Table 5. Accuracy of maps for concepts common to both mapping methods (OM: ontological map, LM: lexical map)

Overall, the two reviewers agreed in 50% of the mappings after the first round of individual assessment. Most differences were resolved after discussion, and only 10% of mappings required the third reviewer’s vote to decide.

Discussion

Creating a map between two terminologies is labor intensive and time consuming. Mapping is not an exact science. Due to the differences in scope, granularity and organizing principles between the source and target terminologies, the mapping experts sometimes have to rely on their judgment, which can result in considerable variability. Common methods to ensure consistency include dual independent mapping (each map created by two mappers independently) and sequential review (review of some or all maps by a second mapper). Automated methods to identify candidate maps can help by suggesting map targets to mappers, which can save time and improve consistency. The candidate maps can also act as an independent source to corroborate the manually-created maps. Our previous study shows that algorithmically created maps can lead to considerable saving in mapping time.16

In our study, 45% of the maps generated by lexical mapping of the ICD-10-PCS index are correct. While this level of precision is not particularly impressive on its own, an additional 44% of the maps are broader maps at the 3- or 4-character level. In the use case of assisting manual mapping, the broader maps are also useful because they lead to the correct table, from which it is relatively simple to pick the correct target code. So we can say that 89% of the maps are useful in this context. Overall, 96% of SNOMED CT concepts which can be mapped in this way will have a useful map. However, the main drawback of this method is the limited coverage, as the index of ICD-10-PCS is not very extensive. Only 569 SNOMED CT surgical procedures can be mapped by this method.

On the other hand, ontological mapping can potentially cover many more SNOMED CT concepts. We are able to find maps for 46% (1,746 out of 3,788) of the SNOMED CT excision procedures. The precision of the ontological map (40%) is slightly lower than the lexical map, and the proportion of broader maps is also lower (5%). Overall, the ontological map is able to find at least one correct or broader map for 78% of SNOMED CT concepts.
Analyzing the reasons of failure enables us to discover ways of improving the performance of the maps. The main reason of failure in the lexical map is insufficient granularity of the codes listed in the index, most of them only at the table (3-character) level. There is no way to get around this at present, unless the ICD-10-PCS developers decide to add new entries or use more granular codes in the index in future. For the ontological map, there are some possibilities for improvement. Body part mismatch makes up the majority of failures. Our method depends solely on the output of MetaMap without manual review. Since the total number of body part terms in ICD-10-PCS is relatively small (less than 800), it is feasible to manually review and correct the maps found by MetaMap, which could improve the overall performance. Another possible improvement is to make use of the approach attributes in SNOMED CT (Access, Surgical approach and Using access device) to match to axis-5 (approach) in ICD-10-PCS. This will lead to better maps when the SNOMED CT concept includes approach information. For example, Laparoscopic adrenalectomy in SNOMED CT has attribute Use access device = Laparoscope, which can be matched to Percutaneous Endoscopic Approach in ICD-10-PCS. Furthermore, the mismatch of excision (removal of part of a body part) and resection (removal of all of a body part) between SNOMED CT and ICD-10-PCS can potentially be resolved by clues in the name of the SNOMED CT concept. For example, SNOMED CT procedures with ‘complete’, ‘total’, ‘entire’ or ‘radical’ in their names can be mapped only to resection, while those with ‘partial’, ‘segment’, ‘wedge’, ‘biopsy’ or the pattern ‘excision of x of y’ (e.g., Excision of cyst of vulva) can be mapped only to excision. In the subset that we reviewed, many of the incorrect mappings can be avoided in this way.

Combining the two maps offers an additional way to use the maps. Maps that agree exactly are much more likely to be correct (93%) than each map alone. The overall performance of the ontological map is just fair because only 45% of the mappings are potentially useful (correct or broader maps). If we restrict to the subset of the ontological map that is corroborated by the lexical map (same map target or agreeing at the 3-character level), the proportion of useful maps will rise to 60%.

In future, we will explore ways to improve the ontological map by curating the body part matches and making use of other ICD-10-PCS axes and SNOMED CT defining attributes. We will also study the possibility of first mapping ICD-9-CM procedure codes to SNOMED CT, and then using the General Equivalence Maps (GEM) published by CMS1 to map from ICD-9-CM to ICD-10-PCS. The ICD-9-CM volume 3 index is another potential resource that can enhance lexical mapping, since the ICD-9-CM index is more comprehensive than the ICD-10-PCS index.

We recognize the following limitations in our study. We only focused on surgical operations but the scope of ICD-10-PCS includes other types of medical procedures (e.g., obstetrical procedures, imaging studies). For the ontological map, we only studied excision procedures, and the results may not be generalizable to other types of operations.

**Conclusion**

We explored two automatic ways of mapping SNOMED CT surgical procedures to ICD-10-PCS: lexical mapping of the ICD-10-PCS index, and ontological mapping by aligning SNOMED CT attributes and ICD-10-PCS axes. Lexical mapping yielded 89% of useful maps (correct or broader) but the coverage of SNOMED CT was limited. Ontological mapping had higher coverage but only 45% of the maps were useful. The performance of the ontological maps can potentially be improved by refining the body part matches and making use of additional information in the SNOMED CT names and defining attributes.

Abstract

There are numerous methods to study workflow. However, few produce the kinds of in-depth analyses needed to understand EHR-mediated workflow. Here we investigated variations in clinicians’ EHR workflow by integrating quantitative analysis of patterns of users’ EHR-interactions with in-depth qualitative analysis of user performance. We characterized 6 clinicians’ patterns of information-gathering using a sequential process-mining approach. The analysis revealed 519 different screen transition patterns performed across 1569 patient cases. No one pattern was followed for more than 10% of patient cases, the 15 most frequent patterns accounted for over half of patient cases (53%), and 27% of cases exhibited unique patterns. By triangulating quantitative and qualitative analyses, we found that participants’ EHR-interactive behavior was associated with their routine processes, patient case complexity, and EHR default settings. The proposed approach has significant potential to inform resource allocation for observation and training. In-depth observations helped us to explain variation across users.

Introduction

Health information technologies (HIT), such as electronic healthcare records (EHRs), are expected to bring significant advancements to healthcare delivery through improved management and availability of patient information. Thus far, there have been mixed results from HIT implementation and use. Problems include EHRs not integrating smoothly into clinical work processes and impacting workflow as seen in altered sequences in which tasks are performed, the duration required to complete tasks, the allocation of tasks among workers, development of workarounds, some resulting in adverse events that compromise patient safety and quality of care delivered. The absence of a focus on system usability and on understanding patterns of workflow is a major impediment to adoption and widespread use.

Usability studies typically employ user-satisfaction surveys, focus groups, expert inspections and experiments involving usability testing. Although these methods are informative, they involve a reliance on subjective judgment, may lack reliability and do not provide a sufficiently rich window into the clinical workflow process. Alternatively, there have been numerous studies of workflow that vary in method and scope. There is a need to scrutinize EHR workflow in situ to surface patterns of interaction, characterize the distributions of those patterns and elucidate the factors that underlie them. In this study, we integrate a quantitative process mining analysis of sequential patterns of data access with a qualitative analysis of user performance to investigate and explain clinicians’ work processes. Specifically, we focus on EHR workflow associated with a routine information gathering task (InfoGather).

Background

There is ample evidence to suggest that the implementation of HIT can negatively impact clinical workflows and thereby create staff dissatisfaction, inefficiency and HIT-mediated errors. Current technologies place a burden on clinicians’ working memory and increase cognitive load, which is associated with medical errors and risks to patient safety. Cognitive load reflects the demands on user’s working memory, and is a function of task complexity, user’s skill level, and system usability. The productive use of HIT is partly dependent on the degree to which it can provide cognitive support for tasks that comprise clinical workflow. It is also reasonable to assume that experienced practitioners can develop efficient and effective methods for executing routine tasks—such as information gathering, progress note documentation and order entry—that better leverage the affordances provided by the EHR. We can also hypothesize that clinicians employ suboptimal strategies that result in unnecessarily complex and inefficient trajectories that are more time consuming and error prone. These patterns are empirically discoverable through automated computational approaches that identify patterns of interaction. Further, we recognize that EHR workflow is not performed in vacuum, but rather is connected to a web of actions, interactions, relationships and dependencies between clinicians and work components (e.g., patient, clinician, information, tools, etc.). This necessitates convergent
methods to surface the various factors that shape interaction. The regularities of cognitive work can only be discovered through detailed, time-intensive study of the specific setting\(^9\).

We have developed a methodological framework that draws on three research traditions\(^8,\ 10\): cognitive engineering, distribution cognition and computational ethnography. Each framework provides a theoretical lens, identifying important foci and a set of methods that illuminate different facets of workflow. The cognitive engineering approach focuses on both the usability of the system or interface in question and in the analysis of users’ skills and knowledge\(^11\). In analyzing performance, the focus is on cognitive functions such as attention, perception, memory, comprehension, problem solving, and decision making. The approach has a lengthy history in the study of human-computer interaction in general\(^11\) and in its application to EHRs\(^12\). The cognitive engineering approach has also been used to explain why users employ suboptimal or inefficient procedures or strategies in interacting with systems\(^13\). The theory of distributed cognition (DCog)\(^9\), conceptualizes cognition as distributed across people and artifacts, and dependent on knowledge in both internal (e.g., memory) and external (e.g., visual displays, paper notes) representations as well as their interactions\(^14\). One can employ DCog to characterize workflow as the sequence, or propagation of internal and external representational states across media, settings and time\(^9\).

Computational Ethnography is an emerging set of methods for conducting human-computer interaction studies\(^5\). It combines the richness of ethnographical methods with the advantages of automated computational approaches. Zheng and colleagues define computational ethnography as “a family of computational methods that leverages computer or sensor-based technologies to unobtrusively or nearly unobtrusively record end users’ routine, in situ activities in health or healthcare related domains for studies of interest to human–computer interaction.” Sequential pattern analysis employs log files to search for recurring patterns within a large number of event sequences. The analysis can be used effectively in combination with other forms of data such as ethnography or video-capture of end-users performing clinical tasks. Zheng et al\(^15\) investigated users’ interaction with an EHR by uncovering hidden navigational patterns in EHR logfile data. Various patterns were seen to be at variance from optimal pathways as suggested by designers and individuals in clinical management. Similarly, Kannampallil et al\(^16\) used workflow logfile data to compare the information-seeking strategies of clinicians in critical care settings. Specifically, they characterized how distributed information was searched, retrieved and used during clinical workflow.

In a previous feasibility study, we conducted a process mining analysis with manually-curated event log data from (Morae™) video recordings\(^13\). We found patient case complexity was associated with the complexity of the clinician-EHR interactive behavior for the computer-based pre-rounds information gathering task. Two analyses were conducted. The first characterized the most common patterns of screen transitions. The second analysis quantified the frequency of each screen transition pattern. We observed 27 total screen-transition patterns, each employed 2 to 7 times. We also correlated patterns with interaction measures including mouse clicks and task duration. The objective was to characterize the difference in complexity for each pattern. We observed that, on average, a screen transition resulted in 2 to 2.5 mouse clicks. The task durations per patient were highly variable and may be associated with other factors such as variation in clinical case complexity.

The objectives of this study are to explain variation in EHR workflow by integrating quantitative analysis of empirical patterns with an in-depth qualitative analysis of user performance. This study is part of a larger research project in which we seek to characterize, evaluate, diagnose and improve clinicians’ workflow in post-operative hospital care\(^10\).

**Methods**

**Clinical Setting & Participants**

Research was conducted in the Colon & Rectal Surgery Department (CRS) at Mayo Clinic, Rochester, MN, an academic tertiary healthcare center equipped with a comprehensive EHR since 2005. Patient data is accessed through a customized interface, Synthesis. In CRS Rochester, patients are cared for primarily by surgeons, fellows, resident physicians, hospitalists, nurses, and pharmacists. Hospitalist, in this context, refers to nurse practitioners (NPs) and physician assistants (PAs) who have responsibilities similar to a resident physician. This study was centered on the hospitalist or resident physician, who share responsibilities for coordinating across members of the patients care team, delivering direct patient care, order entry and documentation. Surgery residents work for an attending physician’s service for 6-weeks before cycling to their next service. To date, we have observed four hospitalists, a PA (H1) and three NPs (H2, H3 and H4), and two residents, a 2nd year (R1) and 4th year (R2). H1, H2, H3 and H4 were experienced users of the system and routinely performed the tasks we observed. At observation, they had worked in the unit between 2 and 3 years. R1 and R2 were doing a rotation in the unit and were less experienced users of the system.
This work represents an extension of a surgery practice redesign project, which sought to understand clinical processes and information needs to inform design of new technologies that can improve patient safety and quality and efficiency of health care delivery. It was reviewed by the Mayo Clinic Institutional Review Board (IRB) and judged to be exempt as human subjects’ research.

Pre-Rounds Information Gathering Task (InfoGather)

The data were collected as the clinicians were completing pre-rounds information gathering task (InfoGather). In context of workflow, InfoGather occurs close to the start of the day shift, approximately 6:00 am. Hospitalists and residents round together immediately afterwards. The goals of the task are to access the most recent information on patients’ medical status, review care plans, as well as to anticipate patient needs for the current day. It is clinicians’ first task and serves to anchor their understanding of their patients and their workload. To conduct the task, each clinician reviews patient data in the computer and paper-based information resources, and annotates a paper document that is subsequently referenced and modified throughout their shift.

Data Collection: System event log files & Observation

We observed clinicians in context of their routine workflow and collected ethnographic data from an electronic source (i.e., system-generated log files for the observed participants and the primary EHR application (Synthesis) used by participants for the task).

Synthesis is a customized interface developed by the Mayo Clinic Hospital in Rochester, MN for EHR data aggregation and visualization. We retrieved system-generated event log files for six participants for the six-week period that coincided with the residents’ (R1 and R2) rotation in the CRS department. We also retrieved EHR event log files for the four hospitalists for an additional two-week period that coincided with other observations in the department. At minimum, each event (row) in a log file has a User ID (i.e., clinician ID), an Event Description (e.g., “Activated tab: Labs”) and a Time Stamp (with date and time). Events that are associated with a patient chart also have the patient’s clinic number.

EHR event log files record users’ interactions with the EHR interface, to include selection of a patient chart in the Navigation Panel as well as screen tabs and their associated subtabs in a patient’s chart. The Synthesis application window includes a list of patient records in a panel on the left-side of the screen (Navigation Panel). Synthesis includes a number of screens, separated into tabs, for viewing patient data (top of Figure 1). There are a total of 13 tabs to include, Summary, Labs, Medications, Vital Signs, Intake/Output, Document/Images, Assessment/Cares, Allergies/Immunizations, Patient Facts, Clinical Problem List, Orders and Viewers/Reports. Several tabs have subtabs which allow access to other screens. For example, the Labs tab has 7 subtabs to include, Labs, Microbiology, Pathology and Pending Labs. For all participants, the Summary screen is divided into six equally sized sections, each with a predefined subset of patient data for Allergies, Intake/Output, Medications, Documents, Vital Signs, and Labs. For example, only a patient’s lab data from the last 24 hours are shown in the Summary screen. The clinician would go to the Labs tab to see all past lab results.

We employed Morae™ video capture and think-aloud protocol of participants engaging in InfoGather to allow for retrospective task analysis. Morae™ software is used for usability studies and it records user activity with no interruption to the user’s work. The software provides a screen capture (see Figure 1), and allows use of a webcam to capture audio of participants verbalizing their thoughts (think-aloud) as well as video recording of the participant’s face or hands (inset image in the lower right corner in Figure 1).

We have a broader understanding of the context of the work environment because it was the setting for a larger research project in which we also conducted semi-structured interviews of clinicians from varying roles (e.g., hospitalist, senior resident, and nurse), collected artifacts including paper documents, observed clinicians’ work across tasks and reviewed patient charts. Interview questions aimed to reveal details of clinicians’ key clinical work activities, to include purpose or goal, tasks associated with each activity and resources used. Retrospective patient chart review was performed to understand the complexity of a patient’s clinical state.
Sequential Data Analysis

We employed temporal data mining (i.e., process mining) methods to identify clinicians’ patterns of EHR interaction performed to complete InfoGather. The analyses were conducted using a business process mining tool, Disco™ version 1.9.3, a process-mining workbench used for business process management. Process mining has been used for a wide range of purposes in relation to business\(^1\) and for adherence to guidelines in healthcare\(^2\). The input of Disco is a set of event logs (in our case, EHR logfiles associated with CRS clinicians), which can be processed, analyzed and visualized. Logfiles were preprocessed using Python. Code was written to de-identify log files by replacing clinician IDs and patient clinic numbers with a study ID. Video recordings of observed cases were reviewed with associated log files to understand how the Event Descriptions aligned with users’ behavior.

Quantitative descriptors examined in this study include the number of cases per screen pattern, screen frequency and screen transitions, which were derived from the log files. These descriptors allow us to quantify and compare participants’ interactive behavior required for the task. The quantities provide relative measures of work and reveal insights into the usability of EHR tools, patient case complexity and individual clinician’s interactive strategies. We describe and examine the variation across patient cases and individual clinicians. Further, we integrate other methods (e.g., chart review, sequential analysis, qualitative analysis) to better explore the factors that contribute to the variation.

Qualitative Analysis & Case Study

We conducted qualitative analysis of clinicians’ think-aloud verbalizations to explain patterns of EHR workflow. One of our objectives was to investigate the causes of repeat screen viewing. This was accomplished by reviewing video recordings of clinicians performing the task. In addition, a case study was selectively used to present detailed analysis of clinical work. It provides an illustration of observed behavior with qualitative data interwoven with quantitative descriptors to better understand users’ behavior. For the selected case study, patient case complexity was evidenced by its quantitative descriptors; screen transitions, mouse clicks and task duration for the selected patient case were more than twice the clinician’s, H1’s, average across H1’s observed cases. We previously published these quantitative descriptors and sequential analysis for a subset of cases, the 66 observed patient cases across five clinicians\(^{13}\).
Results

Screen transition pattern analysis

To investigate clinicians’ EHR interaction patterns for InfoGather, a routine computer-based task, we applied process mining to EHR-generated event log files. Our sample consisted of 1569 patient cases across 6 clinician participants. Participants accessed and viewed 26 different EHR screens. Among them are 12 of the 13 main display tabs (the seven most viewed are shown in Table 1). Also included is the Navigation panel (N), which is a collapsible vertical panel on the left of the EHR interface. We defined it as a screen in this study because it is relevant to users’ EHR-interaction for accessing patient charts. Navigation was accessed for nearly all patients (99.7%, Table 1) because it includes the patient list and the search field for a user to access a patient chart. Once a patient chart has been opened during the user’s session, the chart can be reopened by selecting the patient in the Navigation panel (N) or by selecting the chart’s tab along the top of the Synthesis screen. Summary (S), Labs (L), and Vital Signs (V) were viewed for more than half of all cases, and Documents/Images (D) and Intake/Output (I) screens were viewed for more than two-thirds of all cases suggesting the importance of these displays as information sources. Seven screens (D, I, S, L, V, VwR and M) were viewed more than once for some cases and up to 7 times (S and L) (see max repetitions in Table 1). Repeat viewing is analyzed in greater detail below.

Table 1. Screen statistics. Case Frequency is the number of cases in which the screen was viewed at least once. Absolute Frequency is the number of times the screen was viewed. Max Repetitions is the highest number of times the screen was viewed per one case.

</table>

There were 519 variants of screen sequence patterns (Patterns in Table 2). The 15 most frequent patterns account for just over half of all cases (52.6%). All patterns start at the Navigation panel (N). Upon selecting a patient in Navigation (N), the user is immediately transferred to a screen in the newly opened patient’s chart. As represented in the 15 patterns shown in Table 2, transitions lead from Navigation to Documents/Images (N-D), Navigation to Summary (N-S), and Navigation to Viewers/Reports (N-VwR). This is because the users had one of these three screens set as the default opening screen. Documents/Images (D) displayed when H2 and H3 opened a patient’s chart, whereas Summary (S) was set as default for H1, R1 and R2 and Viewers/Reports (VwR) was the default for H4. Due to default settings, H1, R1, and R2 navigated through the Summary screen (S) for all of their patients, but observation of their behavior revealed that only R1 used Summary (S) to access patient data for the task. Because Summary (S) is not used by H1 and R2, navigating through this screen is an unnecessary “cost” for these clinicians.

Table 2 also indicates the percent of clinicians’ patient cases for which the clinician followed each pattern (normalized by clinician’s total to reduce the bias of varying sample sizes). The most frequent screen transition pattern occurred for 132 cases: Navigation to Documents/Images to Intake/Output (Pattern 1: N-D-I). It was followed by H2 for 23% of H2’s cases, by H3 for 27% of H3’s cases, and by R1 one time (0.3% of R1’s cases). The second most frequent screen sequence occurred 67 times: Navigation to Viewers/Reports to Intake/Output to Vital Signs to Labs (Pattern 2: N-VwR-I-V-L). It was followed by one provider—H4 for 41% of H4’s cases (Pattern 2). Among the top 15 patterns, three other patterns were each followed by one provider—24% of H1’s cases (Pattern 6: N-S-L-V-I-D), 19% of H2’s cases (Pattern 7: N-D-I-V-L), and 11% of H4’s cases (Pattern 14: N-VwR-I-V-L-D). Due to the screen default settings, H2 and H3 sometimes followed the same patterns, while H1, R1 and R2 occasionally followed the same patterns, and they never followed H4’s patterns. More than half of the remaining cases (418; 26.6% of total cases) exhibited a pattern that appeared only once (Patterns 102-519). We use the number of sequence patterns with only one case associated as the measure of variation. Thus, H3’s task performance had the least variation (18% of H3’s cases had a
pattern that appeared once), whereas R1’s task performance had the most variation (38% of R1’s cases had a pattern that appeared one time) (Table 2).

Table 2. Screen sequence patterns and frequency measures for InfoGather. Screen sequences are shown for the 10 most frequent patterns. Frequency gives the number of patient cases per pattern. The third column expresses the frequency the clinician uses a screen sequence pattern as a percent of their total cases. EHR screen codes: N (Navigation Panel), D (Documents/Images), S (Summary), L (Labs), V (Vital Signs), I (Intake/Output), VwR (Viewer Reports). *The percent of cases in which clinicians had a unique pattern served as a preliminary measure of variation.

</table>

Although some of the complexity can be accounted for by users’ system settings, others may be accounted for by the interface or may reflect provider efficiency. For example, Pattern 6, employed by a single clinician for 24% of the clinician’s cases, involved sequential transitions from left to right corresponding to the order of tabs along the top of the screen. Similarly, a different clinician employed sequential transitions that correspond to the order of tabs from right to left (Pattern 7). Still others may reflect variation in patient case complexity, which can be inferred from observations as discussed in the next section.

Analysis of Repeated Views: Of the 66 observed patient cases, 31 had at least one screen that was viewed two times (1/9 for H1, 7/21 for H2, 11/16 for H3, 10/12 for R1, and 2/8 for R2). For example, in the screen sequence N-D-I-L-D, which H3 followed for three patients, Documents/Images (D) was viewed twice per patient. We inferred reasons for redundant screen viewing from clinicians’ observed behavior. For most of H3’s patients, Documents/Images (D) was viewed twice per patient because it appeared to be the clinician’s routine process. H3 first viewed D when a patient’s chart was first opened because D was set as the default screen for this user. H3 explained, “Whenever I launch a patient, I’m looking at the notes to make sure there was no weird note put in overnight.” H3 would view D, which H2 followed for three patients, twice per patient because it appeared to be the patient’s routine process. H2 first viewed D when a patient’s chart was first opened because D was set as the default screen for this user. H2 explained, “Whenever I launch a patient, I’m looking at the notes to make sure there was no weird note put in overnight.” H3 would view D towards the end of the task as well, which would allow H3 to review the notes in context of what H3 learned about the patient during the task. H2 also had D set as the default screen, but, unlike H3, the default did not appear to be useful to H2 for several cases. Instead, H2 seemed to use a two-phase approach. First, for most cases, H2 exhibited a consistent screen sequence (i.e., N-D-I-V-L) at the start of the task. Then, for some patients, H2 also visited additional screens, perhaps to see if there were things missed. R1 had the highest percentage of cases with redundant screen viewing. This is not surprising because R1, a second-year resident physician, was relatively inexperienced with the EHR and the CRS practice. R1 could not easily synthesize and consolidate information from the EHR. R1 selectively uses screens with representations that can provide better cognitive support. For example, R1 views both Summary (S) and Labs (L) screens consecutively and multiple times per task. R1 stated “the way they do electrolytes [in the tabular form in the Labs screen], I can’t even sort through that in my mind very quickly so I go back to the skeleton here [on the Summary screen].” In this case, the most recent lab values are represented succinctly in fishbone format on the Summary screen and were the preferred representation.

Case Study: Micro-Analysis of Qualitative and Quantitative data
To explain variation in clinicians’ patterns, we drew on in-depth observation and qualitative analysis of clinicians’ think-aloud. Here, we present a detailed task analysis for one patient case observed in H1’s InfoGather workflow. H1’s screen transition pattern was not repeated for any other case (Pattern 113: N-S-L-S-L-V-I-D). A review of the patient’s chart conveyed the clinical complexity of the patient case in the reason for admission, length of stay, surgical procedures, number of medical services involved in care, and discharge requirements. The patient’s hospitalization was a readmission for a leak and infection. A leak is an abnormal break in the wall of an organ, such as the colon, that allows for an abnormal transfer of contents from the organ to another organ or the body cavity. Observation was conducted on the thirteenth day of the patient’s hospitalization, which was the discharge day. During the patient’s stay, the patient underwent a re-operation and CRS consulted three other services to assist in patient care—critical care, pain service and infectious disease. These consultations are indicative of patient complexity and increased communication needs because information was distributed across additional members of the patient’s care team.

To complete InfoGather, H1 reviewed patient information in the EHR and annotated a paper artifact (paper print out of the electronic handoff document) with patient data, tasks and reminders. Table 3 gives H1’s think-aloud verbalizations, EHR screens viewed and running time for the one patient case. The verbalizations revealed patient information that H1 gathered from each screen (screen captured by the Morae™ video recording). For example, as shown in Table 3, blood pressure is read on the Vital Signs screen (time 01:15), and oral intake volume is read on Intake/Output screen (time 02:18). H1’s verbalizations also reveal data gathered from the Pain Service and Infectious Disease Service notes on the Documents/Images screen (D) in the patient’s chart (time 02:55 to 08:22).

**Table 3. Case study narrative.** H1’s think-aloud, screens viewed and running time for one complex patient case.

Discussion

We characterized clinicians’ EHR-interactions for the pre-rounds information gathering task (InfoGather) by applying process-mining methods to EHR-generated event log files. We hypothesized that there would be a few screen patterns that could explain a majority of the cases because it is a relatively simple task, there are not many screens that have primary patient data, and clinicians may have preferred patterns of screen transitions, which they follow for most of their patients. Screen viewing patterns may be motivated by an intent to seek out new information (e.g., new lab results). An alternative hypothesis is that there is a large amount of variation in EHR-interactive patterns, which may be explained by the differences in patient problems and patient states. Patients with similar problems and profiles (e.g., age and comorbidities) may require the same information-gathering strategy for the task.

There were 519 variant screen sequence patterns to describe the 1569 cases. No pattern described more than 10% of the sample. Fifteen patterns (3%) accounted for just over half of all cases. Because a majority of cases can be described by 3% of total screen patterns, it may suggest that EHR systems can be designed to better facilitate information gathering across screens. On the other hand, there were 418 patterns that only occurred for 1 patient case, which suggests there is much task variation across users or patient types. No pattern of three or more screens was followed by more than 3 of the 6 clinicians (Pattern 8, N-D, employing 2 screens was followed by 4 of 6 participants). Observations helped to explain some of the screen pattern variation. Across the 6 participants, there were 3 different settings that determined the first screen that was displayed when a patient chart was opened; H1, R1, and R2 had Summary (S) set as default, H2 and H3 had Documents/Images (D) set as default, and H4 had Viewers/Reports (Vwr) set as default. The different screen default settings caused variation in screen patterns.

We hypothesized that the clinicians with less expertise would have more variation in screen transitions. The 6-clinician participant pool limits our ability to address this issue, but it can seed hypotheses for further testing. We expected R1, the least experienced user of the EHR among study participants as well as the less expert clinician, to have the most pattern variation. We observed that 38% of R1’s cases exhibited a pattern that occurred only once compared to a 22% average variation across the four hospitalists. More variation is indicative of an incomplete mental model (e.g., understanding of where needed patient information is located or knowledge of potential shortcuts to access data). This is consistent with research showing that more experienced users develop robust mental models21. When a user follows the same pattern for many patients, it may be indicative of the user’s spatial mental model of the system—where information is distributed across sources (applications and their screens). It may also reflect the user’s information needs, and their preferred information sources. R2, in relation to R1, had more clinical expertise and was a more experienced user of the EHR. As expected, R2’s pattern variation was lower than R1’s (30% versus 38%). In relation to the hospitalists, we defined R2 as having equal or more clinical expertise but a less experienced user of the EHR in the CRS department. As expected, R2’s pattern variation was also greater than the hospitalists’ (30% versus 22% average).

Event log file analysis revealed that residents viewed more and different screens, whereas the hospitalists viewed fewer unique screens during the task. This may be additional evidence that residents are less experienced users of the system and, consequently, not as certain where to find patient data. Alternatively, it could be evidence that residents and hospitalists differ in terms of their information needs (e.g., residents are monitoring different or additional patient care goals so they need different or additional patient data). Further evidence that hospitalists and residents differ in terms of information needs and task goals came from R2’s think-aloud, in which the resident appeared to do more decision-making on patients’ care plans than the hospitalists did.

We hypothesized that most clinicians would conduct the task similarly because the routine nature of the task and, though there may be some variation in care goals across patients, there were care goals common to all patients in the unit. There are any number of reasons that may explain variation in these cases including each clinician’s idiosyncratic strategies and patient-case differences. A second-order analysis in which the sequence was not an exact match (e.g., different starting point, but otherwise follows the same pattern) may reveal additional similarities not detected by the first-order analysis. For example, the number of variant patterns is in part due to the variation in chart default settings. By looking at similarities in smaller units of screen sequences, it may be more informative about shared processes and information needs across clinicians.

We triangulated quantitative variables with patient chart review and qualitative data and found clinicians’ EHR-interactive behavior was associated with their routine processes, patient case complexity, variant screen sequence patterns, and EHR default settings. We presented a case study to help convey these findings. In particular, this case
study exemplifies non-routine requirements of the InfoGather task. Our data suggests the selected patient case is complex because the quantitative descriptors (reported in 13) are more than twice H1’s average interactivity across all nine observed patients. Data presented in this study further supports this assertion: 1) H1 described the patient as “an involved patient”. 2) To complete InfoGather, H1 followed a screen transition pattern variant that was unique in our sample. The pattern involved 7 transitions between main-tab EHR screens and 12 transitions including the EHR’s subtabs and other clinical applications. 3) Among the 7 EHR screens, H1 visited two screens twice (S and L). This may suggest that redundant screen viewing for a patient case is also an indicator of patient case complexity. On the other hand, redundant screen viewing may suggest users’ inefficient task performance, an indicator of system usability or of task complexity (e.g., conflicting data gathered from another screen or from the paper handoff document may cause the clinician to return to a previously viewed screen). As an outlier case, it surfaces some complexities of completing the task and negotiating the information sources.

Process mining enables researchers to variably focus data analysis on clinicians, patients, time, tasks and interactions, thereby providing insights into different dimensions of workflow. The level of analysis is limited only by the granularity of the event logs. A limitation of our data collection is that we only looked at event logs from one clinical information system and in one setting. Future work will combine event logs generated from additional clinical information systems. As we examine how automated event log files are useful to study EHR workflow, we can also inform what user behavior is captured in systems’ event log files. That is, we can determine if there are particular user-computer activities that event logs could capture and that would be informative of users’ cognitive work.

We conducted qualitative analysis on the subset of observed cases to investigate why some screens were viewed two or more times (redundant screen viewing) for one patient case. Three clinicians repeated screen viewing for a third or more of their patient cases. Reasons varied from clinician’s lack of experience, lack of cognitive support provided by the system to synthesize and consolidate patient findings, system default settings and clinicians’ deliberate routine work process. It was assumed that default setting improved workflow so that clinicians would not have to visit the screen twice. It could be that the default setting serves them better on another task. Future design could support task-based navigation through the system, which could reduce cognitive workload.

Future research will employ regression analysis to determine if there are associations between measures of patient complexity (e.g., procedure, primary diagnosis, number of medication at admission, days in hospital, number of services involved in care, etc.) and measures of task complexity (e.g., number of screen transitions, task duration, etc.). The case study supports further investigation of this. If there is an association between patient case complexity and task complexity, it could be used to quantify increased workload on clinicians from complex patients. Also, it could be evidence toward development of advanced clinical decision support systems that facilitate team awareness and collaboration of complex patients.

Cognitive studies grounded in DCog framework examine clinical work in the context of actual practice and can identify issues in human and system performance. A contribution of our approach to cognitive research is that we leverage large data sets of system-generated event log files to investigate users’ behavior in conjunction with observational methods to explain variation in the empirical findings. In this study, we demonstrated the value of integrating quantitative data analysis with qualitative data to examine EHR workflow. This study indicates that process mining techniques can be used to evaluate variation of clinicians’ task behavior across many clinicians, which can potentially be used to direct resource allocation for observation or training when patterns of interaction seem aberrant or inconsistent with clinical pathways. This study presents a part of a larger methodological framework that we are developing for the study of clinical and EHR workflow. In the larger research project, we are studying workflow from multiple perspectives (e.g., tasks, clinicians, patients, tool). As we branch beyond analysis of a single task, we are exploring how to use system log files to examine care team coordination activities, particularly to study patient-centered clinical workflow. Variation in team processes surfaced through process mining can be used to focus observation efforts.

**Conclusion**

The presented study approach addresses the need for an integrated, in-depth approach that facilitates broad investigation of workflow across many settings, clinicians and patient cases, while also facilitating detailed analysis. We used system-generated event log files to characterize clinicians’ EHR-interaction patterns for a routine computer-based task, along with observation to explain variation in the patterns. As demonstrated in this study, computational ethnography can be integrated with observation to balance the advantages and limitations of individual data collection methods and to enable collection of a broad and rich data set for studying clinical work.
Acknowledgements

We would like to thank the Mayo Clinic Office of Information and Knowledge Management (OIKM) for funding this research initiative and Research Fellowship for Stephanie Furniss’s doctoral work. The work was partially supported by a Mayo Clinic Professional Service Award to David Kaufman. A special thanks to the clinicians in Colon & Rectal Surgery Division who graciously volunteered to participate in this study. We are grateful to the efforts of Robert Sunday and Katherine Wright who assisted in data collection.

Abstract

Safety-net patients’ socioeconomic barriers interact with limited digital and health literacies to produce a “knowledge gap” that impacts the delivery of healthcare via telehealth technologies. Six focus groups (2 African-American and 4 Latino) were conducted with patients who received teleretinal screening in a U.S. urban safety-net setting. Focus groups were analyzed using a modified grounded theory methodology. Findings indicate that patients’ knowledge gap is primarily produced at three points during the delivery of care: (1) exacerbation of patients’ pre-existing personal barriers in the clinical setting; (2) encounters with technology during screening; and (3) lack of follow up after the visit. This knowledge gap produces confusion, potentially limiting patients’ perceptions of care and their ability to manage their own care. It may be ameliorated through delivery of patient education focused on both disease pathology and specific role of telehealth technologies in disease management.

Introduction

Diabetes is estimated to affect 21.3 million adults in the United States, with 1.7 million new cases of diabetes diagnosed every year.¹ Compared with non-Hispanic whites, racial and ethnic minorities are more likely to be diagnosed with diabetes, including 9.0% of Asian Americans, 12.8% of Hispanics, and 13.2% of non-Hispanic blacks.¹ California has one of the highest rates of diabetes in the country, with 9.9% of the population diagnosed with the chronic disease.² One complication of diabetes mellitus is diabetic retinopathy, which causes damage to the blood vessels of the retina.³ Diabetic retinopathy is the leading cause of blindness in the United States with more than 100,000 new cases identified each year.⁵

Safety net clinics in the United States offer primary health care services to over 16 million patients nationwide and 2.3 million patients in California, whether or not these patients have the ability to pay for health care services.⁵ Patients in South Los Angeles experience limited access to care, and many are African American and Latino. Limited access to appropriate eye care and delays in diagnosis and treatment can result in advanced disease, such as diabetic retinopathy and vision loss among such populations.³,⁶ In a study of Los Angeles inner city minority residents, patients were 3.5 times more likely to present with advanced diabetic retinopathy and more than 5 times more likely to require immediate intervention, referral or follow-up than newly presenting patients in a predominately white non-urban setting⁶.⁸ The American Diabetes Association (ADA) guidelines for best practices necessitate annual retinal screening examinations, timely disease diagnosis, and on-going treatment to prevent the loss of eyesight due diabetic retinopathy. At-risk patients can benefit from laser photocoagulation surgery if retinopathy is detected early (in an annual examination).⁹

There is a growing body of research evaluating the efficacy of telehealth programs¹⁰,¹¹ and the use of telemedicine to screen for diabetic retinopathy has shown promise as a way to provide screenings to patients in areas where there is a lack appropriate access to these services.¹²¹⁴ Given the shortage of specialty eye care in medically underserved areas, such as South Los Angeles, the larger study of which this paper is a part, examined the use of teleretinal screening as an innovative way to address this gap in care. In the clinical use of teleretinal screening, technology is conceptualized as facilitating communication between a primary care provider and specialists (though other health care team members may be involved); the patient’s retinal images are instrumental to that communication but no direct engagement of the patient by clinicians occurs beyond the generation of retinal image data. Studies of the clinical use of teleretinal screening have focused primarily on providers’ use and perceptions of technology. In this paper, we shift the focus from provider to patient to explore one aspect of the qualitative findings of the larger study: patients’ reported feelings of fear and confusion about teleretinal screening at critical points during the delivery of care. This is especially important to understand given that even with the introduction of teleretinal screening, safety
net screening rates lag behind national screening rates. In order to understand this outcome, it is necessary to explore patient perceptions of telemedicine and the quality of care they received. As the primary setting in which many of the most disenfranchised healthcare users encounter health technologies, safety-net clinics present a particularly important site to understand how structural inequalities preconfigure patients’ interactions with such technologies in the healthcare setting, and how these technological encounters may shape patients’ beliefs and behaviors around the self-management of their chronic disease. Specifically, our findings indicate that these patients’ limited health literacy compounds with pre-existing socioeconomic barriers and low technological literacies to produce a “knowledge gap” that limits patients’ understanding of what is happening with the screening and their ability to comply with prevention goals and treatment plans.

Materials and Methods

Study Setting

The study took place from August 2010 to September 2011 and involved six safety-net primary care clinics in South Los Angeles. During the study period, a total of 2,732 unique patients were screened for diabetic retinopathy by three ophthalmologist readers, with 1,035 receiving a recommendation for referral to specialty care. The study focused on both the technical challenges of implementing and screening patients, as well as the patient and staff perceptions of telemedicine. Each clinic used digital retinal cameras to conduct retinal screenings of Type 2 diabetes mellitus patients. The six clinics primarily serve immigrant Latino and African-American patients in communities that have 28% of the population living below the federal poverty level.

The gold standard for detecting and diagnosing diabetic retinopathy is seven-field 35-mm stereoscopic color fundus photographs and grading protocols, as defined by the Early Treatment Diabetic Retinopathy Study (ETDRS). However, ETDRS photography is impractical for use in clinical settings so the more common method of diabetic retinopathy screening is via an in-person examination with a licensed eye care provider (Optometrist or Ophthalmologist). Diabetic patients in Los Angeles who visit safety net primary care clinics were traditionally referred to the Los Angeles Department of Health Services outpatient eye clinics for yearly retinal screening examinations and treatment of diabetic eye complications, resulting in long wait times for appointments. Prior to the introduction of teleretinal screening, primary care clinic staff report that patients could wait up to eight months to receive an initial retinal examination, diagnosis, and treatment. Complications such as proliferative diabetic retinopathy may result in permanent vision loss when screening and treatment are delayed.

Teleretinal screening for diabetic retinopathy, however, allows for routine screening via retinal images taken with a fundus camera by ancillary staff in primary care settings, with subsequent analysis by trained readers to determine presence and extent of disease. To conduct a teleretinal screening, clinic staff took six retinal images and two external images of a patient’s eyes. The patient’s case, consisting of images and basic biometric data, were then uploaded into EyePACS, teleretinal screening software platform developed at UC Berkley and already in use in over 360 California safety net clinics. Three board-certified ophthalmologists contracted as image readers, assessed patients’ cases, recommended referrals for further care, and rated quality of the retinal images provided.

Approach and Procedures

Focus group techniques were used to assess the acceptability of teleretinal screening among Latino and African American patients who had received screening at one of the participating clinics. Six focus groups were conducted with two groups in English with patients who self-identified as African American and four groups in Spanish with Latinos, most of whom spoke Spanish as a primary language. The subjects were 18 years or older, diagnosed with diabetes, both male and female, separated by gender. Each focus group included 6-9 patients, with the total sample size for the focus groups equaling 42 participants (29 Latinos, 12 African American, 1 unreported). Our study sample is representative of the Los Angeles county health services planning area in which the clinics are located as well as the study clinics’ overall populations. First, 9.5% of LA County population was diagnosed with diabetes in 2011, perfectly mirroring the diabetes rates in the six clinics from which our retrospective study sample.

</table>

Our study sample is representative of the Los Angeles county health services planning area 6 in which the clinics are located as well as the study clinics’ overall populations. First, 9.5% of LA County population was diagnosed with diabetes in 2011, perfectly mirroring the diabetes rates in the six clinics from which our retrospective study sample.
was selected in the same time period. Our sample for the study represented 20% of the diabetes population in the six study clinics and for the most part, reflects the overall clinics’ patient populations. For example, Table 1 shows that the racial ethnic breakdown of the patient populations at the six study clinics and our study samples were very similar. Because recruitment of participants for the qualitative study was opened up to screened African American and Latino patients from all participating clinics, we believe that both our larger study sample and focus group study sample are reflective of the clinics’ overall patient pool. A script guided interviews, with questions arranged by category, focusing on patient perceptions about accessibility, acceptability, and satisfaction with the teleretinal screening that they received, as well as barriers to compliance with ophthalmologic referrals. Each focus group lasted approximately 90-120 minutes and the monolingual Latino groups were conducted in Spanish. All groups were audio taped and transcribed by a professional transcription company (to which participants consented). Upon each subject’s completion of participation in the focus group session, the subject was provided with remuneration of $50.

**Data Analysis**

Using Atlas ti software to help manage and analyze the data, focus group transcripts were coded and indexed by team members to develop analytical categories based on qualitatively informed and modified grounded theory techniques of analysis. Team members performed open coding independently to identify themes and to generate codes. Then transcripts were recoded with the team-developed codes. Constant comparison within and across categories allowed researchers to check codes against the rest of the data to establish categories that reflect the nuances of the data, key themes and theoretical insights. Scientific rigor is strengthened through use of common procedural guidelines for qualitative studies. Credibility of the results is supported through use of data from 6 focus groups with carefully chosen participants, and a team with diverse research expertise and backgrounds. An iterative mode of data analysis by multiple team members increased dependability of the findings. Transferability of findings is made possible through published description of the methods and findings.

**Results**

**Demographic Data**

Table 2 shows participant characteristics. 29% of focus group participants were African American and 71% of participants were Latinos. 50% of all participants were female, with both African American and Latino focus groups being split evenly between males and females. 60% of Latinos had not completed high school, while on average African Americans had attained a higher education status with 50% having attended some college. 62% of participants earned less than the 2012 poverty level of $11,170 per year. Computer ownership was greater among African Americans (50%) than among Hispanic participants (30%). Latinas (56%) reported a slightly higher rate of computer ownership than Latinos (44%), while only 33% of African American females reported owning a computer compared to (67%) of African American males. Among Latinos, internet use was low, with only 17% of participants reporting access.

Table 2: Participant Characteristics
Findings indicate that in teleretinal screening, the patients’ knowledge gap becomes consequential at three critical points: (1) when patients’ pre-existing personal (structural) barriers to care became exacerbated in the clinical setting; (2) during the encounter with technology during the screening; and (3) during the doctor-patient follow-up after the screening. Summary of results are presented in Table 3 below.

1) Patients’ Personal Barriers (Structural barriers)

Patients in this study group expressed concerns about their a) personal barriers to care, including the ability to access care, the quality of care that they receive, the costs of care, and the ability to follow treatment plans as prescribed. Patients also expressed b) confusion regarding the pathology of their disease.

1.a) Nature of personal barriers to care: Participants generally report a variety of barriers to accessing healthcare including, obtaining appointments, long wait-times, need for multiple appointments, loss of patient information by clinic, lack of clarity regarding the cost-of-care to patient, and the receipt of unexpected bills after care. These barriers were compounded by the fact that many participants indicated time pressures due to work and family obligations, transportation issues, as well as, financial pressures. For example, many patients spoke of the difficulty of complying with treatment plans due to daily schedules. Work regularly intervened in participants’ ability to take prescribed medications at the proper time, to eat healthily and consistently throughout the day, and to find the time to exercise. One Latino respondent put it this way, “I sell food in the morning and I practically don’t eat. I eat at around 3:00 pm and that’s not good, so they say…That’s bad, I have to be eating a little every now and then, and eat only once a day.” Compliance with treatment plans was especially difficult for African American men, who spoke of this difficulty at twice the rate of other respondents across ethnicity and sex. One respondent reported that his experience of incarceration made complying with prescribed diet extremely difficult. He said, “I was incarcerated, I cheated (on my diet plan) because we have common food. So when I eat ice cream, I’ve got to work a little harder to burn it off… the doctor told me, mine comes from bad diet. Okay? It’s not hereditary, it’s bad diet.”

1.b) Confusion regarding disease pathology: Further complicating this situation, patients expressed confusion about pathology of their disease. Patients uniformly expressed concerns related to unresolved symptoms they attributed to their diabetic status. Such concerns included, dizziness, exhaustion, circulation-related foot pains, and, most significantly for this study, vision problems. One female Latina participant expressed confusion about her disease pathology in this way: “I had a question - I’m hearing terms like diabetic retinopathy…And then I’ve heard macular regeneration [sic]…And then [the doctor] talked about cataracts…Are those three different ailments of diabetic…symptoms?” Like this patient, the majority of participants expressed uncertainty about how these health conditions. Patients indicated difficulty communicating these concerns to their providers, particularly due to the medical language and communication styles of the clinical setting. Significantly, patients felt that they were not given adequate education before, during, or after their appointments to address their concerns about their health.

Despite this limitation, patients generally expressed a desire to know more about their disease and learn how to manage it better, but were uncertain how to obtain this knowledge easily.

2) Encounter with Technology during Screening

With regards to diabetic retinopathy screening, patients demonstrated a similar lack of clarity as to the technical aspects of the teleretinal screening process specifically, and retinal screening generally. Despite having received teleretinal screening in-clinic, patients were uncertain about 1) the role of the retinal screening in their disease management and 2) what was happening during their encounter with technology in the screening.

2.a) Role of the Retinal Screening: Patients across all the focus groups misunderstood the purpose of the retinal diabetic retinopathy screen. Most patients did not understand that retinal screening is used to detect signs of diabetic retinopathy, with some patients confusing it with visual acuity testing. For example, one Latina female expressed her confusion about the role of teleretinal screening in preventing her diabetes-related retinopathy as follows: “I've been wanting to ask you, the test that we had done for our eyes. Well, they already told me that I had liquid and it was –

retinopathy, with some patients confusing it with visual acuity testing. For example, one Latina female expressed her confusion about the role of teleretinal screening in preventing her diabetes-related retinopathy as follows: “I've been wanting to ask you, the test that we had done for our eyes. Well, they already told me that I had liquid and it was leaking…does that have anything to do with, if I need to increase my [glasses] lenses? The doctor didn’t say exactly the name of the problem. He only said you have this problem, your eyes are starting to leak from inside and that’s it. [I don’t] understand the word.” One African American woman put the confusion this way: “I've been a diabetic for, like, 24 years, and I just started feeling like sometimes I can’t read street signs…When I left from the clinic [after the teleretinal screening], they referred me over to Martin Luther King…got me a new set of glasses and everything…now I’m good, you know. Just I’ve got a large nerve in the back of my eye, and that’s about it.” Some patients who were screened shared that they continued to experience poor vision or undefined eye pain, symptoms although their screening had been negative for diabetic retinopathy. These patients were concerned and felt that the screening received might have been inadequate since they continued to exhibit impaired visual acuity. The examples above demonstrate that the patients did not understand their pathology and the purpose of screening.

