess whether there is a significant difference between the fractions of visits of the two clusters under consideration based on t-statistics. Only the FHFSS with p-value < 0.05 are marked in the last three columns. Group 1 PCPs (n=63) documented 10 out of 15 assertions, and 11 out of 13 denials of FHFSS significantly more frequently than Group 3 (n=20); while Group 2 PCPs (n=61) have significantly more frequent denial documentation behaviors than the other two (see Figure 6)

Discussion and Conclusion

EHR data contains information about both patient’s health characteristics such as the histopathological factors, demographics, treatment history and environmental effects as well as physician’s behavior such as treatment plans and orders and documentation behaviors of patient’s signs and symptoms. The availability of large-scale multi-source health data presents new opportunities and challenges for research that aims to effectively use these data to discover new knowledge to improve current health-care systems [18]. Such useful knowledge will not only help in personalizing healthcare for each patient with more accurate diagnoses, treatments and prevention plans, but also help reduce the unsustainable growth in healthcare cost.

Figure 6: Comparisons of mean documentation frequencies of FHFSS assertions and denials in 3 PCP groups clustered by HCA. The symbols indicate significant differences in pairwise comparisons by t-test (p<0.05). The horizontal axis shows the documentation frequency defined as the percentage of office visit encounters with FHFSS assertions/denials during the 2-year period. The vertical axis shows the assertion and denial FHFSS measure labels.
Finding patterns for a particular disease requires the secondary analysis of the EHR data collected from multiple sources. The recent growth of machine learning and data mining techniques offer a great help in analyzing large-scale healthcare data with new possibilities of developing predictive modeling for early detection of disease. However, traditional data mining and machine learning techniques often cannot be applied directly to EHR data because they are collected retrospectively in time and therefore can contain a lot of underlying bias and noise factors completely unrelated to disease burden [19, 20]. Unlike prospective studies such as randomized control trials (RCTs) which are designed to avoid such sources of noise and experimental biases, EHR data requires more careful analysis strategies to remove the effect of such noise and biases [21].

This study investigated physician behaviors as a source of bias in EHR data and a potential source of confounders for predictive modeling. PCPs were characterized by their documentation profiles of FHFSS. Distinct groups were identified for each of the profiles using hierarchical clustering analysis. Significant differences among the physicians’ practice in the three clusters were observed, which were associated with different documentation behaviors of FHFSS. Most (27 out of 28) of the FHFSS varied among these three clusters.

In terms of future work, we plan to investigate how to incorporate physician behaviors into predictive modeling and to quantify how much value (in terms of prediction performance) is added by eliminating this confounding factor in early detection of heart failure. Another interesting direction will be to further analyze the obtained groups of PCPs for finding their relationships with other potential causal factors such as physicians’ expertise, their training, and the geographic variations of healthcare providers as well as any other characteristics of patients corresponding to each group of PCPs.

Acknowledgement

This study was supported by the National Institute of Health (NIH grant No. R01HL116832). We are grateful to Zahra Daar, Heather Law, Elise Blaese, Harry Stavropoulos and Satish Mudiganti for a variety of contributions to this work, including project coordination, data preparation and database management.

Abstract

Important information is encoded in free-text patient comments. We determine the most common topics in patient comments, design automatic topic classifiers, identify comments’ sentiment, and find new topics in negative comments. Our annotation scheme consisted of 28 topics, with positive and negative sentiment. Within those 28 topics, the seven most frequent accounted for 63% of annotations. For automated topic classification, we developed vocabulary-based and Naïve Bayes’ classifiers. For sentiment analysis, another Naïve Bayes’ classifier was used. Finally, we used topic modeling to search for unexpected topics within negative comments. The seven most common topics were appointment access, appointment wait, empathy, explanation, friendliness, practice environment, and overall experience. The best F-measures from our classifier were 0.52(NB), 0.57(NB), 0.36(Vocab), 0.74(NB), 0.40(NB), and 0.44(Vocab), respectively. F-scores ranged from 0.16 to 0.74. The sentiment classification F-score was 0.84. Negative comment topic modeling revealed complaints about appointment access, appointment wait, and time spent with physician.

Introduction

Patient satisfaction ratings can be a good indicator of clinical effectiveness and patient safety1. However, the free-text comment fields, which are filled out in nearly 50% of patient surveys, are underutilized2. The Center for Medicare and Medicaid Services (CMS) and Agency for Healthcare Research and Quality (AHRQ) developed a national standard for reporting patient satisfaction called the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS). Siegrist et al.2 report that hospital participation in HCAHPS is very high. In fact, the number of surveys collected is higher than other customer satisfaction surveys. The level of patient response indicates that there is an enormous amount of free-text information available. In 2014, the University of Utah collected 105,000 free-text patient satisfaction comments. In order to understand the causes for patient dissatisfaction, quality improvement abstractors review every patient-generated comment, which is both labor-intensive and expensive. Large-scale automated or semi-automated review would save time and money. It would also facilitate scaling the analysis of these comments for benchmarking over time.

Analyzing Free-text comments

The information available in free-text comments has been identified using qualitative methods1,3,4. Lopez, et al.3 developed a complex taxonomy of patient comments (Table 1). It includes global themes of overall excellence, negative sentiment, and professionalism. They also identified specific factors, for example interpersonal manner, technical competence, and system issues. Doyle, et al.1 echoed Lopez’ et al.’s topic categories when they identify search terms for a meta-analysis of patient experience. They divide the terms into relational aspects and functional aspects. Relational aspects are equivalent to interpersonal manner. They include emotional and psychological support, patient-centered decisions, clear information, and transparency. Functional aspects are equivalent to Lopez et al.’s professionalism, technical competence, and systems issues. Functional aspects include effective treatment, expertise, clean environment, and coordination of care.

In terms of sentiment analysis, using a qualitative methodology, Lopez et al.3 categorized 712 online reviews of physicians from the websites ratemds.com and Yelp.com according to polarity and learned that most reviews were rated positive (63%) recommending a patient’s physician to others. Another study by Ellimoottil et al. reviewed physician rating sites for the scores for 500 urologists5. The free-text comments were classified...
as extremely positive, positive, neutral, negative and extremely negative. They found that most ratings (75%) were extremely positive, positive, or neutral. A meta-analysis of six physician rating websites also found that around 70% of ratings were positive.

Natural Language Processing

Manually analyzing hundreds of thousands of free-text comments is difficult. Technology such as Natural language processing (NLP) can be used to make it more manageable. NLP has been used to classify comments by topics (topic classification), to encode the polarity of sentiment expressed within a comment i.e., positive or negative (sentiment analysis), and to determine if comments include unforeseen topics (topic modeling). Greaves et al. used topic classification to classify 6,412 free-text online comments about hospitals from the English National Health Service. They employed three topics – overall recommendation, cleanliness, and treatment with dignity. They created a Naïve Bayes multinomial classifier. It achieved F-measures of 0.89 (overall recommendation), 0.84 (cleanliness), and 0.85 (treatment with dignity).

There has been a lot of work in sentiment analysis both inside and outside of the patient satisfaction domain. In the SemEval-2016 task 4, sentiment analysis on Twitter, the winning team for the two-class (positive, negative) task used a combination of convolutional neural networks, topic modeling, and word embeddings generated via word2vec. They achieved an F-score of 0.80 and an accuracy of 0.86. Other investigators used keywords to indicate sentiment. These papers did not verify the accuracy of their vocabulary-based assessment. They relied on an accuracy measure of 75% for the dictionaries they employed. In a head-to-head comparison between commercial and non-commercial sentiment analysis tools for classifying healthcare survey data, Georgiou, et al. found that the WEKA implementation of Naïve Bayes’ performed the best, with a weighted F-measure of 0.81.

For topic modeling, the Brody et al. study, mentioned above, applied Latent Dirichlet Allocation (LDA) to 33,654 online reviews of 12,898 New York-based medical practitioners. Their model identified words associated with both specialty-independent themes (e.g., recommendation, manner, anecdotal, attention, scheduling) and specialty-specific themes (e.g., general practitioner: prescription and tests, dentist: costs, obstetrician/gynecologist: pregnancy). Maramba, et al. analyzed a free-text response from a post-consultation postal survey using a modified version of the English GP Patient Survey (GPPS) questionnaire. The question asked for any further comment. 3,462 individual comments were collected. They separated patient comments based on their overall rating of their experience on a 5-point Likert scale. Very satisfied and fairly satisfied were grouped as satisfied. Very dissatisfied and fairly dissatisfied were grouped as dissatisfied. The words “surgery”, “excellent”, “service”, “good”, and “helpful” were the five most distinctive words from satisfied patients, while the words “doctor”, “feel “, “appointment”, “rude”, and “symptoms” were the five most distinctive words in the comments from dissatisfied patients.

Our current work builds on these previous efforts by addressing patient satisfaction from Press Ganey patient satisfaction survey data gathered from a health care system rather than publicly accessible online reviews and NHS surveys. Additionally, we developed an NLP-powered classifier that combines vocabulary-based and machine learning-based methods to analyze both the topic and sentiment of each free-text comment. For the long-term goal of this project, we aim to leverage NLP methods to automatically analyze free-text fields in Press Ganey patient surveys at the University of Utah hospital system in order to streamline quality improvement efforts e.g., trending
historical patient experience data, helping direct future quality improvement efforts, and acquiring a better understanding of patient experiences as these relate to patient outcomes more generally. Our short-term goals are to determine common topics of patient satisfaction and dissatisfaction from free-text, patient survey comments, to create an NLP solution to automatically annotate comments with these topics, to analyze these comments for their polarity, and to identify sub-topics described within these comments to assist quality improvement efforts.

Methods

In this IRB-approved study (IRB_00081172), we obtained the 51,234 Press Ganey patient satisfaction responses from the University of Utah Health Care System (UUHCS) that were generated between January 1, 2014 and December 31, 2014. First, we developed a schema for characterizing topics from patient survey responses (Table 2) and validated our schema with an annotation study. Next, we trained two supervised classifiers (one a vocabulary-based classifier and one a Naive Bayes’ classifier) to automatically tag responses with topics from the schema. Then, we identified patient’s emotional valence toward these topics, using a separate trained classifier. Finally, we used LDA to cluster terms associated with negative experiences in an attempt to learn new topics.

Annotation Study

We developed an annotation schema for topics and sentiment recorded in free-text satisfaction responses. Starting with the taxonomy by Lopez et al.3 in Table 1, we added and removed categories in consultation with the Exceptional Patient Experience team (author CD) from UUHSC. In total, we created the 28 annotation categories listed in Table 2. Any group of words could be annotated separately with as many categories as were appropriate. Each annotation was also given a sentiment of positive, negative or neutral, an example is given in Figure 1.

Figure 1. An example of an annotated file.
A set of 300 documents was randomly selected from the dataset of patient survey free-text responses for manual annotation. Annotators A1 and A2 developed the annotation guidelines on batches of 100 documents until agreement was reached using consensus review. We considered inter-annotator agreement (IAA), F1-score, to have reached an acceptable level when the overall agreement, as reported by eHOST, was 0.74. A third annotator (A3 who has experience in the hospital quality domain) was trained in the application of the annotation schema. The annotations generated by the third annotator were compared to the adjudicated set. With our initial annotation scheme, we quickly found that sufficient IAA for all topics could not be reliably maintained. Therefore, we focused on the 7 most common (overall, appointment access, appointment wait, explanation, friendliness, practice environment, and empathy) with positive and negative sentiment, which represented 63% of all annotations.

Figure 2. Chart illustrating the flow of Patient feedback documents through our processing systems.

Topic classification

For topic classification, we developed both vocabulary-based and machine learning-based approaches. Our approach is illustrated in the top line of Figure 2. For the vocabulary-based method (our baseline approach), we used the annotated topics in the 300 adjudicated documents to generate a vocabulary. We gathered the text from each topic and used the Natural Language Tool Kit (NLTK) for Python* to tokenize the comments, remove non-alphabetic characters, stem (Snowball Stemmer) the resulting tokens, and remove stop words from each tokenized comment. We separated the results into n-grams: unigrams, e.g., “terrific,” and bigrams, e.g., “terrific service” (process A in Figure 2). The lists of n-grams were compared so that each n-gram appeared on only one list. If an n-gram was on more than one list, the list with the highest frequency of its occurrence got to retain it. The top five n-grams for each topic are listed in Table 3. From Table 3, we observed that the top n-grams associated with appointment access and appointment wait are associated with time. In contrast, practice environment n-grams are often associated with cleanliness and temperature. Empathy and friendliness n-grams describe feelings and service actions.

* http://www.nltk.org/
We compared two methods for classifying comments into each topic. First, we used a simple dictionary look up approach. For each unigram and bigram in a comment, we found the corresponding topic. All matched topics were retained because many comments had more than one hand annotation. Like all attempts at document classification there was a tradeoff between identifying the document category correctly (i.e., precision) and finding all the documents that belonged in that category (i.e., recall). We observed that allowing n-grams to appear in the lists of more than one topic increased recall at the cost of precision.

Table 3. The five most prevalent unigrams and bigrams for each topic category.

</tbody>
</table>

We first thought to increase precision by creating a dictionary listing for n-grams, which indicate the comment does not contain any of the topics of interest. By creating a list for comments that were “not annotated,” meaning that they did not contain any of the topics we were interested in. However, looking at our low recall scores, further stripping n-grams would be counter productive because it would cause more comments to be missed. So we trained a Naïve Bayes (NB) classifier using the 300 adjudicated documents to classify comments as “topic containing” or “no topic” (process B in Figure 2) before we used the vocabulary-based system and learned n-grams (keywords) on the “topic containing” comments. Otherwise, the system could always find at least one topic matched word in every comment leading to very poor precision scores.

For comparison against the vocabulary-based approach, we trained a machine learning approach leveraging the Naïve Bayes (NB) algorithm. We tested decision tree and SVM models as well, but we found the best performance with Naïve Bayes’. We used the NLTK (i.e., featx) methods to reduce the text to lowercase, stem words to their lemma, group the stemmed words into n-grams, and convert the n-grams into feature vectors. We used the NLTK NB classifier, with default settings. We divided the data set into training/test data sets (75%/25%), one binarized set per annotated topic, each set was balanced between “topic containing” and “no topic” comments (i.e., positive and negative examples of the class). This process is not pictured in Figure 2, in order to retain readability. We applied the trained algorithm to the blind test set. We report the results on the 25% test data compared to the vocabulary approach for the seven most common topics. Performance is reported as precision, recall and F-measure.

Sentiment Analysis

Using the same training and test sets and encoded n-gram features from the topic classification, we developed a classifier to categorize a comment based on its sentiment. In line with the head-to-head comparison performed by Georgiou, et al. and our results with the “topic containing”/”no topic” classification, we chose to again use Naïve Bayes’. Specifically, we trained the NLTK NB approach to classify comments based on sentiment categories of positive or negative (process C in Figure 2). We report the performance for each sentiment category on the test set.
We then ran both the trained and tested NB topic classifier and NB sentiment classifier on the remaining roughly 50,000 patient satisfaction comments. We report the distribution of positive and negative comments by topic class.

**Topic Modeling**

To complement the topics annotated through manual review, we completed an unsupervised topic modeling study. We first classified the full 51,234 comments with sentiment categories using the NB sentiment classifier (process C in Figure 2, repeated in the figure for clarity). For all comments classified as negative, we provided the unigrams and bigrams to an LDA algorithm with a preset maximum of 30 topics using the gensim package* We report the n-grams associated with 10 of the 30 topics learned by the algorithm and if a topic suggests one of our seven most common topics, we also provide a topic label (process D in Figure 2).

**Results**

**Annotation Study**

In total, we annotated 1,374 documents consisting of 2,021 annotations. All three annotators annotated the same 300 documents in 100 document sets. Figure 3 illustrates how IAA changed across the three annotators and 3 document sets. In general, there was little improvement between sets 1 and 2. Some categories’ performance even decreased indicating that new comments were difficult to categorize. Between sets 2 and 3 there is a general increase in IAA indicating that annotators had reached a common understanding. Empathy and practice environment categories, however, still demonstrate a lack of agreement.

Annotators A1 and A2 discussed categories and re-annotated sets 1 and 2 until they reached an understanding. On set 3 their agreement was 0.74 overall as reported by eHOST. At this point the most frequent topics (overall, appointment access, appointment wait, explanation, and friendliness) had high agreement levels of (0.83, 0.91, 0.79, 1.00, 0.76, respectively). Empathy (0.47) and practice environment (0.44) were much lower.

The same procedure of discussion and re-annotation of the first 2 sets was repeated with A3. His overall agreement with the adjudicated document set from A1 and A2 was reported by eHOST to be 0.73 overall. Agreement between A3 and the adjudicated documents for the most frequent categories was 0.77, 0.83, 0.77, 0.86, and 0.77, respectively. Empathy (0.67) and practice environment (0.60) demonstrated lower agreement, although not as low as the agreement between A1 and A2.

Taken across the 2 sets of IAA scores, the categories with the most agreement are explanation (1.00, 0.86), appointment access (0.91, 0.83), overall (0.83, 0.77), appointment wait (0.79, 0.77), friendliness (0.76, 0.77), empathy (0.47, 0.67) and practice environment (0.44, 0.60). Agreement with A3 is tied for the middle three. So the score between A1 and A2 is used to decide order.

*https://radimrehurek.com/gensim/models/ldamodel.html
unigram could not appear in more than one list, the number of unique n-grams is the number of words that were available to identify topics. 58 bigrams (20 of them unique) were found for overall experience. Figure 4 shows the counts of unigrams and bigrams, with the number of unique in each case, across the seven most common topics. Practice environment, appointment access, and appointment wait generated the most n-grams and the most unique n-grams (Figure 4). Looking ahead at the classification results in Table 3, there is no obvious relationship between the number of unique n-grams and performance. Explanation had the fewest unique n-grams and the highest performance. Overall experience had the most unique n-grams was directly in the middle of the performance scores.

Figure 4. Total n-gram counts and unique n-gram counts for each topic. Unigrams = light color (bottom); Bigrams = dark color (top).

The vocabulary was extracted from the 300 adjudicated documents and tested on the remaining 1,074. Table 4 illustrates the results of the topic classification for the top seven topics. NB classification for explanation was good (0.74). Performance for the remaining 6 topics were fair, ranging from 0.36 – 0.57. Generally, precision was higher than recall for the vocabulary matching approach. In choosing the vocabulary, we opted for higher precision. However, this strategy was not successful for the more difficult categories of practice environment and empathy. These were the only topics for which the vocabulary matching outperformed the machine learning approach of applying NB. The precision for the NB overall classifier was high, but recall was lower. The topic classification results echo the IAA results, demonstrating the difficulty of the task. Explanation was the best performer in both places. Empathy and practice environment are at the bottom. Friendliness and overall do not follow this trend.

Table 4. Topic classification for n=1,074 annotations. Classifiers are listed by their highest F-measure. IAA indicates the rank order of the topic IAA scores. Bold indicates highest performance between approaches.

Sentiment Analysis

Separate vocabulary and NB classifiers were developed to analyze the sentiment of a comment. These classifiers used all 1,374 documents split randomly into 75% for training and 25% for testing. The algorithm performed with a precision of 0.90 and recall of 0.80 for positive sentiment, and a precision of 0.79 and recall of 0.90 for negative sentiment. The overall F-score of the system was 0.84.

Combining Topic and Sentiment

We applied the two NB classifiers trained on 1,374 documents. At this point we trained the model on 100% of the documents because we used the trained model to annotate the 49,860 un-annotated patient satisfaction comments.
The classifiers tagged the comments with 73,801 annotations. Overall patients have positive experiences. Specifically, empathy, friendliness, and explanation are more often positive experiences; in contrast, appointment wait, appointment access, and practice environment are more often negative experiences. The breakdown of polarities for the top 7 topic categories is illustrated in Figure 5.

**Figure 5.** Distribution of positive and negative comments according to topic.

**Topic Modeling**

We applied a topic modeling algorithm to patient satisfaction comments from 2014 that had been automatically flagged as negative by our sentiment analysis tool to provide a snapshot of negative topics (Table 5). Topic models can be difficult to interpret\(^\text{14}\), but it can be seen that most of the themes identified refer to discontent regarding the topics we named appointment wait and appointment access.

**Discussion**
In our topic classification study, we found that the common topics of patient satisfaction and dissatisfaction from free-text, patient survey comments were appointment access, appointment wait, empathy, explanation, friendliness, overall experience and practice environment. In just over half of the cases (four out of seven) the NB classifier was more successful than the vocabulary-based system in classifying documents as belonging to the topic in question. Investigating comments for their sentiment, using an NB classifier over the entire document set, we found 70% to be positive and 30% to be negative. This breakdown in sentiment was also found in our manual annotations where 71% of the top 7 annotations and were positive and 75% of all annotations were positive. Using topic modeling to determine if there were topics we had not considered within the negative comments, we found that the topics described within the negative comments, reflect the common topics of appointment access and appointment wait.

Our initial plan was to create a topic classification system that would reflect the full complexity of the topics found using qualitative methods. We created an extensive taxonomy of topics, which could be annotated with reasonable overall agreement. However, IAA was only acceptable for five of the seven most common categories. Empathy and practice environment, although they were commonly used were not often agreed upon. In the case of empathy, it may be due to the difficulty in distinguishing between empathy and related topics, like friendliness. The relatively low agreement for the practice environment category is perhaps due to conflating overall negative experiences with issues relating to the physical environment.

The ability to create a high performing topic classifier may have been affected by the only fair agreement on annotations. The classifier with the best overall F-measure was explanation, which had the highest IAA. The worst performing classifier empathy was for the topic with one of the lowest agreement scores. The middle four NB classifiers did not show a relationship between F-measure and IAA rank. This pattern did not hold for the vocabulary-based systems. The best vocabulary system was for practice environment, which had the second lowest agreement rank. The vocabulary system with the lowest F-measure was for appointment wait, which had a middling agreement rank. We also found that as we added documents that had been annotated by only A3, the classifier performance decreased. It seems likely that A3 experienced drift in their annotations.

Low performance on topic classification, even with our restricted topic set, indicates that perhaps both approaches are unable to capture the semantic information in the patient comments. Performance may be improved by creating an ontology of the dictionary terms, a structure that reflects synonymy, hierarchical relationships between terms, and term function. For instance, “excellent” may be synonymous with “great”, in this context. “Really excellent” may be an intensified version of “excellent” and both “really excellent” and “excellent” can be used in combination with “environment” or “interactions.” The former would be associated with the topic practice environment, while the latter with friendliness. This kind of information may be encoded in convolutional neural networks, which have been successfully used in sentiment analysis.

By focusing on solely on those topics on which annotators can reach acceptable agreement, and conflating easily confused topics, we may be able to dramatically increase our classification performance. Perhaps combining the categories of empathy, friendliness and helpfulness (from our bigger list) we could create a topic that is easier to distinguish from the other topics. It is also possible that the number of annotations of each topic led to poor performance. However, the best performing classifier was for explanation, which had far fewer occurrences (92) than overall (587), which had one of the worst performing classifiers. Future work includes training on a larger set of data and using more semantic features e.g., encoding words from categories such as ‘Time, Affect, Positive Emotion, and Negative Emotion, etc. from the Linguistic Inquiry Word Count lexicon’.

The sentiment classifier performed very well, which is consistent with the larger training set due to a smaller number of classes. Overall system performance was above the threshold of 0.80. It performed within the range of Greaves, et al.\textsuperscript{7,15,16} three-topic classifications e.g., 0.84 vs. 0.89, 0.84, and 0.85. Applying this classifier to our large dataset, we found 70% had positive sentiment compared to Lopez, et al.\textsuperscript{3} who found 63% of online reviews had positive sentiment.

Good sentiment analysis performance allowed us to select the comments with negative sentiment for topic modeling. Our topic modeling results echo our topic classification results in that the predictive topic words indicate two of our most common topics appointment access and appointment wait. These two are also the topics with the most comments with negative sentiment. They are the only topics with more than 50 comments with negative sentiment across the annotated dataset. Brody et al.\textsuperscript{4} also found scheduling to be a common review theme. We may have been more likely to find unexpected topics if we had looked at the least commonly occurring words in the negative comments. However, finding uncommon, unexpected topics may not be useful for quality control.

\textsuperscript{*} http://liwc.wpengine.com/
As we have noted in this discussion, the main limitation of this work is the relatively poor performance of the topic classification and topic modeling systems. However, the problems encountered are common to NLP systems. In the case of topic classification, the more topics you have the more difficult the task becomes for both humans and machines. For topic modeling, the system’s performance was not a problem. The results simply show that there are no unexpected topics found in the most frequent negative comments.

Conclusion

This study is a promising start to creating a method of analyzing free-text comments in patient satisfaction surveys that will help streamline patient satisfaction efforts e.g., trending historical patient experience data, helping direct future quality efforts, and acquiring a better understanding of patient experiences more generally. We are actively improving topic classification algorithm performance, expanding the granularity of sentiment classes to address strength of emotional valence (strong positive, weak positive, neutral, weak negative, and strong negative sentiment) and implementing monthly reports with statistics and visualizations to streamline patient satisfaction improvement efforts at UUHSC.

Abstract

Pandemic simulation is a useful tool for analyzing outbreaks and exploring the impact of variations in disease, population, and intervention models. Unfortunately, this type of simulation can be quite time-consuming especially for large models and significant outbreaks, which makes it difficult to run the simulations interactively and to use simulation for decision support during ongoing outbreaks. Improved run-time performance enables new applications of pandemic simulations, and can potentially allow decision makers to explore different scenarios and intervention effects.

Parallelization of infection-probability calculations and multicore architectures can take advantage of modern processors to achieve significant run-time performance improvements. However, because of the varying computational load during each simulation run, which originates from the changing number of infectious persons during the outbreak, it is not useful to use the same multicore setup during the simulation run. The best performance can be achieved by dynamically changing the use of the available processor cores to balance the overhead of multithreading with the performance gains of parallelization.

Introduction

Pandemic simulation can provide insights in outbreak dynamics and offer valuable information about the impact of different interventions on simulation outcome [1] and researchers have developed several frameworks to support simulation [2,3,4]. However, there are several challenges in pandemic simulation, such as community and disease modeling and development of simulation engines with sufficient performance. Run-time performance is a serious bottleneck because extensive turnaround times make it difficult for public-health analysts to run larger simulations and explore alternative scenarios. Improved run-time performance can create new possibilities for public-health researchers and decision makers to take advantage of pandemic simulation in novel ways, such as scaling to larger models and using fine-grained population and transportation data. In addition, improved performance can ultimately enable interactive simulations where the results change as users vary input parameters and simulation settings.

Discrete-event simulators based on mixing groups model the community as a set of locations where people meet and where transmission may occur. These simulators calculate the probability for infectious members of the mixing group to infect other susceptible individuals. The simulations are probabilistic in the sense that they use random-number generators to determine if individuals get infected, which means that the outcome varies among different simulation runs and that it may necessary to repeat the simulation several times to obtain sufficiently stable results.

The number of floating-point operations required for computing probabilities of infection is often a serious performance bottleneck. Run-time performance is important for scaling the problem to larger populations, running several different scenarios and stepping model parameters, and providing time-critical decision support. The run-time performance challenge is exacerbated by the requirement to repeat the same simulation several times, for instance 10 or 100 times.

The run-time performance is to some extent unpredictable because it depends on the evolving outbreak simulation. When the number of infected persons in the simulated outbreak increases, the number of possible interactions will increase as well, which requires additional computations (mainly floating point operations) to determine the probability of infections. Smaller outbreaks will run faster whereas larger outbreaks take longer time, and they are especially slow at the peak of the outbreak. The use of large mixing groups, such as models of large neighborhoods
and the entire simulated population, will increase the number of interactions and, thus, the run time required for simulation.

We have previously addressed the modeling challenge and introduced the use of ontologies for modeling of influenza outbreak scenarios [5] and for documenting the assumptions made during the modeling process [6]. The aim of this study, however, is to explore parallelization for improving run-time performance in pandemic simulation. Here, we describe an approach to use OpenMP [7] compiler directives for annotating a preexisting simulator and evaluate the impact of using multiple cores for computing probabilities in a pandemic simulator based on mixing groups. Furthermore, we introduce a method for dynamic switching between single and multicore mode based on a threshold for the number of infectious individuals. Finally, we discuss potential approaches for further run-time performance improvements.

Background

It is possible to parallelize pandemic simulation in different ways. If several alternative and independent scenarios are to be evaluated, one approach is to divide the work among several computing nodes, such as nodes as part of a cloud-based platform [8]. For example, simulation studies of outbreaks in communities where alternative intervention strategies are to be compared could run each of the cases on different machines. The disadvantage of this approach is that it only scales to the number of scenarios to run simultaneously (i.e., at most one node per scenario).

For stochastic simulations, where it is necessary to perform multiple runs of the same simulation with the same parameters, it is possible to divide the work of running such iterations among an array of independent computing nodes. This approach scales better than parallelizing scenarios because of the typical number of iterations. For example, 100 iterations could potentially be divided among 100 worker nodes. In this method, it is necessary to ensure that any random-number generator is properly seeded to make the iterations unique and independent. Because of the distribution of iterations over several nodes, there will naturally also be some additional work of collecting and merging the results from the different iterations.

Running several simulations in different operating-system processes on multicore CPUs, rather than on independent machines, may seem like a straightforward way of improving performance. However, this approach does not scale as well because of resources shared among the cores, such as RAM, and limitations in cache memory and memory bandwidth. For example, running four instances of the simulation program on a four-core processor does not result in four times the performance. To fully use modern multicore processors, it is necessary to develop threaded simulators that take advantage of the cores specifically (e.g., by multithreading).

Open Multi-Processing (OpenMP) is a portable programming model for shared-memory multiprocessing [7]. OpenMP provides compiler directives (#pragmas) and libraries for adding parallelism to the programming languages C, C++, and Fortran. OpenMP is designed to give programmers a high-level and an easy-to-use way of adding parallelism to new and preexisting programs. For example, OpenMP takes care of forking and running multiple threads (e.g., on a multicore platform) as well as collecting results from multiple threads running in parallel. In the context of pandemic simulators, one of the main advantages of OpenMP is that it allows for parallelization with minimal changes to the original simulator code and the core algorithms, which is beneficial for simulator transparency and maintainability.