2.b) Concerns about the Technology during Screening: A majority of patients were nervous about their encounter with teleretinal diabetic retinopathy screening technologies. Patients expressed concerns about potential human error in handling of private health information over the Internet, mishandling of the technology by clinic staff, or the feeling that something could go wrong during the screening that might result in damage to the eyes (due to the drops, flash, or camera hitting the eye.). One Latina woman put her fears this way, “[I felt] afraid because I have a sister who lives in Honduras and she had an eye operation and instead of improving her vision they damaged her… And that’s why I got scared… because [my sister] couldn’t see but they made it worse…”

Patients expressed a variety of emotions about the absence of a specialist in the room during the exam, from indifference to resignation to confusion. African Americans in particular seemed to feel resigned to the lack of a specialist in the room. For those who understood the role of the specialist, not seeing a specialist directly seemed to be consistent with their experiences of other types of healthcare in safety net clinics. While the responses were not wholly negative, African American women respondents reported preferring to have the specialist in the room but understanding that this was not always possible due to lack of resources in the clinic. For example, one African American woman said, “…I like personal attention and personal care, so of course, I want the best hands possible. I would want to be in the hands of an ophthalmologist or an optometrist, but in this case, I was going to get a screening. It’s kind of like how you have the PA’s versus a doctor who do the vital signs or whatever, I just thought this was a routine sort of thing. I didn’t know it was like new age…. Well, had I been told that an online person would be evaluating the screening; it may have made me feel like it was less personal. But, to be honest with you, knowing that [the specialist is remote] doesn’t make me feel that different then.” In other words, this patient population is accustomed to being seen by lower level staff than the specialist, or even the primary care doctor.

Having retinal images taken by a technician (medical assistant) rather than a specialist, however, led some individuals, particularly African American and Latino men, to feel a sense of insecurity in the ability of the technicians,. These patients felt that medical assistant photographers lacked the necessary medical/technical knowledge to handle the equipment and could not answer health-related questions. One African American patient described the medical assistants as ‘fresh out of school’ while another said, “[T]he people that they have in there [operating the screening equipment], they’re kids. They don’t know anything. You know? They're looking at you – they're no specialists and they look like they just come out of a training school.” A Latino male elaborated, “…I don’t know if they were well trained or they needed more training to learn how to work with the machine because the person that was taking the photos…wasn’t sure on how to work the machine and I think what that person was supposed to do was something simple and yet it took longer due to the lack of experience.”
3) Impact of Lack of Clinician Follow-up

The large majority of patients in these focus groups expressed concern and confusion about the follow up procedures and the regular lack of follow up, post-screening. In addition, although many patients were pleased with their providers, some patients felt concern about the quality of the interactions they had with the clinician.

3.a) Confusion over lack of follow up: The majority of patients expressed confusion about what to do following the teleretinal diabetic retinopathy screening and about how to get their results, how suggested diagnoses would be returned, and what procedures typically follow the test. Most patients reported never receiving the results, post-screening. One Latino male participant said, “I, at least, expect to know my results because knowing that I have diabetes, you tend to have a little fear…[so] they should tell [me] how I’m doing inside.” While standard protocol is that patients should be informed of a negative screening result, patients were not informed that it may happen at the next follow up visit with the primary care provider and not via special outreach. Another African American male put his concerns over the lack of results this way. “[T]he first time I was diagnosed was with another doctor, and she sent me to the [screening] and I had it. That was over a year ago. I remember [her] just getting back to me with having the tests done again, but I’ve never had anyone respond to me from the clinic about the results of the tests that I had there.” Since patients did not understand the standard procedure for a negative result, they felt they lacked quality care. Part of their confusion stemmed from the challenges of sharing results and information internally among the clinics and between clinics and specialists, which occasionally resulted in patient screening results being lost or misplaced. One Latino respondent described being asked to locate his own results and bring them in to his doctor himself. He said, “They mailed me mine because when I went to see the doctor, the doctor asked me for them and they told me they were going to fax it here but the doctor said he didn’t have them and he told me I had to bring them in. So I had to lose a day from work to pick them up and bring them over to the clinic.” Other patients did not understand why they had not heard back from their doctor after the teleretinal screening.

3.b) Quality of patient-provider interactions: Some of the patients felt that their doctors and medical assistants were rushed and did not take enough time to answer all their questions, and as a result were not being thorough. One Latino male put his concern this way, “…I asked what [the screening] was for and the [medical assistant] didn’t know how to answer and then I asked the doctor and he said, ‘No, everything came out fine.’ But that was the only thing they said.” Similarly, an African American male felt that the doctors were rushed and didn’t take the time to educate him. He said, “…your doctor doesn’t say anything, he just tells you, ‘I’m going to give you some drops’, you know, and send you on your way. But he doesn’t sit down plainly [and tell you what to do].” Consequently, patients such as these were concerned that the care providers’ inability to explain the teleretinal screening was indicative of an inability to provide patients with on-going, quality care.

Discussion

Telemedicine has been lauded in the health information technology (HIT) literature as a means of increasing access to specialty care in low resource settings, such as rural or inner city community clinics. The Chronic Care Model (CCM) includes the use of HIT as one avenue for addressing the challenges of chronic disease care management through use of clinical information systems and clinical decision support21. Health communications studies have also demonstrated the ways in which HITs can be used to a) support individual health information seeking22, b) facilitate doctor-patient communication23, and c) promote consumer understanding about prevention and treatment opportunities24. Overall, patients who participated in this study, too, shared the general perspective that telemedicine advances the delivery of care by improving communication between providers. While this is likely the case in terms of the general adoption of telemedicine at sites where no specialty services existed before, this research team has reported elsewhere the challenges of implementing effective workflow communication pathways in the delivery of telemedicine workflows25. Challenges include missing or misreported patient information, primary care providers’ difficulty interpreting diagnostic results to patients, and the inability to track patients across multiple information management systems. Although unknown to patients directly, these clinical workflow difficulties are experienced by patients in ways not obviously related to the communication challenges in the clinic as reported in the results above.

Patients in the populations studied here face a number of challenges in accessing healthcare. In addition to challenges reported in the literature, participants in this study describe several others, which we conceptualize as a knowledge gap in the clinical setting, which appears to be produced at three points during the delivery of care: (1) through exacerbation of patients’ pre-existing personal barriers in the clinical setting; (2) through encounters with technology during screening; and (3) and through lack of follow up after the visit. In the following discussion, we elaborate on the patients’ experiences of the knowledge gap at the three points and consider the types of knowledge/information that patients are lacking and potential approaches to fill these gaps in the teleretinal screening process.
**Addressing patients’ pre-existing barriers: The role of health literacy**

Participants in this study lacked adequate understanding regarding the purpose, processes and goals of preventative tests such as the retinopathy screening. This finding reflects larger trends in the literature that indicate low levels of health literacy around diabetes pathology among medically underserved minority populations. Retinopathy screening is complicated by the fact that for the most part, the disease is asymptomatic until it gets to the advanced stages, so patients without symptoms may be baffled by the need for screening while patients with non-diabetic symptoms are frustrated by the screenings not addressing their existing symptoms. When told that they needed retinal screening, they were not educated sufficiently about the need for screening in the context of diabetes. From the patients’ perspectives, as demonstrated by focus group data, they often believed they were receiving a visual acuity test, rather than a retinal screen related to their diabetes. While these patients had access to diabetes management classes in some of the clinics, it was clear from their comments that they had not been provided any consistent, structured education about the role of retinal screening in diabetes. Based on our interviews, clinic providers were aware of patient concerns and many actually attempted to provide information to patients but these efforts were neither comprehensive nor systematic and thus obviously not effective. It is important to acknowledge the difficulty that these providers faced in describing disease progression to patients with limited literacy in their native languages. Nevertheless, a comprehensive educational approach that systematically addresses differing levels of patient health literacy with sensitivity to their preexisting barriers is one key factor necessary in addressing the knowledge gap among safety net patients going through teleretinal diabetic retinopathy screening.

Patients also faced significant preexisting socioeconomic barriers that shaped their access to care and their understanding about the importance of care. For example, 25% of the African Americans and 63% of the Latinos had received only a secondary education with, 60% of the Latinos having only some secondary education. Furthermore, 58% of the African American participants and 74% of the Latino participants made less than $1000 per month. Lack of resources such as time, money and information and limited ability to negotiate clinical related interactions resulted in great challenges for these patients to follow recommended treatment plans to manage their health conditions, such as diabetes. It is in the context of such severe preexisting barriers that their knowledge gap becomes consequential for follow through on teleretinal screening. These patients were challenged by limited health literacy when receiving health care in general, and in this instance, resulting in misunderstandings about their diabetic disease pathology and progression. This was most especially observable when patients misconstrued generalized symptoms of discomfort related to the eye (including symptoms unrelated to diabetes or diabetic retinopathy), to have been caused by their disease.

**Addressing patients’ fears during screening: The role of technological literacy**

A second point at which the knowledge gap is consequential is during the visit is when the patient encounters the technology associated with teleretinal screening. Patient engagement can be difficult to attain in the safety net because the typical patient may not understand the health technologies or the implications of their use. Whereas patients from a wide range of backgrounds are increasingly using computers and accessing the internet for health-related reasons, a gap continues to exist between those who can more effectively access and use information technology compared to those who do so less effectively. Healthcare scholarship has linked this gap to a pre-existing “digital divide” among certain groups of HIT users. The low rate at which patients owned computers and had access to the Internet among participants in our study highlights the digital divide experienced by these populations. Only 30% of the Latino participants owned a computer and 17% had access to Internet compared to 50% of the African Americans who owned a computer and 42% had access to the Internet. Whereas the digital divide has conventionally been conceptualized in terms of individual and population-level lack of access to technology (computers, internet), health communications scholarship has noted that ‘access’, particularly in the context of healthcare delivery, also includes meaningful use of technologies and exploring the social context in which people’s interactions with HIT take place. Extending the conceptual reach of the ‘digital divide’ beyond the scope of patients’ individual abilities or technology savvy to include technological literacy in the clinical setting sheds light on the role that limited literacy plays in individual experiences of access in other contexts, especially in the safety-net setting.

Patients who lack familiarity with medical technologies are more fearful of the equipment and are anxious that the machine may damage their eyes during the exam. This perception may discourage patients from complying with screening appointments. Furthermore, patients were concerned that photographers were medically and technically under-skilled. This may have been caused, in part, by high turnover among medical assistants, as well as minimal on-going training and interaction with the technology to maintain photographer technical skills. Also, in one clinic...
out of the six involved, clinic protocols prevented medical assistants from offering any medical or technical education during the screening. For some patients, photographer lack of confidence or unwillingness/inability to answer questions about care coupled with the absence of a specialist evoked concerns about the quality of care and the adequacy of the screening.

Patients’ lack of familiarity with process of teleretinal screening and with medical technologies could be addressed by informing patients about how teleretinal screening works. The first step may be to assess patients’ past experiences with retinal screening since this is the starting point for educating them about teleretinal screening. For example, it was not clear from our focus group data as to how many of our participants had ever received retinal screening for diabetic disease management. Patients may differ on their prior experiences and thus may need different types of information about teleretinal screening. Participants reported being put at ease with the technology and the screening process when there were interactions with their providers, particularly when information and education was provided during the exam. Thus, a systematic approach to educating patients about teleretinal screening should include a focus on a) how technology is used in the screening process, b) how training is provided to photographers/medical assistants and other clinic personnel in the appropriate use of the technology, c) how security of confidential electronic health data is managed during data transfer and d) the role of telehealth technologies in disease management. Such a systematic educational approach would improve patient technological literacy, allay some of their fears and begin to address the knowledge gap in teleretinal screening.

Addressing patients’ confusion after the visit: The role of Improved Provider-Patient communication

Following the exam, most patients appear to have little understanding of the significance of their diagnosis. Typically, patients were not contacted regarding a negative teleretinal screening result, whereas during an in-person retinal screen, a patient is given negative results immediately. Patients do not know how to interpret the lack of follow up by clinics; rather than an indication of a negative screen, lack of communication is perceived as no result at all. As a consequence, patients do not understand their own health-status and are unable to make effective use of the teleretinal screening results to direct and manage their own care.

Since patients do not adequately understand the pathology of diabetes and diabetic retinopathy, they have difficulty interpreting the results that may be delivered by the primary care provider (i.e. one patient reported that the provider only said “You’re fine”). Providers, who must concern themselves with all aspects of a patient’s pathology, may not take adequate time to explain the significance of a negative retinal screening resulting from diabetic retinopathy to a patient or try to work around patients’ perceived limitations. From the patient perspective, the lack of patient education about the role of teleretinal screening in their disease management plan seems to reinforce patient perception that, despite having received the screening, they are receiving subpar or incomplete care. For patients who already face a number of challenges to accessing care, this perception may hinder their ability or desire to comply with preventative screening in the future.

The confusion experienced by these patients with regards to post-screening results seems aligned with the lack of standardized education or consistent communication from providers. Low health literacy patients should be given clear information about posttest protocols - what it means to get no call, that negative results are good and that they have the right to call and find out screening results. Providers and other clinic staff may need to consider how to best communicate information about screening results with adequate detail and depth, nuanced to address the knowledge gaps of patients with differing levels of health and technological literacies and socioeconomic barriers.

Conclusion

In summary, patients’ pre-existing socioeconomic barriers along with their level of understanding regarding their disease and teleretinal screening technologies, combine to produce a knowledge gap in the clinical setting. Confusion about their disease, compounded by fear and lack of knowledge about disease management technology, may cause patients to feel powerless to understand or address their health concerns, their personal health/disease status, and result in unsatisfactory encounters with providers. Each of these outcomes has the potential to discourage patient compliance with treatment plans and to diminish patients’ ability to manage their own health care.

These findings support other studies regarding the challenges of health care access and health literacy in this population, which has been well documented over the last ten years \[1,2,26,27\]. Our research builds on these findings by presenting new information about how patients understand and perceive the digitization of clinical communication and the use of new technologies as an aspect of their chronic diabetes management. Despite their specific confusions related to teleretinal screening, most participants were generally pleased with the quality of care they receive at these community clinics. Patients also reported a strongly positive perception of the incorporation of new technologies...
into the primary care visit, particularly in the context of eye health. They associated such new technologies with progress in science and improved quality of care. While patients were generally satisfied with the overall care they received from their primary care providers, patients were concerned about specific aspects of teleretinal screening that arise as a result of the technology and the clinic protocols.

These findings suggest that patients in this clinical population, who exhibit both limited health literacy and limited technological literacy, need to be educated before, during, and after their telematic appointments. Patient education regarding both the health and technological aspects of the screening is essential in encounters with medical staff of all levels. Such education helps to ensure that patients understand the role of technology in their disease management, the procedures of the test, what to expect after the test, and how to interpret the results of their test. This is likely to have an impact upon patient understanding of teleretinal screening and, ultimately, upon patient compliance with diabetic retinal screening protocols. Our findings call for going beyond a definition of the “digital divide” that focuses on the patient’s personal access to and use of technology to consider how their level of technological literacy, health literacy and socioeconomic barriers together affect their experience of the increasing use of HIT in health care institutions. This will be particularly important, as patients are required to engage more actively in self-management of chronic diseases such as diabetes. Patient education will be important to ensure that telemedicine in the clinical setting does not become an additional barrier that contributes to the knowledge gap that exists among these populations.

There are some limitations to our study and findings. We have a relatively small convenience sample and our participants are not statistically representative of the wider population in inner-city settings and this limits the generalizability of our study’s conclusions. However, as is common to qualitative methods, they represent information-rich cases, homogeneously stratified across race and ethnicity, to allow in-depth understanding of their perceptions and experiences of teleretinal screening among these groups. While five years have elapsed between data collection and presentation of these findings, the results presented here are applicable to other resource-poor clinics implementing teleretinal screening programs to serve similar socio-economic populations.

This paper explored the way in which African American and Latino diabetic patients’ with less access to healthcare experienced teleretinal screening as an encounter with HIT in U.S. urban community clinic settings. This study’s significance lies in its identification of how patient disparities in health literacy, technological literacy and access to healthcare interact to produce a knowledge gap in their experience of teleretinal screening, potentially compounding their confusion and fear about the progression and management of their disease. Consequently, in the safety net clinic setting with a low health literate population, without adequate patient education, teleretinal screening may represent a new challenge to effective disease management. Patient education regarding the function and purpose of telehealth technologies, particularly in the specific contexts of their use in the health care setting, and improved provider awareness and communication of this information to the patient is critical to ensuring effective teleretinal screening, improving patient engagement in the self-management of chronic illnesses and addressing the knowledge gap experienced by most such patients in the clinical setting.

Acknowledgments

This project was supported by the NIH under grant number U54 MD007598-01S2 (formerly U54 RR026138-01S2). We would like to thank Dr. Richard Baker for his role in shaping our clinical understanding of teleretinal screening.

Abstract

In this project we sought to qualitatively describe clinician’s search for information related to the complex construct of adherence. Nineteen think aloud observations and semi-structured interviews were conducted with mental health providers as they prepared for a patient visit. The transcripts were coded according to constructs from information foraging theory (information goal, patch, scent, enrichment, and opportunity cost). The search strategies uncovered were complicated: provider’s searches were sometimes multi-staged (e.g. a search of the EHR led to further enquiry when interviewing the patient), and involved multiple ‘patches’ (i.e. data from the EHR, the patient and other providers were all sought out). In addition, some information that providers considered relevant to understand adherence related questions was non-obvious (e.g. the absence of specific information was considered a useful cue). Providers’ information search strategies for complex constructs are at times non-intuitive; implications for the design of EHR summarization tools are discussed.

Introduction

Clinicians spend significant time and energy searching the Electronic Health Record (EHR)1. They perform these searches to address clinical questions, and to integrate information into a coherent mental picture of their patient’s status 2. Our ultimate goal is to develop an EHR summarization tool that collects information related to a given clinical question and provides an integrated display. We hypothesize that such a tool would minimizing the time and cognitive resources required of help clinicians to locate and make sense of information relevant to the question at hand.

In service of this larger goal, the purpose of this project was to characterize providers’ information needs and search strategies related to a common, but complex clinical question: is this patient adherent? 3 Specifically, this study focused on the information search of mental health clinicians as they addressed questions related to adherence of their patients with Post-Traumatic Stress Disorder (PTSD). PTSD is a chronic mental health problem that is frequently co-morbid with conditions such as substance abuse and depression 3, and in which adherence to recommended treatment and self-care is critically important 4,5. We chose this use case because it is ideal for exploring clinicians’ search regarding adherence: the chronic and changeable nature of PTSD requires clinicians to repeatedly search the EHR in order to assess their patient’s adherence to recommendations and response to therapy.

Prior Studies Examining EHR Usage

The goal of this study was to examine how clinicians use the EHR to answer clinical questions in a real-world setting. This goal requires an in-depth exploration of both how clinicians frame their questions, and how the EHR is used. Our approach is in line with prior work, which has observed clinicians as they use the EHR 6,7,8,9. The novel component of this work is our focus on clinician’s search process as they use the EHR to address their information needs, based on their mental model of the information space. We believe that this approach can derive important implications for EHR design.
**Information Foraging Theory**

In this study, we used the constructs of Information Foraging theory (IFT) as a conceptual framework. IFT has been used to describe and predict individuals’ search behaviors on the internet\(^\text{10}\), and in bibliographic databases\(^\text{11}\). In addition, IFT and its associated quantitative models have been used to develop and evaluate information search and summarization tools\(^\text{12,13}\). We believe these prior successful applications of the theory suggest its possible utility in the development of tools to summarize the information in the EHR.

Information foraging theory (IFT) is based on an analogy with optimal foraging theory (OFT)\(^\text{14}\), which focuses on the optimization of costs/benefits to an animal in its search for energy from food in a given environment. Pirolli describes the essential idea of information foraging theory as:

"The optimal information forager is the one that best solves the problem of maximizing the rate of valuable information gained per unit cost, given the constraints of the task environment" \(^\text{14}\) p. 8.

The theory proposes that the individual spends their time either “within-patch” foraging, or in one of two types of “between-patch” activities: using proximal cues to make decisions about the potential value of information patches (Scent-following), or molding the information environment to either reduce between-patch foraging costs (Enrichment activities). Table 1 describes the theory’s central constructs and their definitions.

<table>
<thead>
<tr>
<th>Construct</th>
<th>Definition / Examples from the EHR</th>
</tr>
</thead>
<tbody>
<tr>
<td>Information Goal</td>
<td>The information sought relevant to the current task / e.g. remind myself of this patient’s plan of care.</td>
</tr>
<tr>
<td>Patches</td>
<td>Physical or virtual areas of concentrated information yield / e.g. notes, tabs, windows, etc.)</td>
</tr>
<tr>
<td>Scent</td>
<td>The individual’s imperfect perception of the values, cost or access path of information sources obtained from proximal cues / e.g. perceptions of the value of information underlying note titles, tab titles, alerts, etc.</td>
</tr>
<tr>
<td>Resource Costs</td>
<td>The actual costs incurred by pursuing a given information source / e.g. time required, clicks required to locate desired information.</td>
</tr>
<tr>
<td>Opportunity Costs</td>
<td>The benefits that would have been accrued in pursuing a different information source, but were not gained due to the given pursuit instead</td>
</tr>
<tr>
<td>Information Diet</td>
<td>The range of foraging choices the individual makes amongst several potential sources.</td>
</tr>
</tbody>
</table>

Two assumptions of the model should be emphasized. First, the theory assumes that the value of information is not intrinsic but is dynamic and task specific. This assumption has face validity in our proposed use case: clinicians searching the EHR for data related to a patient’s adherence to treatment will naturally weigh certain information sources more heavily than others. Second, the theory does not assume that the individual is classically rational with perfect information and infinite computational resources. Rather it suggests that individuals engage in “satisficing” which involves optimizing within the constraints of imperfect information and limited time and cognitive resources. Therefore, the solutions reached are not assumed to be globally optimal but allow for the specification of “information niches” that may be local maxima. Again, this approach has face validity in clinical practice. We do not expect that clinicians exhaust all possible avenues to address an information need. Instead, they make use of the data that is readily available to them to address a question, and often must make decisions in the face of uncertainty.
Methods

Human Subjects

This study was conducted in accordance with World Medical Association Declaration of Helsinki on Ethical Principles for Medical Research Involving Human Subjects, and was reviewed by the Institutional Review Boards of the George E. Whalen Salt Lake City VA Medical Center (SLCVA) and the University of Utah. Informed consent was conducted with both the provider and the patient.

Overview

This was an observation and interview study of clinicians’ information search in a real clinical setting. Clinicians were asked to think-aloud as they prepared to see a scheduled patient and they reviewed the patient’s chart. This study combined direct observation and interviews with a qualitative analysis. The methods chosen for this study aimed to capture clinicians’ information search as closely as possible to their uninterrupted, unobserved real world processes.

Setting

The George E. Whalen Salt Lake City VA Medical Center (SLCVA) is a 101-bed tertiary care center that provides both inpatient and outpatient mental health services. This study took place in an outpatient mental health clinic and targeted patients diagnosed with PTSD.

Description of Participants

Eight mental health clinicians from the SLCVA’s outpatient mental health clinic were recruited to participate in this study. All clinicians were treating individuals with Post Traumatic Stress disorder (PTSD). Of the eight clinicians who participated in this study, seven are psychologists and one is a social worker. Six are female and two male. They ranged from less than one year of clinical experience (a post-doctoral fellow) to more than 20 years of clinical experience. Clinicians were recruited via both in-person requests at staff meetings and follow-up emails. The first author conducted a total of 19 observations (a minimum of 2 and a maximum of 3 observations per provider) in the outpatient Mental Health clinic. To maximize variability each observation was of a unique patient visit (no repeat visits by the same patient were observed). To ensure that adherence was a relevant concern, all appointments were follow-ups.

Procedures

After completing informed consent, mental health clinicians were observed prior to their appointment with patients. As they prepared to see a patient, clinicians were instructed:

“Please review the chart as you normally would and think aloud about what information you are looking for, what information you are finding, and what you are thinking about.”

The duration of the chart review duration was at the discretion of the clinician but was generally brief (5-7 minutes). After completing the chart review, clinicians participated in a semi-structured interview intended to probe for information goals and search strategies for adherence related information (the Appendix contains the interview guide). The interview lasted 10-15 minutes. When the patient arrived for their appointment, the study was explained to them and they then completed informed consent. The patient’s consent simply provided the study team with access to those notes in the patient’s electronic medical record that the clinician had reviewed in preparing for the visit. The think aloud and the interviews were audio recorded and then transcribed by a medical transcriptionist. All individual identifiers were removed from the texts in the process of transcription.
**Data Analysis**

The study team used an iterative process of qualitative analysis using ATLAS Ti@. Each researcher highlighted text they believed to represent information relevant to information search, and/or concepts of adherence. Highlighted areas were reviewed discussed by the group, and given what Patton refers to as “pre-codes” - short descriptions of the content \(^9\). Many of these pre-codes referred to adherence concepts, patient’s response to therapy, risk assessments, and clinician’s mental models of the information space. The goal was to capture concepts relating to clinician’s mental models of adherence, and the information search processes related to those mental models. After additional discussion and review, the constructs were organized through consensus into higher-level categories according to Information Foraging Theory.

**Results**

The results presented here are organized around the constructs of Information Foraging Theory. The analysis is interpretative, using theory to explain and understand results.

**Information Goals**

Table 2 presents examples of text that were coded as exemplars of information goals. Information goals associated with adherence varied, and included: determining compliance with assigned homework, determining the patient’s response to therapy, identifying if the patient was ready for a specific therapy, and looking for evidence of how “activated” the patient was in terms of treatment. In many cases information goals consisted of discrete pieces of information that would be straightforward to electronically query for and represent in a summarization. However, in several cases during their chart review several clinicians reported developing questions that required further follow-up with the patient. This type of information goal, one in which an original search precipitates a second information search via a different “patch” (e.g. the patient) has implications for EHR design which we will discuss later.

**Table 2. Example Text for Information Goals Relevant to Adherence**

**Information Scent**

Table 3 presents text snippets that were coded as exemplars of Information Scent. In most cases these references are simple, explicit cues about informativeness. However, clinicians sometimes mentioned the absence of information as a cue. For example, one clinician noted the absence of emergency department notes as a cue that her patient might be doing better. Several participants mentioned the absence of any notation that the patient was a poor historian as evidence that the patient must be a good historian and several also mentioned that the absence of notes about non-compliance to therapy was a sign that the patient was likely adherent. This particular form of Information Scent, the absence of particular information, has implications for the design of an EHR summarization tool.

</tr>
</tbody>
</table>

**Information Patch**

An information patch is the actual location of information (rather than a pointer to that source). Table 4 presents text snippets that were coded as exemplars of Information Patches. In most cases, our participants visited a limited number of patches- mental health notes and more frequently their own notes, were the most common patches searched. However, in several cases clinicians mentioned information locations outside of the EHR (e.g. patients, other clinicians) as important sources. Again this finding has implication for the design of an EHR summarization tool.
Table 4. Example Text for Information Patch

<td>“We spent 45 minutes in the chart looking”</td>
</tr>
</tbody>
</table>

Enrichment

Table 6 presents texts snippets that were coded as exemplars of enrichment (an individual improving their information environment to improve future yield). Interestingly, several clinicians mentioned a form of enrichment that is unique to the EHR: clinicians often place other clinicians as cosigners on their notes to promote a shared awareness of their patients’ disease state and treatment plans. In addition, several clinicians spontaneously lamented the absence of search tools within the EHR. We note that no text was coded as representative of enrichment by improving within-patch yields, we will return to this in the discussion.

</table>
Discussion

In this project we explored mental health clinician’s information search as they addressed questions related to the adherence of their patients. Our findings indicate that clinicians’ information search in the EHR is complex and at times non-intuitive. For example: clinician’s engaged in information search in one source which precipitated a second search via a different source (e.g. reading a note reminds the provider to ask the patient a particular question during the visit), clinicians reported the absence of information as an important cue (e.g. clinician noting the absence of emergency department notes as a cue that her patient might be doing better) and clinicians communicating with each other by placing each other as cosigners on their notes (a form of enrichment that is unique to the EHR). We believe that these findings regarding searches that are distributed over time and across patches, the absence of information as a “scent”, and the social form of enrichment exemplified by cosigning, have significant implications for the design of EHR search and summarization tools.

This study is one of only a few to use Information Foraging Theory to describe the information search of healthcare workers. Dwairy, et al. studied primary care physicians when addressing clinical questions and found that colleagues and books were preferred sources of information (patches), they concluded that this was likely due to the decreased time required to answer the question compared to an electronic database search 16. Kannampallil, et al. used a think aloud protocol and observation to examine the information search of physicians in an ICU setting. They found that physicians sought out different sources depending upon their specific information goals, and that answering clinical questions required integration of data from multiple sources. In addition these researchers estimated the relative information gain from various sources and found that electronic sources provided more unique information per unit time than paper records 17. Our findings echo this prior work in that the “information diet” of the clinicians we studied included both human and electronic information sources. Our findings expand upon this prior work by identifying the specific patches, scents and enrichment strategies used by clinicians to address their questions regarding their patient’s adherence and by noting areas where our observations will impact the design of our planned EHR summarization tool.

Implications for EHR Design

We believe that our findings offer insights into potential improvements in EHR design. First, this work illustrates how information needs are context dependent, what would seem on the surface to be the same information need: adherence, varies in content and structure depending on why the information is needed. We believe this suggests that EHR designers need to understand the reasons why clinicians might be interested in a specific class of information and then use that understanding to develop an appropriate information display. For example, a clinician wanting to understand their patient’s “dose” of exposure to medical intervention might use the patient’s attendance at medical appointments as one measure but would likely want to correlate this with other measures (e.g. frequency of appointments, number of unique providers, number of medications, etc.). Conversely, a clinician wanting to understand how “activated” the patient is might correlate the same appointment attendance information with a different set of measures (e.g. patient reported activation, reports from other providers, measures of health related behaviors). We believe that our findings suggest that EHRs should provide integrative displays that address the user’s information needs in context. Second, our finding that clinicians use multiple information patches to address a single overarching information need suggests the need for the inclusion of a broader range of data into the EHR. For example including patients’ functional and social data in the EHR 18 would reduce clinicians need to search outside of the EHR for this data, allowing for easier mental integration of this data with clinical data and therefore greater efficiency. Third, the concept of information “scent” seems critical to improving EHR design. Clinicians clearly sought out specific patches depending upon the limited scents available (e.g. note titles). The EHR could provide stronger “scents” regarding the location of specific information types. These scents might include cues as to the content of specific patches as well as critical metadata such as certainty (e.g. provisional vs. confirmed diagnosis) and currency (e.g. historical problems vs. current problems). We hypothesize that an EHR that provided these cues would improve the efficiency and accuracy of clinician’s searches. Finally, our results suggest that clinicians clearly want EHRs that allow them to enrich their information space. This would include: the ability to aggregate data elements that are relevant to specific clinical questions from a variety of patches, the ability to search within patches to more efficiently locate specific data, and tools to communicate and collaborate with other clinicians.
The results of this study will inform our future work in developing an EHR summarization tool. The non-obvious nature of providers’ mental models of the information space suggests that creating a map between clinical questions and information needs will likely require involving providers themselves. One potential method to accomplish this would be for providers to use tagging tools to identify data elements and patches that are relevant to specific clinical questions. This mapping could be available for future use by an algorithm as well as for sharing with other providers (e.g. collaborative search). To address providers’ need for the capacity to enrich within-patch yields, we might provide the ability to search for concepts semantically related to a given keyword within notes. Finally, the use of cosigning to promote shared awareness and the adding of amendments to clinical notes as a tool for collaboration, points to the need for communication and collaboration tools in the EHR.

**Strengths**
This study has several strengths. First, we used a well-established model of information search (Information foraging theory) as our conceptual framework. Second, we used two types of qualitative data (think aloud and interviews) to capture different perspectives on clinicians’ information search. Third, we used iterative thematic coding to minimize bias in our findings.

**Limitations**
This study has limitations. Since the sample size was small and the data collection was restricted to mental health clinicians treating individuals with PTSD, the results may not generalize to other domains, therefore further work is needed to validate these preliminary results. It is also worth noting that we did not address or control for how long the clinicians had been seeing the patient; the duration of this relationship may have affected clinicians information search. Future studies should account for this important factor. In addition our measurement of information scent relied on provider’s report of what they considered cues to important information. In future work we could improve upon this by measuring the clinicians’ gaze, this would allow us to note the information cues that providers both consciously attend to (gaze at and comment upon) and implicitly attend to (gaze at without awareness) and then either pursue or do not pursue, thus providing a much richer representation of information scent. Finally, in this study no text from our transcripts was coded as representative of “opportunity costs.” In future work, this might be addressed by prompting participants to reflect on the expected value of the search within a specific patch relative to querying an alternative source (e.g. look in a different part of the EHR, telephone the patient to answer this question).

**Conclusions**
In this study we combined think-aloud and semi-structured interviews to understand mental health clinicians search for adherence related information. We found that clinician’s information search to understand their patients’ adherence is complex, and at times non-intuitive. We believe this foundational work is a useful first step toward the development of EHR summarization tools that will improve the effectiveness and efficiency of clinicians’ information search.

**Appendix: Semi-Structured Interview Guide**

1. What tells you that the patient is doing better or worse?

2. What in the note informs you if the patient is adherent to recommended treatments or not (whatever the treatment is – e.g. medications, therapy, CBT, group)

3. If the patient is not adherent, what information in the notes is most helpful to determine WHY the patient is non-adherent?

4. What information would inform you about the likely consequences (for the patient and others) that are likely for being non-adherent?

5. Where do you look in the notes to find out if prior interventions have been done to address non-adherence and how well they worked?

6. Looking in the chart, would there be any reason to suspect that the patient is not a good historian?

“Scared to go to the Hospital”:
Inpatient Experiences with Undesirable Events

Abstract
Involving patients in healthcare safety practices has long been an area of priority and importance. However, we still need to understand how patients perceive undesirable events during their hospital stay, and what role patients play in the prevention of these events. To address this gap, we surveyed pediatric inpatients and caregivers to understand their perspectives on undesirable events. By giving them an opportunity to use their own words to describe their experiences, we found a diverse array of undesirable events. Our qualitative analysis revealed four major types of events that patients and caregivers experienced: mismanagement, communication, policy, and lack of care coordination. We also examined the information needs that patients and caregivers experienced during these situations, and learned how they would prefer to receive this information. Based on these results, we provide recommendations for inpatient technologies that could enable patients to identify and prevent such undesirable events.

Introduction
Despite over a decade of national attention to the problem of patient safety, as described in To Err is Human and Crossing the Quality Chasm¹,², a recent study estimates that over 440,000 people die every year from preventable medical errors in U.S. hospitals³. As of 2016, preventable medical errors are considered the third leading cause of death in the United States, behind only heart disease and cancer⁴. Research over the past decade suggests that patients provide a distinct perspective on safety events that is not captured through staff reports and medical record review⁵,⁶. Weissman and colleagues looked at the overlap between undesirable events reported by patients and by physician review of medical records. Their work showed that 23% of 998 sampled patients reported at least one adverse event, compared to 11% of cases identified through medical record review. Moreover, only 12% of the events reported were discovered through both mechanisms⁶. Thus, to identify a comprehensive view of patient safety, we need to understand patients’ perspectives in addition to clinicians’ perspectives. Although several studies have solicited input from patients, these studies use closed-ended questionnaires based on categories of undesirable events that are predetermined and predefined by clinicians and medical researchers⁷,⁸,⁹. Thus, more research is needed to understand patients’ perspectives in their own words¹⁰.

Previous research has shown that patients can play a significant role in a variety of safety-related processes, such as helping healthcare providers confirm an accurate diagnosis, making appropriate treatment decisions, and choosing a good provider that aligns with the patient’s needs and values¹¹. Patients have also been recognized as actors in identifying, preventing, and reporting medical errors. In 2007, Unruh and Pratt described five cases where oncology patients were involved in the identification, prevention, and recovery from medical errors in an outpatient setting¹². Other studies in the inpatient setting have shown that patients notice errors related to their care and bring them to the attention of their providers¹³,¹⁴,¹⁵. However, we know little about what patients’ experiences and perspectives around patient safety are, or how to develop informatics solutions that support patients in their important safeguarding role.

In support of a strong role for patients, evidence from over 50 studies has shown a positive correlation between patient experience (e.g., respect for the preference of patients, inclusion of patients in decision-making, clinicians’ ability to empathize, and provision of information to enable self-care) and patient safety¹⁶. Despite this close relationship between patient experience and safety, existing technology for enhancing the patient experience is not typically designed to support and engage patients as active participants in the detection or prevention of undesirable events. To examine a related area of the role of existing technologies in supporting patient engagement within the hospital environment, Prey et al. found that technologies served a variety of purposes, including the use of entertainment to decrease anxiety and improve rehabilitation treatment, the delivery of general or tailored information to patients and caregivers,
the enrichment of patient-provider communication, and the enhancement of communication and personalized decision support between patients and caregivers\(^7\). However, of the 17 articles included in the review, only two emphasized the technology’s role in improving safety\(^18,19\). Additionally, Greysen et al. conducted a pilot study using a tablet computer-based learning module to help educate patients about safety in the hospital\(^20\). Although these insights help us understand the role of patient engagement technology in the hospital setting, it remains unclear how similar tools, informed by inpatient safety experiences, can effectively support patients in identifying, preventing, and reporting undesirable events.

In this paper, we address these gaps and present the results of a survey asking pediatric inpatients and their caregivers about their prior experiences with undesirable events. Our study provides a rich understanding of these patient and caregiver experiences in their own words. We also identify information needs that participants felt could have prevented these undesirable events, as well as their preferred method for receiving this information. Based on these results, we explore the potential for technology to bridge these information gaps and assist patients and caregivers in preventing errors in the inpatient environment. These contributions have meaningful implications for the design and development of systems to increase the engagement of both patients and caregivers in hospital safety.

**Methods**

To account for a broad range of patient and caregiver experiences, we created a survey with open-ended questions regarding undesirable events. We defined *undesirable event* within the survey as something that: was a small or big concern, was unpleasant or caused harm, and could have been avoided (e.g., not being informed that a scheduled procedure was cancelled, being given the wrong medication). Although these experiences might not typically be recognized as an error by clinicians, and might not match with a clinician’s perspective of what constitutes harm, we need to understand and recognize these events from a patient’s perspective. This study was approved by the authors’ Institutional Review Board.

**Site and Eligibility**

This study was conducted at Seattle Children’s Hospital, which manages over 300 beds, 5,000 hospital employees, and approximately 15,000 annual inpatient admissions. Patients were considered eligible if they were at least 7 years old, spent at least one night in the hospital during their current visit, and spoke English as their primary language. Caregivers were considered eligible if they were caring for a patient who had currently spent at least one night in the hospital, and if English was their primary language. Patients who were not well enough to give informed consent were not approached to complete the survey. We recruited participants from the acute care and intensive care units, and excluded those on the rehabilitation and inpatient psychiatric units due to the potential of our intervention to negatively affect safety, security, and patient care processes.

**Procedure**

We approached patients and caregivers after they spent at least one night in the hospital. A member of the research team described the study, defined the term undesirable event, and asked whether they had previously experienced such an event. If potential participants stated they had not experienced an undesirable event, they were deemed ineligible and thanked for their time. Those individuals who did experience an undesirable event were given further information about the survey instrument, and at that point either declined or consented to participate in this study. The consented participants were administered the survey instrument on an iPad, which was thoroughly wiped down with sanitizing cloths after each use to prevent the spread of infection within the hospital\(^21\). A research team member was available to answer questions or help the participant take the survey if necessary. Because we focus on patients’ perceptions, comparing the events that respondents mentioned in the survey with provider perspectives or official medical record reports was outside the scope of this study.

**Survey Instrument**

Our survey instrument was hosted by SurveyGizmo ([www.surveygizmo.com](http://www.surveygizmo.com)) and went through several iterations of content validity and testing to ensure that the questions were clear, thorough, and understandable for all eligible participants, including children as young as 7 years old. The survey questions related to the participant’s undesirable event were a combination of closed- and open-ended questions asking them: (1) what was the undesirable event that they experienced, (2) what they believed
caused this event, (3) what was the outcome of this event, (4) what they believe could have kept this event from happening, (5) what information the respondent thought they needed during this event, and (6) in what format they would prefer to receive this information. The participant could answer these questions about any previous undesirable event, not necessarily related to their current hospital stay. For example, caregivers could respond to the survey about an event in a different hospital that occurred several years ago with a family member other than their current pediatric patient. This flexibility helped to broaden the types of events we were interested in capturing.

**Data Analysis**

We analyzed the demographic and closed-ended survey question results using the analytical tools within SurveyGizmo. We conducted an inductive thematic content analysis on the responses to the four open-ended survey questions related to the respondent’s undesirable event. The research team met regularly during data collection to read new survey responses and revise the codebook based on emerging themes observed in the data set. Three members served as coders, assigning each survey response one or more codes that represented these themes. Data analysis concluded when themes in the codebook reached saturation and each completed open-ended survey response was assigned at least one code.

**Results**

Our qualitative analysis found four major types of undesirable events that patients and caregivers discussed in their survey responses: Mismanagement, Communication, Policy, and Lack of Care Coordination. For each of these categories, we provide explanations with quotes and anecdotes from our participants below, as well as summarize the outcomes associated with these events (Figure 1). We also examine what information participants thought would have been helpful in preventing or reducing the impact of these events (Figure 2), and how they prefer to receive this information. Patient and caregiver responses are designated with ‘P#’ and ‘C#’ identifiers, respectively. Because we also assigned identifiers to 10 blank and 13 incomplete survey responses that were excluded from our analysis, some identifier numbers are greater than the number of complete responses.

### Participants

Our research team approached 173 individuals in the hospital, of which 83 (47.98%) were considered ineligible because they had not experienced an undesirable event, 22 (12.72%) declined, and 68 (39.31%) completed the survey. Participant demographics are summarized in Table 1. Three of our participants expressed their desire to answer questions about more than one personal experience with undesirable events. Therefore, 68 individuals completed 71 survey responses describing 71 undesirable events, of which 16 (22.5%) identified being a patient, and 55 (77.5%) identified being a caregiver at the time of the undesirable event.

### Mismanagement

‘Mismanagement’ is a term we use to characterize undesirable events that consisted of clinicians’ errors in judgement or decision-making, and problems with the execution of a task or completion of a process. The strongest themes within this category dealt with medication and equipment errors.

### Medications

Patients and caregivers reported a variety of medication errors, including not receiving needed medications, receiving the wrong dosage, and receiving the wrong medication. One caregiver discussed her son not getting a medication for

* 3 respondents completed multiple surveys about different undesirable events

** Participants could choose multiple categories
urinary retention for five days, resulting in the patient holding urine for over 12 hours at a time and the
need to put in a catheter (C53). Regarding medication administration, another caregiver wrote about an
event that happened to her daughter right before undergoing a major procedure: “She was given 5 times to
[sic] much morphine and she was hardly breathing” (C47). In other cases, patients received the wrong
medication intended for another patient. A pediatric patient recalled a mix-up while sharing a hospital room
with his sister: “Someone did not look at the label close enough” (P12).

Equipment
Participants also mentioned the misconfiguration or mishandling of medical devices. One NICU caregiver
noticed that the nurse did not use a board to secure her son’s IV. She later woke in the middle of the night
to find the patient’s IV detached and his hospital gown “soaked in blood.” She recalled: “I didn’t know
what had happened...but it looked pretty scary, and made me wonder when he had last been checked on by
staff” (C45). In another example, C63 woke suddenly for early morning rounds at 6:00 am. As the
examination began, this caregiver noticed the patient’s External Ventricular Drain was not clamped off, and
brought this oversight to the attention of the providers in the room. “At that point they realized they had the
incorrect patient. They were looking for the baby in the next bed. Her parents were not with her...I’m
thankful I came to my senses in time to interrupt them.” Because C63 noticed the problem and shared this
information with the providers, she stopped a treatment from being given to the wrong patient.

Outcomes
Many of the undesirable events were successfully resolved. For example, C53’s son eventually received the
necessary medication, while C47 noted her daughter’s mistake in morphine administration was reversed,
and the patient was able to wake up. Other situations, however, lead to a decline in the patient’s health,
which required additional care. For example, one patient was told she needed to remain flat after a
procedure, but was walked back to her hospital room instead. Severe headaches and vomiting developed as
a result. “My hospital stay was lengthened due to this and has caused lower back pain for several years”
(P94). As a result of these experiences, patients and caregivers reported feeling angry, scared, and worried.

Communication
Many undesirable events discussed by survey respondents involved communication problems that manifested
in different ways: between providers, in receiving information, and in providing information.

Between Providers
Participants identified conflicts and a lack of communication among their providers as a type of undesirable event. Regarding his
diagnosis, a pediatric patient said that “the doctors were disagreeing amongst themselves” and, in this patient’s opinion,
this disagreement caused them to overlook the data and miss “the real problem” (P30). In another example, a caregiver
described an event where disagreements between different teams of providers actually distracted them from the patient’s
increasingly urgent medical situation: “[my son] turned blue and was gasping for air. The nurse my son had that day took charge
and called the charged [sic] nurse for help. As we moved my son to the ICU floor, both team[s] were still arguing ” (C91).

Figure 1. Relationship between reported events and outcomes. We identified 143
unique relationships when coding the undesirable events. Mismanagement and
Communication events account for most of the self-reported events. While there
was more consistency between the different amount of outcomes, impacted care
plans and emotions were mentioned more frequently than other outcomes.
Not Receiving Information

Participants described difficulty in dealing with the lack of information. One parent mentioned, “A doctor I had never met before discussed worst case scenario treatment options in a very casual fashion...He was not a doctor in charge of making treatment decisions but more of a consult however didn’t identify himself that way” (C78). Because this caregiver did not receive more information about the provider, including why he was in the room, it influenced C78’s interpretation of treatment options that were discussed. Another caregiver remembered a time when the IV team was called to repair her son’s leaking line, but took over 2 hours to arrive. When asked about what she thought caused this event, C90 responded, “unwillingness of IV team to give updates despite repeated requests from [hospital department]”. This caregiver felt “caught off guard” because this delay also prevented the patient’s family from receiving critical information about his treatment side effects.

Challenges in Providing Information

Many caregivers felt that their voiced concerns about potential or ongoing problems were not acknowledged. For example, one NICU caregiver kept waking in the middle of the night due to the continuous alarm from the isolette. According to this caregiver, the nurse would come into the room and attempt to shut off the alarm every few minutes. “We were familiar with the isolette…and so could tell she had it on the wrong mode. We continued voicing our concern and the machine kept beeping...finally they had a NICU nurse come down and show her that she didn’t have the temperature probe on the baby’s body...” (C69). Although this caregiver expressed her concern to the nurse, she had to wait for a different provider to intervene and turn off the alarm. In another example, one adolescent patient described his unwillingness to give his providers information because he felt he was not receiving the care he needed: “the doctors [sic] didn’t give me anything to help the pain. It basically felt like they gave up on me and said suck it up...I soon didn’t even want to talk to the doctors [sic] at all because they were being horribly rude to me” (P18).

Outcomes

As a result of these communication errors, patients and caregivers experienced a range of negative emotions (e.g., frustration, stress, unhappiness, distrust, fear), health outcomes, delays in care or discharge, and need for additional care. Some respondents indicated that their undesirable events were successfully resolved. For example, C90’s son eventually had his IV line repaired. A few caregivers explicitly mentioned speaking up and requesting different providers to care for their child (C20, C65). Caregivers also expressed a desire to be more involved in the care process.