Methods

The overall evaluation method is to run repeated simulations with different settings and compare the run-time performance. The performance evaluation used an influenza outbreak scenario as a benchmark for testing the impact of multicore processing. First, we extended the pandemic simulator with compiler directives for OpenMP. In particular, the central loop for calculating infection probabilities for each step in the simulation was augmented with a loop-reduction annotation to parallelize the loop over a number of cores (which was stepped from 1 to 32).

The experiments ran on an HP Z620 workstation equipped with dual Intel Xeon E5-2687W v2 eight-core processors running at 3.4 GHz and 96 GB DDR3-1866 ECC RAM. We specifically selected and installed 3.4 GHz eight-core processors because they provide a reasonable tradeoff between clock frequency and the number of cores deemed suitable for the mixed workload of pandemic simulation. (There are certainly alternative processors with more cores...
but lower clock frequency available, which would have penalized single-thread operation and resulted in less performance for large parts of the simulation.)

The experiment machine ran x86_64 GNU/Linux Debian. Processor hyperthreading was enabled, which means that the total number of cores presented to the operating system was 32. The simulator software was implemented in C++ and was compiled on the experiment machine using gcc with -O2 optimization and -fopenmp settings. All simulation runs were CPU bound rather than memory bound, which means that the amount of installed RAM had negligible effect on performance.

The simulator was extended with additional command-line switches for controlling the relevant settings (such as the number of thread and the threshold for invoking threading) and a shell script was used to run the experiment series under various settings and stepping parameters. The results were stored automatically in a database (SQLite3) and later extracted for plotting using Gnuplot.

Results

Figure 1 shows the benchmark simulation run-time for different numbers of cores and for different thresholds for activating threading. As illustrated by this diagram, the execution times drop dramatically (from 580 s) when enabling the first few cores, but tend to increase again as additional cores are used (due to overhead). Also, note the slight jump in the execution times when going beyond 16 physical cores (and thus using hyperthreading). Furthermore, it is clear from these results that using a threshold for the number of infections persons improves overall performance. There is a slight advantage of using a threshold of 400 infectious individuals over a value of 100, but the difference is not that large. For no threshold, the fastest run time was 144 s using 8 cores, whereas a threshold of 100 achieved 89 s with 13 cores and a threshold of 400 achieved 82 s with 15 cores.

![Figure 1. Simulation run time versus number of cores for different thresholds for activating multithreading.](image-url)
Figure 2. Simulation run time versus number of cores for an intervention scenario where schools close at day 10 and later reopen at day 20.

Figure 3. Simulation run time versus number of cores for an intervention scenario where schools close at day 10 and later reopen at day 20.

Figure 2 shows the effect on the execution times for an alternative scenario with a somewhat different simulator load. Here, the schools close on day 10 and are kept closed until day 20 when they reopen [9]. This intervention will reduce the number of infected during that period. However, the total number of infected during the duration of the outbreak will be similar. For this scenario, the single-core execution time was 564 s, and the best performance with no threshold was 156 s using 9 cores. For a threshold of 100, the fastest run time was 98 s using 12 cores and for a threshold of 400 the fastest time was 91 s using 13 cores.
Likewise, Figure 3 shows the result of closing schools at day 20 and reopening them at day 30. In general, the run-time results from the school-intervention scenarios in Figure 2 and Figure 3 are quite similar, which illustrate that the run-time results apply in different scenarios that are relevant for public-health simulation tasks. For the scenario of closing schools at day 20 and reopening them at day 30, the single-core execution time was 539 s. Using no threshold, the best performance was 144 s with 7 cores. For a threshold of 100, the fastest run time was 93 s using 9 cores and for a threshold of 400 the fastest time was 87 s using 11 cores.

The results presented previously (Figure 1–Figure 3) assume that a single simulation process instance was running at the time. The question arise whether it is possible to better use the cores available in the hardware by limiting the number of cores used and instead use remaining cores for running another simulation process instance. Figure 4 shows the results from running two simulation jobs simultaneously on the same machine. With two simultaneous jobs, the single core execution time (i.e., for each job) was 583 s, and the best performance with no threshold was 143 s with 8 cores. For a threshold of 100, the fastest run time was 106 s using 8 cores and for a threshold of 400 the fastest time was 100 s using 8 cores. These results suggest that it is possible to achieve better throughput by using a limit of eight cores and run two simultaneous simulation jobs (e.g., two scenarios), at least in the context of the benchmark and the dual eight-core processor machine used in the experiment.

**Discussion**

Public health needs improved simulation methods. Advances in simulation performance can benefit the general public by improving public-health decision processes, for example by allowing needed interventions to start faster and avoiding pointless interventions, which burden the communities. We believe that it is essential to develop new methods for improving simulation run-time performance. Such performance gains can allow for interactive sessions where public-health officials and decision-makers explore different scenarios and get a better understanding for the dynamics of an ongoing outbreak. Furthermore, improved performance will make it possible to use interactive simulation as a training tool where the outcome of different decisions can be illustrated through the simulation results. A better understanding of different outbreak and intervention scenarios combined with lessons learned from desktop exercises can contribute to resilience and healthcare preparedness.
In this study, we used a method of taking advantage of modern multicore processors based in a single threshold (i.e., 100 or 400) for activating multithreading. In principle, it is possible to use multiple levels of multicore activation, for example by employing several threshold levels and to ramp up the number of cores gradually. We have found that this method can have some performance benefits, but in general a single threshold is sufficient for controlling the activation of parallelism (because of the overhead of initializing the threading mechanism). However, in situations where several simulation processes run on the same machine simultaneously, there may be an advantage of gradually stepping up and down the number of cores used for the purpose of freeing up resources for the other simulation processes.

There are other alternatives for further improving the simulation run-time performance. One approach is to cache intermediate results and reuse them later in the simulation. For example, it is possible to store the probability of someone getting infected in a certain mixing groups and to reuse this result for another person with similar properties (such as belonging to the same age interval and otherwise have similar properties according to the simulation model). When appropriate, this approach can reduce floating-point operations and improve performance significantly. The drawback of this approach, however, is that caching is only possible for relatively basic scenarios and that reuse of intermediate computations steps are inapplicable for certain types of interventions affecting transmission probabilities (e.g., lowered spreading probabilities for some contagious individuals due to shielding measures).

Another potential approach to improve simulation run-time performance is to take advantage of offloading to GPU devices. GPUs support a massive number of threads and simultaneous floating-point operations, but are simpler devices than CPUs. Offloading typically requires transfer of data to and from the GPU-card over the PCIe bus, which can become a bottleneck. It is possible to use OpenACC [10], which is a standard for compiler directives for CPU/GPU architectures, in the same ways as OpenMP to annotate source code for compilation to CUDA (a platform for parallel computing developed by NVIDIA) and eventually execution on GPUs. However, current compiler support for OpenACC is somewhat limited1. An alternative to OpenACC is to develop directly in CUDA. Because of the bandwidth limitations in transferring data to and from the GPU and the associated overhead, it is difficult to merely accelerate performance-critical regions in the code. A serious implementation in CUDA would require a large proportion of the simulation to take place on the GPU, which essentially means a complete simulator reimplementation for CUDA. Our preliminary tests show that just preparing and packaging the relevant simulation data for transfer to the GPU can easily take more time than simply performing the calculation on multicore processors. Nevertheless, we believe that offloading to GPU is a promising future option because of the potential for scaling simulations to much larger populations and for developing truly interactive simulations where public-health professionals and decision makers can manipulate interventions and see the results instantly.

**Conclusion**

Multicore programming can significantly improve run-time performance of pandemic simulation by allowing for parallelization of repetitive calculations, such as the probability of infection for each individual in a mixing group. OpenMP is a useful approach because it allows the developer to annotate preexisting simulator source code with compiler directives for parallelization. The same source code still works when compiled for in single-core systems and with appropriate the annotations the basic algorithms are clearly expressed even for the parallelized versions. However, because of the overhead of multicore threading, such as starting multiple threads, dividing work, and collecting results, it is not possible to achieve a meaningful speed up at all simulation stages, especially with few infections. The evaluation results show that using an excessive number of cores could lead to less run-time performance, and that it could be more efficient in terms of throughput to limit the number of cores used and run more than one simulation job (scenario) simultaneously than to use all available cores for a single job. Nevertheless, it is possible to achieve massive improvements by dynamically switching between single and multicore mode as the simulated outbreak evolves and the computational load varies.

---

1The GNU compiler collection (GCC) provides partial support for OpenACC since version 5. In addition, there are more mature commercial compiler solutions for OpenACC from PGI, Cray, and CAPS as well as compilers developed as part of research efforts, such as OpenUH and OpenARC.

Integrating the patient portal into the health management work ecosystem: user acceptance of a novel prototype

Jordan Eschler¹, Perry Lin Meas¹, Paula Lozano, MD, MPH², Jennifer B. McClure, PhD², James D. Ralston, MD, MPH², Wanda Pratt, PhD¹
¹University of Washington, Seattle, WA; ²Group Health Research Institute, Seattle, WA

Abstract

People with a chronic illness must manage a myriad of tasks to support their health. Online patient portals can provide vital information and support in managing health tasks through notification and reminder features. However, little is known about the efficacy of these features in managing health tasks via the portal. To elicit feedback about reminder and notification features in patient portals, we employed a patient-centered approach to design new features for managing health tasks within an existing portal tool. We tested three iteratively designed prototypes with 19 patients and caregivers. Our findings provide insights into users’ attitudes, behavior, and motivations in portal use. Design implications based on these insights include: (1) building on positive aspects of clinician relationships to enhance engagement with the portal; (2) using face-to-face visits to promote clinician collaboration in portal use; and (3) allowing customization of portal modules to support tasks based on user roles.

Introduction

Patients with chronic illness have a particularly burdensome health task workload, with effective management of chronic conditions potentially requiring thousands of discrete health tasks annually¹. Patients or caregivers managing a chronic illness must juggle often complex medication regimens, comply with routine screening and testing, and attend regular medical visits². Accordingly, patients or caregivers often monitor their health status daily and communicate relevant changes to their clinicians to maintain an appropriate treatment plan.

As part of managing these frequent, important tasks, reminders and notifications can be essential mechanisms for remembering and accomplishing chronic care tasks. In this paper, reminders encompass (electronic) prompts that were generated by the health care information system and pushed to a patient portal to engage patients and caregivers with upcoming recommended care tasks. Notifications are informational updates provided by the health-care information system for patients or caregivers that enhance communication around health tasks. Because patients are more likely to engage with care tasks if associated reminders and notifications are relevant and actionable³, our study works to incorporate patient preferences with reminders and notifications to enhance engagement with chronic care tasks⁴, ⁵, ⁶, ⁷.

The patient portal offers a powerful platform to customize reminders and notifications. The portal allows patients to view aspects of their electronic health record (EHR) and communicate electronically with clinicians in their health care system. These portals are information systems that could easily incorporate patient-centered approaches, particularly to take into account patient preferences, providing a means to improve illness management by promoting patients’ engagement in their care⁸, ⁹ and adherence to care plans¹⁰, ¹¹. Research has previously demonstrated the health management benefits from patient engagement with portals for specific populations (e.g., people with diabetes¹², teenagers¹³, and people with multiple sclerosis¹⁴). However, as observed in previous qualitative research on use of the patient portal, patients and caregivers experience common frustrations, such as difficulties in following up with clinicians¹⁵, failures in personal reminder systems¹⁶, ¹⁷, and gaps in attitudes between doctors, patients, and caregivers about the use of technology in health management¹⁸.

This study focuses on management of chronic illness in particular. We recruited individuals who manage diabetes for themselves (patients), and mothers who manage asthma for a child dependent (caregivers), to study the use of portal reminder and notification features. We utilize prototype testing to explore patient and caregiver interactions with new features in an existing patient portal that are intended to improve workflow, help users to remember important health tasks, and enhance patient and caregiver engagement and agency in managing chronic illness. This paper provides insights from patients and caregivers from this portal redesign to inform design implications for patient portals. We found that patient portals can best support remembering and accomplishing chronic illness management tasks by: (1) incorporating positive aspects of the clinician relationship; (2) bridging the information worlds of the clinic visit and home-based, self-care tasks; and (3) allowing users to customize patient portal functions based on role and associated tasks.
Participants
Our population of interest consisted of current users of the existing patient portal offered by a regional health care cooperative based in Washington State, U.S.A. The portal is available for patient use and for custodial parents of children 12 and under (i.e., caregivers, who manage health information for a dependent). We chose current users of the patient portal so participants would be familiar with and understand expected functionality of the system. We invited participants from two cohorts: those who manage a chronic illness for themselves (patients with diabetes mellitus), or for at least one minor child (mothers of children with asthma). For patients with diabetes (n=12, average age 63.4 years), we identified and invited individuals who had a diagnosis of diabetes mellitus. Each cohort received a paper prototype appropriate to their role: the diabetes cohort tested a patient-facing portal, and the asthma cohort tested a portal designed for caregivers of minor children. Detailed demographic information for each cohort is shown in Table 1.

Methods
We tested paper prototypes designed specifically for the tasks included in the study. Low-fidelity paper designs represented features in the portal interface, with the study facilitator acting as a computer receiving input and simulating output. We chose such low-fidelity prototypes because participants would be less likely to think of such a prototype as “finished,” and therefore would be more likely to suggest changes. In addition, paper prototypes facilitate rapid iteration and require less “polish” to deploy when testing over short periods of time. We observed participant interactions and behavior with the new features through the prototype, and audiotaped participants using a “think aloud” protocol that gave us additional data to understand how they were thinking about system interactions. The process of our prototype development is discussed in greater detail below.

Procedures
Each session was conducted individually with a participant. We used a set of four tasks to test prototype reminder and notification features that remained consistent between prototype iterations. Test sessions were audio recorded to verify participant quotes and settle disputes between researcher notes, if necessary. To maximize reliability of data collection among participants, we used a session checklist and a structured questionnaire, which was used at the end of the session to elicit additional, unstructured feedback after the task-based activities; we quote participant feedback from the questionnaire in the results. Individual sessions lasted between 30 and 45 minutes, facilitated by one or two research assistants. The three prototypes were tested with 19 individuals: seven participants tested the first prototype (P1), six participants tested the second prototype (P2), and six participants tested third prototype (P3). Most sessions were hosted in clinic conference rooms; however, some participants (n=3 mothers of children with asthma) preferred to participate in their own homes, in which case only one of the authors facilitated the session in their homes. We reached saturation in discovering design flaws after approximately six users, meaning we received similar feedback from multiple participants, which proved sufficient to iterate on the prototype. Each participant was compensated $25.

We recorded data about participant engagement with tasks in two ways. First, tasks were noted as either complete (meaning the participant followed through with the task using the prototype) or incomplete (meaning the prototype had shortcomings that prevented the participant from following through with the task). Second, we recorded other qualitative feedback from the questionnaire and think-aloud audio data to assess whether the participant accepted the task or not. Specifically, when a patient accepted the task, they made remarks that the task would be helpful or

useful; when a patient rejected a task, they made remarks about why the task was inappropriate or inapplicable to them. We articulated these two dimensions to help determine (1) how tasks related to participants’ preferences (accepted/rejected tasks) and (2) when the prototype performance failed (complete/incomplete tasks). That is, it was possible for a participant to reject a task, but complete it, or to accept a task, but fail to complete it.

Description of tasks
In each session, the participant was presented with the home screen of the prototype and asked to talk about what s/he observed and which features s/he noticed, etc. From there, a researcher would move into facilitating four tasks, in the following order: The Lab Result Task, The Urgent Care Task, The Flu Shot Task, and The Custom Reminder Task. The tasks required an increasing amount of “work” as the user learned the system through interaction. The tasks were also designed to represent various levels of task familiarity and different information behaviors (e.g., retrieving, updating). See Table 2 for a detailed description of each of these task dimensions.

The Lab Result Task asked the user to look up a recent medical test result, and initiate a follow-up with their doctor to discuss. Patients have indicated in previous research⁴ that they did not always understand the content of test result notifications and were compelled to use secure messaging or a phone call to request further information.⁵ We refer to this patient preference as a desire to “close the loop” in communication. This task presented a common scenario with an expanded, customized feature that expedited requesting clinician commentary on a given test result, and facilitated extended “tracking” of the issue if necessary.

*Tasks are deemed more familiar if they are similar to current portfolio functionality and less familiar if they introduce new or significantly revised functionality to the portal.

The Urgent Care Task presented a task as follows: verify instructions for a medication prescribed during a recent urgent care visit. For the diabetes patients, users looked up medication instructions for themselves. For the mothers, users looked up instructions on behalf of their child with asthma. Here, we are assessing patients’ acceptance of managing comprehensive medication information online (a feature that is not available on the current patient portal), as well as exploring the type of information that would be most useful to support patient and caregiver management of medication information between clinic visits. This task adds new functionality to the portal, essentially increasing the number of ways to view medical record information about medication history.

The Flu Shot Task presented a scenario where the portal presented a reminder to get a flu shot for the patient or child, but that individual had already received a flu shot outside of the health care cooperative (and therefore the medical record had missing information). The task then requested that the patient or caregiver dismiss a flu
vaccination reminder in the system by inputting information about the flu shot that was already received. This task facilitated two new user abilities: dismissing reminders, and inputting or correcting information in the EHR through the patient portal.

**The Custom Reminder Task** asked users to add to the portal their own custom reminder that would help them to follow through on completing a task with their doctor. The task was presented as follows: your doctor told you/your child to return every six months to manage a health concern; determine when you/your child should go back to the doctor and set a reminder for yourself in the patient portal. Patients and caregivers often manage these reminders in their own calendar/notification ecosystem\(^{16}\), and with this task we tested participants’ acceptance of a feature that would assist them in integrating the portal system into their personal ecosystem of reminders.

In summary, the **Lab Test Result** and **Urgent Care** tasks introduced new ways to complete familiar patient portal tasks, while the **Flu Shot** and **Custom Reminder** tasks introduced new functionality and expanded participants’ abilities in the system. In the following section, we describe the prototype iterations.

**Iterative stages of the prototype**

We created the initial prototype designs specifically for this study based on our previous qualitative research focusing on patient and caregiver management of reminders and notifications and related patient portal use\(^{15, 16, 17, 18}\). Prototype design and iteration is described in more detail below. For all three prototypes, we increased the level of personalization on every screen by displaying the user’s name and photo on the home screen. For mothers of children with asthma, this personalization component also served as the method to toggle from one user to another. By selecting the mother’s picture, or the child’s picture, the user could navigate between profiles, and receive system feedback about which profile was “activated” depending on which name was displayed. Both patients and caregivers were very accepting of these touches of personalization, though opinions about uploading a picture—“like on Facebook,” as several of our participants noted—varied quite a bit. Mothers tended to indicate they would use the pictures (“I’d love to see my kids’ faces,” per A02), though others indicated they would prefer to use an avatar. Patients with diabetes were similarly mixed about their preference to use a picture. Because the patient/caregiver picture feature was generally well received, we retained that feature for all three prototypes. However, other features changed according to participant feedback.

Finally, although the participants interacted with paper “screens” using all three prototypes, using their fingers to complete tasks, the screens themselves were laid out digitally and were of a fairly high-fidelity layout. Feedback detailed in the below sections is from mothers of children with asthma (A# identifiers) or patients with diabetes (D# identifiers). The following sections detail the features of prototypes one through three.

**Prototype 1 (P1)**

We built the prototype’s functionality to facilitate completion of the tasks, allowing users to learn the system. The functionality of these prototypes was not very “deep,” but it gave us a chance to test a much simpler interface than presented by the current patient portal site. The primary features of P1 (see Figure 1) that differed from the current patient portal are as follows:

- Reminders and notifications were centered on the home screen and new items were highlighted in red;
- The menu taxonomy was simplified from the current patient portal menu options;
- The large buttons to navigate through the site were optimized for touch-screen use, rather than a desktop layout (most of our participants use their phones or tablets to interact with the current patient portal application); and
- The “Goals” feature was displayed, but not built out, to start a conversation with participants about what that portion of a portal might entail, and how it might benefit them.

The most common criticism of P1 was that the secure messaging option was now buried in other features. For example, when completing the Medication Task, the
participant needed to navigate to previous test results and then select “Message my care team” to use that feature. However, both cohort’s participants indicated that secure messaging should always be one click away, on every screen, because it was a “top-level” task – i.e., a primary reason for visiting the portal in the first place. Thus, access to the secure message was prioritized in the next two prototypes.

Other feedback about the prototype praised the “simple layout,” which was contrasted against the current portal’s “busy” interface. We retained a relatively simple, touch-friendly layout in subsequent prototypes, but noted that incomplete tasks with P1 stemmed from poor navigation taxonomy. For example, “Tests and care” was too vague for participants to use efficiently. Thus, we overhauled the navigation menu in P2.

Prototype 2 (P2)
We re-organized the menu options (see Figure 2) to respond to the criticisms of P1 that (1) secure messaging should be available at the top level of navigation and (2) that navigation taxonomy needed to use clearer categories. We also added redundant navigation to a side menu, which participants liked because it conveyed “consistency.” One other major change to P2 from P1 was changing the “push” notification indicators. The participants did not understand the list of notifications being front and center on the home screen, as it was in P1: participants preferred for less obtrusive notifications and reminders. We changed the design accordingly, appending relevant push notification indicators to corresponding menu options. Here, we used an iOS-like red number notification to draw the participant’s attention to that area, informed by participant input that they liked the notification styles of their phones and tablets. Participants regularly showed us their own devices during testing, and many used smartphones.

Criticisms of P2 stemmed mainly from the mothers’ use of the system: these participants indicated that they needed more information on the screen. Specifically, mothers stated that they frequently called the clinic while using the portal, particularly when they “hit a wall” in completing a task on the portal. For this reason, mothers wanted their child’s member number and the clinic phone number displayed on every screen. We made this change in P3.

Prototype 3 (P3)
The iteration from P2 to P3 was subtler than the previous redesign (see Figure 3). Most of the changes were made to accommodate mothers’ information needs and behavior, e.g., adding the health cooperative member number and clinic phone number to all screens in the patient’s profile. Another subtle change from P2 was that of using “active” language in the navigation menu to help participants understand how they would use the menu options, which had proved a shortcoming of P2. To remedy this confusion, we changed the wording of menu options to facilitate understand of the tasks supported in each of the site areas. For example, “Upcoming Care” became “Plan a Visit,” to help patients understand that they could still make appointments in the portal. “Care History” also became “View Care History,” to convey that this portion of the site served the “information archive” function that we had heard was a vital part of using the site, particularly for mothers.
Results: Task Outcomes
The following results express the outcomes by each of the tasks, which are summarized in Figure 4. When participants accepted a task, they indicated that being able to carry out the task on the portal was useful in managing health care, and they would be likely to complete the task in the manner presented in the prototype. Sometimes, though, participants did not accept tasks, saying that they would never use the portal for the task as described, or that they preferred to use whatever current solution they had in place, rather than the portal. We had numerous instances where a participant would complete the task but not accept it. In reporting on each of the tasks below, we report on both aspects of the participant feedback to maximize the analysis of the qualitative data collected during the testing sessions. All participant feedback is attributed to asthma mothers (A# identifiers) or patients with diabetes (D# identifiers).

The Lab Results Task
The user acceptance of this task was mixed, in that most of the participants saw the value of the enhanced messaging functionality, but some were reluctant to use the new feature over other communication approaches (in person or by phone). Incomplete tasks using P1 overwhelmingly stemmed from navigation issues. This led to clearer menu options in the second and third prototypes. Participants who succeeded in completing this task using P2 and P3 reviewed the test result, and then messaged the doctor using a new feature that populated a message with a subject heading and some text. A07 stated, “I like the fact that it automatically gives you an option to message your care team based on something really specific...I usually end up copying and pasting [text].” This function reduces patients’ need to remember details about the test to compose (from scratch) a message to their doctor. Incomplete task attempts in P2 and P3 resulted from the participants skipping the step to review test results and instead message the doctor their inbox in the portal. When asked about making this choice, participants stated that they mostly used the patient portal for messaging, and generally headed directly for the inbox. There, they would compose a message that would refer to the test in question, but not integrate details from the test results; instead, they would ask the doctor to interpret the result in prose in a reply. Despite incomplete attempts at the task, overall feedback from this feature was positive. Many participants said they would add some personal text to the message, to carry out the conventions of their offline relationship and to “warm up” the asynchronous communication mode.

The Urgent Care Task
Acceptance for this task was high, as many participants indicated they used the portal as an information archive (e.g., D09, who printed out archived information from the portal as needed). Patients with diabetes tended to like the medication view immediately; many of our participants managed many prescriptions, and drug interactions were a serious concern for them. These patients indicated that they would like to be able to view and edit their medications: “If it were my system,” D05 stated, she would work to “clean up” the medications list and make sure all of the information was accurate. Most existing research excludes patients as stakeholders to medication modules in health information technology, but detailed research about offering medication management tools directly to patients is lacking.

Figure 4: Acceptance and completion outcomes for each of the four prototype test tasks
Mothers indicated they preferred a digital After Visit Summary (which is a paper artifact already used in the health care cooperative system) to manage medications. To increase acceptance of this task, we built redundant navigation in the design iteration to P3. This satisfied both the participants with diabetes, who wanted a medication view, and the mothers managing asthma, who wanted contextual information around prescription medication in the form of the After Visit Summary. In sum, successful completion of this task was relatively high, with factors resulting in incomplete tasks resolved once the redesign for P3 incorporated the mothers’ preferences in navigation.

**The Flu Shot Task**

This task was not well accepted. Participants declined to accept the task based on their rejection of the flu shot as an important task (e.g., one participant, D07, refused one every year as a matter of course; “[the nurse] made a note of it that I didn’t want one and so they don’t do that…I just ignore [flu vaccine reminders]”). In P1, most incomplete tasks resulted from navigation errors. In general, we found, participants had a hard time figuring out where flu shots – or vaccinations in general – “fit” in the patient portal relative to other types of care.

P2’s design was much more successful, due to improved menu options, although most of the participants rejected the task itself, primarily due to rejection of the flu shot in general (as stated above) or an established habit of messaging with the care team to update information on the patient or caregiver’s behalf. In the last case, two of the six participants pointedly refused to add information directly to the medical record, and elected instead to message the doctor directly.

Participants in P3 who did not complete the task overwhelmingly opted to message with their doctor, rather than update flu shot information or dismiss the reminder. Participants stated a preference to have clinic staff update medical record information on their behalf. The primary takeaway is that participants did not necessarily make the connection between having updated medical information at hand and inputting that information into their record, and in fact saw the direct input of information as a “bypass” of the official information channel (clinic staff).

**The Custom Reminder Task**

This task was different from the first three for two reasons: (1) the functionality the system presented in completing the task was new and more unfamiliar to the participants than the first three tasks and (2) patients have existing—and sometimes complex—personal reminder systems, that they might be reluctant to integrate with what they view as an outside system. In the test of P1, most of the incomplete tasks were navigation-related. In P2, participants were more enthusiastic about using the design and chose to send themselves redundant reminders over multiple communication approaches (e-mail and text) to assist in remembering future care tasks. The results in P3 were similar to P2, with the exception that the diabetes patients testing P3 stated they would not use such a feature because they had frequent phone contact with a diabetes nurse from their clinic, and did not require extra reminders.

In the following section, we discuss themes identified from the qualitative data gathered during the testing sessions, and list design implications for patient-centered interventions in patient- and caregiver-facing health information systems.

**Discussion: Themes in Participant Feedback**

The information we elicited from prototype testing not only assisted us in iterating on the portal feature prototypes, but also provided rich qualitative data around the attitudes, beliefs, and behaviors of patients and caregivers as they integrate the use of the portal tool into their day-to-day health management routines. Lim et al. describe prototypes as “a tangible attempt to view a design’s future impact so that we can predict and evaluate certain effects before we unleash it on the world.” The authors go on to outline two purposes for prototyping with users: (1) exploring possible design decisions to manifest iterative simplifications toward a finalized design, and (2) to help designers determine what design dimensions are relevant or irrelevant. Our use of paper prototypes focused primarily on the latter purpose. Below, we elaborate on observed themes during participant interactions with the prototypes.

**The clinician relationship affected portal use**

Sometimes, tasks didn’t resonate with participants due to their strategies for maintaining (or avoiding) communication with clinicians they liked or disliked. D05 stated, “If you have a good relationship with your doctor you can work out goals that are reasonable.” For example, patients who had frequent communication with their doctors (these participants tended to describe their diabetes as “not well-controlled”) trusted their doctors to explain test results in each notification. D10 described using secure messaging: “Even if I ask maybe a dumb question [via secure message], [my doctor] answers it still. He’s very understanding.”

On the other end of the clinician-patient relationship spectrum, one mother (A04) had had a particularly poor experience with her doctors and care team. For this reason, she stated she would never attempt to message about a
test result. Instead, she preferred to use an Internet search (“I would Google something like, ‘when do I start worrying about...’”) to educate herself about the test, rather than initiate an exchange with her doctor over the portal. Previous research upholds the influence of clinician-patient relationships on the use of communication systems. Design implications for the patient portal related to this finding call for patient portal features that can amplify the positive aspects of the patient-clinician or caregiver-clinician relationship. Portal features that could potentially benefit patients who like their doctors and/or care teams potentially include: clinician pictures accompanying secure messages, to put a face to the words in secure messages; or a dedicated resource on the portal to view individual clinician or care team profiles. To accommodate those users with varying levels of rapport with their clinicians, the patient portal could incorporate user preferences to these suggested features (i.e., a caregiver with a poor relationship with clinicians could choose to hide or de-prioritize the care team profiles).

**Context of portal use differed between cohorts**
Although it is easy to assume that participants with diabetes were not technologically savvy because they were older than the mothers of children with asthma, many participants in the diabetes cohort used touch screen devices to use the existing patient portal. One participant (D10) indicated that she “liked to explore” new websites. However, some participants were particularly security conscious: “Security and whatnot...I keep no passwords on my phone whatsoever” (D08). At least one participant in the diabetes cohort used a third-party application for managing medications and remembering dosages and timing (D03).

This participant, and many of the diabetes cohort participants, proudly demonstrated use of personal devices during the course of the testing session, which we found to be helpful information, rather than a consequence of topic drift. Most participants in the diabetes cohort were eager to interact with a redesigned patient portal. We found that although the patient portal can incorporate health tasks more easily, and many patients use the technology perfectly well, it might not be the patient’s preference to do so, due to factors surrounding use. Health literacy, digital literacy, and tool use have a complicated relationship in this sense, as supported by previous research.