Policy

Patients and caregivers found themselves at odds with policies that seemed unreasonable or inconvenient. During a previous admission at a different hospital, P21 made a request for manual chest physiotherapy (CPT), a request that was not fulfilled due to “liability concerns”. The patient described, “I have had manual CPT at every other hospital I have ever been admitted to without any problem and found their policies to be ridiculous” (P21). One caregiver mentioned that hospital policy made it difficult to keep her family physically together: “After we had been asleep a while they came and told us hospital policy that our son cannot stay here but they were trying to approve it. So approve it! It’s been a long day and I don’t see how telling me that when we’re already in bed can help anyone” (C38).

Adverse effects of contact isolation protocols were also mentioned. A patient described her frustration with being placed under isolation when she did not believe she met its criteria. The patient’s siblings were not allowed to visit, and she was unable to receive the emotional support she wanted (P89). C62 was not allowed to store perishable food in the patient’s room according to contact isolation rules. Their room was far from the cafeteria or nutrition room, and an increased financial cost was associated with obtaining a room closer to food storage. As a result, both the caregiver and patient were unable to eat properly during their hospital stay.

Outcomes

Respondents cited negative health outcomes and negative emotions as a result of undesirable events related to policy. Because P21’s preferences were not accommodated, there was “barely any improvement in lung function, followed by another hospital stay for the same lung issues just a few months later.” Due to C62’s
lack of food access, she was unable to eat regularly, resulting in poorer general health. Negative emotions were also mentioned. P89 reported that contact isolation made her feel trapped in her room. “I felt as though [the doctors] didn’t understand how much it affected me as a patient.”

**Lack of Care Coordination**

The term ‘Lack of Care Coordination’ includes problems with scheduling, logistics, or coordination among providers, families, and patients. One participant described: “Care was not clustered and woke baby up repeatedly through the night, often just 30 minutes apart from one another” (C43). Two other caregivers mentioned missed opportunities to speak with providers about their child’s care (C57, C49). For C49, this prevented the patient’s parents from discussing their concerns about the patient’s care. “Further attempts were made by caregiver to state concerns. Hospitalist involved but damage was done.”

A lack of planning caused inconvenient delays in discharge for some patients. P39 stated, “I got discharged on Monday when my doctor said it could have been on Sunday” due to both a lack of coordination and communication. P16, an adolescent patient, experienced a discharge delay “for about a week” because both the patient and hospital staff had difficulty contacting the appropriate caregiver to sign the discharge paperwork. There was no plan in place to accommodate for this situation, and despite being healthy enough for discharge, the patient remained in the hospital until someone was available to provide a signature for her release.

**Outcomes**

In addition to discharge delays, C57’s daughter experienced a delay in care because he was not present for his child’s procedure. Negative emotions were also identified as outcomes of events related to lack of care coordination. C43’s child was “sad” and “cranky” the following day due to lack of sleep, while P16 struggled with unwanted feelings of being alone in the hospital. Respondents felt that proper planning and communication would have prevented these events from occurring. “Coordinate with each other...make sure you know what needs to be done in advance” (C43). C49 expressed a desire for “an agreed upon round time that met [the] schedule of all parties involved.”

**Information Needs and Preferences**

After describing their undesirable event, respondents were provided a list of 16 information needs, and asked if one or more of these items would have been helpful for them to know. The results of this question are shown in Figure 2. Differences in information needs were found across the types of events and between patients and caregivers. For example, patients who experienced mismanagement, communication, or policy errors were most interested in having information about their tests, procedures, and treatment plans. Patients who experienced care coordination problems wanted to know about discharge, while caregivers more interested in the timing of clinician visits. However, across all types of undesirable events that emerged from our analysis, caregivers most frequently indicated their desire to know ‘who to contact for help or questions’.

Respondents were then asked how they prefer to receive these information needs. They selected one or more modes of information delivery, from a list of 9 non-technology
based (e.g., paper handouts, written on the whiteboard, talking with doctors and nurses) and existing electronic (e.g., patient portal, text message, email) methods. Of the 80 total choices that our 16 patient respondents made, 68 (85.0%) fell into the non-technology based category, while 12 (15.0%) fell into the electronic category. Our 55 caregiver respondents made a total of 263 choices, of which 183 (69.6%) indicated non-electronic and 80 (30.4%) were electronic preferences for information delivery.

Discussion
Our participants provided informative data about the context and consequences of patient and caregiver experiences with undesirable events. Our results highlight the value of these perspectives in informing the design, development, and improvement of patient engagement technologies that can support error prevention within the hospital environment.

Undesirable Events from the Patient Perspective
Our findings extend previous definitions of undesirable events by accounting for patient and caregiver experiences. In addition to confirming previous concepts of undesirable events, participants also discussed mismanagement of situations regarding medications and medical equipment, disagreements with hospital policies, and challenges with communication and coordination. In related work, patients were usually asked to provide a binary response (yes or no) as to whether they encountered specific instances of clinician-defined undesirable events. These studies rarely allowed patients to provide further details. Our survey gave patients and caregivers the opportunity to share their knowledge in an unrestricted, open-ended way. This patient-focused approach revealed previously unidentified types of errors, and explored patient-perceived causal relationships between an undesirable event and its impact on the patient and caregiver (Figure 1). This knowledge permits future systems to better align with the needs of patients and caregivers.

Implications for Health IT and Inpatient Engagement Systems
Our results yield three major implications for inpatient information systems designed to increase patient engagement in the prevention of undesirable events. These systems should: (1) accommodate different information needs and preferences, (2) provide real-time information about the patient’s care, and (3) supplement face-to-face communication with clinicians.

Accommodate Different Information Needs and Preferences
Our findings indicate that information needs differed across types of events as well as between patients and caregivers. It is extremely important for patient-facing solutions to provide this range of information, due to current challenges in anticipating the nature of an undesirable event during a patient’s hospital stay. Future work in this area could further explore patterns of information needs associated with types of events, which would assist in the prediction or delivery of this tailored information to the patient and caregiver.

When asked about how they prefer to receive the information above, respondents favored more traditional communication options (e.g., paper handout, written on the patient’s whiteboard, talking with clinicians,) rather than modern solutions (e.g., patient portal, email, text message). This focus on non-technology based solutions could be explained by current hospital practices that tend to rely on such traditional solutions for distributing information, and the barriers patients and caregivers encounter when attempting to capture this information using technology. Despite our respondents’ strong preference for paper, handwritten, and verbal communication, recent work involving pediatric inpatient portals found that 89% of parents thought the use of such a portal helped reduce errors in the patient’s care. More research is needed to understand how the availability and enhancement of similar tools can impact patient and caregiver preferences for information delivery.

Provide Real-Time Information
Patient-facing information systems for the inpatient environment need to provide patients and caregivers with real-time information about the patient’s care. One respondent, a caregiver, described a situation where she did not receive updates about changes made to the patient’s medication plan: “[there were] too many people involved and too many changes made and parents not aware of them” (C15). In this case, not receiving updates about changes to the patient’s medication was the primary reason for the caregiver’s undesirable event. Because undesirable events can arise at any point during a hospital stay, we strongly recommend that systems provide patients and their caregivers with information about their care without any
built-in time delay, providing capture and access functionality that supports retrieval and review at a patient or caregiver’s convenience. These tools have the potential to share information with other family members and caregivers who make critical decisions about the patient’s care. Also, providing additional information (e.g., explaining what a lab result means) allows patients and caregivers to better understand treatments and ultimately strengthen their ability to act as their own advocate.

Supplement Face-to-Face Communication
Inpatient systems also have the potential to offer patients and caregivers alternative communication routes when face-to-face communication fails. Many respondents described different ways in which these failures occurred. For example, one caregiver mentioned a conflict with a nutritionist regarding her son’s diet. The nutritionist “did not listen to what I had to say”, and ultimately the caregiver “got irritated and took matter[s] into my own hands” (C91). In this case, when in-person communication broke down, an electronic system could have allowed C91 to non-confrontationally request support or opinions from another clinician. Another caregiver discussed a time where face-to-face communication with her son’s providers actually caused increased worry and concern: “The resident came in [and] was asking questions that were causing me alarm. It was making me worried about my son and if there was something going on that they weren’t telling me…” (C51). In situations like this, when there is increased potential for miscommunication, or when there is an evident lack of information, inpatient tools can serve as a mechanism for patients or caregivers to request further details and ask follow-up questions when needed.

Limitations and Future Work
Individuals who were not eligible, not well enough to provide consent or answer survey questions, or declined participation were not given the survey. Because of this constraint, other types of undesirable events could have been missed. Three participants responded to our survey more than once, because they expressed a desire to answer questions about multiple undesirable events. Although this introduced a demographic redundancy in our data set, we independently tracked the number of unique individuals we approached during this study, and have reported the differences in these values. A selection bias could influence our results, as respondents were not offered compensation for their participation, and those who were frustrated with their situation might have had increased motivation to participate. Our sample size and single hospital location also limits the generalizability of our results. Pediatric patients were less likely to complete our survey due to illness or ineligibility. Despite their reduced involvement in our study, the diverse experiences of this population indicates an area of further exploration. A better understanding of the perceived usefulness of existing inpatient technologies, and their current or potential role in preventing medical errors is also needed.

Conclusion
In this paper, we presented the results of a survey asking pediatric inpatients and their caregivers about their prior experiences with undesirable events. We categorized the perceived types of events and illustrated their relationship with outcomes that patients and caregivers described. Our findings demonstrate that patients and caregivers have a broad definition of undesirable events, have many unmet information needs that they feel might help prevent such events, and have specific preferences for receiving this information. Based on these results, we made recommendations for future iterations of patient engagement technology, which has the potential to increase support for patients and caregivers in becoming active participants in their healthcare, and help reduce the tragic toll of medical errors.

Acknowledgements
We would like to thank each of our participants for taking time during their hospital stay to take part in this study, the Patients as Safeguards research team, Kathryn Nickel, and members of the Outcomes Assessment Program at Seattle Children’s Hospital (Stephanie Hillman, Emily Dehmer, Jessica Kowalchuck, Kristine Lee, Neil Panlasigui, and Breanna Dolan) for their partnership and support. This research study was primarily funded by the Agency for Healthcare Research and Quality (AHRQ) grant #1R01HS022894, with additional support from the National Library of Medicine Biomedical and Health Informatics Training Grant #T15LM007442.

Abstract

The National Cancer Institute Thesaurus (NCIt) is a reference terminology used to support clinical, translational and basic research as well as administrative activities. As medical knowledge evolves, concepts that might be missing from a particular needed subdomain are regularly added to the NCIt. However, terminology development is known to be labor-intensive and error-prone. Therefore, cost-effective semi-automated methods for identifying potentially missing concepts would be useful to terminology curators. Previously, we have developed a structural methodology leveraging the native term mappings of the Unified Medical Language System to identify potential concepts in several of its source vocabularies to enrich the SNOMED CT. In this paper, we tested an analogous method for NCIt. Concepts from eight UMLS source terminologies were identified as possibilities to enrich NCIt’s conceptual content.

Introduction

Biomedical ontologies and controlled terminologies provide a solid foundation in a variety of healthcare information systems [1, 2]. They have been widely used for encoding diagnoses, laboratory tests, and problem lists in Electronic Health Records [3] as well as in administrative documents such as in billing statements [4]. Moreover, with medical concepts linked by taxonomic and semantic (lateral) relationships, they also play an important role in knowledge management, data integration, and decision support [1]. Complicated and challenging natural language processing tasks also benefit from well-curated domain ontologies and controlled terminologies.

The National Cancer Institute thesaurus (NCIt), accessible through a browser at https://ncit.nci.nih.gov/ncitbrowser/ is a reference terminology developed and maintained by the National Cancer Institute (NCI). Currently, it contains over 100,000 concepts that are hierarchically organized in 19 distinct domains related to cancer research, e.g., neoplastic diseases, molecular abnormalities, and genes. It is a central reference terminology of NCI’s Enterprise Vocabulary Services (EVS) [5]. As medical terminology is constantly evolving, with new concepts in healthcare entering usage, a controlled terminology needs to keep improving its conceptual content to encode these new concepts as they are needed by users. In Cimino’s “desiderata” for controlled medical vocabularies [6], domain completeness is listed as the most desirable property. To improve the conceptual content of NCIt, NCI EVS exploits both its internal quality assurance (QA) mechanisms as well as external participation in the development and QA process of NCIt. A contributor outside of the NCI can suggest new needed terms or larger sets of concepts for NCIt that will be subsequently reviewed by EVS, validated and developed in conformance with NCIt content development and editing guidelines. The monthly update cycle of NCIt also ensures the timely incorporation of new terms.

In previous research, we have introduced a structural methodology to recommend new concepts from a UMLS source vocabulary for inclusion in another source vocabulary where they are “missing” [7, 8]. This algorithmic structural method explores vertical density differences between pairs of terminologies in the Unified Medical Language System (UMLS). The method consists of recognizing trapezoids in the “parent of” relationship structures of terminologies, that is, recognizing cases where concept pairs are present in two terminologies but each terminology offers different intermediate concepts along their "parent of" paths of relationships. It leverages the native term mappings of the UMLS to identify topological patterns that are indicative of a possible import of a concept from one terminology into another terminology. Examples of topological patterns will be shown in the Background and Methods sections.
A variety of vertical topological patterns (‘trapezoids’ of different sizes) were used in previous research to identify a list of candidate concepts for import into SNOMED CT. Human domain experts confirmed the validity of this structural method for enriching the conceptual content of SNOMED CT [7, 8]. In this paper, we apply this topological pattern-based method to recommend new concepts for inclusion in the NCIt. Just as in our previous research, it was hypothesized that a structural difference between two terminologies might suggest a different course of action besides an import, e.g., it might lead to uncovering an error in one of the two source terminologies. Different possibilities will be exhaustively enumerated in this paper.

**Background**

Quality assurance (QA) of the NCIt has been conducted by both NCI and external researchers [5]. Min et al. constructed an area taxonomy and a partial-area taxonomy for the NCIt that highlighted potential errors for manual review by a human expert [9]. Cohen et al. performed an automated comparative audit of the gene hierarchy of NCIt using the Entrez Gene database of the National Center for Biotechnology Information [10]. More recently, Semantic Web technologies have been leveraged to audit the NCIt. Mougin and Bodenreider stored the NCIt concepts in an RDF triple store to assess the consistency of the hierarchical and associative relationships among them [11]. Jiang et al. evaluated the data quality of cancer study common data elements by integrating the NCI Cancer Data Standards Repository, NCIt, and the UMLS Semantic Network with the use of a variety of tools of the Semantic Web [12].

The UMLS is a medical terminological system. Its Metathesaurus integrates over 12 million terms from more than 190 source vocabularies into about 3.25 million concepts, such that terms with the same meaning are assigned the same Concept Unique Identifier (CUI). Due to its large scale, source integration and term mapping are challenging tasks. To aid UMLS source integration, Huang et al. developed an extrinsic method that uses WordNet synonym substitution and showed promising results [13]. Moreover, the syntactic patterns and the semantics of the UMLS have been exploited, supporting ontology alignment for OBO Foundry ontologies [14].

The use of topological patterns was introduced in our previous research [7, 8] and will now be explicated based on “k:1” trapezoids. Figure 1 shows the topological pattern of a k:1 trapezoid with k=2. The instances of the concept A have the same UMLS CUI (Concept Unique Identifier) in both terminologies, which means that the UMLS curators regarded them as the same concept. The same is true for the concept B. The identity of the “two” concepts A in the two terminologies is hinted at by the double line connecting them that reminds of the = symbol. However, Terminology 1 has an additional concept X located on a path from B to A. In our previous work, SNOMED CT was the terminology of interest. Encouraged by the success with SNOMED CT, we are taking steps towards establishing the generality of the method by using a different target terminology, namely the NCIt. Therefore, we will formulate our explanation in terms of the NCIt.

Looking at Figure 1, one can argue that in the limited scope of paths from B to A, Terminology 1 contains more information than the NCIt, by including the additional concept X. The concept X is not just missing on the path from B to A in NCIt, but we ascertain that X does not appear anywhere in NCIt before we consider importing it. The topological pattern illustrated in Figure 1 is referred to as 2:1 trapezoid, because there are two parent-child links on the Terminology 1 side and one parent-child link on the NCIt side with links of equal length connecting A with A and B with B.

Figure 1. Abstraction of a 2:1 trapezoid between Terminology 1 and Terminology 2 (NCIt). Should X be imported into the NCIt?
Methods

In this work, we use the term “candidate terminology” to refer to any selected UMLS source terminology that could potentially contribute concepts to NCIt (version 2014_03E). Candidate terminologies were determined as follows. We first identified all English source terminologies with “PAR” (Parent) relationships annotated with “INVERSE_IS_A” labels that overlap the content of NCIt. The rationale for excluding “RB” (Broader) relationships in this study is based on the fact that “PAR” represents an explicitly defined parent-child relationship in the source, whereas “RB” represents an implicit one, inserted by the UMLS editorial team [15]. In the UMLS 2015AA release, we identified CPM, CPT, FMA, GO, MEDCIN, SNOMEDCT_VET, ATC, and UMD as the candidate terminologies. Table 1 lists the versions and full names of these terminologies. In previous research [7, 8], we have used this method to identify potential concepts in NCIt to enrich SNOMED CT, and vice versa. Thus, in this work, we excluded SNOMED CT from the list of candidate terminologies even though it also has “PAR” relationships annotated with “INVERSE_IS_A” labels.

The topological patterns considered in this paper are $k:1$ ($k = 2, 3, 4, \ldots$) trapezoids, 3:2 and 2:3 trapezoids as well as 2-rectangles. The definitions of these topological patterns are given below.

**K:1 Trapezoids**

In this study, Terminology 1 is always one of the candidate terminologies listed in Table 1. Discovery of a $2:1$ trapezoid suggests that the concept $X$ could be imported into the NCIt. It has been our experience that the owners of several different terminologies have expressed reasons why not to include such new concepts. The main justifications were that “the concepts describe intermediate, non-coding terms or alternative classifications that would not add substantial value” and “we cannot include everything, if we start thinking about what we could include, it never ends.” Thus the final decision whether “X” should be included in NCIt always has to be made by its curators. An alternative classification recognizes the fact that not every concept in one terminology is valid for another, because the two terminologies might have different purposes, or because the concept is part of a different classification schema in the two ontologies. A technical explanation of alternative classification is given below.

We implemented a program that generates all possible $k:1$ ($k = 2, 3, 4, \ldots$) trapezoids for all terminologies from Table 1 with the following termination condition for the size of $k$. For a given terminology $T$ from Table 1, if no $k_0:1$ trapezoid is found, then the algorithm checks whether a $(k_0+1):1$ trapezoid exists. If the answer is “no,” the algorithm terminates for $T$ and continues to the next terminology until all terminologies have been processed. We note that determining the largest value of $k$ for which $k:1$ trapezoids exist is of practical and “academic” interest. For a $k:1$ trapezoid, the $k – 1$ concepts on the path from the concept $B$ to the concept $A$ are then proposed by the algorithm as possible imports into the NCIt to the human expert. The algorithms were published previously [7,8].

**Experiment 1:** For a sample of 2:1 trapezoids we gave our oncology expert (KP) the following choices:

1) The intermediate concept in Terminology 1 (e.g., Concept X in Figure 1) should be imported into NCIt.
2) The intermediate concept in Terminology 1 should not be imported into NCIt because it is not relevant to cancer.
3) The concept structure is incorrect to begin with (e.g., Concept X should not be a child of Concept A).
4) Other (please fill in).

The distribution of concepts between these four choices will be shown in the Results section.
**M:N Trapezoids and M-Rectangles**

*M:N* trapezoids are a generalization of *k:1* trapezoids. Whenever *M = N*, it is geometrically more appropriate to refer to an *M*-rectangle. We formally define 2-rectangles and *M:N* trapezoids as follows:

**Definition 1**: The concepts *A*, *B*, and *X* (from Terminology 1) and *A*, *B*, and *Y* (of NCIt) form a 2-rectangle if and only if:

- The concepts *X* and *Y* have identical parents in Terminology 1 and in the NCIt (in this case *A*).
- The concepts *X* and *Y* have identical children in Terminology 1 and in the NCIt (in this case *B*).
- The concept *X* does not appear anywhere in the NCIt.
- The concept *Y* does not appear anywhere in Terminology 1.
- There is no synonymy relationship and no hierarchical relationship between *X* and *Y* known (in the UMLS).

**Definition 2**: The concepts *A*, *B*, and *X* (from Terminology 1) and *A*, *B*, and *Y* (of NCIt) form an *M:N* trapezoid if and only if:

- The concepts *X* and *Y* have identical parents in Terminology 1 and in the NCIt (in this case *A*).
- The concepts *X* and *Y* have identical children in Terminology 1 and in the NCIt (in this case *B*).
- The concepts *X* do not appear anywhere in the NCIt (*i.e.*, *X* = 1..*M*-1).
- The concepts *Y* do not appear anywhere in Terminology 1 (*i.e.*, *j* = 1..*N*-1).
- There is no synonymy relationship and no hierarchical relationship between the *X* and *Y* known (in the UMLS).
- Every concept *X* is a child of the concept *X* and as parent of *B*. Every concept *Y* is a child of the concept *Y*.

Figure 2 shows an abstract layout of a 2-rectangle to elucidate the above Definition 1.

![Figure 2](image)

*Figure 2*. (a) An abstract layout of a 2-rectangle topological pattern. The double-headed arrow indicates the case that *X* is a synonym of *Y*. The no-fill, one-headed arrow indicates that *X* could be imported into the NCIt as child of *A* and as parent of *Y*. The solid-fill one-headed arrow indicates that *X* could be imported into the NCIt as child of *Y* and as parent of *B*. This scenario is shown in (b). Only one of these three cases is possible. In addition it is possible that there is an error, *e.g.*, *Y* is not really a child of *A*.

In a 2-rectangle there are six possible cases for how *X* and *Y* may relate to each other.

1) It holds that NCIt could contain the path of concepts connected by links *B* → *Y* → *X* → *A*. This import case is hinted at by the no-fill, one-headed arrow in Figure 2(a).
2) It holds that NCIt could contain the path of concepts *B* → *X* → *Y* → *A*. This import case is hinted at by the solid-fill, one-headed arrow in Figure 2(a). The resulting path of this import is shown in Figure 2(b).
3) Concept *X* is a real world synonym of concept *Y*, which was previously not recognized by the UMLS editors. In other words, it holds that *X* = *Y*. More precisely, it holds that CUI(*X*) = CUI(*Y*), using the symbol for identity.
4) There might be a structural error in Terminology 1, *e.g.*, *X* is not really a child of *A*.
5) There might be a structural error in NCIt.
6) The concepts *X* and *Y* are *alternative classifications*. This is the most difficult case from a conceptual standpoint. It indicates two different ways of how to conceptualize a domain that are both valid but not immediately compatible. This is best understood with an artificial example. Assume that *A* = *extremities* and *B* = *left leg*. Then *X* may validly be *upper extremities* while *Y* may be *left extremities*. These are two different, valid ways how to organize the immediate subclasses of *A*, however, a deeper analysis is required to make the two approaches compatible. This case is of limited interest in the current paper.
We are primarily interested in cases 1) and 2), while case 3) may also provide an enrichment of NCIt. We note, parenthetically, that Y might also be imported into Terminology 1 (Figure 2).

**Experiment 2a:** A sample of 2-rectangles was reviewed by YC. YC was given the six choices above.

**Experiment 2b:** SDC reviewed the results of Experiment 2a and commented on them.

We will now advance from 2-rectangles to 3:2 trapezoids. Again, Concept A and Concept B are identical in both Terminology 1 and NCIt. There are two intermediate concepts (Z and Y) on a path from B to A in Terminology 1, while there is one intermediate concept (X) between Concept B and Concept A in NCIt.

**Experiment 3:** A sample of 3:2 trapezoids was reviewed by YC. YC was given eight choices.

1) X and Y are alternative classifications of A. This is analogous to alternative classifications for 2-rectangles.
2) Y and Z are both imported into NCIt and it holds that $B \rightarrow Z \rightarrow Y \rightarrow X \rightarrow A$.
3) Y and Z are both imported into NCIt and it holds that $B \rightarrow Z \rightarrow X \rightarrow Y \rightarrow A$.
4) Y and Z are both imported into NCIt and it holds that $B \rightarrow X \rightarrow Z \rightarrow Y \rightarrow A$.
5) $Y = X$ (Z could also be a child of X)
6) $Z = X$ (Y could also be a parent of X)
7) There might be a structural error in Terminology 1, e.g., Z is a synonym of Y.
8) There might be a structural error in NCIt, e.g., X is not a child of A at all.

We limited the burden for the reviewer by excluding the consideration whether the concepts Y and Z are desirable for import into a cancer terminology, otherwise additional cases would arise, such as:

9) Only Y is a desirable import, and it holds that $B \rightarrow Y \rightarrow X \rightarrow A$.
10) Only Y is a desirable import, and it holds that $B \rightarrow X \rightarrow Y \rightarrow A$.
11) Only Z is a desirable import, and it holds that $B \rightarrow Z \rightarrow X \rightarrow A$.
12) Only Z is a desirable import, and it holds that $B \rightarrow X \rightarrow Z \rightarrow A$.
13) Neither Y nor Z is desirable to be imported into the NCIt cancer terminology.

For a 2:3 trapezoid, analogous cases can be defined, which was done in this research, even though the primary interest is in importing into NCIt. A 2:3 trapezoid would indicate an opportunity of exporting concepts from NCIt.

**Experiment 4:** A sample of 2:3 trapezoids was reviewed by YC. YC was given eight choices as in Experiment 3.

The UMLS contains cycles of hierarchical relationships [15]. Furthermore, multiple parents may lead to overlapping trapezoids which could lead to counting the same intermediate concept multiple times. We eliminated cycles (by detecting the repetition of a CUI along a PAR path) as well as duplicate intermediate concepts in the results.

**Results**

Table 2 shows the numbers of potential import concepts identified in $k$:1 trapezoids. When calculating the numbers in Column 3, we made sure that these are unique concepts (and therefore there might be fewer concepts than trapezoids). Column 4 lists the total numbers of $k$:1 trapezoids found by the algorithm. Among the eight candidate terminologies, MEDCIN could contribute the largest number of concepts to the NCIt, followed by FMA and GO.

Table 3 shows the number of observed $k$:1 trapezoids ordered by increasing values of $k$. The table shows that $k$:1 trapezoids were found with $k$ up to 9. Both the number of trapezoids and the number of potential import concepts decrease with an increasing value of $k$, which is consistent with our previous work for enriching SNOMED CT [8]. For 2:1 trapezoids, we chose a random sample of 30 trapezoids.

Of the 30 randomly chosen 2:1 trapezoids reviewed by the domain expert (KP), the intermediate concepts in 22 (73.3%) trapezoids were recommended for potential import into NCIt, whereas the intermediate concepts in 8 (26.7%) trapezoids were not recommended for import into NCIt. No trapezoids were assigned the choices 3) and 4) in Experiment 1. Among the 22 2:1 trapezoids, KP recommended that the intermediate concepts in three of them should be imported into NCIt with a variation of their original term. For example, “disorders of peripheral nerve, neuromuscular junction and muscle” (C2102996) was recommended to be imported between “nervous system disorder” (C0027765) and “peripheral neuropathy” (C0031117), but with a simplified string, which SDC changed to “peripheral nervous system disorder.” Table 4 shows three example trapezoids in which intermediate concepts were recommended for potential import into NCIt.

Among the eight 2:1 trapezoids from which the intermediate concept was not recommended for import into NCIt, six are from MEDCINE, one is from CPM, and the last one is from FMA. Four out of eight intermediate concepts are assigned the semantic type “Pharmacologic Substance.” One example where import was not recommended consists of A = “Muscle relaxants,” B = “Baclofen” and X = “Skeletal muscle relaxants.” Investigating the definition of Muscle relaxants as it is given in the NCIt, it turns out that it is defined as “Any agent that relaxes skeletal muscles and reduces muscle contraction,” thus its semantics is equal to the semantics of X itself. Thus, importing X would be redundant from the point of view of the NCIt.

Table 4. Example $k:1$ trapezoids in which the intermediate concept in the candidate terminology was recommended.

Table 5 shows the numbers of 2-rectangles, 2:3 trapezoids and 3:2 trapezoids found by our algorithm. In order to analyze the relationships of intermediate concepts in the trapezoids, random samples of two times 30 trapezoids and 30 rectangles were chosen from MEDCIN. That yielded a total of 90 topological patterns for analysis. For all the other candidate terminologies, the domain expert (YC) reviewed all of the trapezoids that the algorithm identified. In total, 100 2-rectangles, 69 2:3 trapezoids, and 71 3:2 trapezoids were reviewed. Subsequently, SDC of the National
Cancer Institute further reviewed the marked up sample of 100 2-rectangles. We measured the inter-rater agreement between YC and SDC using Cohen’s Kappa. The observed Kappa is 0.6175, indicating substantial agreement [16].

Table 6 shows the human review results of the sample of 2-rectangles. All cases except “Error in NCIt” were observed. The results show that 55% of the rectangles in the sample are alternative classifications. Another 20% + 17% = 37% fall into two categories where the intermediate concept in the candidate terminologies could be imported into the NCIt as a parent or child of its intermediate concept. For comparison, in our previous study on SNOMED CT [7], 23.6% of the 2-rectangles in the sample fell into these two categories. Thus, the NCIt is a better target terminology for concept import than SNOMED CT, which may be due to the fact that SNOMED CT is more comprehensive than the NCIt. The percentage of cases of synonymy is 6.0% in this study, which is lower than the 14.5% in our previous study on SNOMED CT [7].

![Figure 3](image)

**Figure 3.** An example 2-rectangle in which the intermediate concept in MEDCIN could be a child of the intermediate concept in NCIt. Neutropenia, a condition in which there is a lower-than-normal number of neutrophils (neutrophilic white blood cell), is a kind of non-neoplastic hematologic and lymphocytic disorder.

![Hematological Disease (C0018939)](image)  ![Hematological Disease (C0018939)](image)  ![Non-Neoplastic Hematologic and Lymphocytic Disorder (C1518374)](image)  ![Cyclic neutropenia (C0221023)](image)  ![Cyclic neutropenia (C0221023)](image)  ![MEDCIN](image)  ![NCIt](image)
Figure 4 shows another example 2-rectangle where the intermediate concept in FMA “White matter of telencephalon” (C2327688) was deemed to be an alternative classification of the intermediate concept in the NCIt “Brain White Matter” (C1706995). In another 2-rectangle, two intermediate concepts “Implantable prosthesis” (C0021102) and “Implants” (C0012202) were deemed to be synonymous by the human evaluator.

Table 7 shows four examples of 2:3 and 3:2 trapezoids. In the first example, the intermediate concept in MEDCIN “Ovarian Carcinoma” (C0029925) was deemed to be a synonym of “Epithelial ovarian cancer” (C0677886). In the second example, two intermediate concepts “oncologic disorders” (C3853943) and “cancer-related problem/condition” (C0280950) were deemed to be alternative classifications. The reason that these are not synonyms is that the hierarchy of oncologic disorders in MEDCIN is used to represent the cancer diagnoses, which is not the same as the meaning of cancer-related conditions (the NCIt term). In the third example, the second intermediate concept “inherited genetic conditions” (C3648695) was deemed to be synonymous with “Hereditary Diseases” (C0019247). The fourth example is another case that is best understood as an alternative classification. Subclavian artery and Axillary Artery are Systemic arteries, but NCIt does not classify arteries as systemic.

Table 8 and Table 9 show the review results of the 2:3 and 3:2 trapezoids. No errors in the sample were observed. The results show that “alternative classification” is the most prevalent case, followed by “possible import as parent or child,” and then “synonyms.” These findings are also consistent with our previous study on SNOMED CT [8].

Discussion and Conclusions

In this work, we applied a topological-pattern-based method to recommend concepts from eight UMLS source terminologies that could potentially enrich the NCIt’s conceptual content. A variety of topological patterns between pairs of UMLS source terminologies were identified by our algorithm with potential import concepts for expert review. Three domain experts reviewed the samples and determined whether the potential concepts in the samples should be imported and suggested how they should be inserted into existing structures of the NCIt. The results demonstrated the effectiveness of the topological-pattern-based method for enriching the NCIt. For 2-rectangles, 2:3 trapezoids, and 3:2 trapezoids, the prevalence of possible relationships between intermediate concepts in pairs of terminologies was consistent with our previous studies on SNOMED CT [8]. The most prevalent cases were alternative classification, followed by various forms of import.

A few limitations need to be noted. In this study, only “PAR” links with “INVERSE_IS_A” annotations were used. We did not look for rectangles larger than 2-rectangles, and we did not attempt to identify 4:2, 4:3, etc. trapezoids. As shown above, even a 3:2 trapezoid leads to a remarkable number of possibilities as to how intermediate concepts could relate to each other. For $M:N$ trapezoids with larger values of $M$ and $N$ there will be a combinatorial explosion of possible cases; that will make it difficult for a human expert to consider all of them even for a small number of trapezoids. Human review is important, however. In [17], we have conducted a preliminary analysis of the difficulty of importing pattern-based concepts into the NCIt. The contexts and definitions of potential new concepts originating from a source need to be evaluated to validate the intended meaning. In a few cases, SDC “overrode” the decisions of YC. We note that the viewpoints of an outside auditor and a curator of a terminology are necessarily different. A curator has a deeper knowledge and better understanding of how individual representational decisions
were reached. We also note that not all the potential concepts identified would be imported, because of the different uses and alternative schemas of different terminologies. However, our method provides a way to look at possibly needed areas for improving domain coverage. In future, it could play a role in regular QA of terminologies at NCI.

In future work, we will investigate the use of the NCI Metathesaurus instead of the UMLS Metathesaurus. It is a subset of UMLS with other sources added, and is well curated in areas of interest to NCI [18]. Moreover, NCIt is more frequently updated in the NCI Metathesaurus than in the UMLS. Another useful source for future work is the NCIt GO mapping of the NCI [19]. We plan to extensively use feedback of the NCI EVS. After getting feedback and arguments for inclusion and exclusion of our suggested concepts, we will refine our methods to produce more accurate recommended concepts accordingly. We also plan to investigate horizontal density differences with varying numbers of sibling concepts between pairs of terminologies to identify more missing concepts for import. Lastly we will work on 3:1, 4:1, 5:1 and 6:1, and 4:2 samples.

Abstract

Supporting adolescent patient engagement in care is an important yet underexplored topic in consumer health informatics. Personal Health Records (PHRs) show potential, but designing PHR systems to accommodate both emerging adults and their parents is challenging. We conducted a mixed-methods study with teenage adolescent patients (ages 13-17) with cancer and blood disorders, and their parents, to investigate their experiences with MyChart, a tethered PHR system. Through analyses of usage logs and independently-conducted surveys and interviews, we found that patients and parents both valued MyChart, but had different views about the role of the PHR for care communication and management, and different attitudes about its impact on the patient’s ability to manage care. Specific motivations for using MyChart included patient–parent coordination of care activities, communication around hospital encounters, and support for transitioning to adult care. Finally, some parents had concerns about certain diagnostic test results being made available to their children.

1. Introduction

In a pediatric cancer care setting, both adolescent patients and family members play an important role in the patient’s care management. Effective communication among adolescent patients, their parents and clinicians has proven to increase the quality and overall satisfaction of the care.¹² However, patients’ limited participation in the clinical setting, due in part to their limited health literacy, communication skills and perceived level of confidentiality, could lower the quality of communication.³

Personal Health Records (PHRs) show promising opportunities to alleviate these concerns, yet most currently do not provide different experiences for pediatric patients and their caregivers.⁴ Moreover, we do not fully understand the different information and communication needs of adolescents and their parental caregivers as they relate to the management of personal health records. Research examining how adolescents and their parents use PHRs has largely been limited due to federal and state regulations governing pediatric access to these systems.

In recent efforts to make electronic health records accessible to all patients, some states now offer patient portal enrollment to adolescents ages 12 and up, with proxy access available to their parental caregivers or legal guardians.⁵ Our research is motivated by the opportunity to investigate adolescents’ and parental caregivers’ experiences and actual use of the patient portal MyChart, a tethered PHR released by the Children’s Healthcare of Atlanta (CHOA). Understanding adolescents’ and parents’ attitudes toward and experiences with the portal—and investigating where they align and where they diverge—can shed light on the electronic information and communication needs of these consumer groups.

We present results of the first study documenting adolescents’ and caregivers’ actual use and reported experiences with a PHR system, along with the first empirical analysis of adolescent patient versus parental caregiver perspectives stemming from their experience with the system. As such, it is guided by the following research questions: Do adolescent pediatric patients and their parental caregivers use a tethered PHR system when it is available? What features of the PHR do they find valuable? How do patients resolve questions about its content? How does the tethered model of control impact these patients’ and parents’ perceptions of usefulness and expectations of privacy? Findings from our study contribute knowledge that can help guide the design of health information technology aimed at supporting adolescent patients with cancer and blood disorders and their parental caregivers.

2. Background

Research aimed at supporting patient access to clinical records through electronic patient portals has gained recently momentum.⁶ For adolescents undergoing frequent hospitalizations and complicated therapies, health IT features prominently in illness management and care. Many state regulations mandate that once a pediatric patient turns 13, parent access to their online record be deactivated. For children ages 13-17, the minor patient must authorize proxy

628
access for the adult. Once the patient turns 18, the now-adult patient must again grant proxy access through an authorization process. In order to make an informed choice to grant proxy access, the patient must understand what such access entails.

Protection of adolescents’ confidentiality in relation to their proxy has been a recent topic of interest in health informatics, with important medical, social and legal implications. Medical communities are aware of the implications of making electronic medical records accessible to minor patients: special requirements and challenges have been outlined, with emphasis on issues concerning the patient’s privacy and their access to sensitive health information. Concerns over lack of perceived confidentiality may deter adolescents from seeking medical care, including consultations with their doctors. Indeed, patients’ development of self-care skills and achievement of autonomy is critical for long-term outcomes. The Society for Adolescent Health and Medicine expressed this viewpoint, stating that “confidentiality protection is an essential component of health care for adolescents because it is consistent with the development of maturity and autonomy and without it adolescents will forego care.”

In theory, a PHR could alleviate some of these concerns by providing different viewing experiences for adolescent patients and adult caregivers. Yet, efforts toward designing for adolescents are still in their early phases. Ongoing efforts to understand adolescents’ attitudes toward health IT reveal tensions in information and communication needs of adolescent patients and their parents. For example, a focus group study with adolescents in a pediatric primary care setting found that adolescents had concerns about a lack of confidentiality of their communication, whereas parents were more concerned about “being left out of the loop,” or not being informed about significant health issues. Realizing the importance of privacy in adolescents’ care, recent efforts are focused on creating personally controlled health records (PCHR) that promise accessibility at the level of controllable individual features tailored to each patient’s needs. Yet, understanding which communications related to adolescent health require confidentiality is a particularly complicated problem, making both individual and hybrid models of control challenging to implement, particularly for complex illnesses that require family involvement.

Adolescents and young adults are known as being highly receptive to Internet search and mobile technology and are often early adopters of computing applications. For example, a recent study of adolescents’ actual use of smartphones revealed that, among many other types of applications, they used an average of ten distinct communication applications during two-thirds of the observed three hour period. A survey study exploring adolescents’ health information needs has shown that they typically searched the Internet to meet these needs. While adolescents are shown to use the Internet to a great extent, they still consider parents as their primary source for health-related information, reporting a twofold increase in satisfaction with parent-delivered information over Internet-acquired information.

Audit log studies on the actual use of patient portals can provide an empirical complement to self-reported attitudes and reveal gaps in uptake. Such analyses report disproportionate enrollment and use of patient portals by certain demographic populations, particularly including white, adult patients who are healthy and without Medicaid. While patient portals are now available to many, issues of information complexity and usability can hinder their adoption. To our knowledge, these difficulties have only been revealed in studies of adult use of PHRs. One study found socio-demographic disparities in their analyses of portal registrations among pediatric patients: the portal enrollment rate was lower for adolescents (12 years and older) as compared to infants and children (0 to 12) for whom their parents were predominantly involved in the enrollment and activation. Still, no studies of which we are aware investigate adolescents’ and caregivers’ ongoing experiences accessing a PHR system.

3. Methods

This work is part of a larger project on health information management practices of adolescents with cancer and blood disorders and their parental caregivers. The full study is an IRB-approved, multi-year and multi-phased project, which began in September 2014 in collaboration with IT staff and clinicians at Children’s Healthcare of Atlanta (CHOA). This paper reports results from a longitudinal exploration of patient and parent experiences with and attitudes toward the CHOA MyChart portal.

3.1. Study Site

Patients and parents were recruited in pairs at CHOA, a tertiary pediatric hospital in Georgia. We recruited participants in two Aflac Cancer and Blood Disorders Centers: Scottish Rite (suburban) and Egleston (urban), with each site serving different demographic populations. State regulations mandate that once a pediatric patient turns 13, parent access to their online record be deactivated. For children ages 13-17, the minor patient’s parent must consent to
allowing access, while their child must authorize proxy access for the adult. Once the patient turns 18, the now-adult patient must again grant proxy access through an authorization process. Our recruitment targeted a convenience sample of patient-parent pairs in the Aflac clinics, and was conducted both in-person and through flyers and email. We provided informed consent and assent forms to patient-parent pairs who met the eligibility criteria and guided each pair through the documents.

3.2. CHOA MyChart

CHOA released MyChart,1 a secure, HIPAA-compliant, tethered PHR in mid-summer 2014. Along with secure messaging capabilities to facilitate asynchronous electronic messaging between parents, pediatric patients and CHOA physicians, the tethered PHR (also referred to as a “patient portal”) includes access to laboratory test results, medication lists, patient allergies, prescription refill functions, appointment scheduling, messaging with clinical staff and the ability to store personal data. Once registered, patients and parents are given separate accounts with which they can access MyChart. The portal does not by default provide different viewing experiences of the patient’s information depending on the user, though proxies can be linked to several patients (their children). Physicians can customize whether messages should go directly to them (rather than being triaged first), to whom their message should go (to the proxy only or to both proxy and child), and whether or not an electronic reply to their message is allowed.

3.3. Study Design

To uncover potential attitudinal and experiential differences between adolescent patients and parental caregivers, we conducted a mixed-methods study comprising: 1) portal usage analysis, 2) small-scale survey, and 3) short interviews (see Figure 1). The usage analysis and interviews were conducted to contextualize survey responses.

Portal Usage Analysis

CHOA IT staff verified patient identification and registration and provided audit log data for patient and proxy usage over the study period. Auditing methods enabled us to examine information access at the level of individual access events (e.g., login events, loading of individual features, composing and sending electronic messages). Only patient log data (i.e., not its contents) were accessible to the research team. MyChart audit data included usage logs collected over a 19-month period ranging from August 2014 to February 2016. We analyzed the data focusing on commonly-used features, when they were accessed, and frequency of access over time.

Survey

Our survey instrument included a mix of open- and closed-format questions and several five-point Likert-style questions with scales designed to capture attitudes and preferences. Table 1 shows major topics covered, with selected questions. The survey took about 30 minutes to complete. Questions were matched for patients and parents, with minor changes to wording to make sure each question adequately addressed the participant type. For example, parents were shown statements such as “after using MyChart, I feel like I know more about my child's health,” whereas patients saw, “after using MyChart, I feel that I know more about my health.” We used REDCap,23 a HIPAA-compliant online research tool, to deploy the survey to patients and parents individually, with individual invitations sent after confirming that participants had used MyChart for at least one month.

---

1 http://www.choa.org/mychart
Interviews
The study concluded with a phone interview, conducted with adolescent patients and parental caregivers individually, once they completed the survey. Each interview lasted about 15 minutes and focused on confirming participants’ responses and eliciting elaboration on open-format responses.

4. Results
A total of 46 participants enrolled in our study including assenting patients (n=23) within the ages of 13 to 17 and their consenting parents (n=23). All recruited patients had been diagnosed with cancer or blood-related disorders. After collecting consent from all 23 parents and assent from all 23 adolescents, we introduced them to MyChart, explained data auditing plans and survey participation. Patients and parents were given separate accounts for logging in. We recruited additional study participants by sending recruitment ads to patients and parents who were already registered with MyChart. Each individual participant received a $25 gift card ($50 per pair) as a gratuity upon completing the study.

Some patient-parent pairs failed to complete MyChart activation. Of the 23 pairs, 12 (52.5%) patients and 15 caregivers (65.2%) responded to the survey. While 12 patients responded to the survey, only ten patients (mean age=15.3; male=3; female=7) and 15 parents (mean age=43.3) completed it. Survey responses were excluded if they were incomplete, or if we learned that someone other than the intended participant filled it out. In the following paragraphs, we report on survey results and audit log analyses for only those participants who completed the survey (Table 2 details patient and parent demographics).

We analyzed survey results and portal usage data using descriptive statistics. To explore similarities and differences in Likert-style survey responses between patient and parent groups, we report the difference in mean (mdiff) between the two groups, along with standard deviation (SD) values, for questions yielding the highest and lowest mean difference between the two groups. Below, we include verbal explanations of which group had higher or lower scores to accompany the mdiff value, which is reported as an absolute value.

We analyzed participants’ interview data through inductive coding to identify relevant themes in an iterative fashion. We organize our findings under three themes: perceived value of PHRs, keeping track of patient’s health, and electronic communication and sharing preferences. For each, we discuss patient and parent viewpoints, drawing attention to mean scores yielding the smallest and largest differences. Below, we refer to adolescent patients and parental caregivers as “patients” and “parents”, or T# and P#, respectively.

![Flowchart of participant enrollment in each study phase.](image-url)
4.1. Shared Perceived Value of PHRs

Analysis of survey responses with the smallest difference in mean showed that patients and parents both perceived MyChart as valuable. Both saw value in using the portal immediately before and after a visit to the doctor’s office. Both saw the most value in using it to navigate the transition from pediatric to adult care. Finally, they agreed strongly about situations when they would not use PHRs. Below we elaborate on each of these scenarios.

Before the visit: reminding and preparing for patient-provider encounters

Before a clinical encounter, patients (mean = 4.4; SD = 0.84) and parents (mean = 4.4; SD = 0.91) indicated that reminders were a valuable feature that allowed them to confirm their upcoming schedule, including future tests and doctor appointments, and to coordinate visits among family members. P12 told us, “I check it when he has an appointment. Sometimes I forget the exact time so I can always go in there. I usually check in a day or two before he has an appointment.” In the survey, T15 said that having the calendar reminder feature helps her make plans for other activities: “so I can plan my day and week and not forget times”

Patients and parents also saw utility in using the portal to prepare for clinical consultations. Both patients (mean = 4.4; SD = 0.7) and parents (mean = 4.53; SD = 0.64) indicated that knowing the information in the medical record in advance, such as lab results or imaging scans, could help them when talking to their doctor. In the exit interview, P12 told us that having access to her child’s record allowed her to seek better understanding of the lab results and their implications by asking targeted questions to the doctor: “because sometimes I see numbers on there that I’m not familiar [with]. They haven’t really explained about [the numbers] so I would go in and ask them.”

Having access to previous records in advance was an important feature for those who lived far from the clinic. P13 lamented about the need to travel long distances in order to receive her child’s medical record. She remarked, “living several hours away from T13’s doctors, it’s sometimes difficult to get info right away or even get in touch with someone who can give us any information. With MyChart, lab results go in, we can view them and decide what we need to discuss with the doctor instead of viewing them while at the appointment and not having much time to look over everything and ask questions.”

After the visit: fact checking and updates to the record

After a visit from the doctor’s office, patients and parents indicated that they would use MyChart to check that electronic information was correct and review updates to the record. For example, P12 said, “I’m trying to see if there are any updates (her labs, or any notes that were added).” The ability to see results after each visit helped one teenage patient talk to his doctor. When asked if using MyChart changed the way he talked to the doctor, T12 responded: “yeah, a little. Like one day I was talking [about] how much it [test results/blood level] would drop for my final week of the chemo and he said it would drop a lot and it [did]–it dropped a lot.”

632
Participants especially appreciated the ability to verify information in the record and promptly receive updates. P11 commented about the means to verify lab results, noting “it saves time. Making sure that everything is accurate. And on top of that I can actually see what the doctor’s put in the notes and everything. They tell you but if you want to get thorough, you can actually see what's going on.” Similarly, T23 responded, “We can usually find out results faster instead of waiting until my next appointment or waiting for the doctor to call.” Having prompt updates of lab results also helped ease T7’s frustration about delays between visits, “Yes. It was easier so I didn't have to wait like a month to ask my doctor these questions.”