Mothers managing asthma on behalf of a child indicated they were busy and totally focused on the child, often prioritizing their children’s health needs over their own health tasks. Diabetes patients, however, tended to be older, and many had retired. These patients were most focused on their own health, and had numerous points of contact with the medical system (pharmacy, laboratory for regular blood tests, nurses, and often multiple physicians managing comorbid conditions accompanying diabetes). While mothers needed to plan ahead for clinic visits, diabetes patients expressed contentment with the social aspects of completing health tasks at the clinic. D12 stated, “I’m more the old school and I’ll call people up on the health team...primarily I find it works better based on my upbringing.”

Patients also felt as though they do not have a relevant ownership stake in portal information, or essentially that the doctor or other clinical staff is “in charge” of that information. Thus, as a consequence of the use context, patient portal use is subject to the power dynamics of the traditional doctor/patient dyad. It is important to recognize that this clinician/patient or clinician/caregiver collaborative stance will probably not be fostered solely through the patient portal approach, but instead requires integration of multiple approaches to encourage patient portal use to benefit both patient or caregiver, and the clinician.

The most enlightening of our findings with regard to context of use was that participants tended to trust their existing reminder systems, and expressed wariness about integrating yet another tool (e.g., the portal) into these systems. Here, we suggest, the design implication for patient portals may be offering a function that assists clinicians in encouraging patients to investigate the patient portal, to bridge the information worlds of the clinic and the home. For example, at the close of a clinic visit, a clinician could suggest that the patient use the portal to track visit follow-up tasks. At this point in the face-to-face visit, if the clinician had access to a module in the EMR to walk a patient or caregiver through portal reminder and notification features, this may prompt the user to re-engage at home.

Using such a module, the clinician could offer to set up a recurring reminder through the portal for the patient to engage with a follow-up task. By offering a visible demonstration of collaboration with a clinician (e.g., a medical assistant) during an in-person encounter, the patient or caregiver may be better able to see the relevance of portal functionality in managing care tasks, and therefore more willing to integrate the portal into their existing reminder ecosystems.
**Workflows depended on role and illness managed**

Our participants were not all simply “patients” or “caregivers.” Mothers were, of course, patients themselves and could use the portals for their own health needs. In some cases, diabetes patients were also caregivers themselves. One participant (D09) looked after her parents, in their 80’s, and did not drive. Most of her electronic calendar was used to track their appointments, and she often neglected herself to look after them: “[Taking care of them] makes me less conscientious about myself, because I’m so focused on making sure they’re taken care of. I feel like a mom.”

In contrasting workflows among users in different roles, it seems insufficient to simply modify the patient portal for caregiver use, although this is the prevailing model for offering custodial parents access to a child’s portal. Design implications of this finding might entail offering a level of customization to the patient portal. For example, users could select frequently used “modules” to highlight on the front page of the portal. Diabetes patients might prioritize modules for (1) alerts about standing orders for blood tests coming up, to keep the patient on schedule; and (2) medications management view. A caregiver of a child with asthma may prioritize (1) the asthma management plan assigned by the doctor, which assigns medication instructions to control asthma symptoms; and (2) archived information, such as summaries of emergency room visits, that the patient could easily share with the doctor to follow up with emergent asthma attacks. Allowing all users to prioritize functions of the patient portal that they use most would maximize flexibility of the patient portal.

**Limitations**

This research was conducted with patients in a single regional health-care system, with participants who had familiarity with the use of patient portal technology. We suggest future work related to patient portal redesign or implementation should incorporate contextual and social aspects of in situ tool use\(^\text{35}\), which our lab-based paper prototype testing did not include.

**Conclusion**

Health management tasks are particularly important and time-consuming for patients and caregivers who are managing a chronic illness. To support these tasks, we designed and tested three prototypes for a new patient portal that incorporates patient-centered reminders and notifications. The information we elicited from prototype testing with our participants helped us to identify participant attitudes, beliefs, and behavior that affect design dimensions for patient-centered reminders and notifications to manage health tasks. First, patient portal design should incorporate features to amplify positive aspects of the clinician relationship, which will benefit those users who feel a personal connection at the clinic and can carry over to the feelings of responsibility and accomplishment related to small, everyday tasks. Second, clinicians should be provided with an easy way to gauge interest in portal use, and encourage patients and caregivers to use the portal to bridge the information worlds of the clinic and the home, where many complicated care tasks occur. Finally, customization of the patient portal modules can provide a flexible platform that supports the roles of both patients and caregivers, offering better solutions for both. These design implications contribute evidence-based insight as to the needs of patient and caregiver stakeholders in patient portal tools. This study gives rich user feedback to inform design opportunities in patient portal systems that can effectively support the sometimes overwhelming tasks of patients and caregivers who manage chronic illness every day.

Modeling the Temporal Evolution of Postoperative Complications

Shara I. Feld, PhD¹, Alexander G. Cobian, MS²,³, Sarah E. Tevis, MD¹, Gregory D. Kennedy, MD PhD¹, Mark W. Craven, PhD³,²

University of Wisconsin-Madison

Abstract

Post-operative complications have a significant impact on patient morbidity and mortality; these impacts are exacerbated when patients experience multiple complications. However, the task of modeling the temporal sequencing of complications has not been previously addressed. We present an approach based on Markov chain models for characterizing the temporal evolution of post-operative complications represented in the American College of Surgeons National Surgery Quality Improvement Program database. Our work demonstrates that the models have significant predictive value. In particular, an inhomogenous Markov chain model effectively predicts the development of serious complications (coma longer than a day, cardiac arrest, myocardial infarction, septic shock, renal failure, pneumonia) and interventional complications (unplanned re-intubation, longer than 2 days on a ventilator and bleeding transfusion).

Introduction

Patients who suffer from post-operative complications have higher rates of post-operative morbidity and mortality, resulting in longer hospital stays, higher rates of readmission and higher cost of care [1-8]. While many studies have evaluated pre-operative predictors of complication development [1, 9-16], recent work has shown that we can extend our analysis to post-operative predictors. Tevis et al. [17] found that there are relationships in the occurrence of post-operative complications. Wakeam et al. [18] found that there are associations between complication timing and mortality. However, prior research has not investigated how sequences of multiple complications develop given post-operative events. Tevis et al. [17] employed a Bayesian network approach that revealed dependencies among multiple complications, but did not account for the ordering or timing of post-operative complications. The analysis of Wakeam et al. [18] used post-operative complications to predict mortality, but did not extend to analyzing cascades of complications.

The goal of this study was to assess whether we could accurately model the temporal evolution of postoperative complications. Specifically, we evaluated how well the likelihood and timing of complication development given prior post-operative complications could be represented using Markov chain models, a well established class of models for characterizing temporal and sequential data [19].

Methods

Complication data

The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database includes 30-day postoperative outcomes for patients who underwent major inpatient and outpatient surgical procedures [20]. ACS NSQIP data are collected by a trained surgical clinical reviewer at each site, and subsequently audited for reliability by the NSQIP program. This study includes inpatient and outpatient surgical cases from over 435 institutions during the years 2005 to 2013.

The complications analyzed were the 21 reported ACS NSQIP complications occurring within 30 days after the operation and post-operative mortality (Table 1). Each recorded complication was annotated with the number of days after the operation that the complication was first diagnosed. If a complication was diagnosed multiple times post-operatively, only the first date of diagnosis was recorded. Complications included infectious types (superficial surgical site infection (SSI), deep SSI, organ space SSI, wound disruption, urinary tract infection, sepsis and septic shock), physiologic complications (peripheral nerve injury, pneumonia, deep vein thrombosis or thrombophlebitis, pulmonary embolism, renal insufficiency, renal failure, stroke or cardiovascular incident, myocardial infarction,
cardiac arrest, or coma longer than 24 hours), and interventional complications (unplanned intubation, cumulative ventilator-assisted respiration greater than 48 hours, bleeding transfusion up to 72 hours post-operatively, and graft failure requiring intervention).

Given the de-identified nature of the ACS NSQIP data, work with this dataset has been deemed exempt by the University of Wisconsin Health Sciences IRB.

Markov models

Markov models allow us to represent the temporal evolution of complications as patients progress through series of health states [19]. We constructed discrete-time Markov chain models to characterize the development of subsequent complications given knowledge of the complications a patient has already experienced. To develop our Markov models, we defined states that represent the patients’ health condition and estimated the transition probabilities of changing from each state to another. The outcomes that we predicted were the occurrence of each of the 21 post-operative complications and mortality. The time scales of the data and model are one day steps, from the day of surgery to 30 days post-operation.
Figure 1. (a) The state representation used by our Markov model. The top part of the panel shows the new complications that are recorded on each of three days in a given patient’s record. The bottom part of the panel shows the vector of binary variables representing the patient’s state on each day. (b) The graphical model representation of our Markov model. Each node corresponds to a random variable representing the status of a given complication on a specific day. Each dashed box delineates the set of variables that represent the state for a given day. The edges impinging on each node represent the potential dependencies of the corresponding variable on the complications from the previous day.

We define a patient’s health state at a given point in time by the set of complications they have experienced prior to this point in time. With this definition, we represent a state using a vector of binary variables, one per complication, where a given variable is set to 1 if the corresponding complication has already occurred, and is set to 0 otherwise. An example using this representation is shown in Figure 1(a). The NSQIP data does not specify the durations of complications or multiple occurrences of a given complication in a patient’s record. Therefore, we designed our state representation to indicate, for a given day, all of the complications that have occurred in the patient up to that day.

Since there are 21 complications (excluding death), there are $2^{21}$ possible states. We use a factored state and transition representation for our models, as shown in Figure 1(b), and thus our models can also be considered dynamic Bayesian networks. Let $C_t$ represent the vector of random variables characterizing the complication state at time $t$, $C_t[i]$ indicate the variable for the $i^{th}$ complication at time $t$, and $c_t$ and $c_t[i]$ represent the assignment of values to the vector and to the $i^{th}$ variable, respectively.\footnote{We use bold symbols to indicate vectors, uppercase letters to indicate random variables, and lowercase letters to indicate values of random variables.}

We consider two different representations for state transitions. In both of them, the probability of a complication occurring at time $t$ is conditionally independent of other complications occurring at time $t$, given the previous state, $c_{t-1}$:

$$\Pr(c_t | c_{t-1}) = \prod_i \Pr(c_t[i] | c_{t-1}).$$

A patient’s history can be viewed as a sequence of state transitions. Since the NSQIP data records events at the time granularity of days, the state transitions in our model occur on a daily basis. In our first representation for state transitions, we use a set of logistic regression models as follows. The probability of the $i^{th}$ complication variable being 1 at time $t$ is given by:
\[
\Pr(C_t[i] = 1|e_{t-1}) = \begin{cases} 
1 & \text{if } C_{t-1}[i] = 1 \\
 \frac{p^{(i)}(e_{t-1})}{1 + e^{-(w^{(i)}e_{t-1} + b^{(i)})}} & \text{otherwise}
\end{cases}
\]

where

\[
p^{(i)}(e_{t-1}) = \frac{1}{1 + e^{-(w^{(i)}e_{t-1} + b^{(i)})}}.
\]

That is, if the variable \(C_{t-1}[i]\) is set to 1, indicating that the \(i^{th}\) complication had occurred by the previous time step, then it must remain in this state. Otherwise a logistic regression model is used to predict the probability of the complication occurring at time \(t\). The logistic regression model uses the state from the previous day, \(e_{t-1}\), for its predictor variables. Note that the model is specific for the \(i^{th}\) complication and hence we use the superscript \((i)\) for the parameters of the model, \(w^{(i)}\) and \(b^{(i)}\). The parameters in the logistic regression models were estimated using the maximum likelihood estimation algorithm implemented in the Matlab 2015a library \textit{glmfit} [21].

A second representation for state transitions we consider is based on the Noisy-Or function using the method of Onisko et al. [22]:

\[
\Pr(C_t[i] = 1|e_{t-1}) = \begin{cases} 
1 & \text{if } C_{t-1}[i] = 1 \\
1 - \prod_{j\neq i, C_{t-1}[j]=1} \left(1 - \frac{1 - p^{(j)}(e_{t-1})}{1 - p^{(i)}(e_{t-1})}\right) & \text{otherwise}
\end{cases}
\]

where the product in the second case ranges over the complications that have been set to 1 on the previous day, and \(p^{(i,0)}\) and \(p^{(i,1)}\) are defined as follows:

\[
p^{(i,0)} = \Pr(C_t[i] = 1|C_{t-1}[0] = 0, \ldots C_{t-1}[20] = 0) \quad \text{and} \quad p^{(i,1)} = \Pr(C_t[i] = 1|C_{t-1}[0] = 0, \ldots C_{t-1}[j] = 1, \ldots C_{t-1}[20] = 0).
\]

In other words, \(p^{(i,0)}\) represents the probability of the \(i^{th}\) complication occurring on day \(t\), given that no other complications have yet occurred, and \(p^{(i,1)}\) represents the probability of the \(i^{th}\) complication occurring on day \(t\) given that only the \(j^{th}\) complication has previously occurred.

In both the logistic regression and Noisy-Or linking functions, the time scales of the data and model are one-day steps, from the day of surgery to 30 days post-operatively. The status of complications that a patient experienced through time is represented by linking the transition functions for the likelihood of complication development over the 30-day post-operative period [19].

For both the logistic regression and Noisy-Or approaches, we consider homogenous and inhomogenous variants of the models. In the homogenous case, the data from all days is pooled and then used to infer model parameters that are invariant throughout the 30-day post-operative time period. For the inhomogenous models, we partition the data into time-based subsets and then learn model parameters that are specific to given post-operative time periods. The partitioning is done such that each period contains approximately 20% of the complications that occurred across the population. These time periods were the day of surgery, 1-3 days after surgery, 3-8 days after surgery, 8-15 days after surgery and 15-30 days after surgery.

**Results**

**Model evaluation methodology**

To evaluate the extent to which our models have captured the temporal evolution and dependencies among complications, we assessed how well they are able to predict a patient’s health state one day in advance given the post-operative complications the patient has experienced up to that point. We did this using a 10-fold cross validation methodology. The data were stratified by patient (i.e., a given patient’s health history was either entirely in the training set or entirely in the test set) and randomly partitioned. The predictions for each test set were made using models learned from the corresponding training set. The test set predictions were then pooled for a cumulative evaluation using ROC curves.
Model predictive value

The ROC curves in Figure 2 display predictive accuracy for the homogenous and the inhomogenous models that use logistic regression to represent transition probabilities. Each curve represents the true positive rate and false positive rate of the model predicting all cases (day 0 predicting day 1, day 1 predicting day 2, up to day 29 predicting day 30) for a specific complication.

The inhomogenous models had significant predictive value for almost all complications. The models were best at predicting 30-day mortality, serious complications (coma longer than a day, cardiac arrest, MI, septic shock, renal failure, pneumonia) and interventional complications (unplanned re-intubation, longer than 2 days on a ventilator and bleeding transfusion). The complications in this set were all predicted with an area under the curve greater than 0.85. The other complications are more difficult to predict because they are likely to occur in isolation, and are not as dependent on prior complications. For example, surgical site infections are dependent on wound closure and post-operative wound management, which are not characterized in the NSQIP dataset, rather than other complications.