Long-term prospects: care transitions

Both patients and parents agreed to a great extent that MyChart could serve to support the transition from pediatric to adult care over the long term, as well as better support communication with doctors in the short term. Interview data with patients revealed why this might be the case.

Both P7 and T7 commented on an upcoming transition to a different provider. In this case, they both saw MyChart as an important tool to archive information about the patient’s illness to retrieve later. For example, T7 remarked, “I think maybe a little bit more about my cancer history and just overall surgeries or just what happened. I think it's just good for me to know. So in the future, (when) I end up going to a different doctor or anything, I kind of know what was done to me.”

Both patients and parents responded that it would be important to refer to the information in MyChart during transitions to adult care (mean=4.6; mdiff=0), as well as to remain in touch with their current doctor once transitioning out of pediatric care (parent mean=4.33; patient mean=4.4; mdiff=0.07), and when speaking with another doctor about their care (parent mean=4.47; patient mean=4.4; mdiff=0.07).

P7 especially considered the need for access to her daughter’s histories, imagining a future scenario when her child would be entering college: “I can speak to her what the historic information is and kind of compare to whatever is told to me currently in regards to [T7]. I mean she's there ready to go to school and if there is a need to see a doctor who doesn’t have her history it would be readily available for them or even for her.”

Unhelpful use cases of MyChart

Not all aspects of MyChart appeared useful to adolescent patients and parents. For example, while both patients (mean=4.4; SD=1.07) and parents (mean=4.6; SD=0.6) appreciated the ability to see doctor's instructions or notes in the patient’s record, they were hesitant about adding new information or their own notes to the record (patient mean=3.5; parent mean=3.4; SD (both)=1.35).

As P7 explained: “my notes are my part of own notes, but I feel like MyChart…there should just be professional notes—nurses and doctors. There shouldn’t be any intertwining, as far as my opinions or my interpretation of that […] I take those notes for me personally in my journal, my book—not solely relying on MyChart.”

For some, MyChart was only useful during stages of diagnosis when patients and their parents were having several encounters with the hospital. Once entering recovery stages and remission, patients saw less value in using MyChart as they did before. T12 expressed this point, “if something comes up, I would use MyChart. But for now, since I'm in the recovering stage, I don't plan to. Like when I got off chemo, I used it one more time and stopped (using MyChart).”

4.2. Keeping Track of Patient’s Health

Analysis of survey responses with the greatest difference in mean showed that patients and parents had somewhat different views about the impact of the PHR on the patient’s ability to manage care. We learned that both used MyChart to make sense of the patient’s illness and treatment process, but they still sought information from external resources to resolve unclear information. Furthermore, adolescents relied on parents to provide explanations of information that was unclear to them. Below, we elaborate on these findings and provide analysis of portal usage activity and most commonly accessed features.

Perceived ease of use of MyChart for managing care

Overall, parents reported having experienced more difficulty than patients when using MyChart to keep track of their child’s health. When asked whether keeping track of the patient’s health was difficult, parents showed mixed sentiment (mean=3.53; SD=1.51; mdiff=1.13). On the other hand, patients were more likely to respond that they
experienced less difficulty in keeping track of their own health \((\text{mean}=2.4; \text{SD}=1.51; \text{mdiff}=1.13)\). Parents were also more likely to report their desire that MyChart be designed differently \((\text{mean}=2.8; \text{SD}=1.37; \text{mdiff}=0.9)\).

When compared to parents, adolescents reported a slightly more positive attitude toward the impact of MyChart on their ability to manage their care. After using MyChart, they reported having known more about their health \((\text{mean}=4.1; \text{mdiff}=0.7)\) in general and the care their doctor provides \((\text{mean}=3.9; \text{mdiff}=0.5)\). They also reported that the information in MyChart led them to ask questions that they might not have known to ask before \((\text{mean}=4.2; \text{mdiff}=0.6)\), and had slightly higher expectations that MyChart would lead them to take actions to improve their health \((\text{mean}=3.8; \text{mdiff}=0.4)\).

**Perceived ability to make sense of illness and treatment**

Having access to digital records allowed participants to engage with and understand their health differently. In the interview, P12 reflected on her experiences both prior to and after using MyChart to make sense of her child’s health: “they would just give us a paper with the numbers, and the following two weeks we had to go back and they would give us another paper so...I had nothing to compare [the current results] to anything before and I didn’t know where we were actually standing...” Since having access to her child’s medical record, P12 shared one of her exciting moments about how MyChart helped her and T12 make sense of the patient’s improved health: “When they told us that he was free of cancer, we saw the levels...we saw how [drastic]...that the numbers changed [...] I showed him where it started, during the chemo cycles and when it ended.”

For many, the portal was not the only source of information. Patients and parents also reported that they sought information on the Internet to help make sense of the medical record and seek additional information not readily available in MyChart. Nine out of 10 patients (90%) and 13 out of 15 parents (86.7%) had searched the Internet in the past to clarify information the medical record that was unclear to them. Reasons for searching typically included understanding medical terminology, interpreting lab results and radiology reports, and effects of medication on chemotherapy. While the Internet served general information needs for many patients and parents, it also seemed limited to some. For instance, P23 responded in our survey, “When reading a copy of the path report, it’s very difficult to just Google a word or term and find its meaning in relation to my daughter’s situation. Finding the words isn’t difficult. Translating what it all means seems almost pointless.” In this case, both P23 and T23 reported using private support groups or blogs to seek more information relevant to the patient’s condition. T23 said that she would look at, “blogs that have other people with the same disease as me.” We saw these preferences reflected in patients and parents’ attitudes about searching the Internet; While most had searched for information in the past, only four out of 10 patients (40%) and eight out of 15 parents (53.3%) reported that they would search the web in the future to understand information in their medical record.

**Mode of access**

When accessing MyChart, adolescent patients reported a greater preference for using smartphones or tablet devices over other modes of access including laptop and desktop PC \((\text{mean}=4.2; \text{SD}=1.03; \text{mdiff}=0.8)\). This finding is consistent with other studies that report adolescents’ inclination to use their smartphone for Internet use.\(^{18}\)

Features accessed
Our analysis of audit logs shows that patients most frequently accessed MyChart features in the following order: Lab Results (25.6%), Messaging (20.4%), Lab Tests (20.3%) and Appointment Review (11.9%). Frequent use of these features supports findings of our survey regarding how patients and parents utilized MyChart for clinical encounters.

Most patients we audited regularly accessed MyChart over the 19-month observation period. Table 3 and Table 4 summarize analyzed usage. Participant activation occurred on a rolling basis over the 19-month period and averaged 8.9 months between the time of activation and the last-recorded activity (mid-Feb 2016). Most had periods of inactivity lasting one month or more. Participants logged into MyChart at least once a month (making it an “active month”) for an average of 5.9 months. Only three patient participants stopped using MyChart after one to two months of use. While patients were actively using MyChart, the period of active use and number of access attempts varied greatly across patients, as exhibited by wide gap between median and maximum access attempts. For example, T23, the most active user in our studied sample, accessed MyChart every month for the entire observed period and her average monthly access attempts equaled 131.8.

4.3. Communication and Sharing Preferences
Analysis of closed-format and Likert-style survey responses revealed insights about how patients and parents prefer to communicate with each other, with clinicians, and other people about their health regarding MyChart. The responses revealed slightly different attitudes and preferences between patients and parents when communicating with clinicians.

Adolescent patients communicated less frequently with clinicians through MyChart than their parents: only one out of 10 patients (10%) reported using MyChart to communicate with clinicians, whereas five out of 15 parents (33.3%) did. Patients’ reluctance to communicate directly with clinicians aligned with their preferences for communicating about their health in general: only two out of 10 patients (20%) reported they talked to their clinical caregivers about their health the most—the remaining eight talked to their parents the most and preferred to take questions about their health to parents over doctors. Seven out of 15 parents (46.7%) reported that they talked to a doctor or nurse about their child’s health more than they do the child. These findings suggest that parents act as intermediaries between clinicians and their children, even when electronic records are accessible to all.

Preferences for communicating about patient’s health
Adolescent patients and parents also had different viewpoints about their intention to communicate the patient’s health status to others, as well as different desires to learn about others like them. When asked if they would like to be able to share their health information with someone else, patients (mean=4; SD=0.94) agreed slightly more than parents (mean=3.6; SD=1.18). They also reported slightly more interest than parents in seeing information about other people who have similar health conditions (mean=3.9; SD=0.99; mdiff=0.37).

Concerns about viewing information in MyChart
The adolescent patients we surveyed indicated having no concerns about what their parents would see in MyChart. When asked if there was information in MyChart that patients would not like their parents to see, all patients reported that they were not concerned. When probed to describe any concerns, most patients reported having none. T23 remarked, “there’s nothing in MyChart that I wouldn’t share with my mom.” The same was true for all parents when they were asked if there was information in MyChart that they would not like their child to see. When further probed, some parents, however, some did have concerns. For instance, P13 noted her concern for the possibility that her child might misinterpret results of the diagnostic test, being concerned about “medical details she might misunderstand or misinterpret that might get her concerned, anxious or upset.”

Two parents noted that information containing a negative test result would be concerning if it were accessible to the patient only. For example, P15 wanted to see the negative result firsthand in an effort to allay the impact it may have on her daughter: “anything that would appear to be negative, I would like to see it first so that I’m prepared for any questions my daughter may have. Soften the blow, so to speak.” In an interview, P7 expressed similar sentiment that she would prefer having the information relayed to her first or when T7 is also present. She also preferred that the information be delivered in a different setting than MyChart. “I would prefer for her to know firsthand through MyChart, if there was a negative result. I would want her to know eventually. I wouldn’t hide that from her. But the way that I would deliver it to her... I would probably want to have that information in a different setting than her actually seeing that on MyChart.... My personal preference would be that the information is relayed to me first or to both of us together, but never to [T7] by herself.”
These concerns were upheld by other survey responses. When asked whether viewing the information in MyChart would make the patient anxious, patients (mean = 3.2; SD = 1.14) tended to agree with the statement slightly more than their parents (mean = 2.73; SD = 1.16).

5. Discussion and Conclusion

Parents and patients reported the importance of using the PHR shortly before and shortly after their clinical encounters. Survey results revealed that parents made more use of MyChart messaging features. Still, patients expressed more confidence in managing their health when using MyChart. They sought information in MyChart, and more broadly, the Internet, to clarify information in their records. Yet, consistent with previous findings, most of the patients in our study regarded their parents as their primary information source for health-related information and preferred to take questions about their health to their parents over their doctors. As part of their gradual transition to adulthood, teenage adolescents reconcile who is an authority on their health. Maintaining adolescent patients’ confidentiality while also meeting caregivers’ needs poses challenge for designers of health IT systems. In Hong et al.’s study of the ways in which adolescents with cancer and blood disorders participate in their care, the authors found that adolescent patients faced challenges representing their interests in communications with their physicians and relied on their parents heavily to manage their personal health.

Innovations in health IT are predicted to play a critical role in decision-making about treatment choices, care continuity, and improved measurement of outcomes of clinical trials. To make PHR systems valuable to adolescent patients and their parents, system design efforts must take into account the need to reconcile differing assessments of illness-related measures, and different communication preferences of adolescents and parents. We believe that many opportunities exist for health IT systems to provide age-appropriate mechanisms for reviewing clinical health data, and reporting on health status, health care experiences, and quality of life.

In particular, our findings point to the importance of further research focused on role of PHRs in supporting parental caregivers in communicating with their children, and in facilitating coordination and communication with clinical caregivers. Studies addressing teenage adolescents’ communication needs and preferences for health-related information will be critical to aiding what is currently a challenging transition from pediatric to adult patient care, particularly in light of the challenges inherent in providing adolescent and family access to PHRs. These challenges include the need to formulate unique consent and privacy laws that align with state and institutional policies, provide content at appropriate health literacy levels, and maintain accountability in the disclosure of health information while meeting expectations of privacy.

Limitations

By studying experiences with a tethered PHR, our study did not focus on the intricacies of enabling access control by patients or parents. To activate their accounts, patients and parents in our study agreed to the release of shared information in MyChart. The experiences, attitudes, and preferences we distilled should be viewed with the understanding that access control lay in the hands of the institution (i.e., limiting the sharing of individual data types or adjusting access control was not possible). We included a relatively small number of participants and focused only on the experiences of patients with cancer and blood disorders and their parental caregivers. We did not find conditions under which adolescents with cancer and blood disorders preferred to limit information, but prior work suggests that situations related to reproductive health, sexually transmitted diseases, substance abuse, domestic violence, and psychiatric concerns will demand fine-grained privacy protections in order to make PHRs useful. Assembling attitudes toward the use of PHRs and preferred avenues for communicating (and limiting or sharing) electronic data for these situations is an important avenue for future work.

Cognitive Errors in Reconciling Complex Medication Lists

Jan Horsky, PhD, Harley Z. Ramelson, MD

Brigham & Women’s Hospital, Boston, MA; Harvard Medical School, Boston, MA; Partners HealthCare, Inc., Boston, MA

Abstract

Discrepancies between multiple electronic versions of patient medication records contribute to adverse drug events. Regular reconciliation increases their accuracy but is often inadequately supported by EHRs. We evaluated two systems with conceptually different interface designs for their effectiveness in resolving discrepancies. Eleven clinicians reconciled a complex list of 16 medications using both EHRs in the same standardized scenario. Errors such as omissions to add or discontinue a drug or to update a dose were analyzed. Clinicians made three times as many errors working with an EHR with lists arranged in a single column than when using a system with side-by-side lists. Excessive cognitive effort and reliance on memory was likely a strong contributing factor for lower accuracy of reconciliation. As errors increase with task difficulty, evaluations of reconciliation tools need to focus on complex prescribing scenarios to accurately assess effectiveness, error rate and whether they reduce risk to patient safety.

Introduction

Adverse drug events cause 770,000 injuries or deaths and cost $1.56 to $5.6 billion each year in the United States. Discrepancies between medications documented in electronic health records (EHR) systems and the actual state of their use by patients contribute significantly to the rate of preventable iatrogenic injuries. Over 25% of inpatient medication errors are due to inaccurate medication lists while errors in prescription medication histories occur in up to 67% of cases. The Office of the National Coordinator for Health IT (ONC) made medication reconciliation a core objective of its Meaningful Use (MU) initiative in recognition of its importance in reducing the incidence of adverse drug events (ADE) and the Joint Commission declared it to be one of National Patient Safety Goals. There is broad consensus that drug therapy errors can be reduced by making a complete, verified account of all medications a patient is actively taking and comparing this true state to lists maintained in one or more EHR systems. These records need to be updated regularly, especially at the time of a hospital admission, discharge or transfer and periodically maintained during ambulatory care. The maintenance process usually involves comparing medication history to the history in institutional records and to current prescription orders, identifying and reconciling discrepancies and documenting changes for future encounters and for other caregivers. Discrepancies between multiple lists and divergence from the true state of actively used medications can have serious consequences such as prolonged periods of over- or under-treatment that can only be detected by active surveillance.

Routine reconciliation is becoming more demanding with the steady increase of medication therapy, polypharmacy and the expansion of specialist care that allows more caregivers to write prescriptions for one patient. A nationally representative survey showed that 39% of adults over the age of 65 use five or more medications regularly. There is a corresponding rise in the difficulty of reconciling ever longer and more numerous lists from different care institutions and larger teams of providers. Reconciliation is conceptually simple and has been shown to be effective in reducing discrepancies but many clinics and hospitals found it difficult to implement a robust and reliable process with effective electronic tools. A recent study that evaluated the rate of inconsistencies and errors in medication lists reported that pharmacists reconciling records in ambulatory EHRs found on average 3.4 clinically important discrepancies per patient record.

There is strong research and anecdotal evidence from practitioners that the process is not supported well by currently available EHRs and that many find their reconciliation modules difficult to work with and poorly suited for the task. For example, a recent report showed that although vendors have been increasingly adding this functionality to their products in order to achieve meaningful use certification, clinicians in more than a third of the surveyed hospitals continued to use a partially paper-based process at admission, discharge or at ambulatory encounters as they were generally dissatisfied with the provided electronic tools.
Human factors and usability evaluation methods have recently started being applied to identify specific design constraints and workflow problems that affect the quality of reconciliation.\textsuperscript{13} Prioritizing recognition over recall, for example, is a common practice used by designers to decrease extraneous cognitive effort.\textsuperscript{14,15} make interaction less difficult and human performance less error-prone. During recognition, more cues and related information stored in memory are activated than in free recall and therefore the target item (e.g., medication name) can be more easily accessed and used in working memory.\textsuperscript{16,17} Guidelines and recommended usability principles commonly advise to use this concept in interface design.\textsuperscript{18} It is of particular significance when clinicians compare medications on two lists for differences and similarities.

As the result of care by many clinicians at different locations, multiple versions of medication lists may be stored on several information systems. What makes reconciliation more difficult is not only the number of medications that need to be reviewed but also the complexity of therapeutic regimens and the extent of detailed dosing instructions that need to be correctly interpreted and updated. While the list length increases the time and effort needed to account for the presence and absence of specific medications, more subtle differences between the same drugs or their generic equivalents present on both lists, such as changes in dose, frequency, route or use instructions, require sustained and focused attention to identify and enter them correctly.\textsuperscript{19,20} Substitutions of drugs in the same therapeutic class also need to be carefully reviewed by a trained clinician to avoid duplicate therapy.

This intrinsic difficulty is compounded by the need to make multiple comparisons to one or more lists and to the true state often confirmed by the patient or a caregiver. Centers for Medicare and Medicaid Services (CMS) estimate that a patient with one chronic disease sees up to four different doctors while those with five or more see an average of 14 different physicians,\textsuperscript{21} requiring more frequent and complex reconciliation of clinical information between all providers. Centers for Disease Control and Prevention (CDC) reported that 37% of Americans over the age of 60 take five or more medications and that the average number rises from five to seven at the age of 85.\textsuperscript{22} Patients with more comorbid conditions then have a higher probability that their medication lists contain errors and are at increased risk for adverse drug events.\textsuperscript{23}

There is a paucity of rigorously designed studies comparing different medication reconciliation practices.\textsuperscript{24} While some studies have shown the benefits of medication reconciliation technology almost all were done with systems developed in academic institutions, not by major vendors.\textsuperscript{24} The MARQUIS study reported, for example, that implementing a vendor EHR more than doubled the rate of medication discrepancies in one hospital.\textsuperscript{25,26} While there are well-designed, commercially available stand-alone systems for reconciliation available they are sparsely used due to the additional expense and difficulties with integration into EHRs that place extra burden on providers.

The majority (60%) of medication histories are shorter than five entries and the effect of list complexity may therefore be obscured in studies that do not stratify observations and results by the difficulty of reconciliation as errors tend to cluster within the subset of long and complex lists.\textsuperscript{9} Poor performance of suboptimally designed tools and their effect on patient safety may therefore be under-reported and under-studied.

The objective of our study was to investigate the effect of two different design concepts of a reconciliation module on human performance and error during a cognitively complex task. We asked clinicians to reconcile identical, standardized sets of medication lists with two different systems and analyzed the rate and character of observed errors. Our findings may inform the design of interventions and electronic tools that effectively alleviate cognitive burden on clinicians during complex reconciliations and reduce the number of errors leading to adverse events.

**Methods**

This study was designed as a standardized task scenario in which 11 clinicians performed reconciliation of two electronic lists containing 16 medications each using two different EHR systems in an alternating counterbalanced order to control for a possible learning effect. There were ten identical (including dose and frequency) medication records common to both lists, six were recorded only in EHR 1 and another 6 only in EHR 2 (Table 1). Reconciliation therefore required participants to make 22 drug comparisons: verify the ten identical entries and make a decision about correct updates to the local EHR system (e.g., add, don’t add, discontinue) on the remaining twelve. The test administrator simulated a patient and answered questions about the veracity of each medication.
The scenario contained four discrepancies that required participants to make a clinical decision rather than simply verifying that a particular medication was being actively taken by the patient. For example, Lasix, present on both lists (Table 1), required visual verification that the entries were identical in all aspects. When working with EHR 1, there was no action required for Ambien that the patient confirmed to be actively taking; however, on EHR 2, the drug would need to be added. Clonidine PO had to be discontinued when reconciling from EHR 1 since the patient was no longer taking it but no action was required when reconciling from EHR 2.

Discordant information presented in the scenario is listed in Table 2. The correct state specifies information confirmed by the patient (test administrator) in response to a direct question by the participant. The actions required to bring the medication list to a true state is shown from the perspective of EHR 2 being the local system. Conversely, the actions would be mirrored when EHR 1 was the local system.

The reconciliation module of EHR 1 had the two lists visible on a single screen, side-by-side in two columns. The lists were also subdivided into therapeutic class sections that were horizontally lined up for direct visual comparison of individual entries within each section. In contrast, EHR 2 was designed with both lists in the same column – the remote list above the local list. Due to their lengths, however, clinicians could only see one at a time as the other was off the screen and required manual scrolling to display. A green highlight would appear over a pair of identical drugs (brand and generic versions) in the two lists on a mouse-over. However, the highlighted drugs could have different doses. A schematic of the basic layout concepts is in Figure 1.

![Figure 1. Schematic representation of the two layout concepts](image)

Participants were ten physicians and one physician assistant who have worked with EHR 2 daily for at least 6 months, except for two clinicians who had 4 months of similar experience. Most performed reconciliations routinely at least several times a week. None had previously reconciled medications using EHR 1 as the module had only recently been developed and implemented. They were shown its function in a short (1 minute) demonstration before the task started. The selected sample of 11 participants reflects a commonly recommended size for formative usability evaluation studies.27,28
Interactions of participants with the modules were recorded and analyzed with Morae 3.3 suite. The number and type of errors in the reconciled list as well as the time to complete tasks were determined. Statistical significance on the difference in the number of errors was evaluated using a non-parametric t-test.

**Results**

Ten clinicians completed reconciliation using EHR 1 with an average of 0.37 errors per participant (range 0 to 2; group total 3). The mean completion time was 5.5 minutes (range 1.96 to 8.95 minutes). Seven clinicians completed the same task (22 comparisons and decisions) using EHR 2 with an average of 1.29 errors per participant (range 0 to 3 errors; group total 9). The mean completion time was 7.8 minutes (range 3.7 to 9.6 minutes). Difference for the mean number of errors between systems approached significance at p≤ 0.057. Participants made between zero and three errors individually in each task (Figure 2).

![Figure 2. Distribution of the number of errors per participant](image)

Seven of the 12 errors observed during both variants of the task had similar characteristics and were aligned with discrepancy types A and B (from Table 2) and two with type C. Descriptions of the errors are in Table 3.

**Observed strategies and workarounds**

Clinicians working with EHR 2 used several strategies to compensate for the inability to see drugs on both lists at the same time for comparison. The most common approach was to scroll up and down for each drug: they asked the patient to verify a medication as being taken, located a matching entry on the local list (below) and updated or added as necessary. Alternatively, they would go through the remote list first in its entirety, added medications not identified by a green highlight as matched on the local list, reviewed the updated local list with the patient and adjusted the dose or discontinued the drug. Additional scrolling back to the remote list (above) was often necessary to compare doses, additional instructions and start dates. Clinicians recalled from memory which drugs have been already confirmed to speed up the process and to check whether there was a dose, brand-to-generic or route change.

Another strategy was to remove medications not being taken from both lists first and then review them one-by-one for differences, again scrolling for each comparison. Two clinicians explained that after a consolidation of the two lists (i.e., adding all drugs from the remote lists that did not highlight as a “match”) they left the module and completed the task using the EHR medication list screen.

**Discussion**

We evaluated two EHRs with differently conceptualized modules for medication reconciliation using a complex scenario and found a clear trend for higher accuracy and shorter completion time for one system. The key design difference was in the form of visual presentation of medication lists. EHR 1 showed lists side-by-side and organized all medications into subsections by therapeutic class that were horizontally lined up for direct visual comparison. EHR 2 presented the lists one above the other in a single column layout, with green highlighting of medications matched on both lists when the mouse hovered over an entry.

The effectiveness of appropriate cognitive support for the comparison task was evident in better performance of clinicians using EHR 1 and was also underscored by the fact that the participants had no prior training or experience with the module except for a short demonstration. In contrast, most participants worked daily with EHR 2 for six months or more and reconciled medications at least several times per week even at places where medical assistants and nurses performed the task routinely.

The most frequently observed error was a dosing error. The dose increase in the scenario was often not correctly interpreted and the locally recorded drug was either discontinued and the remote one not added or the dose difference was noticed and records were not compared to verify which one was active. Clinicians revealed in debriefings that those who relied on the green highlight function of EHR 2 did not realize that only the generic ingredient and route were checked automatically, not the dose. Clinicians who did not rely on the highlighting compared the entries directly and verified the right dose with the patient, as they did when using EHR 1. The ensuing medical error would probably result in therapy with an incorrect dose or no treatment of the condition for which it was prescribed. Although mandatory training for EHR 2 likely covered the meaning and function of the highlight, several participants were not aware of it and at least two assumed that a complete match included the dose was indicated. Problems and errors due to screen artifacts and visual cues that are not intuitive or may be misleading are rarely avoided by mandating more complete and thorough training, especially for very complex software where learning and skill develops over time with repeated use and under real work conditions.

Errors where there was a difference in route were observed on both systems. In EHR 2, clinicians looking at the second list had to recall correctly the entire medication instructions from the first list that was scrolled off the screen. Two participants made an error by recalling only the drug and dose and not the route and another one discovered the discrepancy only on a second review and corrected it. Several clinicians working with EHR 1 commented on the fact that the patch version of clonidine was placed in a different drug class section than the oral version, confounding the visual comparison of drugs within categories.

Duplicate therapy errors occurred only when participants worked with EHR 2. Clinicians correctly identified Lipitor as missing from the local list and added it but two failed to discontinue the existing Crestor. The duplicate therapy alert was not triggered at that point, allowing the possibility of an adverse event due to duplicate statin therapy.
All clinicians correctly revised the list after asking the patient about taking Tramadol and therefore there were no errors where the patient was not taking a medication and the medication needed to be removed from the active list. The other three errors resulted from clinicians not noticing the absence of a medication on the local list and failed to add it from the remote list.

Workarounds and interaction practices not originally envisioned by designers often indicate a poor fit of a tool to the task.\(^3\) In safety-critical work, unintended actions and re-purposed screen artifacts (e.g., free-text entries with content other than expected) also mean that some safeguards may be circumvented and new errors may be introduced.\(^31,32\)

In debriefings and interviews at the end of each session, clinicians recalled strategies and workarounds they use to make the reconciliation easier and faster under the constraints of a typical daily workload. For example, at one clinic, medical assistants were hired to reconcile the lists for all physicians as part of that institution’s transition to a new system. Their work was checked by accuracy for pharmacists who compared a printed version of each reconciled list for all patients at the clinic to an electronic version on the screen. This practice has been reported by other places that found their electronic tools to be lacking in effectiveness and usability.\(^12,33\) However, as two participants noted, off-loading routinely reconciliation to medical assistants to save time before visits is always risky as staff without adequate medical training would “fail to see that treating with Atorvastatin and Crestor would be duplicate therapy” and that their work would have to be double-checked for errors by a physician or a pharmacist. One participant explained that “I usually take a piece of paper, write the dose and date down and check it like that, because the most recent one is probably current; I wish I could see them both and not to have to scroll.”

The extra demand on attention was apparent by repeated checking of the same drug pair and multiple scrolling, especially for medications with similar names such as Lamivudine, Clonidine or Lisinopril when the clinician also had to recall which drug has already been viewed. Duplication of effort and extra time to complete was a common result of workarounds: in the words of one physician, “I would first ask you (patient) what you take and then go back up the list again.” Participants commented that this is “too cumbersome, it would be much better if I could see them side-by-side,” or that “this is a nightmare, I can’t see both.”

The differences in layout represented higher (one column) and lower (two-column) demand on cognitive effort and attention of clinicians. The one-column design was clearly inferior to the two-column concept. It necessitated repeated memorization and recall of items that may have had only subtle differences (e.g., different dose) or similar names (e.g., clonazepam, clonidine), required more attention and produced errors of omission, substitution and other failures of memory.\(^15,34\) When the top list (remote system) had five or six entries, the bottom list of similar length was already partially off the screen and disappeared from view at 12 or 13 entries. The difficulty of comparison would therefore be a problem for a substantial portion of a typical set of patient records in an EHR.

The two-column list allowed perceptual judgments and recognition of items rather than the more difficult recall. Typically, this approach lowers cognitive complexity and produces more accurate results.\(^35,36\) Sectioning of a long list of entries into more manageable chunks by drug class also simplifies a difficult lookup task by transforming it into a series of easier comparisons within each category where there usually are no more than four or five entries that are easier to verify visually. One unintended effect of assigning several categories to one drug was that the same medication with different routes could be displayed in different sections. Clonidine oral and transdermal patch, in our scenario, were not matched into the same sections on both lists, causing at least one error and several comments on this discrepancy from clinicians who eventually corrected their mistakes.

Although the length of the lists in this scenario was not typical, complex regimens are not rare in ambulatory medicine. Patients requiring extensive medication therapy also tend to be sicker and more susceptible to adverse drug events. Usability testing requirements for EHRs (such as those required for ONC certification) should more prominently focus on more complex and longer lists to evaluate more accurately the effectiveness of a tested system in preventing reconciliation errors.

**Limitations**

This was small-scale pilot assessment that will be complemented with a larger study. We have identified a trend in the difference of means of reconciliation errors but the results would have a much more general validity with a
larger cohort. We also experienced several technical difficulties with recording test sessions at locations in several hospitals and clinics that produced gaps in analyses and therefore only seven and nine clinicians completed tasks on each tested system. As planned, each participant would have completed the same task on both systems. However, there was no systematic exclusion and therefore the effect on validity should be minimal.

Conclusion

We tested two electronic medication reconciliation tools designed with different conceptual understandings of cognitively complex tasks. One system, currently used daily by thousands of clinicians, produced triple the rate of errors observed on a system more deliberately designed with sound usability and cognitive engineering principles. There is growing evidence that there are significant differences in the way clinicians interact with an electronic reconciliation tool and that the amount of time required and the accuracy of documentation is dependent on the quality of the design and its usability characteristics. Examining the intersection of health information technology and patient safety with practical conceptual models can advance the EHR-enabled healthcare system towards the goal of improving patient safety.

Acknowledgments

We want to express our gratitude to all clinicians who volunteered their time and contributed their skills and insights to the study. Many thanks are also due to Dr. Elisabeth Drucker for her essential support and help.

Abstract

Clinicians today face increased patient loads, decreased reimbursements and potential negative productivity impacts of using electronic health records (EHR), but have little guidance on how to improve clinic efficiency. Discrete event simulation models are powerful tools for evaluating clinical workflow and improving efficiency, particularly when they are built from secondary EHR timing data. The purpose of this study is to demonstrate that these simulation models can be used for resource allocation decision making as well as for evaluating novel scheduling strategies in outpatient ophthalmology clinics. Key findings from this study are that: 1) secondary use of EHR timestamp data in simulation models represents clinic workflow, 2) simulations provide insight into the best allocation of resources in a clinic, 3) simulations provide critical information for schedule creation and decision making by clinic managers, and 4) simulation models built from EHR data are potentially generalizable.

Introduction

Physicians today are pressured to see more patients in less time for less reimbursement due to persistent concerns about the accessibility and cost of healthcare.1,2 Furthermore, clinicians are concerned that the adoption of electronic health records (EHRs) has negatively impacted their productivity.3–5 For example, at Oregon Health & Science University (OHSU), which completed a successful EHR implementation in 2006 that received national publicity, ophthalmologists currently see 3-5% fewer patients than before EHR implementation and require >40% additional time for each patient encounter.6

Facing these pressures, clinicians lack guidance on how to improve their efficiency while dealing with increased patient loads and time requirements of EHR use. For example, ophthalmologists typically see 15-30 patients or more in a half-day session, utilize multiple exam rooms simultaneously, work with ancillary staff (e.g., technicians, ophthalmic photographers), and examine patients in multiple stages (e.g., before and after dilation of eyes, before and after ophthalmic imaging studies). This creates enormous challenges in workflow and scheduling, and large variability in operational approaches.7 Approaches toward improving the efficiency of clinical workflow using EHRs would have significant real-world impact.

Clinic workflow bottlenecks result when patients arrive and clinic resources (e.g. staff, exam rooms, and providers) are not available to serve them. This mismatch of arrivals and availability can be increased by ad-hoc scheduling protocols that increase patient wait time.8 Testing different scheduling strategies and resource allocation in real clinics is impractical, however, since patient and provider time is too valuable for experimentation. Empirical models of clinical processes using discrete event simulation (DES) can evaluate different clinic configurations effectively before implementing them in clinical settings. DES requires large amounts of workflow timing data, which is available as timestamped EHR data.9 DES has been used for quality improvement in healthcare and scheduling, but not using EHR and detailed workflow data.10–13

In this paper, we present the process and results of simulating four outpatient ophthalmology clinics at OHSU, through discrete event simulation using secondary EHR data. Ophthalmology is an ideal domain for these studies because it is a high-volume field that combines both medical and surgical practices. Our results show that simulations can provide insight into the benefits and drawbacks of adding or removing clinic staff and exam rooms, as well as strategies for improving patient scheduling.

Background: Discrete Event Simulation

Discrete event simulation is a method for analyzing processes with high variability. The processes are broken down into a series of discrete steps whose time requirements are represented by probability distributions rather than constant values. When a simulation model is executed, these distributions are sampled to produce a time spent in each step. Simulations are repeated many times to determine the average behavior of the system. Simulation
models cannot be used to solve for absolute optimality; instead they are used to evaluate different scenarios to determine relative behavior.

For example, a clinic workflow can be modeled as a sequence of steps, such as patient arrival, an initial exam by a nurse or staff member followed by a physician exam as shown in Figure 1. Each of these steps will take a different varying amount of time, so each needs its own probability distribution. Each exam requires the use of finite clinic resources—a nurse or a doctor and an exam room. When the simulation model runs, a time value is determined for each step by sampling its distribution. As the model runs and more patients arrive, it is possible to generate queues of waiting patients for each exam. This happens when patients arrive faster than the exams take and/or there are not enough nurses, doctors or exam rooms for all waiting patients. To determine the expected behavior of the model over time, the simulation must be repeatedly executed.

Discrete event simulations can be used to evaluate changes to the model. For the example of the outpatient clinic, simulations can determine the effect of increasing the number of exam rooms or changing the appointment scheduling, which will both affect the patient arrivals. Each of these changes can greatly impact metrics such as average patient wait time or number of patients seen in a given time period. Simulation provides an easy and rapid way to evaluate these changes without interfering with clinic operations.

Discrete event simulations are used to improve various healthcare operations from emergency department configurations to operating room scheduling. Outpatient clinics have used discrete event simulations for resource allocation decision making as well as scheduling improvements, but mostly focus on individual clinics and use limited data as the basis of their model—multiple days of time-motion studies. In our study, we use multiple years worth of EHR timing data to create models that more precisely represent the variability of clinic workflows. We also parameterize the model so that it may be used for multiple clinics.

Methods

This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU).

Study Environment

OHSU is a large academic medical center in Portland, Oregon. The ophthalmology department includes over 50 faculty providers, who perform over 90,000 annual outpatient examinations. The department provides primary eye care, and serves as a major referral center in Pacific Northwest and nationally. We selected 4 outpatient ophthalmology clinics to study: 1) pediatric ophthalmology (LR), 2) comprehensive eye care (LL), 3) glaucoma (MP), and cornea (WC). These 4 clinics represent the diversity of outpatient care in ophthalmology at OHSU.

Over several years, an institution-wide EHR system (EpicCare; Epic Systems, Madison, WI) was implemented throughout OHSU. This vendor develops software for mid-size and large medical practices, is a market share leader among large hospitals, and has implemented its EHR systems at over 200 hospital systems in the United States. In 2006, all ophthalmologists at OHSU began using this EHR. All ambulatory practice management, clinical documentation, order entry, medication prescribing, and billing tasks are performed using components of the EHR.

Workflow Modeling and Reference Data Collection

Interviews with staff and observations of each of the four clinics were performed to determine the basic patient flow. All four clinics had the same basic clinic flow as shown in Figure 2. Patients check in and wait to be seen. An ancillary staff member performs an initial exam in an exam room. At the end of this exam, the patient’s eyes may be dilated. If this is the case, the patient returns to the waiting room while waiting for the dilation to take effect—about 25 to 30 minutes. After the dilation, the patient is returned to an exam room and waits for the physician exam.
If the patient’s eyes were not dilated, the patient remains in the exam room and waits for the physician. While the patient is waiting for the physician exam, the staff member must complete the documentation of the initial exam before the physician can start the exam. After the physician’s exam, the patients check out and leave. Because OHSU is an academic institution, trainees (residents and fellows) may also examine the patient. Trainees’ exams, however, do not occur at regular points in the workflow. Because of this added complexity, we focus on workflows without trainees in this initial study.

Once the workflow was understood, we performed time-motion studies for 3 - 6 half-day sessions at each of the clinics. One to two observers recorded timestamps of physicians and staff as they entered and exited exam rooms; these timestamps were then processed later to determine the duration of time spent in exam rooms with patients. This observational timing data was used to validate the use of EHR timestamp data to represent workflows and will be used to validate the simulation models in this study.  

Simulation Model Parameters and Their EHR Sources

To build the models for all four clinics, we first had to determine the necessary parameters and the EHR sources for them. In a prior study, we identified sources of workflow data within the EHR. We use the clinical data warehouse and ophthalmology datamart for OHSU’s EHR (EpicCare; Epic Systems, Madison, WI). While these timestamps are specific to OHSU’s implementation in ophthalmology, comparable timestamps are available for other vendors, installations and specialties.

The parameters are based on the clinic workflow, clinic resources and clinic scheduling:

1. **Start and End of Patient Encounter:**
   - **Check in and check out timestamps.** These timestamps are available in the ophthalmology datamart.

2. **Start and End of Staff and Physician Exams:**
   - **Audit log timestamps.** Timestamps from the audit log can be used to represent the beginning and ending of individual exams during the course of the office visit, which can calculate the duration of these exams. Data about providers and workstations was also required to determine the proper context for the timestamps.

3. **Dilation rate:**
   - **Structured ophthalmology documentation form and ophthalmology datamart.** Eye dilation information is entered in the structured ophthalmology documentation form of the EHR and is available from the ophthalmology datamart.

4. **Staff Documentation time:**
   - **Audit log timestamps.** The ancillary staff members must complete their documentation of the initial exam before the provider can start their exam. Using the audit log data combined with user and workstation data, we could measure the documentation time by measuring the time spent on the staff workstations after the initial exam.

5. **Number of ancillary staff and exam rooms:**
   - **Interviews and audit log data.** We used a combination of interviews and analysis of EHR users to determine typical values of these parameters. For many clinics, these parameters could vary from day to day, depending on other providers’ clinics in their specialty who shared these resources.

6. **The number and length of the scheduling blocks and number of patients per block:**
   - **Interviews and clinic encounter data from ophthalmology datamart.** We were able to obtain scheduling templates for each of the four clinics that guided how patients are scheduled; however, clinics rarely follow this template for every clinic day. Urgent patients are added on, schedules are overbooked, patients cancel or do not show. We reviewed the encounter data from the ophthalmology datamart to determine representative schedules for each of the clinics.
7. **Patient arrival patterns: check in and appointment times from ophthalmology datamart.** While all the clinics have only scheduled patients (no walk-ins), patients do not usually arrive at their scheduled time. This variation can have a great impact on the number of patients at the clinic at a given time. Since patients are scheduled, we measured the difference in time from their scheduled appointment time and their check in time. For all clinics, the large majority of patients are early.

**EHR Dataset**
Once we identified the parameters and their sources, we gathered datasets of office encounters for each of the four clinics for two years: 2013 and 2014. As with any large dataset, there are some encounters with incomplete data—we used only those that had valid check in and check out times. Further, we focused only on encounters that did not use trainees, since our initial models did not include them, as mentioned previously. Next, we wanted to find clinic days that represented a “typical” half-day session. This would include patient visits that happened during regularly scheduled half-day clinic sessions without large numbers of no-shows or overbooks. Therefore, we restricted the data to include clinic sessions whose number of patients fell within the 1st and 3rd quartile of all clinic sessions’ volume. We plan to address the atypical clinic days with future models. Finally, for each clinic, we then separated the dataset into a training set for building the model (80% of the data) and a test set for validating the model (20% of the data), in order to avoid overfitting the model.

**Simulation Models & Validation**
We used Arena simulation software to build a model of each clinic’s workflow using the training dataset. We used the same basic model for all four clinics, but customized it for each. We validated the 4 clinics’ simulation models by comparing metrics (total average exam time and average wait time) to the EHR test dataset.

**Model Experiments**
Once the clinic models were validated, we used them to evaluate different clinic scenarios. Specifically, we tested the effect of adding clinic resources such as staff members and exam rooms. Additionally we tested various methods of scheduling strategies in an attempt to better manage the negative impact of patient encounter (visit) variability on the clinic flow. Previous studies have shown that scheduling longer encounters with higher variability at the end of the day helps reduce wait time. To simulate this scenario, we identified the patient encounters that were the longest 1/5 of all encounters in the two year dataset. We then tested schedules with varying numbers of long encounters as well as different placements of these long encounters.

**Results**

**EHR, Observed and Simulated Encounters**
Table 1 gives the number of encounters in the EHR, observed and simulated datasets. The table shows how the number of encounters decreased in the EHR dataset as we restricted the set to encounters with complete data, no trainees, and during a typical day (number of patients is in 1st – 3rd quartile of ½ day clinic volume). The EHR training dataset was used to determine the probability distributions used in the simulation model. The test data, observed data without trainees and the simulated data sets are those that are used for validation.

**Simulation Model Parameters**
Building the simulation models required generating probability distributions for the patient arrivals, staff exams, staff documentation and provider exams and determining values for clinic parameters, shown in Table 2. The probability distributions were fit to the EHR training data. We used the average dilation rate for each clinic to determine the likelihood that a patient’s eyes are dilated after the initial exam, but we used median values for the...
other parameters (number of staff, number of exam rooms, number of scheduling blocks, block length and total number of patients per half-day clinic session) since the model requires discrete values instead of continuous averages.

Table 2: Model Parameters per ½ Day Clinic Session. Parameter values for each of the four clinics that represent a typical ½ day session. Values were determined from audit log and ophthalmology datamart encounter information. All values are medians, except for the dilation rate, which is an average over all ½ day sessions in the clinic dataset.

Validation of Simulation Models

We used the parameters and distributions to build a simulation model for each clinic in Arena. We ran each model 1000 times and compared the patient wait time and total exam time to the averages of the EHR test data set and observed dataset; see Table 1 for the sizes of these datasets. Note: the simulated data set had very large n since we ran the models for 1000 half-day clinics to determine the long-term behavior of the system.

Validating the model is crucial for ensuring that the models are representative. The validation results, given in Table 3, show that the simulated wait and total exam times (staff + provider) are close—within 5.5 – 6.8% on average—to those measured from the EHR test data set. Three out of the four clinics’ models mean wait time and exam time were under 5% different from the EHR test data set. Only two differences of the means were statistically significant—Glaucoma (MP) wait times and Pediatric (LR) exam times.

Because of the differences in size between the datasets, statistical tests do not conclusively represent the similarity or difference between the distributions of datasets. Instead, we present visualizations of the datasets’ distributions for comparison. Figures 3 and 4 show the densities of the three different data sets for wait time and total exam time. The means are close in all the graphs and there is significant overlap for all the datasets in all the clinics, which indicates that the simulated models are representative of real clinic workflows. Because the simulation models have a large n and the plotted data is average clinic wait time instead of individual encounter wait time (a limitation of the simulation software), the plots of the simulated data have a much narrower distribution than the other 2 datasets.
Model Experiments

Once the models were validated, we are able to use them to experiment with different clinic configurations:

1. **Experiment 1: Varying number of staff and exam rooms**

Simulation models were used to determine the effect of changing the availability of resources. For our four clinic models, we investigated the impact of varying the number of available exam rooms and ancillary staff members. Clinic managers commonly make decisions regarding these resources, but do not have good data for supporting them. **Figure 5** plots the simulated patient wait time against number of exam rooms and number of staff members. For each experiment, the non-varying resource was held constant at the value given in **Table 2**. Patient wait time decreases as the number of exam rooms and staff members increases from 1 to 3, but levels off after that point.

---

**Figure 3:** Exam time densities of the three datasets: simulated, EHR test data and observed data. There is significant overlap of the three different datasets which indicated the simulated model is representative of the real clinic workflow.

**Figure 4:** Wait time densities of the three datasets: simulated, EHR test data and observed data. There is significant overlap of the three different datasets which indicated the simulated model is representative of the real clinic workflow.
Table 4: Experiment 2: Simulated Patient Wait Times for Different Number of Long Encounters per ½-Day Clinic Session. When a clinic session has a larger number of long encounters, the simulated average patient wait time increases and the reverse is true for fewer number of long encounters. Ideally, clinics should try to keep the number of long encounters steady per clinic session to avoid the variability in wait times.

</tr>
</tbody>
</table>

Since there is still only one physician in the clinic, adding more resources does not improve wait times since the single physician becomes the bottleneck.

2. Experiment 2: Impact of varying numbers of “long” encounters per clinic session

Simulation models were used to examine the impact of encounters that are “long” and have high variability since long encounters monopolize resources, cause delays and create queues of waiting patients. To investigate the impact that long encounters have on clinic wait times, we first defined long encounters to be the longest 20% of all encounters for a clinic in the two year dataset. On average, we would expect that 20% of patients in a half-day clinic session would fall into this category, but in reality, the number of long encounters per half-day clinic session may vary when schedules do not limit them. We looked at the datasets and determined minimum, maximum and median numbers of long encounters per clinic session for each provider’s ½ day clinic session. We then used the simulated models to measure the range in patient wait times for these differing numbers of long encounters per session. Table 4 shows these results. For all four provider clinics, the wait times increase dramatically as the number of long encounters per session increases. For example, the Cornea (WC) clinic’s wait time increases from 26.9 minutes when there are 0 long encounters to 61.9 minutes when there are 9 long encounters, which is an increase of over 100%. The other clinics are similar. Keeping the number of long encounters steady per clinic session to avoid the variability in wait times.

3. Experiment 3: Determining the optimal arrangement of encounters in a clinic session using competing metrics.

After having established above that keeping the number of “long” encounters steady over all clinic sessions reduces the variability of wait time, simulation models were used to investigate the best placement of long encounters in a clinic session. Anecdotally, we observed that schedulers often put encounters expected to be longer at the start of the session, so that the clinic does not run over time; however, this may worsen patient wait time.

To investigate the impact of long encounter placement on these two competing metrics, we ran simulations to determine the average patient wait time and clinic length for different placements of long encounters. Results are shown in Figure 6. Long encounters placed at block 1 are at the start of the clinic session; larger block numbers...
represent appointment slots closer to the end of the clinic session. The graphs show that mean patient wait time was minimized by scheduling the long encounters at the end of the session, but this has the effect of increasing clinic length. The converse is true—clinic length is minimized by scheduling the long encounters at the beginning of the session, but this also maximizes the mean patient wait time. These graphs and corresponding data can help clinic managers determine the best compromise between the two competing metrics.

Discussion

This study has the following key findings: 1) secondary use of EHR timestamp data in simulation models accurately represents clinic workflow, 2) simulations can provide insight into the best allocation of resources in a clinic, 3) simulations can provide critical information for schedule creation and decision making by clinic managers, and 4) simulation models built from EHR data can be generalizable.

1. Secondary use of EHR timestamp data in simulation models accurately represents clinic workflows. Typically, secondary uses of EHR data have been for clinical research, quality assurance, and public health, rather than for operational purposes. While emergency departments have used EHR timing data for tracking patients and quality assurance, our study focuses on using EHR data for modeling outpatient workflows and studying clinic resource allocations and scheduling strategies. Our study shows that the data needed to study workflow can be mined from the EHR and that it represents general trends of clinic workflow in simulation models—simulated average patient wait time and average exam time are within 5% of the EHR data for three out of 4 of the clinics. Patient flow is a concern for all areas of healthcare, in both inpatient and outpatient settings. As patients move through the stages of their care, bottlenecks occur at points where demand for finite resources (providers, beds, etc.) exceeds availability. Using EHR large-scale timestamp data provides models that accurately represent the variability and can be used to study various clinic configurations.