![Figure 2. ROC curves for the logistic regression-based models showing the true positive rate (TPR) against the false positive rate (FPR). Solid lines show predictive accuracy for the inhomogenous models, heavy dashed lines represent the homogenous models, and the light dashed lines represent the expected curves for random guessing (i.e., no predictive value).](image)

Comparison of homogenous and inhomogenous models

As indicated in Figure 2, the inhomogenous models had superior predictive accuracy to the homogenous models. For all complications, there was improved predictive accuracy in using the homogenous models, and for some, the improvement was dramatic. This result was true for both the models that used logistic regression and those that used Noisy-Or to represent transition probabilities. This result indicates that the transition probabilities and
dependencies vary according to the time elapsed since surgery. Not only does sequencing matter when predicting whether a complication is likely to occur, but how far out the patient is from surgery.

The improvement in predictive accuracy that comes from using inhomogenous models indicates that modeling sequences of post-operative complications requires incorporating multiple factors that influence complication development. Some complications depend on specific timing of occurrence – for example, bleeding transfusions are by design only recorded within the first 72 hours. Other complications may occur in isolation or not in a predictive fashion, such as superficial SSI. In other cases, the inhomogenous model better characterizes transition probabilities that vary throughout the post-operative period.

Comparison of logistic regression and Noisy-or models

The predictive accuracy of the logistic regression and Noisy-Or models was similar in both the inhomogenous and homogenous cases. Figure 3 shows a comparison of these two different approaches for representing transition probabilities. Each point in the figure represents a specific complication, and the coordinates of the point are given by the area under the ROC curves for the Noisy-Or and logistic-regression models. The tight clustering of the points along the diagonal indicates that the two approaches have similar predictive accuracies for every complication.

![Figure 3](image)

**Figure 3.** Scatterplots comparing area under the ROC curves for the logistic regression and Noisy-Or models. Each point represents the area under the ROC curves for a specific complication. Shown are the (a) homogenous comparison and (b) inhomogenous comparison.

How relationships between complications are highlighted

The models can be used to highlight the strength of relationships among the complications that may be anecdotaly understood but not formally measured. For example, the inhomogenous logistic regression model, as depicted in Figure 4, highlights that stroke/cardiovascular event, cardiac arrest, and prolonged period on the ventilator are most predictive for developing a coma. The inhomogenous model is able to parse out the temporal variation in the extent to which predictor complications contribute to the development of the dependent complications. The inhomogenous model further highlights how complications such as surgical site infections (SSI), that may have appeared non-contributory in the homogenous model, can serve as indicators for more serious future complications at different stages of the post-operative course.
Figure 4. Parameters for the logistic regression models that predict the occurrence of the complication, coma > 24 hours. Shown are the parameters for both the homogenous model (•) and the inhomogenous model (bars). In the inhomogenous model, there are separate parameters for each time period: days 0-1 post operation, days 1-3, days 3-8, days 8-15 and days 15-30.

Conclusion

Our empirical results tell us that Markov models can effectively represent risk for later complications depending on the complications a patient has already experienced. We found that complications that are strongly dependent on a given timing (such as bleeding transfusion), dependent on prior complications (such as mortality), or both are modeled well. Complications that occur in isolation and in a wide range of times (such as superficial surgical site infection) are modeled poorly. While Tevis et al. [17] demonstrated that there are relationships among which post-operative complications occur, the present work demonstrates that those relationships are often sequential and thus have prognostic power for assessing patient outcome. The models further indicate the extent to which complications are prognostic for the subsequent occurrence of dependent complications.

Developing the model required considering timing after surgery in addition to which predictive complications have occurred. Prior work indicates that Markov models work well in applications in which the timing of events is important, which is beneficial in medical decision making [19]. We found that an inhomogeneous model, in which dependencies are conditioned upon when the events occurred over the 30-day post-operative period, outperformed a homogenous model in terms of predictive accuracy. This supports prior work noting that complication occurrence after surgery varies depending on time after surgery [24].
The standardization and size of the ACS NSQIP database also strengthens our study. The data is collected in a prospective manner by trained surgical clinical reviewers, complications are strictly defined, and the national database has a large patient population which allows us to assess the temporal dependencies in the <5% of surgical patients included who developed multiple complications.

This study has limitations inherent to the dataset and to our Markov models. We were limited by the prevalence of complications. The dataset does not indicate the durations of complications, and it only includes the first date on which a complication is diagnosed even if the complication is experienced multiple times. Furthermore, the complication diagnosis data is recorded at a temporal resolution of one day, excluding modeling dependencies between same day complications.

The limitations of our models include their first-order nature and their inability to explicitly represent dependencies between complications co-occurring on the same day. We do not view the first limitation as significant given that our state representation encodes the history of complications experienced up to the given day. Our logistic regression versus Noisy-Or comparison suggests that the inability to represent dependencies between same-day complications does not significantly hinder predictive accuracy either. Although the logistic regression models cannot explicitly represent such dependencies, they are able to compensate for their effects somewhat. Our experiments demonstrated that the logistic regression models did not offer any predictive advantages over the Noisy-Or models which assume that there are no such dependencies. Our models could be extended in a number of ways in order to capture more information about the temporal evolution of complications. Some of the more promising extensions would be to use explicit duration modeling, and to incorporate other NSQIP variables (demographics, surgical procedures, comorbidities, etc.) in the models.

Abstract

Abbreviation disambiguation in clinical texts is a problem handled well by fully supervised machine learning methods. Acquiring training data, however, is expensive and would be impractical for large numbers of abbreviations in specialized corpora. An alternative is a semi-supervised approach, in which training data are automatically generated by substituting long forms in natural text with their corresponding abbreviations. Most prior implementations of this method either focus on very few abbreviations or do not test on real-world data. We present a realistic use case by testing several semi-supervised classification algorithms on a large hand-annotated medical record of occurrences of 74 ambiguous abbreviations. Despite notable differences between training and test corpora, classifiers achieve up to 90% accuracy. Our tests demonstrate that semi-supervised abbreviation disambiguation is a viable and extensible option for medical NLP systems.

Introduction

The frequent use of abbreviations in clinical texts is a major challenge for natural language processing (NLP) systems. Medical abbreviations are especially challenging because they tend to be highly ambiguous: a 2001 survey reports that nearly a third of shorter abbreviations catalogued in the Unified Medical Language System (UMLS) are ambiguous;¹ a later study reveals that even the UMLS sense inventory provides spotty coverage of all possible abbreviation senses.² The problem is even worse in clinical notes created for patient care, as opposed to other biomedical texts mostly derived from peer-reviewed literature, due to issues ranging from higher word ambiguity³ to mistakes in spelling and dictation.⁴ Even detecting which words are abbreviations is not a trivial task, and modern clinical NLP systems have much room for improvement in this area.⁵

Resolving ambiguities in clinical texts is a major concern for improving medical information retrieval outcomes.⁶,⁷ As such, an active area of research in medical NLP is in the normalization of abbreviations.⁸ For ambiguous abbreviations, this is generally treated as a special case of the word sense disambiguation (WSD) problem: determining the sense of a single string that may have multiple distinct semantic interpretations.⁹,¹⁰ Supervised machine learning approaches to abbreviation disambiguation based on WSD techniques have been generally successful.¹¹, ¹² However, most prior studies in this domain have evaluated only a handful of abbreviations; the generalizability of these results to more realistic use cases, with hundreds or thousands of abbreviations, is limited.

Fully supervised methods are also subject to the limitation that they require training data that is slow and expensive to obtain. Furthermore, to keep up with the rapid and ongoing proliferation of clinical abbreviations, such data would require constant maintenance. To obviate the need for labeled data, some researchers have proposed unsupervised¹³ or knowledge-based¹⁴ strategies to the disambiguation problem. Still, published research in this area generally focuses on fewer than 20 abbreviations.

Another possibility is a semi-supervised (or “distantly supervised”) approach, which requires some attention to data collection but not nearly the commitment necessary for fully hand-annotated data. Normalizing abbreviations differs from other WSD problems in that the senses (i.e., long forms) have distinct string realizations. This property can be exploited to generate examples of virtual occurrences of an abbreviation by targeting its various long forms in a search of unlabeled text. This general approach has been developed for biomedical texts¹⁵ and clinical notes,¹⁰,¹⁶ with reported accuracy approaching 90%. Stevenson et al. apply a similar corpus generation process to Medline abstracts that have abbreviations co-occurring locally with their long forms.¹¹ (Note that these convenient co-occurrences are rare for clinical notes.) They employ a battery of features to achieve 99% accuracy for 20 abbreviations.

The main objective of the present study was to conduct a large-scale test of the semi-supervised method just described. Ours differs from prior research in two important ways. First, training and test data are drawn from
different corpora. This point is key, as training and testing on homogeneous data is not a realistic evaluation of an NLP application for many cases—versatile clinical NLP systems should be useful for a wide variety of texts, not just those similar to data on which its models were trained. Other studies on semi-supervised biomedical acronym normalization which train and test on different corpora are by Pakhomov et al., who disambiguate 8 acronyms with up to 67.8% accuracy,16 and Xu et al., who disambiguate 13 abbreviations from typed hospital admission notes with up to 87.5% accuracy.12

Second, we test a wider range of abbreviations than has been considered previously: 74 ambiguous abbreviations frequent in clinical texts but not specific to any particular field of medicine. The only other published studies that test a comparable number all focus on the same abbreviations that we do (or a subset of them).17–19 These studies, however, rely on fully supervised cross-validation on a single corpus rather than separately generated training and test sets. By applying a semi-supervised approach to a wide scope of abbreviations in a more realistic test case, we present the most extensible method to date for disambiguating abbreviations in clinical texts. (The test set we use actually comprises 74 initialisms, commonly referred to in the literature as “acronyms,” which are a sub-type of abbreviation that involves the concatenation of initial letters of words in a phrase. We continue to use the term “abbreviation” because our methods should be equally applicable to acronyms and to other abbreviations.)

The semi-supervised method is appealing because it should maintain the high accuracy and efficiency of fully supervised approaches without requiring expensive human tagging of corpora. It does depend, however, upon an assumption that the distributions of an abbreviation and of its long forms are similar. This assumption seems intuitively well supported, but at the same time it is easy to imagine reasons why distributions might differ—abbreviated forms may tend to occur more often in notes more reliant on abbreviations, or a writer may consciously avoid abbreviations in contexts where they would be too opaque or unusual.

That said, it is not evident a priori that these weaknesses in the assumption lead to unsatisfactory results. The present study is an empirical evaluation of the semi-supervised method, simulating a real-world use case: training a normalization system on machine-annotated data and testing it on natural occurrences of a wide range of abbreviations.

Methods

Corpora and sense inventory

Two corpora were used in this study. The first was taken from the Clinical Abbreviation Sense Inventory.20 This publicly available data set (“CASI”) lists 440 common clinical abbreviations along with their long forms, mappings to medical concepts, and other information. Most of these abbreviations were found to have a dominant sense accounting for 95% or more of 500 randomly sampled occurrences; for those 74 that do not, CASI provides anonymized plaintext data and manually annotated senses for 500 samples of each (37,000 total). These samples, minus the 223 marked as having ‘unsure sense’, constitute Corpus A.

Corpus B was built by querying a large clinical data repository in the Fairview Health Services system (about 90 million notes) for long forms of these abbreviations using Elasticsearch. (All notes in the health record were searched, so this corpus contains results from many different types of documents across numerous specialties. We used definitions of notes as based off of the HL7-LOINC document ontology and as catalogued in our data repository.) In most cases, unmodified long forms themselves could serve as queries. A few, however, required slight adjustments. For example, searching for the long form ‘computed tomographic angiography’ returned very few results; the slightly modified (case-insensitive) query ‘ct angiography’ returned many more, while still being unambiguous. In another case, the expansion ‘gutta’ (for ‘GT’) was rare in the corpus (and ambiguous with a physician’s name), while the semantically equivalent ‘gtts’ was more common. Overall, we kept any modification of the searches to a minimum; queries were only altered if an informal examination of the search results showed them to be scant, overly repetitive, or obviously incorrect.

827,647 total notes were returned by queries across 207 different senses, with a maximum of 5,000 notes per sense. Samples were taken from the body text of these notes by identifying the long form in them and matching (greedily) any appearances of that form both preceded and followed by 40 to 100 characters. This step effectively excluded any examples with too little context, such as those from very short notes. Up to 8,000 samples were generated for each sense (allowing for multiple tokens of a sense per sample). In all, a total of 857,724 annotated virtual abbreviations were generated.
The sense inventory used to collect documents for Corpus B was built from CASI. 357 total senses are represented in the data set, although 150 are exceptionally rare (occurring as fewer than 5 of its abbreviation’s 500 samples) and were excluded; in all, these account for 0.6% of the total data. (Note that examples of these rare senses were retained in the test set and thus contributed to the errors of a model not trained on them.) The procedure for generating both corpora is visualized in Figure 1. Histograms showing the number of senses per abbreviation and the number of training samples per sense in Corpus B are given in Figure 2a and 2b, respectively.

**Word vectors**

Feature vectors for each instance of an abbreviation were calculated as simple co-occurrence counts within a window of text, a “bag-of-words” representation. Tokens were lemmatized, case was ignored, and numerals were collapsed into broad categories: single-digit integers, multi-digit integers, and decimals. By these criteria, Corpus A has 13,877 unique words, and Corpus B 72,514. (Note that Corpus A has been anonymized with generic strings whereas B has not, so names, addresses, etc. contribute to the latter’s word count.)
Although word order was not taken into account explicitly, counts were weighted to increase the contribution of words in closer context. Weights were computed by a sigmoid function $W(d)$ that decreases with the context token’s (always positive) distance $d$ in words from the token of interest:

$$W(d) = \frac{1}{1 + e^{a(d-r)}}$$

where $r$ is the number of words away at which weight drops to half and $a$ controls the steepness of the curve. Various parameters for the rate and point of falloff were tested; good values were found to be around $r = 9$ with a shallow falloff of $a = 0.3$. Words weighted at less than 0.25 (greater than 12 words away for these values) were not counted at all. This weighting maintains a minor effect of word order and was found to slightly improve classification accuracy overall. Beyond about 9 or 10 words, a larger window does not generally improve accuracy for this kind of task.\textsuperscript{17}

Researchers have suggested various other features to enhance supervised classification—salient N-grams,\textsuperscript{11} knowledge sources,\textsuperscript{14} neural word embeddings.\textsuperscript{19} The central question here, however, is not how best to tailor features to maximize performance; rather, we are concerned with whether the machine-annotated data can effectively serve as a training corpus given minimal assumptions and adjustments. Bag-of-words features are simple, general, and quite reliable, and they should give a fair indication of whether it is worth the effort to further tune models and features for these data.

**Machine learning algorithms**

Several well-known classification algorithms were implemented, all using the features described above:

- **Naïve Bayes (NB):** A single Gaussian was fitted for each feature across all examples of a given class (sense). Class priors were not considered, as these would favor more frequent classes in the training data, and the relative frequencies for long forms may not be representative of sense frequencies for abbreviations—recall the earlier discussion that some senses are more likely to be abbreviated than others. Hypotheses at test time were chosen by maximizing likelihood, with consideration only of the non-zero entries in the test vector. Given the data’s high dimensionality and natural-language origins, many probabilities at test time come out at or near zero, so natural log probabilities were kept to a minimum of $-100$ to prevent a single unusual or unseen word from dooming a candidate altogether. A separate model was trained for each of the 74 acronyms.