2. Simulations can provide insight into the best allocation of resources in a clinic. Adding resources to clinics can help reduce patient wait times, but only to a certain point—3 staff members and 3 exam rooms for all four of the clinics. As long as there is a single physician for the clinic, additional resources will cause this physician to become a bottleneck. Therefore, the decreasing marginal benefit of additional staff members or exam rooms should be carefully weighed against the costs of adding these resources.

3. Simulations can provide critical information for schedule creation and decision making by clinic managers. Limiting the number of long encounters per clinic session and placing them wisely can help reduce wait time and clinic length. Keeping the number of long encounters stable for all clinic sessions can help reduce variability in wait times from session to session. Further, the placement of the long encounters affects wait time and clinic length with opposing effects—the closer the long encounters are to the end of the clinic session, average wait times are decreased.
and clinic length is increased. The simulated data provides necessary information for clinic managers to decide best how to balance these two competing metrics. We are currently testing schedules in clinic that place long encounters about an hour from the end of the clinic session since this minimizes wait time without unduly increasing the length of the clinic. Preliminary results show that the schedule implementation is effectively minimizing patient wait time.

4. Simulation models built from EHR data can be generalizable. By creating models for multiple outpatient clinics, we show that this approach is not limited to an individual clinic. As long as the simulation parameters are modified for each clinic, the models will still be representative. Further, even though the four clinics we modeled were quite different in terms of their clinic parameters (exam distributions, number of staff, number of exam rooms, number of patients, etc.), they all displayed the same general trends in all of the experiments. This gives us confidence that these trends are accurate and generalizable to other clinics.

Limitations

There are several limitations to our study. First, in order to identify audit log entries that correspond to exams, we had to discern when a staff member or physician was using the EHR during a patient interaction. At OHSU, we have uniquely named workstations in each exam room, which makes identifying patient interactions easier. If laptops were used, it would be much more difficult to determine when a provider was with a patient versus charting in an office. Second, the EHR timestamps do not always capture time spent with patients when the staff or doctor is not using the EHR. While we can determine what times the providers are not using the EHR, we cannot pinpoint what they are doing at those times. Second, the difference in size between our datasets (namely, the small observed set) that we used for the simulation validation limits our ability to use formal statistical methods for comparison. We are currently investigating methods for improving our observed clinic data collection so that we can easily increase the size of this dataset. Third, we limited this initial study to encounters that did not include trainees because of the differences in how trainees interact with the workflow. We are expanding our models to include this important activity to determine its impact on resources and scheduling. Finally, scheduling long encounters wisely improves patient wait times, but requires predictions of encounter length. We have performed preliminary studies using the relationship between clinical and demographic factors and visit length using timing data from the EHR; we are continuing to study this area, including adding physician’s input.

Conclusion and Future Directions

Simulation models based on secondary EHR timestamp data can be powerful tools for improving clinic workflows. Multiple years worth of clinic data provides an accurate representation of workflow variability in the models, which allows them to accurately evaluate the impact of clinic changes, whether it be adding staff or exam rooms or investigating novel scheduling approaches. The multiple models indicate that observed trends are real and generalizable. This implies that secondary use of EHR timestamp data for simulations broadens EHRs from a repository of clinical data to a holistic tool for managing clinical workflow.

Abstract
Robust order set catalogs are considered to be a vital part of a computerized physician order entry (CPOE) implementation. Tools and processes for building, localizing, and maintaining these content sets in a centralized repository are important in facilitating the knowledge management lifecycle. Collectively, these order sets represent a significant investment of effort and expertise in capturing and distributing best clinical practice throughout an enterprise. In order to address an important gap of understanding how order sets are both created and used in practice in a current EHR installation, we have developed tools to analyze how order sets are used and customized in clinical practice. In this paper, we present the capabilities of these tools. We further characterize early development patterns in our enterprise order set catalog in early phases of a system-wide vendor EHR rollout. We present data that show how personalized order sets (favorites) are authored and then used in clinical practice. We anticipate that this type of utility will provide useful insight and feedback for those tasked with content governance and maintenance in CPOE systems.

Introduction
Computerized physician order entry (CPOE) systems pose an interesting challenge in clinical knowledge management. Order sets, or standardized groupings of orders targeted to specific clinical conditions or scenarios, have been shown as an important part of user acceptance of CPOE. When physicians use order set templates, they often find personal benefit from the convenience of large groups of clinically-relevant orders being readily available for selection and customization. Organizations can also find benefit, often using order sets as a vehicle to drive standardization processes and reduce unnecessary variation in clinical care.

While electronic health record vendors provide tools and infrastructure for supporting computerized ordering processes, the population of knowledge in the form of order sets is often left to the institution itself. Typical implementations often involve a significant effort or investment in building (or purchasing), refining, localizing, and maintaining order set catalogs.1,2 These content libraries are designed to support routine procedures and common conditions treated by care teams in clinical domains.3 Previous research4-9 has detailed many of the challenges associated with knowledge maintenance in order set catalogs, including:

- Lack of personnel and resources to build order set libraries at the enterprise level
- Immature and poorly-adopted standards for order sets and orderable catalogs impede the effective sharing of order sets from one institution to the next
- Building and maintaining order set catalogs requires a sizable investment in time and resources
- Implementations often suffer lower uptake of order sets within CPOE due to gaps in content coverage in order sets libraries
- Conversion of purchased libraries to local practice requires refinement
- Clinical knowledge advances rapidly and the need to update and maintain content within order sets is constant

The various phases of the knowledge management lifecycle are depicted in Figure 1. In preparation for an enterprise installation of a new EHR and CPOE system, we identified that visibility in order set authoring and usage data would be a key gap in our knowledge management processes.10 Content authors were quick to indicate their desire for systems that present utilization data as feedback to assist in refining their order sets. Previous research has shown that automated processes for summarizing utilization data can be turned into reporting feedback loops that facilitate content change.11-13
**Background**

Intermountain Healthcare is a not-for-profit integrated healthcare delivery system based in Salt Lake City, Utah. It provides healthcare for the residents of the Intermountain West, including the entire state of Utah and parts of southern Idaho. Intermountain maintains a health insurance plan, 22 inpatient hospitals (including a children’s hospital, an obstetrical facility and a dedicated orthopedic hospital), more than 185 outpatient clinics, and 18 community clinics serving uninsured and low-income patients. Collectively, it provides primary and specialty care for nearly half of the residents of the state of Utah. Informatics teams provide support to clinical users in the form of clinical decision support, clinical knowledge management, content maintenance and software development for unmet clinical needs.

In late 2013, Intermountain Healthcare and Cerner Corporation announced a strategic partnership, including an enterprise rollout of the Cerner EHR platform, and a joint development effort aimed at delivering novel informatics solutions for healthcare organizations. Implementation of the system is still underway, with several sites in the enterprise currently live on the new software. One of the strategic priorities of Intermountain’s Cerner installation focuses on implementing and measuring utilization patterns of best practice care process modules into the system, in the form of order sets, decision support rules and care pathways. In order to address the need of understanding and reporting how knowledge content input into the system is actually being used we set about to build an interactive dashboard that illustrates the usage of order sets, personalized order sets derived from them (hereafter referred to as ‘favorites’) and how collective differences in the composition of favorites, in concert with utilization data can drive suggestions for optimizing order sets.

![Knowledge Management Lifecycle](image)

*Figure 1- Knowledge Management Lifecycle. In this cycle, content is created, distributed, and used within a clinical system. Detailed usage data is captured, transformed into specific feedback, and provided back to content owners to facilitate further refinement.*

**Methods**

Working with technical staff and data analysts, we extracted data from relevant tables in our production Cerner Millennium database environment and moved the data to Intermountain’s data warehouse. For the purposes of development, approximately 12 months of usage data were extracted (February 2015 to February 2016). This resulted in data derived from nearly 300,000 order set usage instances. Filtering this data to exclude data derived from technical staff and/or testing data reduced the data set by approximately 20%.

Following several sessions with clinical sponsors focused on design and requirements definition, we used Tableau software to prepare an interactive dashboard that presents visual depictions of order set usage. Figure 2 shows the main view from this dashboard, in which all order sets in the catalog are visible, ranked by overall usage, with two
main color depictions illustrating overall ordering volumes from the standard template, as well as the collective favorites that were derived from it.

Figure 2 - Main view of order set utilization dashboard, showing content, usage data, filters, and order volume derived from the main template and its associated favorites. This specific view is focused on order sets in the Critical Care (CC) domain.

Figure 3 presents a graphical view of overall usage of an order set over time, also with baseline template and favorite ordering volumes depicted. Dynamic filters allow the user to focus strictly upon specific regions, facilities, providers, roles, or timeframes of interest to the user. Drill-down capability allows the user to select portions of the display and view only the data that pertains to the selection itself.

Figure 4 shows the ‘phylogeny’ of an order set, including timestamps, authors, and difference counts across the main versions of the order set itself. It further shows detail about the ordering physicians that have taken time to create favorites against the template, including timestamps, names, counts and drilldown views into the changes made in the favorite, and data regarding the number of times in which the favorite was used. At a high level, it illustrates the branching and evolution that can occur in the main order set template and the favorites derived from it.
Figure 5 depicts a line-item view into the details of an order set. When set to show all versions, the visual cue of color blocks next to each of the orders demonstrates the presence or absence of an order from a particular version of an order set. When viewed against the entire version history of the same content (or against favorites derived from the template) the color patterns show the evolution of the content itself, including orders that are added, removed, or updated over time. The color of the blocks themselves represent selection status in this view, indicating whether the order was preselected or not. Numbers across the top show the various versions of the content itself, as well as corresponding ‘denominators’, which indicate the number of times in which that particular version of an order set was ordered against. Numbers overlaying the orderable blocks themselves show the frequency with which particular orders were ordered against in the ordering sessions that used these order sets.

---

Figure 4 - Version and Favorites Tree for the CC General ICU Admission Order Set from the Intermountain Healthcare order set catalog. This view shows the version history, favorites branches, as well as the corresponding timestamps, authors (names and roles), number of ordering instances, and modification counts derived from each knowledge artifact.
This dashboard utility and these specific visualizations have allowed us to compile useful information about the scope of our current order set catalog and the extent to which it has been revised and used. It has also given us new insight as to the frequency with which our users are using personalized order sets to find, tailor, and adjust the enterprise order sets themselves. The insight is useful both in comparisons of templates to their derived ‘favorites’ collections, as well as across versions of the enterprise order set template itself.

**Results**

Our efforts in extracting these data sets and consolidating them have allowed us to summarize and describe the artifacts in the order set catalog itself. Table 1 contains data pertaining to the main order set templates in the library itself, their usage to date (with the understanding that our enterprise installation is still in early phases), and the number of authors responsible for the content. It shows that less than half of the available enterprise order sets available in the order set catalog have been used to date.

Table 2 summarizes similar data for favorites saved to the order set catalog as well as corresponding usage data. This table contains two fewer order set types, as users do not have the ability to set favorites on future (day of treatment) and phased order sets in the Cerner system. It also shows how many order set templates have been ‘favorited’ and the average number of favorites per ‘favorited order set’. This table also shows the number of ‘cloned’ favorite order sets, in which the user has personalized the order set in name only (the content of the personalized order set does not differ from that of the template from which it was derived).

Figure 6 depicts the additions to the collection over time as authors added to and updated existing content in the set. It shows additions to the order set catalog in the year prior to the initial go-live in Intermountain’s Cerner installation (February 2015). Favorites are shown in orange, while main templates and revisions are shown in blue.

![Figure 6 - Content additions to the Intermountain order set catalog (consisting of both enterprise order set templates in blue and the entire personal favorites catalog in orange) in 2014 through early 2016. Enterprise order sets and revisions are shown in blue, personalized order sets or 'favorites' are shown in orange.](image)

Figure 7 shows the overall volumes of orders derived from order sets coming into the database from the initial enterprise installation to present (February 2015 to February 2016). This graph, combined with the data shown in
Tables 1 and 2 show that despite the large numbers of favorites available in the Intermountain order set catalog, most of the order volume derived from CPOE is coming from enterprise template order sets, not favorites. Growth in the volumes shown in the order curve are derived largely from new sites and regions coming online with the new Cerner EHR system.

**Figure 7 - Order Set usage data since initial Cerner implementation at Intermountain Healthcare.** Order sets entered via 'favorites' are shown in orange, enterprise-level content is shown in blue.

**Discussion**

We have constructed tools that allow order set content owners to quickly identify their content, view its utilization over time, and understand specific details of how, where, and who is using the content. Further, material views make it relatively straightforward for content owners of order sets to understand how their content is being used. As we have developed and presented these views back to the clinical teams responsible for the content, they have expressed both interest and enthusiasm in being able to quickly visualize how and where their content is being used. Several key themes have emerged as we have reviewed this data and presented it back to users.

**Departmental differences over Favorites**

Different departments and clinical programs inside Intermountain Healthcare have strikingly different views on the place of personalized order sets within a CPOE system. Some clinical groups (like cardiology) are patently opposed to users utilizing them and have configured the system to disallow specific user roles from creating them. Other departments are much more relaxed in this regard and go as far as encouraging them and training users how and when to go about it. As a result of these differences, departmental level views of order set utilization can be very different, with cardiology-specific content showing almost no utilization of favorites, to the other extreme in
obstetrics/gynecology where over 70% of postpartum discharge orders are entered via favorites. Despite the difference in philosophy or approach on personalized order sets, both departments have expressed value in being able to visualize the usage patterns of their content.

**Namespacing or ‘initialing’ of content**

As shown in Table 2, between 10 and 15% of all favorites in the Intermountain catalog are exact copies of the enterprise order set from which they were derived, or ‘clones’. In many cases, the only material difference between these personalized order sets and the templates from which they were built is the name. Many users applied a namespacing approach in which they preprended or appended their initials to the title of the order set. Others renamed them to facilitate searching using terms they would think of when using the search mechanism of the Cerner CPOE system. Due to the updating features of the Cerner EHR system, these users’ content will remain consistent with the enterprise template as it evolves.

**Content gaps**

The phylogeny-based view of the order set content also revealed interesting perceived gaps in the order set catalog itself. Simple inspection of the obstetrics/gynecology order set data showed large amounts of favorite use in the postpartum discharge order sets. Upon inspection of the favorite sets built against this template, key themes emerged from the order set titles, in particular the groundswell of desire from the users to separate the content into separate groupings of ‘C-section discharge orders’ and normal or vaginal delivery C-section orders. When content authors originally built this order set, they had grouped these two use cases (post C-section discharge orders and normal vaginal delivery orders) into one order set intended to support both. Yet the users’ creation and subsequent use of these two separate ‘favorites-based’ sets indicates a strong preference for separate content to support both scenarios. This type of feedback allows content owners to revisit and potentially re-prioritize content development efforts.

**Unused content**

In both the enterprise order set and favorites libraries there were significant numbers of order set templates that have not yet been used. This is not entirely unsurprising, as Intermountain is still relatively early in its implementation of the Cerner EHR system. The significant number of unused ‘favorites’ is somewhat more difficult to characterize, though some of that may be due to content created by physicians during their training with the software or time with physician coaches who are orienting them to the features present in software that is unfamiliar to them.

Over time, this usage data may bring to bear content that is present in the library, but semi-obscetate from a utilization perspective. Seldom-used order sets may be considered for deletion from the library in such circumstances, so as to optimize the users experience with the software, as well as to minimize the already significant maintenance costs that come with keeping them current with best practice and standards given in the medical literature.

Some clinical groups have been a bit surprised by the utilization data, in that they have in some cases created content that is rarely used. Some clinical workflows and even training routines that are part of implementation favor other methods for ordering, including quick orders, workflow-driven wizard screens and other modules. In some of these cases, content owners have shifted some of their focus away from order set development for all scenarios, targeting instead those where they feel that other options don’t address the clinical users’ needs adequately.

**Ownership/governance**

Tables 1 and 2 illustrate the scope of authors required to create the order set library that we are characterizing. It details that there are just over one hundred content authors who maintain the enterprise order set library and well over 1400 individuals that have personalized order sets. At Intermountain, the order set creation and update effort is spread across clinical programs at the corporate level, with regional representation from the various sites/regions and input from clinical, administrative, and central groups (e.g. compliance, legal, etc). It also has input from clinical service lines, local units, physician champions and specialists. Clearly there are many other individuals beyond the 100+ specific content authors who are expending significant effort in curating/refining content in the enterprise content development teams. The overall effort necessary to build these libraries is significant.

**Order volume**

Figure 7 shows that most of the order volume derived from order sets does indeed come from enterprise-level order sets, and not from personalized ones. More than 80% of the volume collectively comes from the standard content.
There are clear exceptions to this, as noted above, and these differences may reflect different philosophical approaches in clinical divisions, content gaps and/or other reasons specific to the users. Our hope is that presenting these data to content stewards can stimulate meaningful conversation amongst authors and users of these knowledge artifacts to optimize users’ experience with the order sets.

Limitations
We have not looked at complete ordering patterns within the Cerner toolset, only those derived from order sets. Quick orders and other workflows support ordering and encompass the broader picture of medical orders in the clinical setting. Our analysis has not yet extended itself to differences in order sentence construction. We have also not yet undertaken the visual analysis of phased or component order sets which are common to multiple parent or pathway order sets.

Next Steps
We intend to extend the capabilities of the visualization toolset to drill down to the details of the orderable/order sentence level, further illustrating the specifics of how the orderables are being used. We also plan to work with clinical analysts from each of the clinical specialties to begin to attach cohort specifications as an applicable filter for viewing order set utilization data (e.g. to show usage of the febrile infant order set specifically for patients who met the febrile infant definitions from the clinical data).

Acknowledgments
We acknowledge the Cerner technical engineers who have played an important role in orienting us to the nuance of the clinical data used in the analysis. We likewise express appreciation for the support from Intermountain Healthcare’s enterprise data warehouse team. We thank Sameer Badlani, former CHIO at Intermountain, for his inspiration to begin the effort.

Conclusion
We have constructed tools that allow order set content owners to quickly identify their content, view its utilization over time, and understand specific details of how, where, and who is using the content. Materializing this information visually has illustrated some key themes of content usage, needed areas for refinement, and greater visibility into the actual consumption of knowledge content produced by central content teams. We anticipate that this vision into the data will lead to optimization and enhancement of content over time.

Discordant patient pain level reporting between questionnaires and physician encounters of the same day

Abstract

We examined the consistency of pain reporting by patients in a community pain management practice in Michigan. We compared pain levels (range 0-10) entered by patients in questionnaires versus those provided during their face-to-face physician encounter on the same day. Both of these values were available for approximately 10,000 encounters during the study period (2010–2014). Two subpopulations of patients were identifiable. One was consistent in reporting worst or least pain levels on the questionnaire and during the provider encounter. The other was discordant. Factor analysis had previously identified severity scales for patient biopsychosocial characteristics derived from the full questionnaire. The two subpopulations differed in their factor profiles even though they had similar demographics. In general, pain reported directly to physicians was more correlated to biopsychosocial indicators. Pain self-reporting using questionnaires has often been assumed to be ground truth, but those obtained during the physician encounter may be more reliable.

Introduction

Chronic pain in the US is a massive medical problem and treating pain is a major challenge, as emphasized by the Institute of Medicine’s report on relieving pain in America1,2. That report offers several recommendations to address chronic pain, which include the need to better understand pain in the population and the need to offer tools to community physicians for pain management. There is a growing consensus that evidence-based medicine should be the guide for developing these tools and treatments, but this is challenging because the biopsychosocial nature of pain must be addressed and the linkages between diagnoses, treatments, and outcomes must be discerned on a scale to match the problem.

To move toward addressing these issues, there is a need to capture and analyze both the patient and provider perspective during the routine encounters of clinical practice4. Patient perspectives are critical because there is no instrumentation to quantify pain levels and the patient’s psychosocial attributes contribute to their condition. Provider perspectives are critical because chronic pain is a set of complex syndromes that requires years of experience to understand and an ability to interact with the patient in pain. Currently, the medical information from routine clinical encounters is locked away in patient charts. Extracting such content from community pain medicine clinics would constitute an opportunity for retrospective comparative effectiveness evaluations to help build an understanding of existing treatments and patient phenotypes within the community.

Toward that end, this work utilizes a data repository from the Michigan Pain Consultants (MPC) group, which has electronically captured both the patients’ and physicians’ perspectives from thousands of patient-visits in a multi-clinic community pain medicine practice in Western Michigan. Michigan State University (MSU) has partnered with MPC and their practice management group, ProCare Systems, Inc. (ProCare), to share data and expertise.

The first step in the analysis of clinical data is to evaluate the reporting of pain by the patient. Relaying pain levels to the care provider is fundamental to proper patient evaluation and its accuracy is intertwined with the patient’s physical and emotional state together with their desired goals5. Pain levels can be captured as structured data within questionnaires or EMR fields, and/or as unstructured data within physician notes summarizing discussions during the patient-provider encounter. We compared two of these reporting mechanisms and have discovered that some patients significantly alter their pain reporting in the presence of the physician. This behavior allowed the identification of patient subpopulations that differed in their questionnaire pain reporting and provider encounter reporting for the same pain query, on the same visit.

In this paper, we extract pain values from progress notes using natural language processing (NLP) approaches and examine their frequency distributions after sorting by pain values recorded in the patient pre-encounter
questionnaire. Patient subpopulations exhibiting concordant and discordant pain reporting were detected within distributions for worst pain, least pain, and today’s pain queries. These populations could be isolated for least and worst pain allowing comparisons to previously determined biopsychosocial factors derived from subsets of questionnaire items. We show that pain values reported during the physician encounter were more highly correlated to severity levels of the biopsychosocial factors than those pain values provided on the questionnaire in the waiting room just moments before the encounter. This phenomenon grew more robust during follow-up visits. It is an effect that would go undetected by examining questionnaires alone and indicates that interpretation of biomedical data in electronic health records must account for the manner in which it is collected and the potential psychological drivers influencing patient veracity. We briefly discuss these findings in light of the importance of both physician and patient reports of pain and the implications for data capture in pain research.

Data and Methods

Data

The partnership between MSU, MPC, and ProCare, and the nature of the questionnaire data has been described previously. The content of MPC’s clinical records comprises practice management data, results from detailed patient questionnaires, and detailed progress notes, all derived from approximately 95,000 patient visits per year. MSU access to the data was facilitated by a Business Associates Agreement and the study has received exempt status by the MSU IRB.

As part of MPC’s regular assessment, patients are asked to complete a pain health assessment questionnaire (PHA ™), which is a patient self-assessment instrument that provides demographic, medical and social history, as well as patient-reported outcomes (PRO). This has been described in detail previously. During the study period, a total of 22,691 intake questionnaires (iPHA) and 61,175 follow up or cumulative PHAs (cPHA) were completed by patients during their initial visit and selected repeat visits, respectively. Among the iPHA, 12,983 could be linked to physician notes for the same day and, similarly, 37,348 of the cPHA questionnaires could be linked to progress notes generated during the same follow-up visit. (Note: Not all visits entailed seeing the physician and not all physician encounters resulted in progress notes being generated.)

Analysis Overview

The overall outline of the steps in the data extraction and analyses is as follows: 1. Identifying pain in progress notes using NLP; 2. Collect progress note values into histograms sorted by PHA questionnaire pain values; 3. Decompose histograms into peaks representing two patient groups; 4. Identify concordant (sync) and discordant (nonsync) pain reporting patient subpopulations; and 5. Compare characteristics of the two subpopulations.

Progress Note Natural Language Processing (NLP)

Background. The dictated progress notes are in the form of letters to referring physicians. In prior work, a random sample of 500 clinical notes was drawn from the year 2010 (stratified by age, sex, number of ICD-9CM codes per patient, number of CPT codes per patient, and clinical note length), as described previously. Analyses of these notes revealed a highly organized structure generally following a SOAP note (Subjective, Objective, Assessment, Plan) structure although more comprehensive. The pattern typically comprises; reason for visit, pain status, past outcomes, history, findings, diagnosis, plan, procedure (if any), and current outcomes. The progress notes provide a rich source of information on patient status seldom captured in structured fields of EMRs. Our goal is to use this information to help construct phenotypes for patients in chronic pain.

This sample of 500 notes was annotated to a pseudo-ontology class hierarchy by four annotators trained in scientific writing, English, and Nursing. The hierarchy contained 13 top level classes with multiple sublevel branches, ending in 460 terminal leaf classes. Approximately 150,000 class annotations were created with approximately 136,000 linking attributes, providing approximately 80% coverage of each document. Detailed NLP procedures, including sentence identification, class assignments, scoring schemes, etc, will appear in a later publication, but a summary and focus on pain extraction is included in the next section.

Extraction of Pain Numbers. The extraction of pain numbers from the progress notes entailed initial identification of sentences that contained pain status or pain level information. The initial identification utilized the bank of class annotations and the attribute bank (class linkages). This was followed by the use of a set of regular expressions to pull only those numbers associated with pain and assign them to worst pain, least pain, today’s pain, or average pain. The bank of annotations and their class assignments were used in an exemplar or instance-based approach (implemented as a variation of past work in NLP and psychology) which compared all possible overlapping
sentence segments from the target text of size 1 to 5 words (bag of words style) to the entries in the annotation bank. The highest overlap scores (Jaccard Index: ratio of set intersection to set union) were retrieved and sorted. To capture misspellings and word roots the text instances in the annotation bank were also rendered as overlapping bi-letter sequences (spaces removed) and the n-gram word sequences in the target text were rendered similarly. The Jaccard Index overlap scores were calculated for these two sets of bi-letters. The highest score for the n-gram in the target text was retained. Class assignments for the n-gram where assigned to each word in the n-gram. Each word in the target text appeared in multiple n-grams. All the class assignments associated with a word were captured and aggregated by class. The result was a word-by-class array, for each sentence, containing values representing the class weights for each word.

Sentences containing words with non-zero scores for the classes shown in the first column of Table 1 were further processed to identify those sentences satisfying the class-attribute-class patterns shown in each line of Table 1. To satisfy a given pattern, the distances between the class, attribute, and class had to be within those seen in the annotation and attribute repository.

Once candidate sentences were identified, regular expressions were used to pull numbers from 0-10, not preceded by a letter (as c3, l4, t2, s2, representing vertebra number); Ordinal numbers (1st, 2nd, 3rd, 4th…); or number plus unit (e.g., 4 years, 4 months, 7 days, 42-year-old, 10 mg, 20 mcg, 5%, 7 percent, etc). Neighboring key words were then examined for possible assignment of numbers to worst, today, least, and average pain (e.g., “wors”, “escalat”, “most”, “today”, “now”, “least”, “lowest”, “down to”, “best”). Finally, patterns were parsed to identify such constructs as: “pain of 5 on scale of 1-10”; “pain of 10 out of 10”; “usual pain 4, low pain 1, highest pain 10 out of 10”; “low pain 5/10; high pain 10/10”; “pain 4 in range 1-10”; “pain today is 6, least it gets is 3, worst it gets is 9, on a scale of 0-10”; etc. (Additional details of these methods can be obtained from the first author.).

Recall and precision for success in selecting documents containing sentences with pain numbers were determined by blindly choosing a random sample of documents and manually determining the confusion matrix against those predicted by the algorithm.

**Beta Distribution Analysis of Pain Number Frequencies**

Patient visits containing pain numbers in both the PHA questionnaire entries and progress notes were analyzed in detail. Frequency histograms were created over the range of pain numbers extracted from progress note for each of the pain levels (0-10) from the matching PHA question. This method was applied separately for worst pain, least pain, and today’s pain for both the intake PHA (iPHA) and the follow-up visits PHA (cPHA). These histograms were often bi-modal and highly skewed in shape. To extract the two apparent modes, each histogram was estimated by the mixture of two best-fitting beta distributions. The beta distribution arises in many contexts. In order statistics, it describes the distribution of the k-th smallest variate in a random sample of n uniformly distributed variates. As such, it is applicable to finite sequences of ordered variates with bounding limits on the values of a random variate. It is only defined over the interval 0.0 to 1.0 and can be used to model distributions that are confined to an interval and exhibit left and right skewed shapes that are typically non-normal. The probability density function for the beta distribution is given by:
where $(\alpha, \beta)$ are two shape parameters and $c$ is normalizing constant. The mean and variance are $\frac{\alpha}{\alpha + \beta}$ and $\frac{\alpha \beta}{(\alpha + \beta)^2(\alpha + \beta + 1)}$, respectively. While the beta distribution is defined over the interval (0,1), we make the assumption that it can be a valid approximation for the uniformly spaced, ordered 11-point Likert pain scale used throughout the PHA questionnaire. Furthermore, we mapped the 0.0 to 1.0 beta distribution range to an extended -1 to 11 scale. This choice greatly reduced boundary effects that often reduced the quality of the fits. The fitting of the mixture of two beta distributions was performed using least squares regression implemented with the non-linear truncated Newton algorithm. For analysis of factor distributions for testing differences between patient subpopulations, maximum likelihood algorithms were used for parameter estimations, as implemented both in Stata™ using the third party module betafit, and with python scripts using the scipy.stats.fit module (http://docs.scipy.org/doc/scipy-0.17.1/reference/stats.html). These gave very similar results.

**Results**

**Extraction of pain numbers from progress notes**

NLP analysis of the 12,983 progress notes linked to intake PHAs (iPHAs) of the same day indicated that 3,891 had pain number sentences located in the text (Precision = 1.0, Recall = 0.96). Similarly, NLP analysis of the 37,348 progress notes linked to cPHAs of the same day indicated that 6,140 had pain number sentences located in the text (Precision = 0.98, Recall = 0.99). The reason not all notes had pain numbers is that pain status was consistently stated but actual pain numbers were less commonly provided. (The manner in which the progress notes where constructed was left to the physicians.) When present, they often took the form of indicating worst pain, least pain, average pain, or today’s pain, for example: “The patient indicates that pain today is 6. Least it gets is 3. Worst it gets is 9.” (See Methods for details of extraction.) Documents that contained occurrences of pain numbers averaged approximately 2 instances from these four types.

Within iPHA-linked progress notes, worst pain existed in 3,414 documents, least pain in 3,328, today’s pain in 1,542, and average pain in only 804. These were aligned with questions within the iPHA questionnaire that were also directed to these pain categories. (See Juckett et al, 2015, Table 3.) For progress notes occurring on the same day as a cPHA questionnaire, worst pain existed in 3,588 documents, least pain in 3,424, today’s pain in 3,755, and average pain in only 1,415.

**Sorting progress note pain values into PHA response groups**

Pain levels detected in progress notes were sorted into the 11 levels of pain (Likert scale) representing pain levels 0-10, as defined by the answers the patients gave on the PHA questionnaire during the same clinical appointment. These sorts were constructed for least today, worst today, current pain today, and average pain in the past four weeks. Only least pain, worst pain, and today’s pain are presented in this paper. For the least pain today question in the iPHA, the raw frequency histograms are shown in the left panels of Figure 1. In each panel, the histogram represents the pain levels extracted from the progress notes of patients that all entered a particular value for least pain in the questionnaire – as noted within the panel.

Examination of these histograms revealed the appearance of at least two distributions in each panel. One appeared to be a narrow region that was concordant with the value of the iPHA response associated with that panel. The other appeared to be a broad distribution that was offset and shifted from the first. These histograms were fit with the mixture of two beta distributions, as described in Methods. The results for iPHA least pain are shown in the right panels of Figure 1. In each panel, the two beta distributions are shown as histograms (solid bars for the narrow distributions, open bars for the broad distributions). The root mean square error is given within each panel as a percentage deviation of the fit to the original histogram. The relatively low values appear to justify the use of only two beta distributions in the fit.
Figure 1. Histograms of raw frequencies for least pain values, extracted from progress notes sorted according to iPHA-reported pain values. (Left panels) Histograms of pain values extracted from progress notes linked to PHA responses for the same visit. Each panel represents a different pain value recorded on the iPHA, as noted. Within each panel is the distribution of pain values extracted from the progress notes for those patients reporting the iPHA pain value associated with the panel. (Right panels) The two best-fit beta distributions for the corresponding panel on the left. The root mean square error (RMSE) of the fit is shown in each panel.

Figure 2. Plots of means and square roots of variance for best-fit beta distributions to histogram sets similar to Figure 1. The two components extracted for each histogram generate two vertical points at a given PHA pain level on the horizontal axis: (closed circles) peaks tracking with the PHA response; (open circles) broad peaks not tracking with PHA response. (Some distributions exceed 10 because the best-fitting beta distribution was highly skewed to the right and generated a mean above 10.) Points are plotted as pain from physician progress notes versus pain recorded on the PHA questionnaire for the same visit.  

- a) Least pain category captured in the iPHA (intake) and physician notes. The regression line for the synchronized points has slope = 0.98, $R^2 = 0.99$.  
- b) Worst pain category captured in the iPHA and physician notes. The regression line for the synchronized points has slope = 0.81, $R^2 = 0.90$.  
- c) Today’s pain captured in cPHA and physician notes. The regression line for the synchronized points has slope = 0.96, $R^2 = 0.97$.  
- d) Least pain category captured in the cPHA (cumulative) and physician notes. The regression line for the synchronized points has slope = 0.90, $R^2 = 0.96$.  
- e) Worst pain category captured in the cPHA and physician notes. The regression line for the synchronized points has slope = 0.82, $R^2 = 0.97$.  
- f) Today’s pain captured in cPHA and physician notes. The regression line for the synchronized points has slope = 0.93, $R^2 = 0.99$.  

Table 2. Relative sizes of sync and nonsync populations and the purity (non-overlap percentage).
The mean and square root of variance for each distribution in the right side panels in Figure 1 are plotted in Figure 2a. A similar compilation for worst pain from the iPHA is shown in Figure 2b and for today’s pain in Figure 2c. The least pain category (Figure 2a) reveals that the regression of the narrow peaks is linear with slope near 1.0 and has a high regression coefficient (see legend). The means of the broad distributions deviate significantly at the high PHA pain levels and they have large variances. These deviations reveal that some patients are discordant in their pain reporting. Discordancy patterns were observed in the other pain categories as well. The pattern for worst pain (Figure 2b) shows the discordancy occurs in the low pain region. The pattern for today’s pain shows discrepancies at both high and low pain, but these are not as dramatic as those for least and worst pain.

In Figure 2d-f, similar plots from analysis of the cPHA are shown. The cPHA is given approximately every six months to long-term patients. It includes questions related to outcomes and satisfaction in addition to most of the questions contained in the intake PHA.

**Selecting concordant and discordant subpopulations**

In least and worst pain categories there are regions where the two subgroups defined by the beta distribution are sufficiently separable to select two subpopulations of patients for further comparisons. That is not the case for
today’s pain category and therefore subpopulations could not be identified for this category. Those patients in the groups defining the diagonals on Figure 2 are referred to as the synchronous group (sync) because the pain levels in the progress notes are highly concordant to the values in the PHA. Those patients in groups off the diagonal are referred to as the non-synchronous group (nonsync) because their reported pain levels are discordant. Selection of subpopulations of patients from the nonsync groups can be done fairly robustly because there are regions along the horizontal axes of the histograms (see Figure 1) were the two populations do not overlap strongly. Selection of subpopulations of patients representing the sync groups yields some uncertainty because of the overlapping distribution fits. The relative proportions of patients in the sync and nonsync groups, as well as their purity (non-overlap percentage), are shown in Table 2.

**Biopsychosocial differences between sync and nonsync populations**

A question to consider is whether there are differences between the sync and nonsync subpopulations. The latent factors derived from the question items in the PHA can be used to explore differences in the biopsychosocial patterns of these populations. How patients answer the various questionnaire items indicates how severely their pain status impairs mental health, physical health, social activities, work, etc. in their daily lives. From 67 of the biopsychosocial question items in the PHA we previously identified 15 latent factors that help identify patient phenotypes. The biopsychosocial factors were all scaled between 0-10, in the same manner as pain, with low values indicating small effects of pain on a given factor and high values indicating large effects of pain on a given factor.

The differences between corresponding distribution means for the biopsychosocial latent factors of the nonsync and sync subpopulations are shown in Figure 3. The [nonsync-sync] difference values fall along a severity scale spanning positive and negative values. Positive values indicate that the nonsync subpopulation experienced more severe effects of pain on the biopsychosocial factors. Negative values indicate that the sync subpopulations experienced more severe effects of pain on the factors. The four panels represent the least and worst pain categories for both the iPHA and cPHA. Three of these pain categories have clear trends.

For the iPHA least pain category (Figure 3a), the differences for many of the factors are shifted to less impairment caused by pain, indicating that the nonsync distribution means have lower values than the sync distribution means. Many of these are significant or approach significance at the 95% confidence level, while the total trend is almost uniformly the same for all the factors. For the iPHA worst pain category (Figure 3b), the results are less dramatic, with only a few latent factors showing significant changes. Many of these exhibit a shift similar to the least pain category.

A consistent pattern appears in both the least and worst pain categories of the cPHA (Figures 3c, 3d). In the least pain category, the differences for the nonsync minus sync distribution means indicate less severe impairment for all biopsychosocial factors. Seven of the factors are significantly shifted at the 95% confidence level. In contrast, the factor differences for the worst pain category are significantly shifted to more severe impairment.

The interpretation of these findings is that the nonsync subpopulation patients in the least pain categories, who report lower pain to the physicians than they enter on the PHA (Figures 2a, 2d) are, in fact, experiencing lower severity on their biopsychosocial indicators (i.e., nonsync minus sync < 0). Similarly, the nonsync subpopulations in the worst pain category during follow-up visits are experiencing higher severity on their biopsychosocial indicators (i.e., nonsync minus sync is >0), consistent with what they report to physicians (see Figure 2e). In these three cases, the pain expressed to the physician correlates more closely to their biopsychosocial indicators of health.

**Discussion**

Patient pain reporting has been analyzed for patients seen at MPC between April, 2010 and Aug, 2014. Patients reported pain in a questionnaire (PHA) administered in the waiting room prior to their visit with the physician. Many also reported pain levels to the physician during the visit and this was often included in the physician’s progress report. Worst pain, least pain, and today’s pain values were extracted from the progress notes using natural language processing techniques and compared to corresponding questions in the PHA. Once extracted, sorted, and compared to the PHA values, two subpopulations of patients were evident; those that were concordant in their reporting on the PHA and in the physician encounter, and those that were highly discordant. These subpopulations exhibited differing biopsychosocial characteristics, as determined by their response profiles on the latent factors detected previously among the other items of the PHA questionnaire. The most important observation was that the concordant and discordant subpopulations were identified solely by the differences in their pain reporting between the questionnaire and the physician encounter. Yet, this single criterion yielded separate populations with consistently different biopsychosocial characteristics.
Although not shown, there were no significant differences in subpopulation demographic characteristics nor their ICD-9CM classifications. For the cPHA categories, there was no difference in the average number of follow-up visits among patient subpopulations. We are currently exploring the differences in treatments between subpopulations and this will be reported separately. Early indications are that drug-seeking behaviors are not involved.

It is important to recognize that the differences in outcomes and other biopsychosocial factors identified with the sync and nonsync subpopulations were derived from patient PHA reports. If one questions the veracity of patient pain reporting in the PHA, then one must be prepared to question the veracity of the other items in the PHA. The results of this study, however, reveal the complexity of the issue. If one looks at the patients that report high levels of pain in the least pain category in the PHA (high ‘x’ values on Figures 2a, 2d) and tell the physician something lower (‘y’ values), one might expect that they would also report worse outcomes and more severity in the other biopsychosocial factors in the PHA. However, these patient subpopulations report just the opposite. One would expect that if they exaggerate pain levels in the PHA, they would exaggerate other items. This does not seem to be the case. Instead, pain reporting seems to be unique and highly influenced by the differences between direct and indirect questioning. Furthermore, the fact that the biopsychosocial factors are latent factors derived from multiple items may also diminish any discordant reporting within the bulk of the PHA. Clearly, this is a matter for additional research. As one strategy to examine this phenomenon, we are currently examining outcomes and other patient histories extracted from the progress notes using NLP. It is likely, however, that case-control prospective studies will be the most valuable approach in shedding further light on this behavior.

Veracity in various settings has been the focus of several studies. Capturing patient-reported outcomes has been a focus of studies to support FDA guidance in regard to clinical trials. This issue is important to the FDA’s evaluation of drug candidates and allowable claims by the pharmaceutical industry. Several studies have also looked at subject veracity and data equivalence in other settings. A comparison between online versus in-person questioning of adolescents regarding social and inter-personal issues recently found no differences. On the other hand, a laboratory experiment examining in-person versus video conference in the context of intentional deception looked at the ability of interviewers to detect intent. The results indicated that interview modality did play a role in perception. Within the health domain, a recent study showed that some discrepancies exist among clinical data element fields of research data and clinical practice data on the same patients. The authors defined three levels of accuracy which can be useful in cohort discovery in the clinical research setting. This sampling of approaches to veracity in various settings highlights the importance of being aware of possible discrepancies in subject declarations. This is particularly important in pain reporting because decisions in pain management depend heavily on capturing patient perceptions.

The psychology and psychometrics of pain reporting has a rich literature spanning the psychosocial characteristics of a person in chronic pain to tools for patient self-reporting. To our knowledge, however, this is the first exploration of discordant pain reporting within the same clinical visit between questionnaires and face-to-face encounters. While this is an uncontrolled, retrospective study in the community setting, it has the strength of large numbers and the simultaneous capture of numerous biopsychosocial features.

**Conclusion**

Do we really know how to obtain the ground truth on a patient’s pain level? Depending on the setting, pain may be assessed differently. In the acute pain, hospital setting, pain levels are usually reported to nursing staff. In chronic pain clinics, it may be captured by physicians, physician assistants, or nurses. In observational studies, pain levels can be captured by an interviewer or by patients filling out questionnaires. In each case, the captured pain levels are typically assumed to be the ground truth; but are they? When pain is secondary to the treatment of another disease, knowing true values may prevent inducing drug dependence during the treatment of the primary illness. When chronic pain treatment is the primary medical goal, true values are critical to therapy choices. Since capturing these true values is not an obvious process, we must not be lulled into believing that entries in EHRs are the ground truth. Tools should be built with the capability of capturing the various estimates of pain perception to allow assessment and decision making, particularly in settings where pain plays a major role in healthcare.

Key Words: EMR implementation, Clinical Decision Support, Healthcare quality

Abstract

The Ministry of Health (MoH) rollout of electronic medical record systems (EMRs) has continuously been embraced across health facilities in Kenya since 2012. This has been driven by a government led process supported by PEPFAR that recommended standardized systems for facilities. Various strategies were deployed to assure meaningful and sustainable EMRs implementation: sensitization of leadership; user training, formation of health facility-level multi-disciplinary teams; formation of county-level Technical Working Groups; data migration; routine data quality assessments; point of care adoption; successive release of software upgrades; and power provision. Successes recorded include goodwill and leadership from the county management (22 counties), growth in the number of EMR trained users (2561 health care workers), collaboration in among other things, data migration (90 health facilities completed) and establishment of county TWGs (13 TWGs). Sustenance of EMRs demand across facilities is possible through; county TWGs oversight, timely resolution of users’ issues and provision of reliable power.

Introduction

Electronic medical records (EMRs) have been embraced across public, private, and faith-based health facilities in Kenya. Perceived benefits driving uptake of EMRs in general include: optimizing documentation of patient encounters; improving communication of information to physicians; improving access to patient medical information; reducing errors; supporting administrative management; forming a data repository for research and healthcare quality improvement; and reducing use of paper¹,²,³,⁴.

The Ministry of Health (MoH) in Kenya rolled out EMRs in facilities beginning November, 2012. KenyaEMR's implementation was spearheaded by I-TECH with funding from President's Emergency Plan for AIDS Relief (PEPFAR). The system runs on an open source platform named Open Medical Record System (OpenMRS)⁵. In total, 342 instances of KenyaEMR have been implemented across four regions in Kenya: Central, Nyanza, North Rift Valley, and Western. KenyaEMR initially targeted services within the national HIV/AIDS care and treatment program, as well as related Tuberculosis (TB) and maternal child health (MCH) services. There is presently interest in expanding the system to cover other outpatient primary care services as well as inpatient services. Guidelines from the National AIDS and STIs Control Programme (NASCAP) defined the scope and workflows within KenyaEMR and all the implemented instances of the system have the same functionality. Functionality includes patient registration, triage, clinical assessment, documentation of diagnoses, prescriptions and laboratory orders, care alerts and reminders, automated monthly reporting, cohort reporting, and continuous quality indicator reporting. No interoperable provider order entry or laboratory results transfer is presently available and functionality related to billing is also absent, as services are offered at no cost to patients. The vast majority of data is captured in structured formats based upon standardized concepts⁶. Progressive software
releases have taken into consideration feedback from end users and stakeholders—including health facility staff, members of County Health Management Teams (CHMTs), and representatives of PEPFAR-supported service delivery implementing partners (SDIPs) tasked with technical assistance to public sector HIV program sites—about desired functionality.

While the anticipated benefits of adopting EMRs may be great, the processes of adopting EMRs can be highly disruptive to conventional workflows. Successfully sustaining EMRs demands a high level of organizational change centered on people, processes and technologies in healthcare, as described in various socio-technical frameworks for information systems success. This paper focuses on the specific activities undertaken by I-TECH in Kenya in support of the Ministry of Health (MoH) in Kenya focusing on the people, processes and technologies employed in EMRs implementation.

Methods

I-TECH pursued a range of strategies for assuring sustainability of EMRs implementation. We describe each strategy and its results according to the socio-technical “people, process, and technology” framework for organizational capacity to meaningfully use and sustain health information systems. The observations we report are based upon routinely-gathered monitoring and evaluation (M&E) data, as analyzed by the authors (who have been part of project implementation and M&E teams since project inception in 2012). The data has been collected through tools such as form hub, Google sheet on post implementation monitoring tool and quarterly reports shared by I-TECH regional staff “train smart” application that supports monitoring of EMRs training among other tools. Once collected, I-TECH M&E staff conducts analysis of the data on a quarterly basis for purposes of reporting on project results, successes and challenges to the funder. This study represents a synthesis of these project reports from 2012-June 2016

People:

- **Sensitization of leadership**

EMR implementation began with sensitization of local leadership on the site readiness criteria and the steps for preparing public health facilities for EMR implementation, the initial scope of the EMR functionality, the expected role of local leaders in identifying “model sites” for initial implementation (where best practices could be established) as well as subsequent “scale up sites”, and the process of engaging and communicating with target health facilities. Inadequate communication can lead to divergent understanding among health workers on the role of EMRs, and problems at the organizational level with change management. Initially, sensitization of local leadership involved outreach to provincial teams in 8 provinces; however, once Kenya adopted a new constitution in 2010, decentralizing governmental functions to 47 newly-formed County governments, sensitization was expanded to leadership in 22 of the 47 counties covering the regions of KenyaEMR implementation. Sensitization was conducted by I-TECH in collaboration with representatives from the national MoH.

- **User training**

User training is the process of building skills among target system users to use and maintain the systems. EMRs users were categorized into 3 cadres; end users; health managers; and system administrators. I-TECH supported the MoH in Kenya to develop distinct training curricula targeting each of these groups. The training was conducted in a cascaded mode. First, training of trainers (TOTs) were conducted, reaching a small pool of lead trainers in each county. Next, TOT participants helped train KenyaEMR end users as well as “KenyaEMR Champion Mentors” (referred to henceforth as ‘champions’). Champions were front-line health care workers based at the target health facilities, who were nominated based on high interest and knowledge in the EMRs, willingness to support other users in the EMRs use, and strong post-test scores during the end user trainings. Champions
represented a variety of health workers cadres (clinician, data clerk, health records officer, nurse). Champions were prepared for their role through supplemental mentorship trainings. End user trainings also targeted diverse cadres involved in HIV care and treatment programs during training of 3-5 days. The management at the facility was targeted through the health managers’ curriculum which equipped them to provide oversight for the use of the EMRs at the facility level. The system administrators training was designed to prepare IT specialists based within County Health Management Teams (CHMTs) and large health facilities to trouble shoot EMRs hardware and local network problems, data backup and restoration procedures, management of user accounts, and other technical and “help desk” issues.

- **Multi-disciplinary teams**

Health facilities have multi-disciplinary teams (MDTs), supported by the PEPFAR SDIPs to address cross-cutting issues in HIV/AIDS service delivery. The MDTs comprise the doctors, clinicians, nurses, peer educators, mentor mothers, nutritionists and counselors working within the Comprehensive Care Center (CCC), the department specializing in HIV/AIDS care. Each MDT is chaired by the doctor or other clinician who directs the CCC and other services (the “facility in-charge”). EMR champions and facility in-charges facilitated the inclusion of the EMR-related topics alongside other agendas discussed by the MDTs. Examples of EMR-related issues addressed by MDTs include: roles and responsibilities in oversight of EMR activities, planning for legacy data migration, routine data quality assessment, and planning to reduce various barriers to EMR use.

- **County Technical Working Groups**

As part of the transition of EMRs to sustained local leadership and ownership, I-TECH collaborated with the SDIPs and CHMTs to form eHealth Technical Working Groups (TWGs) to oversee the EMRs agenda within each county. The TWGs deliberately comprised officials with authority and capacity to undertake timely decision making. Each county TWG is typically chaired by the County Director of Health and in his or her absence, by the County Health Records Information Officer (CHRIO). Members include other representatives from the County Health Management Team (CHMT), from EMR technical assistance partners, and from PEPFAR SDIPs.

Given the access of the TWGs to the county leadership, the groups have facilitated adoption of a number of proposals. Examples include recommendations that senior county leadership take into account EMR skills and experience when managing health worker employee transfers between health facilities (i.e. transferring EMR-experienced health workers to other sites with EMRs), that they plan for EMR-related costs when determining budget allocations during the annual work planning meetings. Allocated budgets should support EMRs maintenance, EMRs review meetings, and routine data quality assessments, among other EMR-related activities.

- **OpenMRS community building**

In an effort to increase the local support available for further KenyaEMR software enhancement and support I-TECH Kenya convened a meeting of OpenMRS implementers in Kenya and organized OpenMRS and KenyaEMR boot camps. The implementers meeting targeted developers and implementers from organizations customizing EMRs on the OpenMRS platform, in order to share best practices and identify areas of collaboration. The boot camps targeted university students pursuing information technology and computer science courses, in their final or penultimate year of study. This was to sensitize and orient them to the basics of the OpenMRS platform and to stimulate interest in health informatics careers.
Process:

- **Data migration**

  Public sector HIV/AIDS care and treatment programs in Kenya date back to 2005. Facilities offering such care have patient records since the inception of the service by the MoH. The current policy on paper records requires their preservation up to a period of 10 years. As facilities adopted EMRs, there was a need to have the historical patient data captured on the EMRs, to support continuity of care. Effective HIV/AIDS care can only occur when clinicians have access to key historical data for each patient and can track their response to treatment over time.

  To understand the effort needed in legacy data migration, we sampled the largest of the KenyaEMR databases from a large referral hospital in the Nyanza region of Kenya, with 26,971 patients’ records as of January, 2016. The total number of patient visits from the instance was 612,521 and the total number of observations (i.e. individual data elements) was 6,905,588. Therefore, the average number of visits per patient was 22 (612,521/26,971), and the average number of data elements captured per visit was 11 (6,905,588/612,521). With exception of the patients’ demographic information which is mostly captured once, legacy data migration would need to capture 242 data elements per patient. The number of patients per facility ranges between 500 and 26,000 patients. Together, this implies a heavy load of legacy data migration across KenyaEMR sites.

  To support the transfer of paper records to EMRs, data clerks were recruited and orientated to the data capture process to ensure that paper-based records were migrated into the electronic record. Data migration efforts were initiated immediately after the end user training. I-TECH collaborated with CHMTs and SDIPs to conduct intensive legacy data migration initiatives over a period of 3 months, whereby supplemental data clerks were recruited and assigned to specific health facilities.

- **Routine Data Quality Assessment (RDQA)**

  RDQA refers to the continuous assessment of the quality of data contained in the EMRs. It involves comparing patient data captured on the EMRs against the data contained in the source paper records for consistency of information. KenyaEMR provides an automated RDQA report that draws a random sample of patient records from the EMR, to enable comparison with other data sources, with a sample size intended to estimate the concordance level of data within +/-5%. Using the RDQA report, facility personnel or external assessors can compile comparison data values within an Excel-based workbook which is pre-programmed with charts and graphs to show RDQA results. Upon completion of each RDQA, sites identify action plans to address data quality gaps. Sites with weak concordance of data (<80%) are encouraged to follow standard operating procedures for data review and cleaning, and to undertake repeated RDQAs every 3-4 months until data quality reaches expected levels.

- **Point of Care (PoC) adoption**

  EMRs implementation in Kenya occurred in either PoC or Retrospective Data Entry (RDE) mode. PoC refers to a setup where a computer terminal is implemented at every patient service point within CCC, TB and MCH services. RDE refers to a setup where clinicians use paper records to serve patients and later have the paper records captured into the EMR at a single centralized data entry point by themselves or designated health facility workers. 

  PoC adoption permits use of clinical decision support functions within KenyaEMR. Available alerts include: patient due for viral load testing; patient eligible for ART; patient lost to follow-up. These features promote timely action towards healthcare quality improvement.
Upon initial assessment for EMR implementation readiness, facilities that had physical security gaps (e.g., no grills on windows, no bugle-proof doors) were recommended for RDE implementation. County and facility management were informed of the gaps. At sites where the gaps were remediated, subsequent transition from RDE to PoC implementation was possible.

**Technology:**

- **Successive releases**

  The initial KenyaEMR software release was based on an HIV/AIDS module for use in CCCs. This was augmented over time in response to the MoH users’ needs and with support from I-TECH to include maternal child health (MCH) care and Tuberculosis (TB) care modules. Additional features include Data Quality features, Reports Generation among others. There is presently interest in expanding the system to cover other outpatient primary care services as well as inpatient services.

- **Power sources**

  KenyaEMR implementation involved readiness assessments at each health facility to identify presence or absence of resources needed for EMR implementation. The assessments addressed physical security, electricity, presence of existing EMRs, and other issues. Where facilities were estimated to have electricity up to 75% of the time and met other required factors, the site was approved for implementation. However, power availability was often over-estimated. In reality, power supply is highly dynamic, with frequent power blackouts arising from normal rationing, other faults, or power cuts due to non-payment of bills.

  I-TECH collaborated with the CHMTs and SDIPs to analyze and compare costs of alternative power sources. Kenya has sunlight for more than 90% of the day with exception of the wet season. In the wet season, rationing of power is less common due to sufficient supply of water to the hydroelectric dams that provide electricity. Solar power was found to be cheaper than setting up a generator (US$7,940 vs US$19,250 for a solution supporting a load of up to 1.5 Kilowatts, or US$18,940 vs. US$74,690 for a solution supporting a load of up to 6 Kilowatts, each running for 8 hours per day over a period of 10 years (Table 2). Having alternative backup sources of power at health facilities has been identified as a critical factor preventing the piling up of backlogged patient records.

**Table 2:** Comparative costs for setting up and running backup source of power (8 hours per day x 10 years)

Results

People
I-TECH supported sensitization of 678 participants from the county leadership. This bore fruits in their facilitation of EMR related activities, including: recommendation of health workers to participate in planned EMR training; supervision of EMR use at the facility level; convening review meeting across the regions where facilities shared their experiences and best practices.

I-TECH further supported the training of over 2561 health care workers (42 doctors, 189 lab technologists, 868 clinical officers, 777 nurses, 370 health records and information officers and 315 other cadres) in 297 trainings across 22 counties in the four regions of Kenya (Table 3).

Champions conducted one-on-one sessions with users to train them on specific tasks or to bring newly appointed staff members up to speed on the EMR. Altogether, Champions reported mentoring 1754 facility staff mentored across 180 health facilities. Staff also interacted with the KenyaEMR “help menu” containing job aids, video tutorials, and two self-paced eLearning modules. In addition, Champions and KenyaEMR end users initiated region and county specific user support groups, via the “Whatsapp” mobile phone application

The “Whatsapp” groups have been formed across all 22 counties, and serve as a forum for peer-to-peer trouble shooting and bug reporting. On average, about 10 issues are resolved per county per month across the 22 counties implementing KenyaEMR. Facility staffs are further empowered through services such as toll free lines through which they can receive technical support and an online help desk management and bug reporting tool called Redmine.

Process
Out of the 342 implemented KenyaEMR instances, 90 health facilities had achieved 100% data migration while 252 were yet to fully migrate the legacy data into the EMR, by January 2016. The persisting need for legacy data migration has been occasioned by factors such as: downtime due to fluctuation of electricity; lost capacity following transfer of EMR trained health workers; increased workload due to double entry of patient records in both paper-based and EMR data systems; lean staff across health facilities; and slow data migration of patient records contained in non-standard MoH tools.

Specific data cleaning efforts have since been initiated to address identified gaps. In an analysis of baseline vs. follow up RDQAs conducted across 27 health facilities, there were 2,411 patient charts reviewed during baseline RDQAs and 2,381 patient charts reviewed during follow up RDQAs. At baseline, the concordance of data for mandatory data elements was lowest for dates of first and last CD4 test (13% and 11%, respectively) and highest for program of enrollment and patient sex (79% and 84% respectively). Follow up RDQA scores improved on average by 1.8 points on a 20-point scale across the 27 health facilities.

Technology
Overall, 208 (61%) initial KenyaEMR implementations were of the PoC model while 134 (39%) were of the RDE model. Additional 27 facilities have been assessed for upgrade to PoC implementation. This has been
facilitated by continuous improvement of physical security paving way for deployment of additional computing terminals.

Although power supply is a principal challenge to EMR use, only 50 out of 342 health facilities have an alternative power source that is maintained by the health facility (8 in the Central region, 16 in the North Rift Valley region, 9 in the Nyanza region, and 17 facilities in the Western region). This has greatly facilitated the continuity of EMR use in the absence of power from the national grid.

Overall results
An impact evaluation of the KenyaEMR implementation in improving quality of HIV/AIDS care is planned. Presently, qualitative feedback from EMRs users shared during county-level TWG and EMR review meetings indicate general satisfaction with KenyaEMR. Champions and end users have noted, for example: improved ease of retrieving patient records, reduced data entry errors owing to the presence of validation rules at data entry, reduced duplication of patient records due to easy-to-use patient lookup feature, increased ability to easily detect and resolve duplicate records based upon a feature that identifies potential duplicate records using patient demographic data.

Discussion

Lessons learned for EMR success
Our experience with EMR implementation at 342 health facilities in Kenya underscored many lessons learned for sustainable success of the systems. The process of EMR implementation brings with it numerous expectations, some of which are realistic and others which are not, such as: ability to immediately eradicate use of paper records\(^{13}\), automatic reduction of errors\(^{14}\), patient data security and confidentiality, and even loss of jobs for health workers. There is need to manage the expectations and demystify myths well in advance to reduce reluctance to use EMRs, calm users’ frustrations, and set reasonable expectations about the effort required for successful EMR implementation. Further, specific efforts should be made to actively monitor the successes and challenges encountered during the implementation stage. Health workers expectation has been cited as one of the factors that affect users’ satisfaction in EMRs\(^{15, 16}\). Others include practicality of use, impact on delivery of care, organizational support and variation from familiar practice\(^{17}\).

Without buy-in from the senior leadership it becomes a struggle getting health workers to use EMRs and an EMR project can easily be labeled as a failure\(^ {18, 19, 20, 21}\). Health facilities have different dynamics in uptake of EMRs and it is important to actively engage health facility leadership before proposing implementation plans\(^ {22}\). The process of EMRs implementation is cost intensive in the hardware acquisition, data migration, users training, provision of alternative power sources, among other key activities\(^ {23}\). A costing evaluation covering I-TECH’s direct costs of EMR implementation showed an average site-specific cost of US$9,879 per facility to implement an EMR\(^ {24}\). It is paramount that county teams and facilities identify sponsors beforehand to ensure that the funds available can support the different EMRs projects to completion. Recurrent costs including replacement of hardware should further be considered and planned for by the project owners. Besides sourcing funds, the benefits of such interventions should be clear to win the support of the sponsors.

Creating avenues for communication between the system users and the support and development teams ensures that the users never feel stranded and without help. In addition it creates avenues for the EMRs to improve with the growing end-user needs. This further builds confidence for the EMRs leading to indirect influence on the acceptance and readiness to use EMRs. Past experiences show that EMRs have failed where user acceptance needs have not been addressed\(^ {25}\). Our experience showed a strong enthusiasm for forums where peers can engage and discuss issues affecting their EMR use. These have reduced the time taken to resolve issues, and have led to knowledge sharing and better capacities across health facilities.

Future Activities
Legacy data migration has proven to be a formidable challenge, but steady progress has been made. As of June 2016, I-TECH, NASCOP, CHMTs and SDIPs were engaged in an intensive push to complete legacy data
migration at all sites with remaining backlogs of historical records. Completion of data migration will allow health facilities to engage in data quality improvement activities, and to facilitate transition to Point of Care (PoC) system use which takes advantage of the clinical decision support function within KenyaEMR.

Several SDIPs which have experienced benefits from the EMRs implementation are in advanced stages of planning to support alternative power sources. For example, one partner plans to install solar generated power and voltage stabilizers across 13 health facilities with a high number of HIV/AIDS patients, to maximize system uptime and minimize risks to hardware and data due to power surges. Efforts are underway to move towards paperless operations at sites which have demonstrated strong EMR data quality and with stable power availability. For example, one partner plans to pilot a reduced use of paper tools for parallel data entry in 21 health facilities, an important step in fulfilling the promise that EMRs can enhance rather than hinder the productivity of health care workers.

Users’ needs have further grown leading to extension of the KenyaEMR roadmap to include additional functionality including; support for outpatient and inpatient departments, data exchange between different systems; EMRs to laboratory information systems, EMRs to pharmacy information systems, and incorporation of national unique patient index (NUPI) that would facilitate patient tracking and identification across health facilities.

**Conclusion**

EMR uptake has grown over time in Kenya and the expectations from users have grown in equal measures. Timelines in EMRs upgrade to include additional features being requested by users will attract confidence and drive data use to greater heights. Availability of reliable power from the main grid and alternative sources will ensure sustained uptime of the EMRs and reduce the temptation to fall back to papers. Data exchange between EMRs will further eliminate duplication of effort in patients’ registration, further strengthening the users’ experience. Overall, the change process in EMR implementation ought to respond to the people, process and technology issues to increase the chances of successful EMR implementation.

Abstract

The Chronic Care Model (CCM) is a promising framework for improving population health, but little is known regarding the long-term impact of scalable, informatics-enabled interventions based on this model. To address this challenge, this study evaluated the long-term impact of implementing a scalable, electronic health record (EHR)-enabled, and CCM-based population health program to replace a labor-intensive legacy program in 18 primary care practices. Interventions included point-of-care decision support, quality reporting, team-based care, patient engagement, and provider education. Among 6,768 patients with diabetes receiving care over 4 years, hemoglobin A1c levels remained stable during the 2-year pre-intervention and post-intervention periods (0.03% and 0% increases, respectively), compared to a 0.42% increase expected based on A1c progression observed in the United Kingdom Prospective Diabetes Study long-term outcomes cohort. The results indicate that an EHR-enabled, team-based, and scalable population health strategy based on the CCM may be effective and efficient for managing population health.

Introduction

Chronic diseases such as diabetes mellitus are the leading cause of death in the United States,1 with almost half of all adults having at least one chronic illness.2 Therefore, there is an urgent need to identify and deploy effective and scalable population health strategies for chronic disease. The Chronic Care Model (CCM) is a promising approach for population health management that encompasses six elements designed to make the care of chronic conditions proactive, planned, and population-based rather than acute and reactive: delivery system design, clinical information systems, decision support, organizational support, self-management support, and community interaction.3,4

The CCM has been generally shown to be effective for improving process measures in published studies, but the CCM has not been found to be uniformly effective for improving clinical outcome measures.5 Similar promising, but non-uniform, results have been reported when various components of the CCM were implemented in various combinations.5 Moreover, under traditional fee-for-service payment models, the financial benefits of improved population health can accrue to insurers, while the costs of implementing improved population health management generally fall on providers.5 Therefore, cost-effective, scalable approaches are needed that do not require significant additional resources. For example, while Piatt et al. demonstrated that a CCM-based intervention can significantly improve process and outcome measures for diabetes management, this intervention required resources that would not be generally available to primary care practices, such as chart auditors to provide performance feedback reports and on-site diabetes educators supported by the investigators.6 Moreover, the increasing shift from “volume-based” to “value-based” payment models7 is making it imperative for health care providers to efficiently improve the health of their patient populations. To succeed in this new environment, health care providers must develop population health strategies that deliver greater value through improved outcomes and lower costs.

Given the promising, but non-uniform, results from previous evaluations of the CCM, as well as the need for further evaluations of pragmatic, scalable population health strategies based on this model, the present study was conducted. We evaluated a CCM-based population health program that was in operational clinical use at 18 primary care practices of the Duke University Health System from January 2009 until June 2011, when a new electronic health record (EHR) system was implemented. While the population health program encompassed several chronic
conditions as well as preventive care, this study was focused on diabetes due to its inclusion in the population health program from the initial program deployment and the availability of a widely accepted physiological measure of disease control in the form of hemoglobin A1c (A1C) levels. A1C levels reflect average blood glucose levels over a three month period and are strongly correlated with adverse outcomes.

Because diabetes is a progressive condition characterized by worsening insulin resistance, A1C levels typically increase over time despite treatment. For example, a literature review of the expected progression of type 2 diabetes found that A1C levels increase by an average of as much as 0.5% per year (absolute change) even with therapy. While such disease progression is managed through therapy intensification, including the addition of new therapeutic classes such as insulin, A1C levels are still generally expected to increase over time. For example, based on long-term data from the United Kingdom Prospective Diabetes Study (UKPDS), and as incorporated into the UKPDS Outcomes Model, an individual starting with an A1C of 7% is expected to experience an A1C increase of approximately 1.5% per year (relative change) despite therapy. Thus, while reducing A1C levels (e.g., to < 8% or < 7%) is an important clinical goal, maintaining or slowing the increase in A1C levels is also an important goal.

Prior to the introduction of the EHR-enabled, team-based, and scalable population health strategy in this study, a labor-intensive, disease registry-based approach had been in place for diabetes management at the study sites. The objective of this 4-year longitudinal study was to evaluate whether the more efficient and EHR-based population health strategy could maintain or potentially surpass the glycemic control achieved under the previous, labor-intensive approach. A before-after study design was used in conjunction with an interrupted time series analysis.

Methods

**Study Site and Participants.** The study was conducted at 18 primary care practices of Duke Primary Care (DPC), which is a community-based primary care system affiliated with the Duke University Health System and centered in Durham, North Carolina. DPC serves a seven-county area with internal medicine, family medicine, pediatrics, and urgent care services. DPC is comparable to a community primary care system, with no residents and some teaching provided for medical students, physician assistant students, and nurse practitioner students. During the intervention period, DPC was staffed by over 100 physicians and 15-20 physician assistants and nurse practitioners.

Study participants were adult patients with diabetes mellitus types I and II who were patients of DPC during the study period (2007-2010). Detailed inclusion criteria are as follows: (i) at least 18 years old as of January 1, 2007; (ii) had at least one ICD9CM diagnosis for diabetes as defined by the National Quality Forum in the first historical control year (2007) and also at least one diabetes diagnosis in the year prior (2006); and (iii) were seen at least once in the study practices in each of the four study years, as well as in the year prior (2006). The ICD9CM diagnosis codes used to identify diabetes were 250, 250.X, 250.XX, 357.2, 362.0, 362.0X, 366.41, 648.0, 648.00, and 648.0X. The study was approved by the Duke University Institutional Review Board (protocol # 00042607).

**Study Period.** The study period was January 2007 through December 2010, with the intervention rolled out across the study sites in January 2009. The study period was ended in 2010 because the EHR system was changed in 2011.

**Interventions.** The intervention was a Chronic Care Model (CCM)-based population health program for diabetes. This multi-faceted intervention included the use of an EHR system for pre-visit planning, the implementation of a point-of-care clinical decision support (CDS) system, the implementation of a quality reporting system, team-based care, active engagement of patients, and provider education. Care team development and patient engagement were integral to the intervention. The care team consisted of clinicians (physicians, physician assistants, and nurse practitioners), as well as certified medical assistants, licensed practical nurses, and registered nurses. Patient self-management was supported through pre-visit planning and education from clinical support staff. The population health program was piloted on a small scale at the end of 2008 and rolled out across all sites in January 2009.

In order to promote external generalizability and scalability, the population health program was designed and implemented in a manner that could potentially be replicated widely. In particular, the need for labor-intensive tasks such as manual data entry was minimized, so that the approach could be sustained in typical clinical settings with existing clinical staff. Moreover, the point-of-care CDS system and quality reporting system were implemented using a software module that can be integrated with various EHR systems through a standard Health Level 7 (HL7) Web service interface. Consequently, the informatics approaches leveraged in this study could potentially be deployed to other institutions and information system environments.
The details of the CDS system have been previously described.\textsuperscript{18} Briefly, the CDS system was available as a link within the EHR system and provided a dashboard for managing diabetes, including care metrics (e.g., appropriate laboratory monitoring), the patient’s current status on the metrics (e.g., not due, due now, almost due), relevant data (e.g., date and value of most recent laboratory test), and a summary of relevant guideline recommendations (Figure 1). This CDS system initially supported diabetes, hypertension, and health maintenance, and it was later enhanced to support other conditions including congestive heart failure, asthma, and chronic kidney disease. Diabetes care recommendations were based on American Diabetes Association guidelines.\textsuperscript{12} As noted earlier, this study was focused on diabetes \textit{a priori} due to its inclusion in the population health program from initial deployment and the availability of a widely accepted physiological measure of disease control (A1C levels).

![Figure 1. Screenshot of point-of-care CDS system.](https://clinapp6.duhs.duke.edu:8081)

CDS recommendations could be obtained in a disease-specific manner (e.g., using the “Diabetes” tab in Figure 1), or for all supported conditions at once by selecting the “All” tab. This point-of-care CDS system was designed to align with the findings from a previous systematic review of CDS interventions, which found that computer-based CDS interventions that provided actionable recommendations automatically and at the appropriate point in clinical workflow significantly improved clinical practice in over 90\% of randomized controlled trials.\textsuperscript{19}

In a typical clinic visit, clinical staff used the CDS system to generate the care reminders, which were printed and provided to clinicians for use during the encounters. This approach worked well due to the routine use of a visit billing form to which the printed reminders were attached. Alternatively, clinicians retrieved the care reminders directly through the EHR. Furthermore, standing orders were in place for clinic staff to perform required interventions per protocol and as identified by these tools. For example, if the CDS system identified that a patient was in need of an A1C test, nurses were empowered to obtain the required test. This team-based care involved the use of existing clinical staff (i.e., clinicians, nurses, and medical assistants), rather than the addition of care providers who would generally not be available in a typical primary care practice (e.g., dedicated dietician, pharmacist, etc.). Most data points (e.g., laboratory test results, blood pressure values, vaccinations, eye exams) were retrieved from the EHR and did not require additional data entry. Clinic staff facilitated any supplemental data updates (e.g., to document that an eye exam was not indicated because of blindness), and the clinic staff also facilitated the completion of needed care interventions. Clinicians engaged patients through discussion of the care reminder summary and needed interventions.

The quality reporting system (Figure 2) provided the clinic managers and designated nurses of each clinic with monthly reports on performance measures, which were then used to recall patients to obtain necessary care.
The goal of this intervention component was to identify patients who were outliers in relevant physiological measures (e.g., A1C levels), so that designated nurses could increase patient engagement in their care, identify and seek to address barriers, and schedule follow-up appointments. The quality reporting system was included in the intervention based on a previous randomized controlled trial that showed that adding a clinician feedback component increased the effectiveness of a CDS system. Implementation of this approach was challenging, however, due to the labor-intensive nature of the required follow-up and difficulty in reaching some patients.

Figure 2. Quality reporting system with views for clinic group (top), clinic (middle), and clinician (bottom).
Pre-Intervention Population Health Management Approach. During the historical control period, usual care was provided using a labor-intensive approach centered around the use of a commercial disease registry tool known as DocSite. In our implementation, DocSite was a stand-alone disease registry separate from the EHR, with data imports available only for demographic data. Clinical staff were required to manually enter all other data (e.g., blood pressure values, immunization records, and laboratory values). In a typical clinical visit, a visit planner similar to that in Figure 1 was printed, which included information on what was due and what was done previously. A medical assistant would fill out information on needed data points (e.g., relevant laboratory results), and clinical staff would transcribe that data into the registry. The main differences of the study intervention compared to the historical control were (i) little or no manual data entry was required for the intervention, versus significant manual data entry required for the historical approach; (ii) integration of the population health management system with the EHR; and (iii) the availability of more sophisticated algorithms in some cases, for example for vaccination logic.

From an end-user perspective, the functionality of the DocSite system was quite similar to the study intervention except for the extensive need for manual data entry. Specifically, the DocSite system provided clinicians with diabetes care recommendations during clinic visits and outlier reports were available for identifying patients in need of targeted follow-up. Thus, even a demonstration of non-inferiority would show value, as the intervention significantly reduced the labor resources required for managing the health of patients with diabetes.

Evaluation Measures. The primary evaluation measure was the change in A1C levels among study participants during the intervention period compared to the historical control period. A potentially important confounder in the use of clinically measured A1C levels is that diabetes care guidelines recommend that A1C levels be measured more frequently among individuals with higher A1C levels. Pursuant to these guidelines, for example, the point-of-care CDS system reminded clinicians to test for A1C levels every 3 months if the last A1C level was >= 7%, and only every 6 months if the last level was < 7% (Figure 1). In order to address this potential source of confounding, as well as to reduce the impact of any random measurement errors, we estimated the A1C level of each patient on the 15th day of each month. If the patient had a test on the 15th, that value was used. Otherwise, the value was estimated through the interpolation of the nearest values (i.e., the latest test result from before the 15th and the earliest test result from after that date). This approach ensured that all patients had an equal number of A1C level estimates (48 values, one for each month of the four year study period).

A secondary study measure was the proportion of encounters at study clinics by study participants which resulted in use of the CDS system for diabetes. The system was considered to have been used for the encounter if system use logs indicated that the diabetes module of the CDS system had been activated for the patient on the day of the encounter or up to three days prior to the encounter in preparation for the visit.

Estimate of Expected A1C Progression. We estimated the expected progression of average A1C levels in the study population over the study timeframe using an A1C progression equation in the United Kingdom Prospective Diabetes Study (UKPDS) Outcomes Model© (https://www.dtu.ox.ac.uk/outcomesmodel/). This equation was developed based on the UKPDS long term outcomes data, with patient level A1C data from our study cohort used in the model as the input for time zero A1C. We did not use this estimate for hypothesis-testing purposes, but we used it to contextualize our findings in the absence of a comparison group.

Analysis Approach. The study cohort was identified using a guided database query tool known as DEDUCE, which provides a Web-based interface for identifying patient cohorts and for obtaining approved data from the Duke University Health System’s data warehouse. Most study data were obtained through this tool. Data on the utilization of the point-of-care CDS system was obtained from the Duke Clinical Data Repository.

A software program was developed in Java to prepare the data in the format required for statistical analyses. Statistical analyses were conducted using SAS Enterprise Guide Version 4.3 (SAS Institute, Inc., Cary, NC, USA). Usage rates for the point-of-care CDS system were summarized graphically and using descriptive statistics. To estimate the changes in A1C levels during the pre- and post-intervention periods, a mixed linear model analysis was performed using the PROC MIXED procedure with maximum likelihood estimation. In the analysis, the patient was the class, the number of years since the beginning of the evaluation period was the predictor, and the A1C level was the dependent variable. To evaluate whether the changes in A1C levels in the intervention and pre-intervention periods were different, the PROC MIXED procedure was used with maximum likelihood estimation, with the patient as the class and with the years before or after January 2009 as the predictors. For all analyses, indicator variables for the months of the year were included in the models to adjust for seasonal variation, and sensitivity...
analyses were conducted omitting these variables. To the best of the investigators’ knowledge, no other population health management or clinical practice changes believed to have influenced diabetes care and outcomes were undertaken during the study timeframe.

The sample was restricted by the number of patients meeting inclusion criteria seen at the 18 primary care clinics. With a sample of 6,768 subjects, for the primary measure, we estimated a power of >99% to detect an improvement in A1C levels during the intervention period at least 0.5% greater than the change during the control period. These calculations were based on a one sample t-test with a 2-sided type I error rate of 0.05.

Results

There were 6,768 individuals with diabetes mellitus who received care at the study sites, met the study inclusion criteria, and were included in the analysis. All patients meeting inclusion criteria were included. These individuals had an average of 8.7 distinct A1C test results on record during the four year study period. The average A1C level for this population during the study period was 7.2%, with a standard deviation of 1.4%.

Usage of the Point-of-Care CDS System. Figure 3 shows the usage of the point-of-care CDS system for the study population for diabetes care. As noted, prior to the intervention start date (January 2009), there was limited usage of the CDS system for diabetes care for several months due to pilot use of the system by some sites. To roll out the population health intervention, the Duke Primary Care leadership notified each clinic of the switch-over from the manual data entry-driven approach to the more automated intervention approach, and basic on-site education and training were provided at each practice by clinic staff. Immediately following the start of the intervention period, usage rates increased to approximately 45%, and steadily increased to approximately 70% by the end of the study. Stratified at the clinic level, the highest usage rate in the final month of the study was 88% at one clinic; 5 clinics had usage rates > 80%; 6 clinics had usage rates > 70% and < 80%; 3 clinics had usage rates > 60% and < 70%; and 4 clinics had usage rates < 60%. Usage therefore was high but not universal. During the intervention, usage of the tool was not monitored at an individual provider level. While we did not measure the time required to use the system during this intervention, there was significant manual work that was required for data entry in the pre-intervention period. Based on expert opinion (JBA, Duke Primary Care Chief Medical Officer), we estimate that in the post-intervention period there was a savings of at least an hour a day for the clinical support staff at each clinic, depending on the size of the practice and number of providers.

Figure 3. % of encounters at study sites by study participants with CDS system use for diabetes care. Month 25 = January 2009.
**Hemoglobin A1c Levels.** Figure 4 provides an overview of the study population’s A1C levels during the historical control and intervention periods. The A1C levels remained relatively unchanged during both the control and intervention periods. During the pre-intervention period, the A1C started at 7.17% in January 2007 and ended at 7.20% in December 2008. During the intervention period, the average A1C level remained essentially unchanged, starting and ending at 7.24%. Included in Figure 4 is the expected A1C progression from the UKPDS long term outcomes study, with an expected A1C level of 7.59% (0.42% absolute increase) by December 2010.

![Figure 4. Average A1C levels over time for study population (2007-2010)](image)

Table 1 provides the model for the A1C level during the pre-intervention period, and Table 2 provides the model for the A1C level during the intervention period. As noted, the slope for the A1C level was 0.01%/year for the pre-intervention period and -0.02%/year for the intervention period. This difference in slope was statistically significant (p = 0.01). However, we do not consider this difference in slope to be clinically significant.

The intercept was higher in the intervention period compared to the pre-intervention period. However, the overall trend in A1C was essentially flat throughout the study period, starting at 7.17% in January 2007, going to 7.24% in January 2009 (the first month of the intervention), and ending at 7.24% in December 2010.

Sensitivity analyses were also conducted in which indicator variables for the months of the year were removed. These sensitivity analyses without adjustment for seasonal variation resulted in similar findings as the primary analyses with seasonality adjustment.

### Discussion

#### Summary of Findings.
In this study, a pragmatic, scalable, and CCM-based population health strategy for diabetes care was evaluated in 18 primary care clinics using a before-after study design with an interrupted time series analysis. A key component of the intervention, the point-of-care CDS system, was well accepted, with usage rates rising to approximately 70% of primary care encounters by study participants by the end of the intervention period. Potential reasons for non-universal system use may have included chronic disease care being of secondary concern during clinic visits for acute medical conditions, as well as individual providers making limited use of the tool. Given a usage rate of 88% in one clinic by the end of the study period, and a rate exceeding 80% in five clinics, a system usage target of > 80%, or perhaps even > 90%, appears to be an attainable goal for this type of CDS tool in primary care.

After adjusting for seasonality, the rate of change in A1C levels during the intervention period was -0.02%/year, as compared to 0.01%/year during the historical control period (p = 0.01). However, we do not deem this difference to be clinically significant. Overall, the A1C levels remained remarkably stable during both the pre-intervention period (increasing from 7.17% in January 2007 to 7.20% in December 2008) as well as the intervention period (unchanged, at 7.24% in both January 2009 and December 2010). The overall change in A1C levels over the course of the entire study period, encompassing both the pre-intervention and intervention periods, was 0.07% (7.17% to 7.24%). This change was only 17% of the 0.42% increase expected based on the UKPDS long-term outcomes data and the baseline A1C levels. Thus, the study results suggest that both labor-intensive, disease registry-based population health approaches as well as an EHR-enabled, CCM-based population health program are capable of slowing A1C progression and presumably the associated complications. As noted in the descriptions of these two population health approaches, however, the EHR-facilitated population health program required much less time and resources to operate compared to the stand-alone disease registry-based approach.

In summary, this study contributes insights on the long-term clinical outcomes of an EHR-enabled, team-based, and scalable CCM approach to population health management. Additionally, this study provides validation for the enterprise-level use of standards-based CDS Web services to enable population health management, including for point-of-care CDS and feedback reporting.

#### Limitations and Strengths of Approach.
A limitation of our study is the lack of a concurrent control group, with its associated potential for confounding and the difficulty of definitively attributing the patient outcomes to the study intervention. While clinical leaders were not aware of any other major interventions or changes in clinical practice related to diabetes care during the study period, other confounding factors may have impacted the A1C trends that we observed. To contextualize our findings in the absence of a control group, we estimated A1C progression in the study population using the A1C equation embedded in the UKPDS Outcomes Model. We recognize that this equation is based on the UKPDS long-term outcomes population and has not been validated in a US cohort.
However, we are not aware of published data on long-term A1C progression in patients treated per usual care in the US that we could have used to estimate A1C progression. Another limitation of our approach is the inability to distinguish between the impacts of different components of our multi-faceted intervention. Our inclusion criteria also required patients to be seen at least once a year at the study sites during the study period; therefore, our findings may not be generalizable to patients with diabetes who do not consistently receive primary care. As another limitation, our estimate of time savings from the intervention is based on expert opinion rather than explicit measurement. Also, due to our focus on improving clinical outcomes, we did not evaluate for process measures (e.g., guideline compliance rates), which could have provided more insights into the mechanisms underlying the observed clinical outcomes. Finally, we used A1C results collected as a part of the routine care process, rather than A1C results collected specifically for the study, and at set time points. However, to account for this final limitation, we used interpolation to ensure that all patients had the same number of observations to contribute to the analysis.

A strength is the use of a large sample size, which increases the precision of our findings. In addition, our evaluation encompasses four years of data, which allows for a long-term assessment of the impact of the population health strategies under study. Third, the use of a historical control period provides some level of protection against confounding. Fourth, our system and analyses are population-based and not limited to a subset of poorly controlled patients who might experience substantial A1C improvement with disease management. Finally, the intervention evaluated was pragmatic and scalable, with clear benefits compared to a labor-intensive approach to population health management.

Implications and Future Directions. Overall glycemic control in the study population was quite good both before and after the intervention, with average A1C levels very close to 7%, which is the target goal for many individuals with diabetes. Moreover, A1C levels increased by only 0.07% during the entire evaluation period and remained unchanged during the intervention period, compared to an expected increase of 0.42%. Thus, an important implication of this study is that a team-based, EHR-enabled population health program based on the CCM is capable of effectively managing a population of patients with diabetes. Key components of this population health strategy include the empowerment of care team members, e.g., to order needed laboratory tests by protocol; standard care protocols that harness the efforts of the entire care team, such as the removal of shoes by patients with diabetes during the rooming process to facilitate recommended foot exams; and providing feedback to clinicians to reaffirm the importance of their population health management efforts. While our study design was not capable of teasing out the impact of these various facets of the intervention, our empiric observation is that each of these various facets of the intervention played an important role in the overall effectiveness of the population health program.

Another important implication of our study is that an automated approach to population health management can be just as effective as a highly labor-intensive approach. Indeed, by leveraging the data captured in EHR systems as a part of routine clinical care, an EHR-enabled population health program may be pursued in a highly automated fashion with minimal need for duplicate, manual data entry.

Looking into the future, we anticipate that the increasing adoption of EHR systems, combined with increasing financial pressures to more efficiently and effectively manage chronic conditions, will result in continually greater use of EHR-facilitated, team-oriented, and CCM-based approaches to improving population health. This study contributes to this increasingly important area of biomedical informatics research – the leveraging of information technology to more efficiently manage chronic conditions and improve population health. In the future, we anticipate that many more studies will be conducted by ourselves and others to evaluate how best to improve population health using these technology-enabled and team-based approaches.

Conclusion

An EHR-enabled, team-based, and scalable population health strategy based on the CCM was associated with limited A1C progression among patients receiving outpatient diabetes care. These benefits were comparable to the limited A1C progression associated with a labor-intensive population health management approach requiring extensive manual data entry.

Abstract
The information needs of clinicians, as they interact with the EHR, are well-studied. Clinical researchers also interact with the EHR and, while they might be expected to have some similar needs, the unique needs that arise due to nature of their work remain largely unstudied. For clinicians, infobuttons (context-aware hyperlinks) provide a mechanism of studying these information needs. Here we describe the integration of infobuttons into i2b2, a popular data warehouse commonly used by clinical researchers, using a plugin. A preliminary survey of i2b2 developers indicates a general interest in infobuttons for i2b2 and indicates good likelihood for their deployment, where they may be used as a tool for further studying these needs in greater detail.

Introduction
Clinical information systems such electronic health records (EHRs), now widely available, address many of the information needs of their users,1,2 yet they simultaneously evoke many new information needs.3,4 The greater availability of EHRs has led to their use by a new constituency: clinical researchers.5,6 Similar to their clinical counterpart, these individuals often provide health care for their subjects as patients and therefore might be expected to have similar information needs. However, this new group of users would also experience different information needs based on their unique use cases, including managing the research workflow of their subject,7 responding to clinical problems that arise because of the research procedures, analyzing the data they collect across their cohort of patients to generate new knowledge,6,8 and using that knowledge to generate new research questions.9,10 It is our hypothesis that these tasks entail information needs that differ from those of routine patient care. However, while the information needs of clinicians have been widely investigated,11–14 an extensive search of PubMed and Google Scholar for studies on those of clinical researches fails to reveal research in this area.

One method for addressing information needs of EHR users is through the context-aware hyperlinks, known as “infobuttons”, that provide patient-specific, just-in-time knowledge at the point of care.15,16 When integrated into EHRs, infobuttons serve not only as a mechanism for decision support, but as a method for studying clinician information needs.17,18 As clinical researchers often access EHR data through clinical data repositories, we believe that integrating infobuttons into these repositories could serve similar dual purposes.

We have therefore developed a method for integrating infobuttons into a popular data warehouse (i2b2). We refer to this version of infobuttons as i3b3. The purpose of this paper is to describe the development of i3b3, explore the interest of the i2b2 community in having such a capability, provide instruction on how i2b2 installations can avail themselves of our software, and discuss the opportunities that i3b3 provides for exploring the varied information needs of clinical researchers.

Background
OpenInfobutton
OpenInfobutton is free-for-use, HL7-compliant infobutton manager provided by the University of Utah (http://www.openinfobutton.org/) that acts as an information broker between infobutton implementations and knowledge resources.14 The EHR infobutton passes relevant, contextual information about the patient, user and user’s status from the originating system using the HL7 standard to OpenInfobutton, which uses that information to select relevant information resources (for example, a drug dosing reference source). It then constructs links to those
resources, customized with the contextual information (for example the drug and patient age and gender). The links are presented back to the user, who can then select those that appear to address his/her information need.

**LITE**

The selection of resources by OpenInfobutton, and the customization of links to those resources, is made possible by a knowledge base used by OpenInfobutton that contains institution-specific information provided by an analyst or librarian responsible for the infobuttons in the institution’s EHR. This customization is provide be a tool called the Librarian Infobutton Manager (LITE), which is also freely available from the University of Utah (http://lite.bmi.utah.edu).

**i2b2**

The i2b2 (Informatics for Integrating Biology and the Bedside) system (https://www.i2b2.org/) is a popular patient data warehouse consisting of a repository for storing patient data and a user interface for rapidly querying the data for research cohorts that meet pre-selected criteria. This system was built by separating individual components into “cells” (interoperable modules) of a larger “hive” that communicate with each other via web protocols. This architecture allows the system to be highly extensible through the development of additional cells and plugins in order add desired functionality. In order to interact with the data repository in the cells, i2b2 provides two types of user interfaces (UIs): a workbench and a webclient. The workbench is a Java-based thin client that requires local installation and configuration on each computer that needs to interact with i2b2. The more common webclient is a browser-based UI built with standard web technologies that interacts with i2b2 via a web proxy server.

**Methods**

**i2b2 Plugin Development**

i2b2 can installed on many different server architectures and it’s functionality can easily be extended through cell or plugin development. Cell development allows the addition of new server-side functionality to i2b2 through communication with other cells in the hive, and can allow additional data to be retrieved directly from the data repository. While this provides extensive flexibility over data manipulation at the database level, cell installation in currently implemented i2b2 instances requires substantial modification to server configuration files. Additionally, user interaction with a custom i2b2 cell typically requires the development of an externally-facing plugin on the webclient as well.

Because we desired to make installation of our i3b3 infobuttons as simple as possible, we chose to develop a plugin. These can be installed into i2b2 by simply adding the plugin’s directory structure to a standard location in the webclient’s web server and by changing a single configuration file.

In addition to i2b2’s standard plugin structure, we connected two other systems to it in order to establish communication between i2b2 and external knowledge resources. Briefly, i2b2’s data are sent via a HL7-compliant HTTP GET web request to OpenInfobutton. OpenInfobutton then generates a set of links to external resources based on prior settings configured in LITE. The links are then returned to the user as a list of uniform resource locations (URLs) displayed in a browser window for user interaction.

**Information Needs Survey**

In order to make a preliminary determination of the general interest in the integration of infobuttons into i2b2, we constructed a Google survey (http://goo.gl/forms/Xulqq5s3QW) (see Figure 1). As the survey was a preliminary information needs assessment, we kept the survey short and briefly reviewed the two included questions before finalizing it. The first question was simply, “Would you be interested in infobuttons for i2b2?” (yes/no). The second question was only revealed to participants if they responded “Yes” to the first question. In order to provide participants with a framework for possible locations that infobuttons could be integrated into i2b2, this question began with a screenshot of the i2b2 plugin that we developed. The question following the image, “Where would you like to integrate infobuttons into i2b2 (choose as many as apply):”?, then provided both a list of checkboxes of logical locations to integrate infobuttons.

After completing and reviewing the survey, we emailed generated link to the survey to all recipients on the i2b2 mailing list and posted the link on the “i2b2 Install Help” Google group.
We collected responses for the following 10 days followed by creating a summary of the data collected.

### Question 1

**Interest in Infobuttons for i2b2**

Infobuttons are context-aware links that have been integrated into EHRs for retrieval of information from external resources. Their ability to perform context-aware searches allows them to perform faster searches for more relevant information than a simple web search for the same information. While infobuttons have been integrated into EHRs in the past, they may provide a similar benefit for informational retrieval regarding patient sets if integrated into research data management systems such as i2b2.

* Required

Would you be interested in infobuttons for i2b2? *

- Yes
- No

### Question 2

**Where would you like to integrate infobuttons into i2b2 (choose as many as you want):** *

- Diseases
- Medications
- Laboratory Results
- Demographics
- Procedures
- Imaging
- Radiology
- Pathology
- Clinical Notes
- Navigation Terms
- Previous Queries
- Other:

Figure 1. Information needs survey for assessing infobutton interest in the i2b2 community and desired locations for integrating infobuttons located at [http://goo.gl/forms/XuIqq5s3QW](http://goo.gl/forms/XuIqq5s3QW). The first question (Question 1) simply asks the respondent if they are interested in having infobuttons in i2b2 (yes/no). If they answer “yes”, the second question allows the respondent to detail where they would like infobuttons to be integrated. At the beginning, question 2 shows a simple screenshot of the plugin’s UI for reference and then provides several locations for integration including several concept classes present in i2b2 and a fill-in-the-blank response for alternative suggestions.

### Results

#### Plugin Development and Use

Integration of infobuttons into the i2b2 system combines the plugin system, OpenInfobutton, and LITE. The plugin consists of two main components: a UI, built with HTML5 and CSS3, and a controller, built with JavaScript and Prototype (a JavaScript framework), each constructed according to the i2b2 plugin standard [https://community.i2b2.org/wiki/display/webclient/Web+Client+Plug-in+Developers+Guide](https://community.i2b2.org/wiki/display/webclient/Web+Client+Plug-in+Developers+Guide). Figure 2 provides a schematic view of the components and processes involved.
After selecting the plugin from i2b2’s list (see Figure 3), a user can select a concept class, such as *diseases* or *medications*, to investigate in a patient set and then drag a previously created patient set into a text box in the plugin window. This action will cause the controller to generate an AJAX (asynchronous JavaScript and XML) request directed toward the i2b2 data repository, which will respond with an XML message containing the requested information. After receiving the response, the controller parses through it to prepare it for display to the user. Once finished, the controller updates the UI with a list of the patients in the set and the respective information requested (i.e. a list of diseases or medications for each patient; see Figure 4).

![Image](image.png)

**Figure 2. i3b3 plugin architecture.** Initially, a i2b2 user creates a patient set in i2b2 and loads the i3b3 plugin. The user can then drag the previously created patient set into the i3b3 frame (1) causing a list of patients and associated concepts (medications and diagnoses) to be displayed. Clicking on an infobutton next to any of the concepts opens a secondary browser window (resource window) and sends context-specific information to OpenInfobutton (2). OpenInfobutton queries to its resource knowledge base (created using LITE - the Librarian Infobutton Tailogin Environment) and generates a list of customized hyperlinks (3) that link to selected resources (4). The user can select one or more of the available resource links in the resources window to receive information to their initial question (5).

Next to each of the concepts listed below each patient, the controller places an infobutton icon that contains a URL with HTTP GET parameters to be passed to OpenInfobutton (see Figure 4). The parameters in the URL, which include the displayed concept, the patient’s age, and the patient’s gender as well as the institution (“UAB”) and the task (“i2b2”), are context-aware and translated from i2b2’s terminology into HL7-compliant terms. A user’s click on one of the infobutton icons sends a request to OpenInfobutton containing the previously mentioned information. The infobutton manager will then utilize a pre-configured, XML settings file (created with LITE) to select appropriate resources and construct links to those resources that include the appropriate parameter values obtained from the plugin. The links to each resource are combined into a final output in a secondary window. Each resource returns a result set on the original concept automatically refined by the concept’s original context. The result is context-specific links to knowledge resources based on the original concept that was selected (see Figure 5).
Figure 3. Initial state of the i3b3 plugin after loading. A user can select the plugin from the list of i2b2 plugins in the “analysis tools” section [(A); shown enlarged in (B)]. The plugin is then loaded into the right panel (C) with brief instructions displayed at the top and more detailed instructions in a “Help” tab located at the top of the plugin panel.

Figure 4. Example of user interaction with i3b3 and the response provided. (1) A user selects a class of concepts that he/she desires to know more about from an available list (example depicts “Medications” chosen). (2) The user then selects a patient set from a previous query (shown enlarged in “A”) and (3) drags and drops it into the available space in the plugin panel. (4) i3b3 will then return a list of the patients in the set and the associated concepts initially chosen in step (1). Each concept (in this case, medications, shown enlarged in “B”) has an associated infobutton that links to OpenInfobutton.
The finalized infobutton plugin has been distributed via our institution’s GitHub page found at https://github.com/uab-informatics-institute/i3b3. This release method, combined with the design of the system as an i2b2 plugin, allows for rapid installation in any i2b2 instance requiring only minimal instructions that are provided on the GitHub page. Additionally, GitHub provides a simple method for community contributions to future development of the plugin. Following construction and distribution, the plugin was easily installed by a system administrator in our institution’s i2b2 development environment with only the GitHub URL and confirmation of the i2b2 concept pathway structure provided. This highlights the fact that the i3b3 plugin remains independent of the actual ontology used in an i2b2 installation and needs only a minor setting modification in order to provide the location specific classes of concepts desired to be present for user selection.