- **Multinomial logistic regression (LR):** A classifier was trained for every abbreviation. The intercept term typical of logistic regression was not used, for the same reason class priors were not used for NB. Models were trained by 100 iterations of gradient descent, which usually converged in 3 to 10 iterations. Regularization generally did not improve results and was not used in the reported tests.

- **Support vector machine (SVM):** This classifier was identical to LR but with a standard hinge loss function ($\varepsilon = 1$) rather than log loss.

- **Cosine similarity (COS):** Test items were classified by maximizing the cosine of the angle between the test context vector and a normalized vector representing the centroid of all training items of each sense. Two other adjustments were made to these centroid sense vectors before normalization. First, all values were compressed via a square root, which effectively favors less common words and therefore diverse lexical contexts (note that this would have little effect for other classifiers, which do not average training examples). Second, words in training and testing context vectors were weighted by their inverse document frequency (IDF). The cosine similarity metric is not a discriminative or maximum-likelihood strategy, so it is essential to reduce the impact of words with low predictive power.

**Other features: hyperdimensional indexing**

Another method that has received some recent attention has been the use of high-dimensional vectors to represent words. Rather than unitary representation as a single dimension in a context vector, word vectors themselves are “hyperdimensional,” having on the order of a few thousand dimensions. (Note that word vectors are actually of lower dimensionality than the “one-hot” vectors used for a traditional word vector space, but that these representations depend on encoding several of these dimensions, whereas the one-hot vectors are predictable from the vocabulary.) Context vectors are represented by “bundling” word vectors, typically through a sum or similar operation. Word vectors are not orthogonal as unitary word vectors in a traditional vector space are, but are all
nearly orthogonal due to their high dimensionality. Context vectors are equidimensional with word vectors, so they are actually shorter (but less sparse) than the context vectors considered for the other classifiers. Two hyperdimensional approaches were tested:

- Random indexing (RI): Each unique word is represented as a ternary vector of 1,800 elements, with a random four values set to 1, another random four to –1, and the rest to 0. These are the same parameters described by Kanerva et al. Other hyperparameter values were explored but did not significantly improve classification. Context vectors are created by summing word vectors within the context window (9 tokens on either side) subject to the same IDF weighting used for the vector space model. Senses were chosen by the same similarity criterion as the COS classifier described above. In the clinical domain, RI has been applied effectively towards capturing distributional similarity between long forms and their abbreviations.

- Binary spatter code (BSC): Each unique word is represented by a 10,000-dimensional binary vector, with all values randomly assigned. During training, context vectors are calculated not for the senses themselves, but for all words within 9 tokens of an abbreviation, by summing together vectors that are the “product” (bitwise XOR) of an abbreviation and its labeled sense. Word frequency is accounted for in these sums by entropy weighting, and the final vector chosen by voting on the weighted counts of ones and zeros in each dimension. For testing, contexts are “divided” (XOR again) by the abbreviation vector to recover a context vector correlated with the most likely sense. The implementation hews very closely to the description given by Berster et al.; see also Kanerva for a theoretical discussion and Moon et al. for its suitability to abbreviation normalization.

Test conditions

Recall that this study considers two corpora derived from clinical texts—Corpus A, smaller and hand annotated; and Corpus B, larger and automatically annotated. We performed tests with each as the training set and each as the test set. Whenever a single corpus was used for both training and test, 10-fold cross-validation was performed.

The original aim of the study was to evaluate an abbreviation normalizer that is not dependent on fully supervised data. Corpus B can be created cheaply, while A contains actual occurrences of abbreviations; thus, training on B and testing on A is the intended use case and gives the best indication of performance on real-world clinical data.

To mitigate problems related to overdeveloping to this use case, we halved Corpus A into development and validation sets. Examples were split by stratified random sampling: for every sense of every abbreviation, half of the examples selected at random went to each set, with the validation set receiving the remainder for odd counts. All refinements of the models were performed according to performance on the development set (18,278 samples total), and all statistics reported in this paper are from the validation set (18,499 samples total). For conditions other than training on B and testing on A, this split was ignored and Corpus A was used in its entirety.

We have made code for the experiments in this study available online (https://github.com/gpfinley/towards_comprehensive). Corpus A is freely available; however, Corpus B contains protected health information and cannot be publicly shared.

Results & discussion

Classification accuracy

The results for classifiers tested on Corpus A are reported in Table 1. Scores reported in the left column are results of 10-fold cross-validation, applied in a classically supervised manner to Corpus A. The right column of the table represents the intended use case of the semi-supervised method.

Baseline accuracy for tests on Corpus A is defined as the majority sense—the score obtained by simply guessing the most common sense for each abbreviation. Recall that no classifiers tested in this study explicitly take sense frequency into account.

The results of cross-validation on Corpus A confirm that traditionally supervised methods are highly accurate. Hyperdimensional approaches were slightly less accurate but still reasonable. For the semi-supervised case, however, all classifiers suffered somewhat. The drop in performance, as compared to the fully supervised cross-validation results, was modest for classifiers operating on word count vectors, with COS losing only 6.1% accuracy.
Table 1. Classification accuracy for classifiers tested on the hand-annotated Corpus A. Scores in the left column are averages of 10-fold cross-validation. Baseline is the average majority sense score for all abbreviations.

Recall the assumption that abbreviations and their long forms share the same distribution in text. Given that this assumption is certainly not guaranteed, it can be said that LR, SVM, and especially COS perform fairly well to any variation introduced by training on long forms and testing on short forms. Corpus B was built with very light supervision, so other sources of noise probably also contribute to the drop in accuracy.

The hyperdimensional classifiers, on the other hand, showed a sharper drop in performance, up to 17.4%. Lexical differences between the two corpora may be responsible: high-dimensional word vectors are not perfectly orthogonal, causing some overlap in context vectors that would be difficult to account for if some words are present in one corpus but not another. Alternatively, it may be that hyperdimensional context vectors are especially sensitive to other differences between corpora that are unimportant for abbreviation disambiguation.

Whatever the explanation, it is clear that the RI and BSC algorithms suffer more from using machine-annotated training data than those classifiers based on the vector space model. Hyperdimensional approaches certainly have some advantages for representing lexical semantics in NLP, such as compactness and flexibility, but they appear ill suited to the task here (especially because maintaining context vectors for abbreviation senses requires less storage than for an entire vocabulary). This result is especially noteworthy given the excellent results reported for BSC in fully supervised abbreviation disambiguation by Moon et al.\textsuperscript{18}

The same classifiers were also evaluated using Corpus B as a test set, with results shown in Table 2. Note that this is a highly artificial case, as the notes used to derive Corpus B contain the long forms rather than ambiguous abbreviations. Note also that a majority-sense baseline is less meaningful for Corpus B (it would be 54.6%), which targeted the long forms directly rather than sampling actual occurrences of the abbreviation, and thus is not thought to be representative of actual sense frequency.

Fully supervised cross-validation was even better for Corpus B than Corpus A, a fact which may be due to the sheer size of Corpus B, the frequent use of boilerplate language in the source notes, or even altogether redundant notes, which were not screened out when searching the database.

In the reverse case, training on Corpus A and testing on B, no classifier performed exceptionally well (the COS classifier achieves the highest accuracy with 80.4%). Such a condition—normalizing virtual abbreviations in texts originally lacking them—is unlikely to arise in practical use. However, it may speak to fundamental differences between the corpora. While it is true that Corpus B is much larger, it is unlikely that this discrepancy alone leads to poor performance, given the finding by Moon et al.\textsuperscript{17} that a training set a fraction of the size of Corpus A can still give decent results for abbreviation normalization. A more likely explanation is that Corpus A is simply less general and diversified than B: data in Corpus A are primarily verbally dictated and transcribed, whereas Corpus B contains notes created through dictation as well as a variety of combinations of preformed templates, macros, typing, and voice recognition software. Variation inherent to Corpus A is present in B, but not vice-versa. (Note also that the impact of domain transfer may be overstated in these results because we have not controlled for the differences between hand- and machine-labeled annotations; i.e., instances of abbreviations in Corpus A are not found using semi-supervised methods.)

In terms of practical application, the performance discrepancy between the two experiments emphasizes the importance of using well-diversified data to train robust WSD systems. The semi-supervised approach, in conjunction with access to a large database of clinical notes, handles this with ease.

**Error analysis**

We also investigated several of the abbreviations that were responsible for the accuracy lost between the fully supervised and semi-supervised conditions (i.e., the two columns of Table 1). Our focus is specifically on the COS classifier, as it had the best performance. All abbreviations with an accuracy differential between the two tasks of at least ten percentage points are shown in Table 3.

**Table 3.** Differences in the accuracy of the COS classifier for the semi- and fully supervised cases. Only abbreviations with a performance differential of at least 10 percentage points are shown. Sense counts exclude very rare senses.

</table>
For most of these abbreviations, it is not immediately evident why the semi-supervised classifier performs poorly. For a handful, though, some educated guesses can be made:

- **MOM**: Nearly all of the errors on this abbreviation were misidentifying the sense ‘multiples of median’ as ‘milk of magnesia’. The former long form was difficult to target in the notes corpus, as it is usually abbreviated, so there were few training examples for what happened to be the most common sense of ‘MOM’.

- **T1**: ‘thoracic (level) 1’ was frequently misidentified as ‘T1 (MRI)’, which was difficult to target as a long form. We ultimately designed the query for the latter to match ‘T1’ in close context with ‘MRI’, and it appears to have erroneously matched several uses that refer to the first thoracic vertebra in an MRI context.

- **PAC**: ‘physician assistant certification’ was often missed. This sense almost always follows a name, and a key difference between Corpus A and Corpus B is that the former has had all names collapsed as part of de-identification.

- **IT**: The pronoun ‘it’ was frequently identified as an abbreviation. The contexts for ‘it’ are exceptionally diverse, so it may have been difficult to motivate ‘it’ over other hypotheses. These errors could easily be sidestepped if tokens were tagged for part of speech, as most medical NLP systems do, by assuming that pronouns are not abbreviations.

It is fair to say that certain senses of these abbreviations are represented in Corpus B differently from in A. Some differences arise from terms that rarely appear as long forms (e.g., ‘multiples of median’), whereas others may reflect difficulties inherent to the semi-supervised approach (‘T1’, ‘PAC’).

Some errors, particularly in this latter category, could be substantially reduced with more attention paid to the searches used to retrieve data. The intent for this project was specifically not to do so; the goal was to determine how well minimally managed data collection would work to train machine learning models. The results obtained here for the semi-supervised case should be considered a conservative estimate of performance, and more systematic attention to queries will likely increase accuracy further.

**Extending to other abbreviations**

Our test set encompasses hundreds of senses from 74 unique abbreviations. If a system were required to only account for these 74, then a fully supervised approach might be the best recommendation. Of course, this is but a fraction of known medical abbreviations. Though our coverage is still incomplete, the semi-supervised methods that we validate here are extensible to other abbreviations and their known senses. More comprehensive sense inventories could be built either from existing medical knowledge sources, such as the SPECIALIST Lexicon, or by using unsupervised machine learning methods, such as the clustering approach proposed by Xu et al.

Evaluating the accuracy beyond these 74 is difficult without acquiring more hand-annotated test data. Nevertheless, there is no reason to believe that other abbreviations should be less suitable for the semi-supervised approach. Our tests are also rather conservative, in both the minimal treatment of database queries and the use of very general machine learning methods.

Generally speaking, better performance on primary NLP tasks such as WSD should improve outcomes in secondary tasks. While an in-depth discussion of WSD applications in clinical NLP is beyond the scope of the present paper, we would like to note briefly that the ability to identify context-appropriate senses of ambiguous medical terms, abbreviations in particular, is fundamental to several higher-level NLP and information retrieval tasks, including accurate concept mapping to standardized vocabularies and conceptual indexing of electronic health records. Fully supervised systems are feasible only for a small and static set of ambiguous terms; however, clinical notes are “living” documents whose authors often do not follow conventions and abbreviate medical terms ad libitum for convenience and speed of documentation. Unsupervised or semi-supervised systems of the kind described in this paper offer the potential to keep up with these new ambiguous patterns dynamically introduced into clinical documentation. It may even be of interest to have models configured to text in specific clinical domains, especially if there are idiosyncrasies in documentation style between providers or specialties.

**Comparison to other published results**

A subset of the data from Corpus A was also used for training and testing by Moon et al. and Moon et al.; the former tested Naïve Bayes and SVM classifiers, the latter a hyperdimensional binary spatter approach. Figures reported previously in the current study are on all 74 abbreviations of the published data set. When testing on only
the 50 abbreviations considered in the other two papers, our accuracy results are extremely similar: marginally lower for BSC (our 92.9% versus their 93.5%) and higher for NB and SVM (our 94.2% and 96.2% versus their 93.7% and 93.9%).

Note that the above comparison is only for fully supervised methods. Comparisons to other tests of semi-supervised methods are difficult to make because most other studies draw training and test items from the same corpus, which simplifies the problem considerably. The closest comparison is with Xu et al.,12 who investigate 13 abbreviations that have at least one disease sense. They draw training data from dictated discharge summaries and test data from typed hospital admission notes. Their methods for generating the corpora are nearly identical to ours: training samples are built by targeting long forms directly in a text search, while test samples are manually annotated. As such, some performance comparisons can be reasonably made. Our peak performance at 90.0%, using only bag-of-words features (with some positional weighting), slightly exceeds theirs at 87.5%, which uses a combination of bag-of-words features, positional features, section headings, and sense frequency information. Xu et al.’s reliance on sense frequency in particular may introduce bias because frequencies are calculated off of the test corpus itself, albeit with unsupervised methods. (We use sense frequency only initially to determine if any senses are vanishingly rare, and not as a feature for classification.) Xu et al. report accuracy of 79.2% when not using sense frequency.

**Limitations**

There are a few limitations to this study that should be considered. First, we do rely somewhat on sense frequency in Corpus A to exclude rare senses (less than 1% of a given abbreviation’s occurrences) from consideration. Including these senses would have required the acquisition of much more training data and would probably have had some negative impact on accuracy. Some degree of medical expertise would be helpful to determine which senses are very rare.

Second, several of the database queries that we perform do require some attention and modification. The amount of labor is significantly less than that required for fully supervised labeling of examples, and it does not scale with the size of the data set. Nevertheless, queries optimized for one database and search protocol might not transfer well to others.

Finally, implementing the semi-supervised method with clinical notes as training data requires access to an appropriately large database, which many members of the larger research community do not have. Sharing models trained on clinical note data, such as the ones in this study, is difficult due to confidentiality concerns and would require removal of potentially identifying information.

**Future work**

Though our results show some success with semi-supervised methods, a more thorough investigation should be conducted to quantify the actual distributional similarity between abbreviations and their long forms and to understand how the assumption of similarity affects the results. Our own preliminary investigation has found that this assumption generally holds but is much more valid for some abbreviations than for others. Distributional similarity may depend on a number of factors—such as text domain, writing style, and accidental homonymy with other terms—and may interact with NLP task accuracy in interesting ways.

**Conclusion**

In this study we demonstrated the suitability of a semi-supervised approach for disambiguating abbreviations in clinical text on a large scale. Our tests covered more data and more distinct abbreviations than have been tested previously by this method, and our test conditions are a better representation of real-world problems. Generating machine-annotated training data requires little human supervision and can be easily extended to other abbreviations. Applying this method has the potential to significantly improve information retrieval outcomes for clinical text.