Survey Responses
The distribution method of the survey allowed it to reach a wide audience from new to experienced researchers and clinicians along with several system analysts responsible for installing and maintaining i2b2 at their institution. The survey reached approximately 285 individuals through the “i2b2 Install Help” Google group and an unknown number through the mailing list. In total, the survey received 19 responses with all answering “Yes” to the question about interest in infobuttons for i2b2 (see Figure 6). In response to the question regarding desired infobuttons domains, participants requested infobutton integration for Diseases, Medications, Laboratory Results, and Procedures most frequently while others received a much lower frequency of requests. This trend may indicate the greatest, unmet information needs that arise in clinical researchers during interaction with i2b2.

Most respondents did not take advantage of the “Other” category, suggesting that the majority of potential locations for infobutton integration were already present in the survey options. Of those participants that did choose the
“Other” category, one simply suggested that all of the categories listed as answer choices would be useful and added that an infobutton for genotypic data would also be useful. Taken together, these results suggest the presence of unmet information needs in the i2b2 community, potentially extending to clinical investigators. Additionally, the survey responses indicate that these information needs may be further studied and potentially met with the use of infobuttons in applications that clinical investigators frequently interact with during the course of their studies.

Figure 6. Results of the i2b2 infobutton survey. There were 19 total responses to the survey. All respondents answered “Yes” to the first question asking about interest in infobutton for i2b2. The figure above shows the responses to the second question asking about location integration. General concepts such as diseases, medications, laboratory results, and procedures received the highest recommendations with most other options chosen much less frequently.

Discussion
This paper describes an easy-to-adopt solution to the integration of infobuttons into any i2b2 installation. Coupled with the freely available OpenInfobutton and LITE, any i2b2 instance in the world can now provide its users with context-aware knowledge resource links and, based on our survey, it seems there is significant interest in doing so.

What links to provide remains an open question. The literature has few studies investigating the information needs of clinical scientists, and managers of i2b2 systems should not be quick to assume that the needs of clinical researchers will be the same as those of clinicians. More studies of clinical researchers’ needs will be required as studies of clinicians’ needs consistently show that those needs are task-dependent. While clinical researchers may have similar needs because they may have similar tasks (that is, caring for patients in their studies), they have additional tasks related to research, including adherence to study protocol, analysis and publication of data, and new hypothesis generation, all of which may be triggered by the same EHR data that trigger clinician needs. Those studies also consistently show that information needs cannot always be predicted without empiric observation. We conclude, therefore, that the information needs of clinical researchers should be a target of future study as part of the deployment of infobuttons. As with studies of clinician needs, infobuttons themselves (in this case, i3b3) can serve as a valuable tool in such studies.

The plugin we constructed was only developed and tested within the purview of a single hospital. However, we do not believe that our hospital environment and clinical research environment differ from other hospitals in ways that would impact i2b2 implementation, and we believe that our experience is applicable to many other medical institutions. Although our integration of infobuttons into i2b2 through a plugin was limited in the number of
contexts in which information needs might be addressed, the results of our survey show that the initial scope chosen for the plugin covers some of the most important contexts, according to the i2b2 developer community. Furthermore, the design of the plugin easily allows for the scope to be extended in order to cover or exclude those information needs deemed important or irrelevant for future study respectively. While the plugin was developed for installment into a single data management system, i2b2, and might not be able to be easily installed in a different data warehouse, i2b2 is a popular option for installation at many hospital systems and i2b2 is not dissimilar to other data management systems that are available. Additionally, while the plugin does not incorporate group metrics for its context-aware searches, we believe that i3b3 provides an initial step in studying the clinical scientists information needs with group metrics being an additional feature that could be added as needed. Therefore, the results of this study, including the infobutton plugin, should be applicable to research institutions without i2b2 instances.

**Conclusion**

We have developed software that enables interested i2b2 developers (of which there are at least 19) to provide infobuttons to their users. OpenInfobutton and LITE, also freely available, provide a comprehensive infobutton management strategy. What to do with infobuttons in i2b2 contexts is currently unknown, but the installation of i3b3 provides a mechanism for studying this question, much as infobuttons have been used to study information needs in clinical settings.

Feasibility of Extracting Key Elements from ClinicalTrials.gov to Support Clinicians’ Patient Care Decisions

Heejun Kim, MS¹, Jiantao Bian, MS², Javed Mostafa, PhD¹, Siddhartha Jonnalagadda, PhD³, Guilherme Del Fiol, MD, PhD²

¹School of Information and Library Science, University of North Carolina, Chapel Hill, NC, USA; ²Department of Biomedical Informatics, University of Utah, Salt Lake City, UT, USA; ³Division of Health and Biomedical Informatics, Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Abstract

Motivation: Clinicians need up-to-date evidence from high quality clinical trials to support clinical decisions. However, applying evidence from the primary literature requires significant effort.

Objective: To examine the feasibility of automatically extracting key clinical trial information from ClinicalTrials.gov.

Methods: We assessed the coverage of ClinicalTrials.gov for high quality clinical studies that are indexed in PubMed. Using 140 random ClinicalTrials.gov records, we developed and tested rules for the automatic extraction of key information.

Results: The rate of high quality clinical trial registration in ClinicalTrials.gov increased from 0.2% in 2005 to 17% in 2015. Trials reporting results increased from 3% in 2005 to 19% in 2015. The accuracy of the automatic extraction algorithm for 10 trial attributes was 90% on average. Future research is needed to improve the algorithm accuracy and to design information displays to optimally present trial information to clinicians.

Introduction

Evidence Based Medicine (EBM) is the application of the best and up-to-date scientific evidence available from rigorous clinical studies to guide the care of individual patients. To practice EBM, clinicians need to retrieve, appraise, and integrate the latest research findings into decisions for a particular patient. However, clinicians often cannot process the large amount of recent research results within the typical busy patient care environment. As a result, over 60% of the clinical questions that clinicians raise go unanswered due to the amount of time needed to spend on the search task. Systematic reviews are a common approach to synthesize the evidence on a specific clinical topic, but the process is slow and expensive. As a result, many clinical topics have no systematic reviews and a large percentage of published reviews are outdated. Hence, solutions are needed to help clinicians use the results of original clinical studies in the care of their patients.

To improve the efficiency of information seeking, substantial progress has been made to improve the evidence retrieval process. Several approaches are available to help clinicians identify high quality and high impact clinical studies. However, less attention has been dedicated to help clinicians quickly judge the relevance of a clinical study to a particular patient and understand the gist of the study findings. To improve the search process, clinicians have been suggested to formulate their questions according to four components: patient population, intervention, comparison, and the outcome of interest (PICO). While several information retrieval studies have used the PICO framework, most prior work has focused on the search process. Preliminary studies have demonstrated the feasibility of automatically extracting core clinical trial characteristics and results from narrative text such as journal article abstracts. There have also been several studies that extracted PICO elements from narrative text. More recently, the increased use of clinical trial registries that record semi-structured trial information provides a unique opportunity for improving the information extraction process.

The overall goal of the present study is to assess the feasibility of automatically extracting PICO elements of clinical trials from ClinicalTrials.gov. Specifically, we aimed to (1) assess the coverage (i.e., the rate of high quality clinical trials indexed in PubMed that have been registered in ClinicalTrials.gov) of ClinicalTrials.gov for high quality trials to examine its comprehensiveness as a data source; and (2) develop and assess the accuracy of an algorithm to extract PICO elements from ClinicalTrials.gov that overcomes unexpected patterns of registration. Both coverage and
extraction algorithm accuracy are important for the feasibility of extracting PICO information from ClinicalTrials.gov. The resulting algorithm can be used as a component of tools that support clinicians’ decision making.

Background

ClinicalTrials.gov is an online registry of clinical research trials established by the US National Library of Medicine (NLM) in 1999 aiming for increased transparency in clinical research. ClinicalTrials.gov archives over 209 thousand trials from 192 countries as of February 2016. Since 2007, trials covered by the Food and Drug Administration Amendments Act (FDAAA) are required to be updated within one year of completion with basic summary results data. A ClinicalTrials.gov record contains detailed information about a clinical trial in semi-structured XML format. Trial records include information such as conditions, eligibility, sample size, study methods, study arms, and study outcomes. In the present study, we leverage the semi-structured information from ClinicalTrials.gov to automatically extract PICO elements.

Links between Medline and ClinicalTrials.gov. When registering a trial on ClinicalTrials.gov, a unique identifier (“NCT”) is assigned automatically by the registry. The NCT identifier is also recorded in the Medline citation of articles that report the results of a registered trial, establishing a link between Medline citations and ClinicalTrials.gov records. The International Committee of Medical Journal Editors (ICMJE) has required that all clinical trials be publicly registered before manuscripts are submitted and accepted for publication. ClinicalTrials.gov provides two types of XML files: general information about the trial methods and the trial results. These files can be retrieved through a RESTful (Representational State Transfer) Web service, which was used in our study method.

Huser and Cimino examined links between ClinicalTrials.gov records and PubMed citations for trials completed between 2006 and 2013. They found that 28% of the trial records had at least one linked article. The study also found that 27% of the trials completed by 2009 had basic results. In our study, we looked at the reverse, i.e. links from clinical trial citations in PubMed to ClinicalTrials.gov. For clinical decision support purposes, it is more reasonable to start the information seeking process by searching for relevant high quality trials in PubMed than by searching for trials records in ClinicalTrials.gov.

Previous studies extracting PICO elements. In a systematic review, Jonnalagadda et al. found four studies that automatically extracted PICO elements from biomedical publications. Huang et al. used a naïve Bayes classifier, Boudin et al. used a combination of multiple classifiers (random forest, naïve Bayes, support vector machines, and multi-layer perceptron), and Demner-Fushman and Lin utilized a rule-based approach to detect PICO elements in medical abstracts. Boudin et al. utilized features such as Medical Subject Headings (MeSH) semantic types, word overlap with article title, and number of punctuation marks, while Huang et al. used terms with highest frequency. The average precision over PICO elements for these studies ranged from 0.63 to 0.84.

Method

The study method consisted of: (1) retrieving citations of recent high quality trials from PubMed and examining coverage of ClinicalTrials.gov for high quality trials; (2) retrieving ClinicalTrials.gov records for the trials retrieved in Step 1; (3) selecting 40 random ClinicalTrials.gov records from the set in Step 2 and manually inspecting the PICO elements from the records of these trials; (4) writing a set of rules to extract PICO elements from trial records; and (5) evaluating the accuracy of the rules with an independent set of 100 trials.

Retrieving citations of recent high quality trials from PubMed. To identify high quality clinical studies in PubMed, we utilized the machine learning classifier developed by Kilicoglu et al. This classifier uses a Naïve Bayes algorithm and utilizes features such as word frequency, semantic features, and citation metadata from PubMed. The precision of the classifier is 83%. We retrieved 178,302 citations of high quality studies from PubMed published in high impact journals between December 2005 and December 2015 by applying the classifier. Next, we used the E-utils API to retrieve full PubMed citations in XML format. A Python script was used to extract the ClinicalTrials.gov identifier (NCT) from the <AccessionNumber> tag where the value of the parent <DataBankName> tag was “ClinicalTrials.gov” (Figure 1).
For instance, the following URL can be used to retrieve the PubMed citation in XML file for the article with PubMed identifier 24725238: http://eutils.ncbi.nlm.nih.gov/entrez/eutils/efetch.fcgi?db=pubmed&id=24725238&report=xml. The coverage of ClinicalTrials.gov for high quality trials was calculated by dividing the number of PubMed citations with a link to ClinicalTrials.gov by the total number of high quality citations. Annual coverage rates were obtained for the 2005 to 2015 period.

Retrieving ClinicalTrials.gov records. We used the ClinicalTrials.gov Web service API to retrieve trial records in XML format. For each trial, we retrieved two types of XML files using a Python script: general information about the trial methods and the trial results. For instance, the methods record for the trial with identifier “01768286” was retrieved using: http://clinicaltrials.gov/ct2/show/NCT01768286/?displayxml=true. The trial results record was retrieved with: https://clinicaltrials.gov/ct2/show/NCT01768286/?resultsxml=true (Figure 2). There is a temporal gap between registration of clinical trials methods and reporting their results, so there are cases in which the registered trials do not include results. Only trials that have been completed with basic summary results were selected for the extraction study. We also calculated the percentage of those ClinicalTrials.gov records that reported trial results.

Selecting ClinicalTrials.gov records. From the trial records retrieved in the previous step, we selected a random set of 40 records (development set) out of 463 trials completed in 2014 to develop a set of rules for PICO extraction. An independent random set of 100 records (evaluation set) was selected from the same 2014 set for evaluating the accuracy of the algorithm.

PICO extraction rules. One of the authors (HK), assisted by two co-authors (GDF, JM), manually reviewed the 40 trial records in the development set. Based on this review, rules were developed to automatically extract PICO elements from the trial records. We referred to the ClinicalTrials.gov XML schema (https://clinicaltrials.gov/ct2/html/images/info/public.xsd) to guide rule development and to understand how ClinicalTrials.gov users are instructed on registering trials.

Rules were designed to extract 10 trial attributes associated with PICO elements (Table 1). The rules are basically a combination of XPATH expressions. For example, from the <condition> tag (Case 1, Table 2), <minimum_age> tag (Case 2, Table 2), and <enrollment> tag (Case 3, Table 2), we extracted data elements related to the study population, i.e. the main condition of interests in study participants, minimum participant age, and number of total participants in the study inclusion criteria.

Figure 1. Fragment of a Medline citation in XML format retrieved using the NCBI E-utilities. The squares highlight the relevant nodes for the extraction of ClinicalTrials.gov identifiers.

For instance, the following URL can be used to retrieve the PubMed citation in XML file for the article with PubMed identifier 24725238: http://eutils.ncbi.nlm.nih.gov/entrez/eutils/efetch.fcgi?db=pubmed&id=24725238&report=xml. The coverage of ClinicalTrials.gov for high quality trials was calculated by dividing the number of PubMed citations with a link to ClinicalTrials.gov by the total number of high quality citations. Annual coverage rates were obtained for the 2005 to 2015 period.

Retrieving ClinicalTrials.gov records. We used the ClinicalTrials.gov Web service API to retrieve trial records in XML format. For each trial, we retrieved two types of XML files using a Python script: general information about the trial methods and the trial results. For instance, the methods record for the trial with identifier “01768286” was retrieved using: http://clinicaltrials.gov/ct2/show/NCT01768286/?displayxml=true. The trial results record was retrieved with: https://clinicaltrials.gov/ct2/show/NCT01768286/?resultsxml=true (Figure 2). There is a temporal gap between registration of clinical trials methods and reporting their results, so there are cases in which the registered trials do not include results. Only trials that have been completed with basic summary results were selected for the extraction study. We also calculated the percentage of those ClinicalTrials.gov records that reported trial results.

Selecting ClinicalTrials.gov records. From the trial records retrieved in the previous step, we selected a random set of 40 records (development set) out of 463 trials completed in 2014 to develop a set of rules for PICO extraction. An independent random set of 100 records (evaluation set) was selected from the same 2014 set for evaluating the accuracy of the algorithm.

PICO extraction rules. One of the authors (HK), assisted by two co-authors (GDF, JM), manually reviewed the 40 trial records in the development set. Based on this review, rules were developed to automatically extract PICO elements from the trial records. We referred to the ClinicalTrials.gov XML schema (https://clinicaltrials.gov/ct2/html/images/info/public.xsd) to guide rule development and to understand how ClinicalTrials.gov users are instructed on registering trials.

Rules were designed to extract 10 trial attributes associated with PICO elements (Table 1). The rules are basically a combination of XPATH expressions. For example, from the <condition> tag (Case 1, Table 2), <minimum_age> tag (Case 2, Table 2), and <enrollment> tag (Case 3, Table 2), we extracted data elements related to the study population, i.e. the main condition of interests in study participants, minimum participant age, and number of total participants in the study inclusion criteria.
Table 1. Trial attributes extracted by the PICO extraction algorithm for each PICO element.

<table>
<thead>
<tr>

<td>Number of study arms and study arm interventions</td>
</tr>
<tr>
<td>Outcome</td>
<td>Number of participants who started the trial, number of participants who completed the trial, primary outcome, and results for the primary outcome.</td>
</tr>
</tbody>
</table>

The rules retrieved scattered PICO elements over two XMLs from several tags and merged them based on the study arm intervention. For instance, the number of participants who completed the trial is only available from the `<participants>` tag (Case 5, Table 2) under the `<participant_flow>` tag. However, the study arm design is often changed and needs to be verified from the `<title>` tag (Case 4, Table 2) under the `<outcome_list>` tag if it is the final study arm intervention. If there is discrepant information (e.g., pre-arm design before trials and real-arm intervention), the latest information is selected.

We retrieved outcome elements from the `<clinical_results>` tag. Description for the primary outcome measure was extracted from the `<title>` tag under the `<outcome>` tag. The actual outcome measurements were retrieved from the `value` attribute of the `<measurement>` tag as in Case 6 (Table 2). The algorithm produces an output in XML format according to the XML schema available at (https://sites.google.com/site/automaticpicoextraction/xml-schema). The complete rules set is available at (https://sites.google.com/site/automaticpicoextraction).

**Evaluation.** Two of the co-authors (JB, GDF) rated the algorithm output for the 10 attributes described above. To determine the accuracy of each extracted attribute, the raters compared the algorithm output with the original trial record at the ClinicalTrials.gov Web site. An attribute was considered to be accurate when the attribute value in the algorithm output was identical to the value that could be manually searched in ClinicalTrials.gov. After an initial round of calibration with 20 trials, the Cohen’s Kappa inter rater agreement was 0.51. Disagreements were resolved by consensus between the two raters. For instance, in one case there was disagreement on successful extraction of study arm interventions. The algorithm correctly identified three out of five arm interventions. One author considered it as accurate because three arms were extracted correctly, but the other author considered it inaccurate due to incompleteness. We agreed that the algorithm is expected to extract all the arms correctly. With the calibrated evaluation criteria, one of the evaluators (JB) continued the evaluation on the remaining 80 trials. For one attribute (number of participants who completed the trial), there were 9 trials that did not have data in ClinicalTrials.gov. They were excluded from the evaluation. In total, 991 trial attributes were evaluated.

**Results**

**ClinicalTrials.gov coverage.** Out of 178,302 high quality clinical studies indexed in PubMed between 2005 and 2015, 15,360 (8.6%) had a record in ClinicalTrials.gov. Among those registered trials, 3,496 (22.7%) trials had basic results. The coverage of ClinicalTrials.gov for high quality clinical studies has increased from 0.2% in 2005 to 17% in 2015 (Figure 3). The percentage of trials in ClinicalTrials.gov that included results has increased from 3% in 2005 to 19% in 2015. The rate of coverage for trial results peaked (28%) in 2012, but decreased afterwards.
Algorithm accuracy. Out of 991 trial attributes extracted from 100 trial records, 893 (90%) could be accurately extracted. Overall, the population-related elements (94%) and intervention- and comparison-related elements (97%) were relatively easy to extract compared to the outcome-related elements (83%). The algorithm extracting the total enrollment hit the highest accuracy (100%) and the algorithm extracting the number of participants who started the trial showed the lowest accuracy (70%). Table 3 provides the accuracy for each trial attribute.

Discussion

In this study, we aimed to assess the coverage of ClinicalTrials.gov for high quality trials indexed in PubMed and to examine the feasibility of extracting PICO elements from ClinicalTrials.gov records. To our knowledge, this is the first attempt to examine the feasibility of extracting PICO elements from ClinicalTrials.gov to support clinicians’ information needs. According to our analysis, although the overall coverage of ClinicalTrials.gov is still relatively low, the coverage has steadily increased since 2005 and clinical trials with higher impact should be more likely to be registered due to regulatory and publication requirements. For trials that are registered, most PICO elements could be accurately extracted from the randomly selected 100 ClinicalTrials.gov records using simple XPATH-based rules. Our proposed method could be used to enable alternate information displays to summarize evidence from clinical trials in a way that reduces clinicians’ cognitive effort. For example, in a study by Slager et al., physicians rated an information display structured according to PICO elements more favorably when compared with PubMed narrative.
The algorithm developed in the present study can be used to support the implementation of such structured displays.

Several studies have attempted to extract PICO elements with machine learning algorithms and/or simple rules. Previous approaches were assessed in terms of precision (63-84%) because PICO elements were extracted from narrative texts and therefore the methods were framed as information retrieval problems. However, our approach aimed to extract PICO elements from semi-structured data, with only one extraction target per data element. Thus, we used accuracy (90%) for measurement. As a result, direct comparisons with previous studies are difficult. The level of extraction among studies was also different. Three of those studies classified PICO elements at the sentence-level, while one study extracted PICO elements at the object-level like ours. Overall, our rule-based approach showed fairly good performance most likely because previous approaches relied on the extraction of information from narrative abstracts. However, unlike ours, previous methods do not depend on trial registration in ClinicalTrials.gov and work with any clinical trial published in PubMed. An optimal solution could be to combine both methods, i.e. PICO extraction from ClinicalTrials.gov whenever a trial record is available and extraction from PubMed otherwise.

Extracting the number of participants enrolled in a clinical trial was the easiest task, since the actual sample size was consistently recorded in ClinicalTrials.gov. Overall, elements related to the population and study arm intervention were also easy to extract. Other tasks for extracting main condition of participants, number of participants who started/completed, and results for primary outcomes required careful considerations for unexpected patterns of registration. After accounting for most of the variation in our sample, the algorithm accuracy for those challenging cases was fairly high (70% to 86%).

The main challenge of applying the proposed approach is the low rate of high quality trials that are registered on ClinicalTrials.gov and variation in trial registration format and content. The coverage of ClinicalTrials.gov (11.2%) and the rate of trials with results (21.3%) are fairly low in 2014, however, they have increased gradually likely due to increased regulatory pressure. Moreover, some systematic delays are expected in registering the summary result, as trials covered by the Food and Drug Administration Amendments Act (FDAAA) are required to be updated within one year of completion. If there is a certain degree of delay, PICO elements from ClinicalTrials.gov will not be available in a timely manner for recent trials. An analysis of common algorithm errors is described below.

**Algorithm error analysis.** First, the rules extracted only one condition regardless of the multiple conditions for study participants registered in ClinicalTrials.gov. This error can be fairly easy to correct so that higher accuracy is expected for the next phase of the development. However, there were some cases in which registered information was incomplete. For instance, “Opioid-Induced Constipation (OIC)” was the original condition registered in the ClinicalTrials.gov and extracted correctly by the rules, but our evaluator (JB) found “Non-cancer-related Pain” as an additional condition by reading other tags (Case 7, Table 4).

Second, there were several time series measurements in the results for primary outcome, but the rules could not extract them properly. In Case 8 (Table 4), there were 11 measurements registered in the time series, but the rules extracted only the first. In the Table 4, three measurements were only included for explanation. Corresponding enrollment information on each study arm per each point of measurement were recorded in `<period_list>` tag. The revised rules should process those multiple measurements.

Finally, outcome related attributes such as number of participants who started/completed and results for the primary outcome were the most challenging task while extracting PICO elements from ClinicalTrials.gov. As mentioned earlier, there are two types of XML files in ClinicalTrials.gov: general information about the trial methods and the trial results. There is a temporal gap between inputs for two XMLs. Usually, the former is input before the actual trial, and the latter is input after the actual trial. During this period, the arm design can be changed for several reasons. Thus, there can be different arm information in two XMLs. Moreover, there are several tags containing arm related information such as `<participant_flow>` tag and `<outcome_list>` tag. Unfortunately, users of ClinicalTrials.gov often input data inconsistently so that study arm related information becomes challenging to extract.

As in Case 9 (Table 4), there were six cases in which the values of tags for study arm interventions were changed completely. In the beginning of the study, all participants in the study were to be treated with directional atherectomy. However, primary patency rate was measured with patients treated for Claudication RCC 1-3 in the real study. Since the number of participants who completed the trial is only recorded in the `<participant_flow>` tag and the final intervention design is only recorded in `<outcome_list>` tag, there is no way to match the study arm intervention with the number of participants who completed the trial. ClinicalTrials.gov needs to consider a way to alert its users when
they register a different study arm intervention from the study plan so that they can update misinformation accordingly based on the changed study design. There were also nine cases in which the arm names were slightly changed. For instance, in the trial of NCT00211887, the arm name “Interferon Beta 1a” was changed to an acronym, “IFN-1a.” The next phase of the development should incorporate advanced text extraction algorithms, such as named-entity recognition (NER) and medical semantic networks such as Unified Medical Language System (UMLS) to overcome the current limitation of the rules.

Limitations

This study had several limitations. First, a small sample (n=100) of trial records was used to test rules for the automatic extraction of PICO elements from ClinicalTrials.gov. Future studies are needed to test generalizability of the handcrafted rules with a larger dataset. Second, the study was limited to ClinicalTrials.gov. There are other large clinical trial repositories that could be used to increase coverage, but different methods will be needed since there is not a standard format for trial registration across registries. Third, our findings are specific to high quality clinical trials published in high impact journals. Still, these are the trials that are most likely to be useful for clinical decision support. Last, we did not evaluate the usefulness and readability of extracted PICO elements. Future studies are needed to investigate the design and assess the usefulness and readability of extracted information for patient care decision-making. Another important step is to map the extracted information to standard controlled vocabularies whenever possible to increase utility of extracted PICO elements.

Conclusion

Our study found that the coverage of ClinicalTrials.gov for high quality trials published in high impact journals, although relatively low, has continuously increased over the last ten years. Our method, based on a set of rules, was able to accurately automatically extract the majority of PICO elements from a sample of 100 clinical trial records. The study suggests that using ClinicalTrials.gov for extracting key clinical trial information to support patient care...
decision-making is feasible. Future studies include assessing and tuning the algorithm on a larger sample size, expanding our work to other clinical trial repositories, developing structured information displays according to PICO elements, and assessing the usefulness of this type of information display for supporting patient care decisions.

Abstract

We explored the feasibility of representing nursing research data with the Observational Medical Outcomes Partners (OMOP) Common Data Model (CDM) to understand the challenges and opportunities in representing various types of health data not limited to diseases and drug treatments. We collected 1,431 unique data items from 256 nursing articles and mapped them to the OMOP CDM. A deeper level of mapping was explored by simulating 10 data search use cases. Although the majority of the data could be represented in the OMOP CDM, potential information loss was identified in contents related to patient reported outcomes, socio-economic information, and locally developed nursing intervention protocols. These areas will be further investigated in a follow up study. We will use lessons learned in this study to inform the metadata development efforts for data discovery.

Introduction and Background

Wide adoption of Electronic Health Record (EHR) systems and the development of secure cloud-based infrastructure to store large amounts of clinical and health research data have been opening new opportunities for data-driven discovery and validation of knowledge. Observational and pragmatic studies are gaining traction as alternatives to Randomized Controlled Trials (RCT) [1–3]. Although the highest quality of clinical evidence is still produced via RCTs [4], it is infeasible to perform an RCT for every clinical problem of interest for every possible patient situation. Pharmaco-surveillance [5,6], various comparative effectiveness studies [7,8] and cohort discoveries [9,10] are a few example areas that have benefited by the increasing availability of health data. However, these data also pose non-trivial challenges such as the handling of missing and/or noisy data and the integration of data generated from various sources, each with its own idiosyncratic representation. The Big Data to Knowledge (BD2K) initiative by NIH aims to address such challenges and to promote the utilization of large amounts of biomedical data (i.e., “big data”) by improving discoverability, accessibility, interoperability, and reusability of data and advanced data analytics [11,12].

bioCADDIE – indexing for big data discovery

bioCADDIE (biomedical and healthCAre Data Discovery Index Ecosystem) is a BD2K consortium dedicated to establishing a user friendly and robust means to discover and index biomedical data [13,14]. At its core are the bioCADDIE metadata, a minimum set of information about a dataset that needs to be made available to data seekers to facilitate search for data sets. The bioCADDIE metadata specification was developed by incorporating existing major metadata schemas in the biomedical domain (i.e., top-down) and high-priority dataset search use cases identified by the bioCADDIE leadership group and the user community. The version 1 metadata specification was released in August of 2015 and is currently under revision based on the feedback obtained from the bioCADDIE community [15]. Some of the referenced existing metadata and use cases reflect clinical and/or healthcare domains to a certain extent (mostly diagnoses, laboratory tests, and medications). However, overall, clinical and healthcare research domains are relatively under-represented in bioCADDIE metadata when compared to omics research domains. As a first step to augmenting the clinical and healthcare domains, the bioCADDIE team has started exploring the interoperability between the bioCADDIE metadata and the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM), a widely accepted, standardized model for healthcare data [16].

OMOP CDM – a common data model for healthcare research data

OMOP was formed as a partnership between public and private sectors to establish the safe and effective use of observational healthcare data to study the effectiveness of medical products [17]. Observational Health Data
Sciences and Informatics (OHDSI) is an international collaboration that aims to promote data reusability of the observational healthcare data produced from various venues by achieving data interoperability among them [18]. The OMOP CDM is adopted and now continuously revised by OHDSI [19]. Patient Centered Outcomes Research network (PCORnet), a national network funded by PCORI, is another major effort that aims at utilizing large scale clinical and healthcare data research networks for patient-centered outcomes research. A CDM plays a critical role in achieving data interoperability [20–22]. PCORnet CDM [23] and OMOP have recently been cross mapped by the OHDSI research team [24].

Gaps in representing nursing data for big data science

Many studies explored the use of the OMOP CDM to conduct large scale drug surveillance studies as well as to integrate clinical data repositories [22,25–29]. However, few studies reported the experience on standardizing and integrating data generated from clinical or healthcare research with OMOP CDM, except for studies that involved drugs or medical devices.

The recent Precision Medicine Initiatives (PMI) calls for collecting and utilizing a full spectrum of biomedical data to improve patient care: from microbiology to physical exams, laboratory tests, behavioral and environmental exposures [30]. In addition, the National Academy of Medicine (NAM), formerly Institutes of Medicine (IOM), recommended the incorporation of social and behavioral domains of data in EHRs in such a way that would support the reuse of those data in patient care and research [31]. Therefore, integrating different types of data in a way that supports secondary analyses has become critical. Nursing research targets a wide range of nursing interventions and problems, which often may not involve specific drugs, medical devices, or medical diagnoses. It often includes topics such as patients’ functional status, education, satisfaction toward the provided care and quality of life. This might indicate that nursing and nursing research data present a unique opportunity to understand the challenges and special considerations in integrating data generated in variety of health domains. However, few studies investigated the feasibility of representing various types of nursing and nursing research data with a CDM except for a very specific nursing domain such as pressure ulcer risk assessment and prevention [32,33].

The purpose of this study was to test the feasibility of representing nursing research data with the OMOP CDM using data reported in published articles and subsequently indexing them with the bioCADDIE tools. Specifically, we evaluated (1) the content coverage of the OMOP CDM (version 5) toward the data content reported in 256 published nursing research articles and (2) the feasibility of conducting data searches using the use cases extracted from the 10 randomly selected research articles.

Materials and Methods

Data preparation

In a prior separate study, we reviewed 192 articles on clinical trials published in nursing journals between 2006-2015. From this review, we annotated the articles with a list of metadata such as study types, target research problems, key interventions, comparison groups, sample demographics, data items used/generated, data sources, funding supports, data access information, and locations and settings of the studies. To augment this collection with observational studies we conducted additional literature review. Using PubMed and its structured search filters, we retrieved articles classified as Observational Studies published in Nursing Journals for the past 3 years (i.e., 2013 ~ February of 2016). This search yielded 203 articles. We randomly selected about half of the retrieved articles (N=98). We then read the full text articles and annotated each article with the same set of metadata.

During the full text review we excluded 34 articles for which full text papers were not easily obtainable (N=3) or the articles that did not investigate patient problems from nursing perspectives thus consequently no patient outcomes were reported (N=31). For example, behavioral issues among nursing students [34], assessment scale development [35], observing hand washing behavior among nurses without reporting associated patient safety outcomes [36] and nursing management topics such as nursing shifts and workload estimation [37,38] were excluded from this review. With this additional review, we generated metadata for 64 articles on nursing observational studies. Therefore, combining the new articles with the previously tagged ones, we included a total of 256 articles to this study. The article selection process is summarized in Figure 1. We also classified the data items reported in 256 articles based on the modes of data collection – i.e., routinely collected clinical data, Patient Reported Outcomes (PRO), and data collected through mobile devices.
Mapping to the OMOP CDM

A total of 2,438 data items were extracted from the 256 articles. After removing duplicate entries we classified 1,431 unique data items into concept classes of the OMOP CDM to establish a high (i.e., general) level of mapping. This mapping was largely guided by the definition and usage description provided for each concept class in OMOP CDM. However, we also checked the attributes of concept classes to ensure a given data item had a relevant attribute that could be used to hold the information about the data item. For example, one might expect that various socio-economic, and demographic items such as marital status and education level would belong to the PERSON class as done in many healthcare databases. However OMOP’s PERSON class does not provide a place to hold those items as it was designed to hold permanent information about a person such as birth year and race. Two of the authors (HK, JC) collaboratively conducted this high level mapping. We also aimed at identifying data items that did not fit into any of the OMOP CDM classes during this high level mapping activity.

Next we conducted a small scale, deeper level mapping and investigated to what extent the semantics of the content items presented in the selected articles were represented in the OMOP CDM. We fully utilized the attributes and the constraints associated with the concept classes for this mapping. We first created 10 data search use cases from 10 articles randomly selected from the 256 articles pool by asking ourselves “how do you query a clinical data repository to replicate the study reported in this article?” These use cases incorporated the eligibility criteria of the studies and thus provided an opportunity to evaluate additional content items not reflected in the data items at the deeper level (i.e., value level). Next we simulated the dataset search use cases by converting them into a data query form similar to the SQL code style (i.e., pseudo SQL codes). We used the mapping established between the OMOP CDM and the data items as a database schema of a hypothetical data repository. A use case and its data query form are presented as an example in Figure 2.

To simplify the conversion we omitted certain details and employed a few of our own conventions: we did not specify the primary key and foreign key relations to simplify the conversion. We used standardized concept id
attributes (e.g., gender_concept_id, observation_concept_id, etc.) to represent data item names and non-numeric data item values. Instead of specifying mapped standardized concept codes, we put data item or value names in brackets to imply the values are the concept codes of the concept names presented in the brackets. For example, the code observation_concept_id [ ] = [marital status] in Figure 2 implies that the observation_concept_id attribute takes the concept code of an OMOP-recognized standardized vocabulary of choice, for instance “125680007” when the Systematized Nomenclature of Medicine- Clinical Term (SNOMED-CT) is used to encode values.

Figure 2 Data search use case and data query form translation

Results
The majority of the data items identified from the 256 articles were mapped to the concept classes in the OMOP CDM, except for 16 data items. A few examples of unmapped items were the socio-economic and/or demographic information of health care providers (e.g., “number of years working as a nurse”) and the items that potentially embedded multiple content items, each of which would need to have been mapped to different concept classes. For example, “operating room nurses’ task list” and “advice provided by healthcare provider” might need to be mapped to different classes depending on what values they take.

MEASUREMENT was the concept class that most data items were related to, followed by OBSERVATION. The data items mapped to each concept class in the OMOP CDM is summarized in examples in Table 1.

PRO items collected using a questionnaire (both standardized or custom developed) were reported in 82 articles and
data generated through mobile devices were reported in 2 articles.

Our attempt to simulate data search from the use cases was not completely successful in all 10 cases. We observed potential information loss in 2 cases where (1) the study outcomes were assessed by comparing dates and times of a surgical procedure and (2) a device study that required dates and times of certain clinical findings. The PROCEDURE and DEVICE classes of the OMOP CDM stored only date information, thus precise comparison was not deemed possible. The metadata annotated for the 256 articles, the full results of CDM mapping, and data search use case simulations are available to download from https://idash-data.ucsd.edu/download/folder/4825/AMIA2016.zip.

Discussion

We attempted to represent the data contents reported in 256 nursing articles on health studies using the OMOP CDM version 5. Our goal was to start understanding the scope of the representation supported by the OMOP CDM, a major information model standard, with regards to content areas not related to conventional comparative effectiveness research, using the data from nursing research. It is promising that the majority of the clinical contents used in nursing research were well represented in the OMOP CDM, especially through the Standardized Clinical Data domain. However, it is our conclusion that the OBSERVATION and the MEASUREMENT classes had to be somewhat abused in this mapping as a place to hold many non-clinical and/or unusual clinical findings and assessment items.

Representing socio-economic and demographic information of patients, family members, and healthcare providers

PERSON and PROVIDER are two classes of the OMOP CDM that hold information on human subjects in the healthcare domain. The former is dedicated to describing patients, and the latter describes healthcare providers. Family dynamics is expected to have a significant impact on patient outcomes therefore it is an important research topic in nursing. Many articles reviewed in our study reported information about family members, especially those who play the role of a main care taker. We mapped those items into the OBSERVATION class, although this class was designed to capture the clinical facts not represented in other concept classes in the OMOP CDM. Similarly, many socio-economic items (e.g., marital status, education level, employment status, etc.) about patients had to be mapped to the OBSERVATION class since attributes in the PERSON class are limited to key “unchangeable” demographics such as age, gender, race, and ethnicity. Similar challenges were observed with the socio-
demographic information about healthcare provider. We did not map these items to OBSERVATION, as the latter is to capture “any clinical facts about a patient obtained in the context of examination, questioning, or a procedure”[17]. These additional socio-demographic items on healthcare providers seem to be potential areas for expansion to fully support observational studies in nursing.

Representing patient reported outcomes

A third of the articles reviewed in this study reported assessment of patient status using standardized and/or custom-built assessment scales and survey questionnaires. Some of these assessment tools are completed by patients and some are by healthcare providers. Differentiating the source of information is important as it provides additional context to consider when studying patient outcomes. Of note, the CONDITION table of the PCORnet CDM captures this information through the condition_source attribute, whose structured value set contains patient reported medical history. It might be possible to infer the source of information for the outcomes measured with standardized scales that are widely used and well documented, although this practice still increases the risk for information loss by requiring additional steps for obtaining and associating the information. However, the source of information for outcomes measured with custom-built survey questionnaire is still highly likely be lost.

Representing nursing specific intervention concepts

Many articles we reviewed reported the effectiveness of specific nursing interventions, which often include new care protocols and complementary therapies. As recognized by the leaders in nursing informatics as a high priority task in nursing informatics, having nursing specific data sufficiently represented in “big data” sets is important to promote the incorporation of nursing’s holistic approaches to patient care into data-driven knowledge generation [39,40]. Despite the relative small scale of concept mapping for nursing interventions pursued in this study, we found that the majority of complementary therapies are covered by SNOMED-CT. However, locally developed specific care protocols are challenging to represent, since they are built from a collection of nursing actions. Consequently, a care protocol name used to describe an intervention concept might be considered less informative than the listing of nursing actions. Although it seems somewhat convoluted, this challenge can be addressed by establishing a member relation between a set of nursing interventions and a specific care protocol through the FACT_RELATIONSHIP table. We will continue investigating this issue in future studies.

Nursing problems cover wide areas of health domains: from disease-oriented matters to emotional wellbeing. Nursing research thus also includes concepts there are not frequently used in other clinical studies. However, we found that the OMOP CDM provides sufficient representation capability, even for unusual nursing problem concepts through less restrictive concept classes like OBSERVATION and MEASUREMENT, along with CONDITION_OCCURRENCE.

Limitations and future directions

This study used data items reported in a small sample of nursing research articles. Therefore, its findings may not be generalized to the entire content domains of nursing research data. In addition, the OMOP CDM strives for a high level of standardization and hence all key concepts in the CDM classes are required to be encoded with a standardized vocabulary. This means that the class and attribute levels of association does not always result in successful representation of nursing research concepts, as information loss can occur due to the lack of a standardized concept code. Using the OMOP CDM as a hypothetical database model to simulate data search use cases is another limitation. Information loss can happen during the transformation of a local database model to the OMOP CDM, and our simulation approach might not have been robust enough to capture this type of loss.

Recognizing these limitations, along with potential over-use of certain concept classes as previously described, we plan to continue this work by expanding the scope and revisiting identifiably challenging cases. We also plan to seek collaboration with OHDSI to discuss and substantiate lessons learned in this study.

Conclusion

Nursing research targets wide ranges of topic areas that are not limited to diseases or medical treatments. Therefore, investigating the standardized representation of the data contents in published nursing research provides a unique opportunity to understand challenges and opportunities in representing various types of health data so that they can be found and reused. In this study, we explored the feasibility of representing nursing research data with the OMOP CDM, using the data items reported in 250 nursing articles. The OMOP CDM provided a good representation for the majority of data items but we also observed potential gaps that might lead to information loss. These gaps will be
further investigated in a follow-up study. Lessons learned in this study will help inform metadata development efforts for the Data Discovery Index.

Abstract

The Medicare Shared Savings Program (MSSP) is the larger of the first two Accountable Care Organization (ACO) programs by the Centers for Medicare and Medicaid Services (CMS). In this study we assessed healthcare cost and utilization of 1.71 million Medicare beneficiaries assigned to the 333 MSSP ACOs in the calendar years of 2013 and 2014, in comparison to years 2010 and 2011, using the official CMS data. We employed doubly robust estimation (propensity score weighting followed by generalized linear regression) to adjust the analyses to beneficiary personal traits, history of chronic conditions, previous healthcare utilization, ACO administrative region, and ZIP code socioeconomic factors. In comparison to the care delivered to the control cohort of 17.7 million non-ACO beneficiaries, we found that the care patterns for ACO beneficiaries shifted away from some costly types of care, but at the expense of increased utilization of other types, increased imaging and testing expenditures, and increased medication use, with overall net greater increase in cost instead of smaller increase.

Introduction

The Medicare Shared Savings Program (MSSP) was launched by the Centers for Medicare and Medicaid Services in 2012 as one of the first two Accountable Care Organization (ACO) programs as envisioned by the Patient Protection and Affordable Care Act (PPACA), which seek to coordinate and improve healthcare delivery by means of value-based reimbursement models. Considerable work has been done to study ACOs, including assessments of previously existing pilot programs and state-specific value-based reimbursement models1-7, early studies of expected implications and qualitative analyses of impacts8-10, studies focused on specific medical specialties2,3,10-16, and more recent data-based reviews of the Pioneer ACO program, also launched in 201217,18.

In 2015, CMS made available, through their privacy-protecting Chronic Conditions Data Warehouse19 (CCW), the complete list of all beneficiaries assigned to and all providers enrolled in MSSP ACOs until December 31st, 2013. In 2016, the continuation of this dataset was released which extended data availability until the end of 2014. Combined, these two datasets cover all 333 ACOs that joined the MSSP between April 1st, 2012 and January 1st, 2014, and all Medicare beneficiaries assigned to them. The retrospective and detailed nature of the algorithm that CMS uses to assign beneficiaries to ACOs requires knowing the proportion of the total care received by each beneficiary that was delivered by ACO-enrolled providers, as well as the specialty of the physicians involved20, and this information is difficult to infer without the authoritative datasets that CMS released in 2015 and 2016. As of July, 2016, there is a single publication32 analyzing the CMS MSSP data released in 2015, but no published analysis using both 2015 and 2016 datasets to assess the effect of the MSSP ACOs on resource utilization and cost. Here we report such an analysis. For simplicity, starting from this sentence the term “ACO” will always mean only MSSP ACO, never Pioneer ACO, except at the Discussion section of the paper.

Methods

Reproducible research

As a commitment to the transparency and reproducibility of our work, we voluntarily release for free download the complete source code used in this paper, under an Attribution-NonCommercial-ShareAlike 4.0 International29 license, in an online GitHub repository at the link http://github.com/fabkury/cisa. It is important to remind here that for re-executing the code an interested researcher needs his/her own Data Use Agreement with CMS, by which one can receive access to the CMS claims files. The GitHub repository provides solely the source code and the full set of results produced by that source code.
Study design

We compared cost and utilization in the care provided to the beneficiaries assigned to ACOs with those not assigned using a difference-in-differences analysis of the trends in each group between before and after the start of the MSSP. The before period (baseline period) we defined as the combination of years 2010 and 2011, while the after period (outcome period) was the combination of 2013 and 2014. We ruled to completely ignore year 2012 as means of minimizing noise, upon recognizing that several of the most important variables we desired for analysis were available only at year-level granularity, while some ACOs had their agreement start date in April 1st, 2012 and some in July 1st, 2012. All ACOs from 2013 dataset (released in 2015) had their start date on or before January 1st, 2013, and those on the 2014 dataset (released in 2016) had their start date on or before January 1st, 2014. We additionally ruled to ignore any beneficiary that changed his or her U.S. state of residence at any moment between 2010 and 2014, as this could impart noise due to different healthcare pricing levels at different states.

Inpatient, Outpatient, Skilled Nursing Facility (SNF) and Physician Part B (Carrier) claims were aggregated by these four types as they are available in their separate CMS Research Identifiable Files (RIFs). Components of care such as Intensive Care Unit days, hospice days, imaging and laboratory events and expenditures, Home Health visits, among others, were aggregated separately as available in the CCW Master Beneficiary Summary and MedPAR files, which identify these items using revenue codes.

Beneficiary eligibility for this study

To be sure that we had complete claims data needed for these analyses, we only included beneficiaries who were fully enrolled in Medicare Parts A and B during the entire years of 2010, 2011, 2013 and 2014, and had zero months of Health Maintenance Organization (HMO, Medicare Part C) enrollment in those four years. This also means that any beneficiary either not enrolled in Medicare since January 1st, 2010, or not alive until December 31st, 2014, was excluded. For defining the cohort of ACO-assigned beneficiaries, we further only considered those with ACO assignment during both complete calendar years of 2013 and 2014. For the cohort of non-ACO beneficiaries, we considered only those never assigned to an ACO at any moment.

Statistical analysis

We first used the propensity score approach to mitigate differences in beneficiary-level characteristics between those enrolled in ACO and those not. We employed a binary logistic regression model to calculate the predicted probability of enrolling in an ACO using 66 covariates obtained from the baseline period (years 2010 and 2011). Covariates used in the propensity score included beneficiary-level characteristics such as age (at the end of 2011), gender, race, presence of 26 CMS predefined priority chronic conditions (by the end of 2011), region of residence as defined by
the ACO regional offices, reason for Medicare eligibility, and several separate counts and costs of drug and non-drug care received. Each possible region of residence, chronic health condition, race, reason for Medicare eligibility, as well as gender, was a binary flag. The remaining covariates were numerical values.

We then used a generalized linear regression model with the propensity score weight to compare outcomes of interest between those enrolled in ACOs and those not. The propensity score weight was defined as the inverse of the predicted probability of enrolling in an ACO. Individuals with a high predicted probability of enrolling in ACOs, who actually enrolled in ACOs, receive a lower weight compared with individuals with a low probability of enrolling in ACOs. In this regression model, outcomes of interest from the ACO and the non-ACO groups were compared not only weighted by the propensity score, but also controlled again for beneficiary-level and also beneficiary ZIP code-level characteristics, forming a doubly robust estimator. The generalized linear regression model included 48 covariates, of which 45 were also included in the propensity score. In total, the statistical analyses adjusted for 69 covariates. We conducted all statistical analyses using SAS software, version 9.4 (SAS Institute Inc., Cary, NC), inside the CMS Virtual Research Data Center (CMS “Enclave”).

For economy of space, the covariates included in the propensity score and in the linear regression model are specified together with their balances before and after the propensity score weighting in Table 1 at the Results section. All 26 chronic health conditions were included in both propensity score and linear regression, but were omitted from the table in this paper for economy of space – they are available in the full set of results for download at the online repository.

Outcome measures

We considered an extensive list of 151 outcome measures, as well as separate measurements of number of claims and total cost of filled drug prescriptions aggregated by 493 different ATC-4 classes that matched the NDCs present in the Medicare Part D claims of the beneficiaries included in the study, totaling 1,137 comparisons between the ACO cohort and the Non-ACO cohort. Due to the obvious lack of space, we opted to include and discuss in this paper only the differences that were most insightful to our opinion. The selected measures are depicted in Tables 2, 3 and 4 at the Results section. The complete list of outcome measures can be downloaded, along with our complete source code, at the online repository.