Abstract
In 2015, ICD-10-PCS replaced ICD-9-CM for coding medical procedures in the U.S. We explored two methods to automatically map SNOMED CT surgical procedures to ICD-10-PCS. First, we used MetaMap to lexically map ICD-10-PCS index terms to SNOMED CT. Second, we made use of the axial structure of ICD-10-PCS and aligned them to defining attributes in SNOMED CT. Lexical mapping produced 45% of correct maps and 44% of broader maps. Ontological mappings were 40% correct and 5% broader. Both correct and broader maps will be useful in assisting mappers to create the map. When the two mapping methods agreed, the accuracy increased to 93%. Reviewing the MetaMap generated body part mappings and using additional information in the SNOMED CT names and definitions can lead to better results for the ontological map.

Introduction
After being used for over 30 years for reimbursement and other purposes in the U.S., the ICD-9-CM coding system was finally replaced by ICD-10-CM in October 2015. While procedures were included as part of ICD-9-CM (volume 3), they are not part of ICD-10-CM. To replace the ICD-9-CM procedure codes, a brand-new coding system called ‘The International Classification of Diseases 10th Revision Procedure Coding System’ (ICD-10-PCS) was created by the U.S. Centers for Medicare and Medicaid Services (CMS) through a contract with 3M Health Information Systems1, 2. ICD-10-PCS is now used in the U.S. for the reporting of inpatient procedures. Other countries that have used ICD-9-CM are also transitioning to ICD-10-CM and ICD-10-PCS. Belgium made the transition in early 2015, and similar changes will happen in Spain and Portugal in the near future. In the realm of electronic health records (EHR), SNOMED CT has been designated as the clinical terminology standard. The Meaningful Use of EHR incentive of CMS specifies SNOMED CT as the terminology for the encoding of problem lists and procedures3. Many of the member countries of the International Health Terminology Standards Development Organisation (IHTSDO) are using, or have plans to use, SNOMED CT to document medical procedures. To facilitate the interoperability and integration of clinical and administrative data, it is evident that a map between SNOMED CT procedure codes and ICD-10-PCS will be necessary.

A project group was formed under IHTSDO in early 2015 with the goal to create a map between SNOMED CT and ICD-10-PCS.4 The group includes representatives from Belgium, Spain, Portugal and U.S., together with medical terminology and informatics vendors. The map is expected to provide the following benefits:

- Improve ICD-10-PCS coding efficiency, consistency and accuracy
- Promote re-use of clinical data for administrative, epidemiologic and statistical purposes
- Facilitate integration of clinical and administrative data to support data analytics

Another potential benefit of the map is related to CPT (Current Procedure Terminology), another procedure terminology maintained by the American Medical Association (AMA). CPT is used in the U.S. for the billing of medical procedures and physician services. There is ongoing negotiation between IHTSDO and AMA to build a map between CPT and SNOMED CT. If both CPT and ICD-10-PCS are linked to SNOMED CT, SNOMED CT can become a lingua franca to facilitate interoperability between the two procedure coding systems.
Among the topics discussed by the project group are automated ways to map between the two terminologies. It is understood that the mappings generated by algorithmic methods will still need human validation, but reviewing candidate maps that are of reasonably high accuracy is easier and faster than creating a map from scratch. Among the methods considered, the group identified lexical matching of the ICD-10-PCS index terms and ontological alignment as among the most promising approaches of automatic mapping. This paper describes the two mapping methods and results of their evaluation.

**Lexical Mapping**

Various methods of automatic mapping have been studied. Generally, these are either lexical or semantic methods. Lexical methods rely on terms matching, while semantic methods depend on relationships. The axial structure of ICD-10-PCS poses special challenges and opportunities to automatic mapping.

Traditional lexical mapping depends on finding matches between names of codes from two terminologies. String normalization can improve matching rate by reducing variations due to punctuations, upper/lower cases and lexical variants such as conjugation. However, direct lexical mapping between SNOMED CT and ICD-10-PCS names does not work well because of two reasons. First, ICD-10-PCS names are composite terms created by combining the values in the various axes, which are often different from terms used in clinical discourse. For example, the ICD-10-PCS name for laparoscopic appendectomy is *Resection (or Excision) of appendix, percutaneous endoscopic approach*, which will not match the common clinical term *Laparoscopic appendectomy* used in SNOMED CT. Second, there is mismatch in granularity between SNOMED CT and ICD-10-PCS. A full ICD-10-PCS code often includes information about approach (e.g., open approach, via natural or artificial opening), device (e.g., synthetic substitute, metallic joint prosthesis) and intent (e.g., diagnostic). In SNOMED CT, such additional information is only included in a minority of surgical procedures.

On the other hand, the ICD-10-PCS index is more promising for lexical matching because it contains many ‘clinician-friendly’ terms, such as:

![Image of ICD-10-PCS codes]

**Ontological mapping**

ICD-10-PCS is built on a multi-axial structure. The seven characters in the code correspond to the seven axes, each describing a particular aspect of the procedure.

This structure makes ICD-10-PCS expandable because new procedures can be easily incorporated as unique codes. In SNOMED CT, concepts are logically defined by attributes, which is in some ways similar to an axial structure. SNOMED CT descends from predecessors that are based on an axial structure. The use of attribute-value pairs in definitions liberates SNOMED CT from the limitations of earlier axis-based definitions, but the compositional nature
of the terminology remains.\textsuperscript{12,13} By aligning the ICD-10-PCS axes and SNOMED CT attributes, it is possible to identify equivalence between the two terminologies (table 1). For example, laparoscopic appendectomy is defined in SNOMED CT by the attribute-value pairs: Method = Excision, Procedure site - direct = Appendix structure and Using access device = Laparoscope. By aligning the three attributes Method, Procedure site - direct and Using access device to Root operation (axis-3), Body part (axis-4) and Approach (axis-5) respectively in ICD-10-PCS, and matching the values for these attributes/axes, one can find the equivalent ICD-10-PCS codes 0DTJ4ZZ or 0DBJ4ZZ (figure 1).

Figure 1. An example of ontological mapping, based on matching attributes and values at source and target systems. A source SNOMED CT procedure concept (1) has some attributes and values defining the concept; SNOMED CT attribute Method can be aligned to PCS target axis Operation (2); Procedure site - direct can be aligned with Body part(3); Using access device can be aligned to Approach (4)
Methods

Creating the lexical and ontological maps

From the 2016 version of the ICD-10-PCS Index xml file, we extracted main index terms and the associated codes listed with the main entries and sub-entries. We mapped the index terms to SNOMED CT concepts using NLM’s MetaMap program (2015 version).\textsuperscript{14, 15} Since the ICD-10-PCS index also included terms that were not procedures (e.g., body parts and devices), we restricted the SNOMED CT concepts to surgical procedures, defined as descendants of \textit{Surgical procedure} (387713003). We considered all ICD-10-PCS codes included under a main index term as candidate map targets for the SNOMED CT concept mapped to that index term.

For the ontological map, we first collected all the body parts values used in axis-4 of ICD-10-PCS. To this list, we added the inclusion terms, which were finer-grained terms included by the body part values (e.g., auditory ossicle includes incus, malleus and stapes), as defined by the ICD-10-PCS Definitions xml file. We mapped all body part terms to SNOMED CT using MetaMap, restricting the output to SNOMED CT body structure concepts. In this study, we focused on the ICD-10-PCS codes with excision or resection as the root operation. For all surgical procedures in SNOMED CT, we identified those with \textit{Method} = \textit{Excision}, and matched the \textit{Procedure site – direct} value to body part terms in ICD-10-PCS. If there was more than one relationship group in the SNOMED CT definition, the body part match had to come from the same group as the excision method. We considered all ICD-10-PCS codes with root operation of resection or excision, and a matching body part value, to be candidate map targets for that SNOMED CT procedure.

Evaluation of the maps

We selected a random sample of 100 concepts from each map, among which 50 concepts were common to both maps, to be reviewed by two of the authors (JX and FA). Each individual mapping was rated independently by each reviewer as:

\begin{itemize}
  \item a. Correct, no better codes available
  \item b. Too specific, should use more general codes
  \item c. Too broad, should use more specific codes
  \item d. Related somewhat, not broader/narrower, better codes available
  \item e. Target codes unrelated to source concept
\end{itemize}

If the mapping was correct, the reviewer would also determine if all correct map targets had been identified. For each incorrect mapping, the reviewer would assign a reason for failure. Results from the reviewers were compared, and the differences were discussed until a consensus was obtained. If a consensus could not be reached, a third reviewer (KWF) would cast the deciding vote.

Results

Lexical mapping

A total of 2,557 unique main entries were extracted from the ICD-10-PCS index. MetaMap mapped the index entries to 569 unique SNOMED CT surgical procedures, which were in turn mapped to 5,679 unique ICD-10-PCS codes. The majority of the SNOMED CT concepts (95\%) were mapped to four or less ICD-10-PCS codes, mostly at the 3 or 4 character level. A random subset of 100 SNOMED CT concepts was selected for review, excluding concepts with maps to over 20 ICD-10-PCS codes. In the review subset, 100 SNOMED CT concepts mapped to a total of 141 unique ICD-10-PCS codes (54 4-character and 87 3-character codes). Among them, 33 concepts mapped to only one ICD-10-PCS code, 52 concepts to two codes, with the maximum of nine codes (one concept). There were altogether 197 mappings (unique pairs of SNOMED CT and ICD-10-PCS codes) for review. Table 2 summarizes the review results for lexical mapping.
Table 2. Results of lexical mapping

Overall, 45% of the maps were correct. Among the incorrect maps, the following reasons of failure were identified:

1. **Index not sufficiently granular**

The index pointed to a 3- or 4-character code, but the correct map was more specific. For example, the index for choledochectomy led to 0F[B/T], but the correct map should be 0F[B/T]9.

2. **MetaMap error**

MetaMap mapped to the wrong SNOMED CT concept. For example, Osteoplasty was mapped to Bone fusion.

3. **ICD-10-PCS index entry was questionable**

In some cases, we think that the ICD-10-PCS index was not correct. For example, Colpocentesis pointed to drainage of the vagina (0U9G) while the correct map should be drainage of the cul-de-sac (0U9F). Another example is Gastroenterostomy, which pointed to either bypass or drainage. We think that drainage is not the correct root operation in this case since the procedure aims at altering the route of passage of the contents of the stomach to the small bowel, rather than letting out fluids from the stomach.

Looking at the results from the perspective of SNOMED CT concepts, 44% of the concepts had at least one correct map, and 96% had at least one correct or broader map. For those concepts with correct mappings, there were no missing map targets that the map failed to identify.
**Ontological mapping**

There were altogether 19,658 surgical procedures in SNOMED CT, and each procedure was defined by at least one *Method* attribute, whose value was restricted to the *Surgical action (129284003)* sub-hierarchy. *Excision* was the most common method, followed by *Surgical action* and *Repair* (table 3).

Table 3. Distribution of methods in the definitions of SNOMED CT surgical procedures

Ontological mapping found maps for 1,746 SNOMED CT surgical procedures, mapping to 689 unique ICD-10-PCS codes (all 4-character). 95% of the concepts were each mapped to 10 or less ICD-10-PCS codes. The review subset consisted of 100 randomly selected concepts, excluding those mapping to over 20 ICD-10-PCS codes. Altogether, the 100 concepts mapped to 237 unique ICD-10-PCS codes. Most of the concepts (82 concepts) mapped to one to four ICD-10-PCS codes. There were a total of 362 mappings for review. The results are summarized in table 4.

</tbody>
</table>

Table 4. Results of ontological mapping

Overall, 40% of the maps were correct. Among the incorrect maps, the following reasons of failure were revealed:

1. **Body part mismatch**

The map was incorrect due to the body part term in ICD-10-PCS being mapped to an incorrect body structure in SNOMED CT concept. In most cases, the SNOMED CT body structure was too broad, which resulted in the mapping of a broad SNOMED CT procedure to an overly-specific ICD-10-PCS code. For example, MetaMap mapped *Face artery, Thyroid artery* and *Hand artery* in ICD-10-PCS to *Arterial structure* in SNOMED CT. As a result, *Excision of artery* in SNOMED CT was mapped to *Excision of face artery, Excision of thyroid artery* and *Excision of hand artery* in ICD-10-PCS.
2. **Missing approach information**

In this study, we did not make use of information about surgical approach for mapping. Some SNOMED CT concepts containing approach information were therefore mapped to ICD-10-PCS codes that were too broad. For example, *Laparoscopic adrenalectomy* in SNOMED CT was mapped to excision/resection of left/right adrenal gland (e.g., 0GB2 – Excision of left adrenal gland), while the correct map target should include the approach (e.g., 0GB24 – Excision, left adrenal gland, percutaneous endoscopic approach). Other examples included *Transurethral prostatectomy* and *Thoracoscopic excision of neoplasm of pericardium*.

3. **Excision vs. resection**

While SNOMED CT considered excision and resection as synonymous, they were considered different root operations in ICD-10-PCS. In ICD-10-PCS, excision was defined as “the cutting out or off, without replacement, a portion of a body part”; while resection was “the cutting out or off, without replacement, all of a body part”. Generally, the correct mapping of a SNOMED CT excisional procedure should include both the excision and resection options in ICD-10-PCS. However, in cases where the SNOMED CT concept referred specifically to a partial or complete removal, a more specific ICD-10-PCS code should be used. For example, *Excision of focal lesion of larynx* should only map to *Excision of larynx (0CBS)* and not *Resection of larynx (0CTS)*. On the other hand, *Total thymectomy* should map to *Resection of thymus (07TM)* but not *Excision of thymus (07BM)*.

4. **Root operation mismatch**

In SNOMED CT, excision is used broadly to define procedures that involve removal or destruction of a body part, regardless of the method used. In ICD-10-PCS, the codes may be different depending on the method and what is being removed. For example, *Chemothalamectomy* was a destruction operation in ICD-10-PCS. *Vasectomy using silicon plug* would be coded as occlusion. *Removal of sequestra from bone* was an extirpation procedure.

5. **ICD-10-PCS inconsistent**

There was one case in which the reviewers found conflicting information in the ICD-10-PCS index. While the entry *Cricoidectomy* pointed to the excision of larynx, the entry for Cricoid cartilage suggested to use trachea as the body part.

6. **Unclassifiable**

There were three SNOMED CT concepts that we considered not classifiable in ICD-10-PCS. *Excision of accessory or ectopic lung tissue* was not classifiable because the location of the ectopic lung tissue was not known (could be in the thorax, abdomen or subcutaneous). *Excision of benign lesion of trunk* was not classifiable because trunk was not a defined body region in ICD-10-PCS. *Laparoscopy with excision of lesion* was too broad to be meaningfully classified.

Looking at the results from the perspective of SNOMED CT concepts, 68% of SNOMED CT concepts had at least one correct map, and 78% had at least one correct or broader map. Among the SNOMED CT concepts with correct maps, the map missed some target codes in four concepts because the SNOMED CT concept contained more than one procedure. One example is *Anterior resection of rectum with colostomy* in which the target code for colostomy was missed.
Comparing the two maps

Half of the reviewed concepts were common to both maps by design, so that we could compare the two mapping methods. For the 50 concepts in common, there were 101 lexical and 182 ontological mappings. We analyzed the mappings by whether they had: a. exact same target in the other map b. matching map target in the other map at the 3-character level c. no matching map targets (table 5).