Part D drug claims and cost measures

The measurements of drug claims and costs aggregated by their ATC-4 classes (which were mapped from the drugs’ NDC codes) are not presented in this paper. They are available only for download at the online repository. We made this decision for three reasons. First, we preferred to prioritize other content in our limited space in this paper. Second, this specific part of the analysis relies solely on a 10% purely random sample of the beneficiaries, which is the sub-cohort from whom we have Part D claims as per our Data Use Agreement with CMS, while all other parts of this paper enjoy access to the totality of Medicare beneficiaries that met our eligibility criteria for this study. Third, the costs of Part D claims do not count towards the performance of a MSSP ACO as per the program’s definition, therefore the ACOs have no direct incentive to save on expenses that are billed to Part D. None of these three reasons are the case of drugs administrated inside health care facilities and billed to Medicare Part B. The costs of all drugs billed to Part B for all beneficiaries are included in the drug usage measurements in Table 3. Table 4 contains, separately, the total sum of costs of drugs billed to both Medicare Parts B and D and covers the totality of beneficiaries (not 10%).

Exclusion of outlier claims

Because our analyses processed hundreds of millions of individual claims from millions of beneficiaries, we were concerned about potential outlier values among the claims, e.g. data entry errors or faulty data for any reason. In order to mitigate the potential impact of unknown outliers on our calculations of averages, we implemented a mechanism for ignoring extreme outlier claims. Any claim whose cost ranked at the top 0.01\textsuperscript{th} percentile (0.01%, not to be confused with top 1\textsuperscript{st} percentile) of its data source (i.e. each CMS file available in the VRDC) was deemed a potential outlier and therefore ignored.

Data Sources

This study was performed using the CMS claims data available to our group inside the CMS Virtual Research Data Center via our Data Use Agreement #26250. The claims files used were full-size (100% of the Medicare beneficiaries) Inpatient RIF, Outpatient RIF, Skilled Nursing Facility RIF, Carrier RIF, MedPAR, and Master Beneficiary Summary File segments A/B, Chronic Conditions, and Cost & Use. Socioeconomic variables for each ZIP Code Tabulation Area (ZCTA) were retrieved from the FactFinder tool at Census.gov. The mapping of
beneficiary ZIP code to ZCTA was performed using the crosswalk table produced by the Robert Graham Center upon funding by the Health Resources and Services Administration. The mapping of Medicare Part D drugs from their NDC codes to ATC-4 classes was performed by querying the RxNorm API web service using an R language script, which is also available for download in the online repository.

Results

After applying all restraints described in the Methods section, we had a cohort of 1,708,888 ACO-assigned beneficiaries and a control cohort of 17,741,210 Non-ACO beneficiaries. The outcomes included 151 measurements plus 986 drug class utilization and cost measurements, so the total number of outcome comparisons between the ACO cohort and the non-ACO cohort was 1,137. Due to the very large size of the studied cohorts, the p-values were very small, although in many cases the identified differences was also small if not frankly negligible. In the great majority of the cases, the resulting p-value was smaller than 10^{-6}, so we thought there was little need to perform corrections for multiple-testing, as it was unlikely that we would arrive at a non-negligible probability of having committed a statistical Type I (“false positive”) error. Unless otherwise indicated, a p-value below 10^{-6} is to be assumed for all comparisons included in this paper, except for those in Table 1. The p-values of all comparisons (including those of Table 1) can be found, rounded to 9 decimal places, in complete set of results available for download at the online repository. All monetary values are expressed in U.S. dollars.

Covariate balancing by the propensity score

Table 1 depicts all variables included in the propensity score (PS) – except for the 26 CCW chronic conditions, here omitted for economy of space, which were also included – and their balance before and after weighting. Due to the very large number of beneficiaries in both ACO and non-ACO cohorts, even despite the small differences in the averaged values after weighting, all but 9 p-values when comparing the two groups post-weighting were below 10^{-6}.

Table 1. Cohort characteristics and covariates used in the statistical analyses, along with average values pre and post propensity score weighting, except for the 26 chronic health conditions. Numbers are average per beneficiary in years 2010 and 2011 ± standard error. The binary flags are indicated by the absolute count followed by the percentage of the total that the count represents.

</table>
Out of the 69 covariates considered, 58 had a p-value below 10^{-6} even after the propensity score weighting. Despite the low p-values, as one could expect from an analysis totaling 19.45 million individuals, the propensity score was effective in balancing their means between the ACO and non-ACO cohorts. The full list of covariates, including the 26 chronic health conditions and all p-values, can be downloaded at the GitHub repository.

Comparison of overall claims by type of healthcare facility

Table 2 shows that the average number of claims per beneficiary, as well as average cost per beneficiary, increased more in the ACO cohort than in the non-ACO in outpatient and physician Part B (carrier) settings, while at inpatient and skilled nursing facility settings it was the opposite. The numbers under the Non-ACO and ACO columns in Tables 2, 3 and 4 are the difference between the average per beneficiary in the baseline and outcome periods, i.e. average per beneficiary at outcome period minus average per beneficiary at baseline period, along with the standard error of the average. The Difference column is defined as Non-ACO value minus ACO value, while the Percent difference column is [Non-ACO value minus ACO value] divided by unsigned Non-ACO value. Therefore, in those three tables, negative differences (as well as negative percent differences) indicate that the average per beneficiary increased more in the ACOs cohort than in the non-ACO cohort from the baseline (before) period to the after (outcome) period.

Table 2. Claims aggregated by type of healthcare facility. Numbers are differences in average per beneficiary between the baseline and outcome periods.

Comparison of components of care at inpatient and skilled nursing facility settings

Table 3 depicts some of the outcome measures available from the MedPAR file, which covers inpatient and skilled nursing facility (SNF) claims. It seemingly shows a trend of health care shifting away from expensive types of care such as stays in heart transplant and myocardial infarction specialized Coronary Care Units (CCUs), at the expense of increased use of intermediate CCUs and ICUs and increased expenditures with therapeutic Radiology. In these two care settings (inpatient and SNF), diagnostic radiology claims, laboratory charges and ambulatory surgical care claims
increased faster in the Non-ACO cohort. The overall net effect here was positive for the ACO cohort, i.e. smaller increase in total cost.

Comparison of components of care in all care settings as available in the Master Beneficiary Summary File (MBSF)

The Master Beneficiary Summary File (MBSF) has an important advantage over all other files as it provides data already aggregated, per beneficiary, from the entirety of the CMS claims regardless of whether your specific Data Use Agreement with CMS covers the files from which the claims were retrieved. For example, our DUA does not cover Durable Medical Equipment claims, notwithstanding their aggregated events and costs are available, albeit at year-level granularity per beneficiary, in the MBSF. This also means that the MBSF provides the most reliable measure of total costs, which, as depicted in Table 4, we found to have increased faster in the ACO cohort than in the non-ACO cohort ($390.77 greater increase in average per beneficiary). In some cases, the non-ACO cohort saved money in comparison to its own baseline, while the ACO cohort did not.

Table 4. Components of care and total costs across all care settings. Numbers are differences in average per beneficiary between the baseline and outcome periods.

† Defined by the CMS as the number of 30 days of individual drug fills. 12 months of one drug produce fill count of 12. 12 months of 2 drugs produce 24. For more information, see the ResDAC website11.

Discussion

For the most part our data suggests that the cost for the care given to beneficiaries assigned to MSSP ACOs increased faster from the baseline period (2010 plus 2011) to the outcomes period (2013 plus 2014) than the cost of a control cohort, even after adjusting for a total of 69 covariates in a doubly robust estimator – propensity score weighting followed by re-adjustment in a generalized linear regression model. The covariates included spanned beneficiary personal traits, medical history, ACO administrative region, and socioeconomic factors of the beneficiary’s ZIP code of residence, in correspondence to the covariates used in previous studies17,22.

It is expected to see generalized increases in average number of claims per patient, since the fixed cohorts will have aged from 2010 to 2014; and it is expected to find generalized increase in costs since, on top of the increased number of claims, the monetary values are not adjusted for inflation. It is hard to explain, though, why the ACO cohort exhibited net greater increase in total cost than the non-ACO cohort.

Our results are different than those from studies of the Pioneer ACO program17,18 and the Blue Cross Blue Shield of Massachusetts’ Alternative Quality Contract1,2,4,6,7, and the recent analysis of the first year (2013) of the Medicare Shared Savings Program22. Our results suggest an opposite effect which we cannot easily explain. McWilliams et al.12 identified savings among the MSSP ACOs with agreement start date earlier than January 1st, 2013, but not among the ones that started precisely on January 1st, 2013, suggesting that the capacity to generate savings might take some time to be developed. In our study, however, after ignoring year 2012 and analyzing the claims of all 333 MSSP ACOs up until the end of 2014, we found negative savings. Moreover, it may also be worthy of notice that McWilliams et al. emulated as possible the CMS’ algorithm for retrospectively assigning beneficiaries to MSSP ACOs using the official list of MSSP ACO providers, and did so using a 20% random sample. In our study we did not consider the list of MSSP ACO providers. We used only the official list of beneficiaries assigned to MSSP ACOs as provided by CMS via the CMS Virtual Research Data Center (VRDC), and had access to the totality of beneficiaries, albeit our study design drastically reduced the number of beneficiaries considered due to our eligibility criteria.

In an effort to assure complete data for all of our outcomes of interest, we excluded beneficiaries with anything less than complete data in all years under study, as described in the subsection Beneficiary eligibility for this study. The eligibility criteria resulted in the loss of 46.5% of the beneficiaries enrolled in Medicare in all four years considered, and inclusion of only 36.5% of the beneficiaries enrolled in Medicare during the study period that were ever assigned to a MSSP ACO, as depicted in Figure 1. In future analyses we plan to look for unbalances in the patients who were excluded from this study that might help explain our present results.
The figures presented by The Centers for Medicare and Medicaid Services for MSSP SCOs were positive\textsuperscript{30,31} in comparison to the benchmark defined for each MSSP ACO, with $705 million saved by 58 MSSP ACOs in Performance Year (PY) 2013 and $806 million saved in PY 2014 by 92 MSSP ACOs. However, the methods used by the MSSP for quantifying savings are quite different from those of this paper. The MSSP compares actual post-ACO expenditures against ACO-specific projected expenditures\textsuperscript{20} derived from the historical, fee-for-service Medicare Parts A and B expenditures, specific to the beneficiaries assigned to each ACO, while adjusting for beneficiary characteristics and other factors and correcting for the projected growth in national per capita health expenditures. The details of these projection methods can be found in the references\textsuperscript{30}.

Conclusion

Our results suggest that over its first two years the MSSP ACOs may have increased the costs of Medicare spending when comparing to an adjusted control cohort of beneficiaries never assigned to a MSSP ACO, but these results contradict other studies on other types of value-based healthcare reimbursement models, and also a recent study of the first year of the MSSP. Further analysis is needed to understand the differences between our results and previous studies.

A Connectivity Framework for Social Information Systems Design in Healthcare

Abstract
Social information systems (SISs) will play a key role in healthcare systems’ transformation into collaborative patient-centered systems that support care delivery across the entire continuum of care. SISs enable the development of collaborative networks and facilitate relationships to integrate people and processes across time and space. However, we believe that a “connectivity” issue, which refers to the scope and extent of system requirements for a SIS, is a significant challenge of SIS design. This paper’s contribution is the development of the Social Information System Connectivity Framework for supporting SIS design in healthcare. The framework has three parts. First, it defines the structure of a SIS as a set of social triads. Second, it identifies six dimensions that represent the behaviour of a SIS. Third, it proposes the Social Information System Connectivity Factor as our approximation of the extent of connectivity and degree of complexity in a SIS.

Introduction
Healthcare systems worldwide are undergoing innovative transformation into networked systems that deliver collaborative patient centered care delivery across the continuum of care1. The design of healthcare systems has not been traditionally focused on facilitation of integrated and collaborative care delivery and, therefore, health information systems (HISs) will play a key role in transformative efforts2, 3. Social information systems (SISs), defined as “information systems based on social technologies and open collaboration”4, will play a particularly significant role in these transformative efforts because of their ability to facilitate and support social processes of healthcare delivery5, 6. SISs have a different focus than traditional HISs since their purpose is to facilitate collaboration and networking over time as opposed to the automation of specific tasks such as order entry7. The fundamental tenet of SISs are the need to support and nurture the development of social and collaborative competencies over time. Therefore, the scope of SISs is much broader than task based HISs such as decision support or order entry systems as SISs must facilitate provision of a service (e.g. patient participation, community resilience) while also developing the social competencies inherent within these systems. Although we adopt the definition of SIS proposed by4 we believe that SISs in healthcare present more challenges compared to SIS design in general. These challenges are related to the extent of openness, transparency, and open collaboration, the hallmark of SISs4 which are more complex in healthcare compared to other sectors.

Despite SISs being a recent phenomenon they have shown potential for redefining the way in which clinical care or public healthcare can be provided. Examples of SISs can be seen across the healthcare spectrum. Coiera8 has described how social relationships and networks can lead to new approaches for diagnosing and managing illness. At the micro (clinical) level, social networking tools like Dr. Google and PatientsLikeMe® provide information to patients about illness and treatments and enable connectivity for patients’ discussion groups. At a macro (public health) level, activities such as disaster management and community resilience have benefited from social networking applications because they have enabled social interaction and collaboration that is a key aspect of public health activities9, 10. However, despite their benefits, there are also challenges in designing and implementing SISs that must be properly addressed. At a micro level, simply providing patients with access to data in inappropriate contexts may overwhelm patients and provide overload from the information and opinions that they receive through support groups11. Similarly, at a macro level, it has been challenging to develop SISs due to the disparate and multidisciplinary nature of the communities where these systems are used, and the range of user needs within SISs12.
One essential lesson that we have learned from the implementation of HISs is that unintended consequences will arise post implementation. These unintended consequences occur for a number of reasons but a common issue is changes to work practices resulting from technology mediated connectivity, people, and processes. SISs and the connectivity they enable provide a bigger base for unintended consequences to occur due to the web of connections enabled by SISs. Before we can manage unintended consequences we first need to understand how they originate. However, this is particularly challenging in SISs because of what we refer to as a “connectivity” issue, which refers to the scope and extent of system requirements for a SIS. SISs create connectivity that is unparalleled, and further coupled with the fact that there are different users and patterns of use, SIS connectivity can be a substantial design problem.

We define “connectivity” as the organizations, tasks, people and technology needed to achieve an outcome. Connectivity is a common challenge in HIS design and thus there have been several attempts to understand it in HIS design. Sociotechnical approaches for systems design such as Sittig and Singh’s eight step Sociotechnical Model defines sociotechnical “connectivity” by such dimensions as people, workflows, technologies, and policies associated with designing, implementing, and using HIS. Participatory design facilitates “connectivity” in design by engaging end users and binding design in user needs. Behavioral design approaches like Task Technology Fit (TTF) or Cognitive Task Analysis (CTA) use tasks (e.g., decision making needs) to bind system design parameters. Outside of healthcare, Supply Chain Management (SCM) defines system requirements according to business models that articulate the necessary connectivity to facilitate supply chain activities. For example, SCM has a common reference model called the Supply Chain Operations Reference (SCOR) model with five general processes (plan, source, make, deliver and return). The SCOR model has been used to understand supply chain connectivity for IS design and the development of metrics.

While existing SIS research has developed frameworks for technical architectures and identified challenges to developing SISs, studies on how to model connectivity as a means of SIS design and evaluation do not exist. SIS design in healthcare is particularly challenging as it requires the connection of people, processes and technology across different workflows and user roles. Healthcare SIS design requires new approaches that enable us to understand complex connectivity as a precursor to systems design. Coiera proposed Interaction Design Theory (IDT) as a systems design approach that focuses less on individual issues or technologies and instead tries to understand the web of interactions that exist within a system. IDT allows designers to make predictions about how a group as a whole will interact in complex settings.

However, there is limited work that has looked at SIS design in healthcare to identify specific elements of social connectivity and how they impact systems design. The main contribution of this paper is the Social Information System Connectivity Framework for SIS design in healthcare. The framework has three parts. First, it defines the structure of a SIS as a set of social triads. Second, it identifies six dimensions that represent the behavior of a SIS. Third, it proposes the Social Information System Connectivity Factor as our approximation of the extent of connectivity and degree of complexity in a SIS. The paper has four sections. Section 1 was the introduction. Section 2 is the materials and methods. Section 3 is the description of the Social Information System Connectivity Framework for supporting SIS design in healthcare. We conclude with a discussion of the implications of our work and the next steps from the research presented in this paper.

Materials and Methods

Data Sources

Two data sources informed our study. First, the authors have studied HIS design to support social and collaborative health delivery at clinical and population health levels including studies on perioperative systems, palliative care systems, and community resilience as part of designing disaster management systems. The common thread across all these studies was to understand different types of collaboration, and how it informs HIS design to support the development and maintenance of collaborative and social practices. The case studies involved user engagement methods such as community based participatory research and participatory design. In the context of these methods we spent considerable time with users in order to gain an appreciation of social needs and competencies and how they develop over time.

The second data source was a literature search on SISs, networks, and modelling approaches for SIS design in general and in healthcare. Scopus, IEEE Xplore, and the ACM Digital Library were searched. The literature search provided additional insight on SISs, in particular frameworks for representing and modeling them.
Data Analysis

We used descriptive qualitative content analysis on the literature we retrieved and the integrated findings from our case studies. Our objective was to integrate the empirical data from our studies with the literature on SIS modeling and design to develop a general framework on SIS design in healthcare. To provide a framing for our analysis we drew upon a paper that described how accountable healthcare delivery must be viewed from the perspective of a structure and a set of behaviours. We adopted that framework as we analyzed our data so our analysis identified structural and behavioral aspects of SISs.

Results

Our results are presented in two sections. First, we describe the connectivity framework for SIS design. Second, we present the three specific components of the framework corresponding to the structure and behavior, and third, we describe operationalization of the framework as the Social Information System Connectivity Factor.

Connectivity Framework for SIS Design

Figure 1 shows our connectivity framework for SIS design in healthcare. The framework addresses the previously described shortcomings in the literature such as the need to represent healthcare delivery as a complex ecosystem that can include multiple actors, settings and information flows that may be subject to different degrees of governance. A first step towards understanding connectivity based SIS design is to decompose the components of the system so they can be modelled. Our framework is labeled with three parts: structure, behavior and operationalization as the Social Information System Connectivity Factor (SISCF). Each part is described in detail below the figure.

![Connectivity Framework for SIS Design in Healthcare](image)
Connectivity Framework – Structure

The structure of the connectivity framework represents a social ecosystem as a number of interrelated social triads with three concepts: person, process and technology. Those three concepts were common in the literature we retrieved on SISs in healthcare as well as in social modelling approaches. Studies on social networks or technologies to support healthcare delivery most often focused on people, processes (e.g., information exchange, communication, care coordination), and technology that is used.

From the literature review on social modeling we identified social modelling languages such as Social Business Process Model and Notation (SBPMN) that emphasize modelling of social activities such as community generated events and social relationship links. The social triad aspect of our framework represents the necessary connectivity for SIS design. A social triad can be at the micro level of an individual patient where the extent of social linkages would be at the level of processes and interactions that a patient uses as part of his/her social network for managing his/her own chronic illness. In that example, the connections we would be interested in modelling would be the clinicians (e.g., physician, pharmacist, dietician) that are part of the patient’s social ecosystem as well as the processes (e.g., glucose or diet monitoring, exercise regime) and communication that a patient goes through as part of his/her disease management. If we move to meso level care delivery, we would be linking together two or more social triads such as for the integration of multiple units in a hospital, or multiple clinics that work together as part of providing integrated collaborative community care delivery. The connections we would be interested in modelling at that level would include collaborative care processes (e.g., joint decision making) and integrated data sharing. At the macro level, we would be integrating multiple social triads as part of modelling population health initiatives such as community resilience to support disaster management, or public health initiatives such as managing an influenza outbreak. The connections we would be interested in modelling at the macro level would include collaboration, interoperability and governance across communities and organizations.

Connectivity Framework - Behavior

The behavioral component of our framework defines how the social triads (e.g., structure) work for a particular SIS. From our analysis of the two data sources we identified six behavioral dimensions relevant to SIS design in healthcare: user driven design flexibility, empowerment and responsibility, workflow extensibility, process immaturity, data standards & interoperability, and governance complexity. The behavioral dimensions span a range of considerations from workflow and motivation to use a SIS, to system interoperability and governance issues. Below we discuss the six behavioral dimensions and how they help us understand the degree of complexity as part of SIS modelling and design.

User Driven Design Flexibility

One of the key challenges of SISs is that they are driven by the needs or requirements of users. This introduces two sets of challenges. At a micro level, patient participatory medicine is dependent on the willingness of people to be the active stewards of their own care delivery. Further, SISs to support patient participation can range from basic information retrieval to information exchange and partnership and collaboration on the content. Those different tasks require very different design solutions. SISs require much more flexibility due to the nature of how people conduct tasks. Similarly, at macro levels it has been shown that the diversity of end users necessitates consideration of the needs of diverse individuals. While the premise of SISs is connectivity and socialization across human networks, achieving that goal makes user driven design more challenging. To address that issue, the diverse users of SIS and their needs must be identified and used to inform systems design. However, a social community may have users with a range of technological skills and that needs to inform systems design. One of our case studies on SIS design to support community resilience for disaster management highlighted that system design requirements have to start technologically at the lowest common denominator to enable all users to become engaged and comfortable with using the system.

Empowerment and Responsibility

Unlike HISs designed to support a specific task, SISs are dynamic systems that are intended to develop and maintain relationships over time. That puts the burden of responsibility on system users to maintain activity in the SIS over time to enable it to grow and develop. SISs provide a means of empowering people, but empowerment brings with it certain responsibilities. At a micro level, patients recovering from an illness see something explicit in using a SIS to guide their therapy and disease recovery. However, people may be less motivated to use it for data collection for routine monitoring (e.g., blood pressure measurement, diet). Research has shown that a relatively low percentage of patients adequately document the necessary data for disease management and also that while patients may initially be
very keen to collect illness data, the enthusiasm wanes over time\(^9\). Macro level public health initiatives have a similar challenge in that community resilience efforts to support disaster management relies on a mixture of private and public and paid and volunteer workers to maintain progress\(^{23}\). A key public health issue is that disaster management or disease surveillance are preparing for events which may never happen and thus keeping parties motivated to continue to use and maintain a SIS can be a challenge\(^{12, 33}\).

**Workflow Extensibility**

A challenge with socially driven care delivery is the processes that are done may lack rules of engagement for how they are to be conducted. In our case studies we found that workflows for social processes were often poorly defined at both micro and macro levels. At a micro level, patient participatory medicine requires the creation of new workflows to accommodate both patients and clinicians with respect to information exchange and decision making\(^{29, 34}\). As more care delivery moves outside traditional settings such as hospitals and into the community (e.g. initiatives such as aging in place) it adds more people such as informal caregivers to a social triad which adds further workflow complexity. Therefore, workflow modelling must be done in a way that takes into perspective all of these diverse user groups\(^{39}\). Similarly, workflows are often undefined for community level initiatives such as disaster management that can necessitate the need for workflows that span micro (individual) and macro (community) perspectives\(^{36, 37}\).

**Process Immaturity**

While relationships, social connectivity, and collaboration are the tenets of SISs, a challenge is that many of the social processes that we are trying to implement are still maturing and may be in an evolutionary state. At the micro level, patient centred care and patient participatory medicine are evolving concepts\(^{34}\). Similarly, collaborative team based care delivery at the meso level has been described as existing more in name than in actual implementation\(^{38}\). The rules of engagement for how collaboration needs to occur have to be better understood and defined before we can expect a SIS to implement and foster collaborative care delivery\(^{39, 40}\). One of our macro level case studies described how the common ground needed for social collaboration in a community goes through a development cycle where people need to first develop coordination and communication practices before they can collaborate\(^{24}\).

**Data Standards & Interoperability**

Interoperability across different settings is an essential requirement of HISs\(^{41}\). A key driver of HIS interoperability has been the development of standards for data exchange (e.g., HL7) and terminology (e.g., SNOMED). On one hand, SISs offer the potential for social triad interoperability and data collection beyond traditional healthcare settings and systems, but they also introduce connectivity complexity to traditional interoperability standards. As we use more social media applications (e.g., Facebook) or self-monitoring tools (e.g., Fitbits, Smartphones) as sources of healthcare data, it threatens to erode the extensive work that has been done in developing formal interoperable healthcare data standards. In recognition of this issue, recent research has suggested the need to change the focus from developing formal data standards to developing tools to enable extraction and analysis of social media application and self-monitoring application data\(^{42, 43}\).

**Governance Complexity**

Governance complexity refers to the need to consider activities within the larger social structure where they occur, including the relationship across entities (e.g., organizations) that may impact social structures by exerting influence or autonomy\(^{24}\). SISs cross different units both within (i.e., intra-organizational) and across (i.e., inter-organizational) settings. The more social triads that are integrated as part of healthcare delivery, the greater the governance complexity challenges in the form of cross-organizational information sharing and the need to integrate different types of agents, policies, and procedures\(^{23, 45}\). Governance issues can at times be a significant impediment to the development of social relationships, at both micro and macro levels, an example being the inability to share necessary information to support social healthcare processes\(^{24, 44}\).

**Connectivity Framework - Operationalization**

To operationalize the connectivity framework, we introduce the Social Information System Connectivity Factor (SISCF) – bottom of fig.1 - as our approximation of the extent of connectivity in a SIS. The SISCF is comprised of two elements, the connectivity complexity (CC), and the connectivity time (CT). The CC helps us approximate and understand the complexity of the structural and behavioral components within a SIS. For example, connectivity is more complex for a meso level SIS that integrates five social triads compared to a SIS integrating two triads because there will be more connections and relationships to consider. As more behavioral dimensions (e.g., governance across multiple settings, different workflows, disparate forms of social data, needs of a variety of end users) are incorporated
into a SIS, the degree of complexity also increases. It must also be emphasized that there is no one pattern of alignment for the structural and behavioral dimensions in our framework. Sittig and Singh point out that sociotechnical frameworks in healthcare need to be viewed as complex adaptive systems and that framework dimensions must be studied in a non-linear manner with an emphasis on how different dimensions interact and relate to each other. An implication of implementing multi-dimensional connectivity is that trade-offs will have to occur in many of the behavioral dimensions. In one of our case studies we showed that providers and administrators can have different needs with respect to how a collaborative HIS is used. Administrators wanted data to support organizational decision making on workloads and to provide necessary reporting for healthcare accreditation bodies, but collecting that data increased the data entry workload of the front line clinicians. In that situation the workflow and governance behavioral dimensions were in conflict with each other. Similarly, establishing the level of common ground necessary for social processes often means that individuals may have to change how they do things in consideration of social good. Again, that requires behavioral changes at the individual level as a precursor to achieving social connectivity at a group level.

The CT refers to the length of time that social connectivity has taken place, as some of the above CC dimensions are influenced by temporal properties. A key time related factor is the maturity of processes. Many of the social processes that are done in healthcare such as collaborative healthcare delivery or patient participatory medicine are still maturing and thus will develop over time. Even if a SIS is designed to support social processes such as collaboration and coordination there may be a stepwise progression to using it to its full capacity. One of our case studies showed that even though we designed a palliative care system with alerting and reminder features to support collaborative care delivery they were not used to capacity because the technology was more advanced than the care processes that were using it. A different study on HIS implementation described how users initially used an EHR system solely as a documentation tool but over time they developed and adapted social coordination strategies that were enabled through the EHR. Social technologies are multi-purpose tools that can provide a range of social functionality depending on the degree of social processes which are using them. For example, Twitter and Facebook were initially designed for social communication at a personal level but they evolved in use to include clinical and public health activities. The first step in the development of SISs must be an analysis of the behavioral dimensions of a social system using the above described behavioral dimensions as there is little point in implementing SISs that are more advanced than the people and processes using them. Once the social process baseline has been identified, an SIS can then be designed, which must include tools and features to support social processes in the present while also helping the processes mature and evolve over time.

**Discussion**

SISs offer great potential for improving healthcare delivery in that they can support the development and ongoing maintenance of relationships to support collaborative healthcare activities. Managing chronic disease at the micro level is dependent on our ability to connect a patient with information, processes, people and technology as part of disease management. Similarity, public health efforts like disaster management and community resilience are dependent on relationship building over time that encompasses a wide variety of user groups. However, SISs introduce a connectivity problem in that the system design considerations, and potential UICs of systems design, are so vast that SIS design becomes a significant challenge. This research helped to address the above issue by proposing the Social Information System Connectivity Framework for SIS design. The framework defines the structure of a SIS as a set of one or more social triads and the behaviour of a SIS according to six behavioural dimensions. The framework is operationalized through the Social Information System Connectivity Factor and the connectivity complexity (CC) and connectivity time (CT) concepts, which help us understand how the degree of connectivity and temporal aspects of social connectivity will impact SIS modelling and design.

SISs present a new perspective on the design and evaluation of health information systems. We do not believe it is possible to eliminate all unintended consequences from SIS implementation due to the complexity of the healthcare domain. Rather our focus should be on identifying and managing unintended consequences. The value of our framework is that it enables us to proactively identify and understand the connectivity complexity of SIS design. We emphasize that we do not provide a prediction of SIS connectivity complexity but rather provide a way of understanding the complexity and temporal considerations associated with it. This research is complementary to existing work that has developed architectures for SIS design or identified challenges in performing SIS design as well as to system design approaches like Interaction Design Theory. While technical aspects of SISs are essential for designing system infrastructures, perhaps a bigger challenge in SIS design are the behavioural dimensions identified in this paper. For example, processes like patient self-disease monitoring (e.g., blood pressure, diet) and community preparation for disaster management are both preparing for events that may not occur for some time (i.e.,
illness, natural disaster), if at all. Therefore, keeping users motivated to keep a SIS active in the present moment, as well as enabling it to evolve and mature, presents a significant challenge. Similarly, while the value of SISs comes from the social network of users within it, it also introduces connectivity challenges with respect to adaptiveness of workflows to address the dynamic nature of the system, incorporating social data standards, and managing cross organizational interoperability and governance. A significant implication of multi-dimensional connectivity is that SIS design cannot satisfy everyone, and therefore trade-offs will have to be made with respect to the behavioral dimensions of a social system. An example of such a trade-off is in the governance complexity dimension where traditional information sharing agreements that impede cross organizational information sharing will need to be loosened to enable development of social networks. Trade-offs at the individual level as a precursor to achieving common ground at a group level is another example of a trade-off as part of social connectivity.

One significant finding from our work is that the development trajectory of SISs is understated. While social technologies are well developed from a tool perspective, the social processes that use the tools are not nearly as well developed. Therefore, our effort moving forward needs to focus on understanding how to design SIS to provide the necessary connectivity to support present needs but also to enable the ongoing development of social processes. Bottom line is we cannot implement SISs without ensuring that the social processes that will use them have sufficient maturity to benefit from the implementation. Another implication for SIS design from our framework is the need to study how different social networking tools contribute to a SIS. Self-monitoring tools such as Fitbits are fairly bounded in terms of the data they collect (e.g. steps, heartrate) compared to tools such as Twitter or Facebook that are far less bounded in terms of data collected. Thus, there is a need to study connectivity implications for these different data sources. Further, increased sharing of data brings about privacy and security issues, and, while not discussed explicitly in this paper, they are important considerations in SIS design.

Limitations of our research are that we have developed but not used the connectivity framework to model or design SISs. The next stage of our research is to use the framework to design and evaluate SISs at the clinical (micro and meso) and community health (macro) levels.

**Conclusion**

SISs will play a crucial role in healthcare transformation at all levels (micro, meso and macro). Therefore, there is a need for approaches that help us to understand and model the complex connectivity that is inherent in a SIS. This paper proposed the Social Information System Connectivity Framework for SIS design. This research helped to address the above issue by proposing the Social Information System Connectivity Framework for SIS design. The framework defines the structure of a SIS as a set of one or more social triads and the behavior of a SIS according to six behavioral dimensions. The framework is operationalized through the Social Information System Connectivity Factor and the connectivity complexity (CC) and connectivity time (CT) concepts, which help us understand how the degree of connectivity and temporal aspects of social connectivity will impact SIS modelling and design.

Abstract

The Zika virus (ZIKV) outbreak in South American countries and its potential association with microcephaly in newborns and Guillain-Barré Syndrome led the World Health Organization to declare a Public Health Emergency of International Concern. To understand the ZIKV disease dynamics and evaluate the effectiveness of different containment strategies, we propose a compartmental model with a vector-host structure for ZIKV. The model utilizes logistic growth in human population and dynamic growth in vector population. Using this model, we derive the basic reproduction number to gain insight on containment strategies. We contrast the impact and influence of different parameters on the virus trend and outbreak spread. We also evaluate different containment strategies and their combination effects to achieve early containment by minimizing total infections. This result can help decision makers select and invest in the strategies most effective to combat the infection spread. The decision-support tool demonstrates the importance of “digital disease surveillance” in response to waves of epidemics including ZIKV, Dengue, Ebola and cholera.

Introduction

Zika virus (ZIKV) is an arbovirus belonging to the family Flaviviridae, and is closely related to the dengue, yellow fever, Japanese encephalitis, and West Nile viruses. It was first isolated from a monkey in the Zika forest of Uganda in 1947. In 1948, the second isolation was made from Aedes africanus mosquitoes in the same forest. Although earlier studies have suggested the possibility of human infection, before 2007, ZIKV rarely caused recognized ‘spillover’ infections in humans, even in highly enzootic areas. Since 1951, human ZIKV infections have been reported in African countries including Uganda, Nigeria, Senegal, and Gabon, and parts of South Asia including India, Malaysia, and Indonesia. In 2007, the first documented ZIKV outbreak was reported from Yap State, Federated States of Micronesia. French Polynesia also reported an outbreak with 28,000 estimated cases in 2013. Since April 2015, Brazil has been experiencing a ZIKV outbreak. The outbreak has subsequently spread to other countries in South America, Central America, and the Caribbean.

ZIKV is primarily transmitted by the bites of infectious Aedes mosquitoes, especially Aedes aegypti and Aedes albopictus. Non-vector borne transmissions, though rare, have also been reported. Symptoms of ZIKV infection include fever, rash, conjunctivitis, and retro-orbital pain. These symptoms are usually mild and unspecific. The ZIKV infection is difficult to detect since its symptoms are similar to those of dengue and chikungunya. Asymptotic cases are also frequent, which makes it even harder to precisely diagnose the ZIKV infection. Although the symptoms of ZIKV infections are usually mild and unpleasurable, it has recently been connected to microcephaly in infants born to mothers infected with ZIKV during pregnancy, suggesting the possibility of intrauterine infection. ZIKV is also suspected to be linked to Guillain-Barré Syndrome (GBS), a muscle weakness caused by the immune system damaging the peripheral nervous system.

With the ease of modern transportation, there is a potential that the ZIKV outbreak may become a global public health crisis. Therefore, it is crucial to understand the transmission dynamics of ZIKV and establish a set of strategies that help to contain the outbreak effectively. Mathematical models have long been used to analyze infectious disease outbreaks to facilitate development of policies and strategies for understanding disease propagation and containment strategies. Since ZIKV is closely related to West Nile, dengue, and yellow fever viruses, it can be modeled with similar techniques. Because of dengue’s global impact, its disease dynamics have been studied extensively, and compartmental models based on Susceptible, Infectious, Recovered (SIR), and Susceptible, Exposed, Infectious, Recovered (SEIR) hosts have been proposed and analyzed. The population dynamics and life table of the major vector of ZIKV, Aedes mosquitoes, are also well studied, and can be incorporated in the compartments for vectors.

In this work, we present a compartmental model for ZIKV based on SEIR host model and SEI vector model, using logistic growth in human population and dynamic vector population. We conduct sensitivity analysis on multiple parameters to understand the risk and transmission of ZIKV, and evaluate the efficiency of different containment strategies. We discuss how this may assist in decision making to control and mitigate outbreaks.
Method and Design

The compartmental model consists of two parts: the compartments for human, subscripted with $H$; and compartments for vectors, subscripted with $V$. Although there have been a few reported deaths related to ZIKV, most ZIKV cases only result in mild symptoms among infectious individuals. We use an SEIR (Susceptible, Exposed, Infectious, Recovered) model to describe the disease spread among the human population. Let $S_H(t), E_H(t), I_H(t)$ and $R_H(t)$ denote the number of individuals in each compartment at time $t$. The human population at time $t$ is given as $N_H(t) = S_H(t) + I_H(t) + R_H(t)$. During the outbreak, the human population is assumed to follow a logistic growth with carrying capacity $K_H$.

The compartments for vectors consist of both the infectious status and the life stages of the mosquito. In particular, a typical life cycle of a mosquito has four stages: egg, larva, pupa, and adult. Let $V_1(t), V_2(t)$ and $V_3(t)$ denote the number of eggs, larvae, and pupae of vectors in the environment. Since only female adults bite humans and transmit the virus, there are no infectious compartments for these three stages. Let $S_V(t), E_V(t)$ and $I_V(t)$ denote the number of susceptible, exposed, and infectious female adults in the environment at time $t$, and denote the total female vector population as $N_V(t) = S_V(t) + I_V(t) + E_V(t)$. Due to their short life cycle, the birth and death rate of vector population is taken into consideration. The transmission from susceptible to infectious in both human and vector population is associated with mosquito bites. Figure 1 shows the transition diagram.

Let $b$ denote the average biting rate per unit time of a female mosquito: $b$ typically ranges from 0.3 to 0.5 per day\(^{41, 43}\). Let $\beta$ represent the percentage of bites that transmit ZIKV. In addition, let $M$ denote the amount of alternative hosts besides human in the environment. Then the number of bites received by a human per unit time is $bN_V/(N_H + M)$, among which $I_V/N_V$ are from infectious mosquitoes. Therefore, the exposure rate of a human is given by

$$\beta \frac{bN_V}{N_H + M} = \beta b I_V$$

Similarly, the exposure rate of a mosquito is $\beta b I_H/(N_H + M)$. Assume the inverse incubation time of ZIKV for human is $\alpha_H$, and the recovery rate of an infectious individual is $\gamma$. The human population growth rate is $\lambda$, and the decreasing human population due to limited carrying capacity is $\lambda N_H^2/K_H$, and this amount is distributed in the four compartments according to their relative size. Then the transitions between compartments for human can be described by the following system of ordinary differential equations:

$$\frac{d}{dt}S_H = \lambda N_H (1 - \frac{S_H}{K_H}) - \beta b I_V - \frac{\mu_H}{N_H + M} S_H$$
$$\frac{d}{dt}E_H = \beta b I_V + \frac{\mu_H}{N_H + M} S_H - \alpha_H E_H - \frac{\mu_H}{N_H + M} E_H$$
$$\frac{d}{dt}I_H = \alpha_H E_H - \gamma I_H - \lambda N_H \frac{I_H}{K_H}$$
$$\frac{d}{dt}R_H = \gamma I_H - \lambda N_H \frac{R_H}{K_H}$$

For the vector compartments, let $e_V$ denote the number of eggs laid per female mosquito per unit time, and $\alpha_V$ the inverse incubation time of ZIKV in vectors. Let $\tau_i$ and $\mu_i, i \in \{1, 2, 3\}$ be the reciprocal of the development time and mortality rate of vectors in stage $i$, respectively. In addition, let $\mu_V$ denote the mortality rate of adults. Assume $q$ is the percentage of females among adult vectors. Since mosquito larvae live in water with limited resources, the dynamics of the larvae population is also assumed to follow a logistic growth with carrying capacity $K_V$. The mortality rate of larvae caused by limited carrying capacity is denoted as $\kappa$. Then the transitions between compartments of vectors are described by the following system of ordinary differential equations:

$$\frac{d}{dt}V_1 = e_V N_V - (\tau_1 + \mu_1) V_1$$
$$\frac{d}{dt}V_2 = \tau_1 V_1 - (\tau_2 + \mu_2) V_2 - \kappa \frac{V_2}{K_V}$$
$$\frac{d}{dt}V_3 = \tau_2 V_2 - (\tau_3 + \mu_3) V_3$$
$$\frac{d}{dt}S_V = q \tau_3 V_3 - \frac{\beta b I_H}{N_H + M} S_V - \mu_V S_V$$
$$\frac{d}{dt}E_V = \beta b I_H + \frac{\mu_V}{N_H + M} S_V - (\mu_V + \alpha_V) E_V$$
$$\frac{d}{dt}I_V = \alpha_V E_V - \mu_V I_V$$

Figure 1. Transition diagram of the compartmental model. The dashed lines refer to the transitions associated with bites. The lines for vector birth and death are omitted for simplicity.
To quickly contain the outbreak and reach a disease-free equilibrium, it is desirable to reduce the basic reproduction number $R_0$, which is the average number of secondary infections produced by a single infected individual in a completely susceptible population. To achieve this, we may alter the parameters by introducing interventions to contain the outbreak. In particular, the following two strategies are considered:

1. Reduce biting rate $b$ by avoiding mosquito bites, using insect repellents, wearing long-sleeved clothes and long pants, and using air conditioning and window/door screens to keep mosquitoes outside.

2. Reduce adult female vector population or increase adult female vector mortality rate $\mu_V$ at equilibrium $S^*_V$ by widely applying insecticides in areas with high (infectious) mosquito population, or introducing genetically modified Aedes mosquitoes, which will cause its offspring to die by reducing larval survival rate and adult longevity.

Thus, containment is achieved when $R_0 < 1$. In that case, an infected individual produces less than one new infected individual during its infectious period, thus the outbreak will start to contain. Using the $R_0$ formulation, we may alter the parameters by introducing interventions to contain the outbreak. In particular, the following two strategies are considered:

Table 2 summarizes the parameters used in modeling the Zika disease dynamics for Rio de Janeiro State (Sentinel surveillance sites reports) and for a town with 100,000 people. Between January 2015 to July 2015, a total of 364
suspected cases were reported in Rio de Janeiro State. By November, the outbreak was contained with approximately 440 infection cases.

Table 2. Estimated parameter values used in the simulation.

**Rio de Janeiro State, Brazil** Figure 2 contrasts the reported cases versus simulation by varying the recovery time ($\gamma$) and the incubation time of human ($\alpha_H$). The results suggest that Table 2 provides good estimates for the reported cases (green solid curve vs red dotted curve). When the recovery time increases from 6 to 8 days (dotted vs dashed green curves), the cumulative infections increases from 340 to 566 by July 2015 (66.5% increase). Longer recovery time also leads to delayed containment. This confirms that recovery time has significant impact on disease containment. Thus timely treatment and vaccination for combating ZIKV are critical.

Varying the human incubation period from 2 days to 4 days has a relatively minor influence on the overall infections (from 427 to 459, 7.5% increase) and the outbreak trend (contrast the three solid lines).

**Figure 2.** Varying recovery time and incubation time for human and its effect on overall infection and containment.

Figure 3 contrasts containment effectiveness for four strategies: reducing biting rate ($b$), increasing adult vector mortality rate ($\mu_V$), reducing larvae carrying capacity ($K_V$), and reducing adult female vector population ($N_V$). Without these strategies, total infection reaches 443 and will be contained by October 2015. In our analysis, we assume each strategy is implemented on May 1, 2015. Figure 3(a) shows that reducing biting rate by a mere 20% will lead to an early containment by August 2015 (90 days after implementation) with 270 total infections (39% reduction). The containment is achieved rapidly (< 60 days after implementation) with total infection under 200 when biting rate is
reduced by at least 40%. This proves that reducing biting rate is highly effective. This strategy is also relatively easy to implement.

Increasing the mortality rate of adult vectors is also effective. Figure 3b shows that increasing the vector mortality rate by 20% will lead to an August containment with total infection of 282 (36% reduction). Containment will be achieved instantly with no more than 220 infections if the mortality rate is increased by at least 40%. While this strategy can be achieved by introducing genetically modified mosquitoes to the environment, it is difficult to realize and economically inferior when compared to other strategies.

The larva carrying capacity has to be reduced by 80% in order for total infection to reduce to 330 (26% reduction) with containment achieved by October (Figure 3c). Nonetheless, examining and clearing the water ponds and humid areas where the larvae live remains an important strategy for public health protection.

Reducing vector population not only affects the number of infections at containment, it also changes the trend of the outbreak (Figure 3d). Specifically, reducing total adult vector population by 20% would postpone the outbreak by a month and reduce total infection to 334. Containment can be rapid when reduction is targeted at 80% (total infection reduces to 130). Figures 3c and 3d highlight that reducing adult population is more effective, though applying insecticide widely may come with numerous environmental and health issues.

![Figure 3](image)

**Figure 3.** Contrast of total infection and outbreak trends for four containment strategies.

In practice, combination strategies are often most effective. For brevity, Figures 4a and 4b report containment results for combination of two strategies only. In both figures, the vertical axis represents the cumulative number of human infections at containment. When 40% reduction is achieved in both biting rate and larvae carrying
capacity, it results in 180 total infections (Figure 4a). Similarly, the combination of reducing vector population by 20% and increasing vector mortality rate by 20% results in 232 total infections (Figure 4b).

Since it can be difficult to achieve high effectiveness using a single strategy, combination strategies are appealing. Our results (Figures 4a and 4b) also display marginal improvement beyond certain threshold values in the strategies. This helps policy makers to invest their resources optimally for best possible gain.

Figure 4. Cumulative number of human infections at containment under combination strategies.

**A Town with 100,000 People** To better understand the behavior and sensitivity of our model and the disease spread characteristics, we perform the analysis on a town with 100,000 people, using the parameters given in Table 2. Without any intervention, containment will occur at Day 900 with 42,000 overall infections.

We observe some similarities as in the Rio de Janeiro State analysis. An increase in human recovery time delays the containment and increases the total number of infections (Figure 5a). Similarly, the incubation period for humans has little effect on the overall disease trend (Figure 5c). On the other hand, the incubation time for the vectors significantly affects the overall number of infections while exhibiting the same outbreak pattern (Figure 5d).

We explore alternative hosts and their impact on the pandemic. Increasing the number of alternative hosts from 20,000 to 100,000 (Figure 5b) will slow the outbreak and reduce the total number of infections by 83.3%. This suggests that introducing alternative hosts has potential in mitigating an outbreak. However, it is possible that these hosts can get infected with ZIKV and spread it to humans via other means. The ecological and disease impact cannot be fully assessed at this point, thus rendering it an unsafe venue for ZIKV disease containment.

We assume each strategy is implemented on Day 100 after the outbreak. Figure 6 reports containment effectiveness for each strategy. Reducing bite rate by 20% (Figure 6a) and increasing vector mortality by 20% (Figure 6b) have similar effectiveness in containing the disease spread (Day 500 vs Day 300) and with comparable overall infection (12,000 vs 11,000). Both strategies are very effective – reducing infections by over 70%.

Reducing larvae carrying capacity has a significant impact on the outbreak (Figure 6c). In particular, over 40% reduction in infection is observed when 20% reduction in carrying capacity is in effect. On the other hand, reducing vector population is not as effective in containing the ZIKV outbreak (Figure 6d). Nonetheless, reducing vector population does influence the pandemic course: when the vector population is reduced by 20%, it postpones the onset of the outbreak by approximately 100 days, and reduces the total infection by 9.5%. These results are different from the findings in the Rio de Janeiro State analysis where reducing the carrying capacity of larvae proves to be not very effective.

Figure 7 shows the combination strategies that can be implemented in practice in a cost-effective manner. Figure 7b shows the marginal gain in infection control through reduction in vector population.
Figure 5. Varying recovery time, alternative hosts, and incubation time for human and vector and their effect on overall infection and containment.
Discussion
This work demonstrates the key importance of “digital disease surveillance” in response to waves of epidemics including ZIKV, Dengue, Ebola and cholera. Specifically, we develop a compartmental model with a vector-host structure utilizing logistic growth for human population and a dynamic vector population describing its full life cycle. We analyze the development of ZIKV outbreak and explore key parameters that influence epidemic severity. We study the effect of ‘average’ recovery time (of human) from infection, the number of alternative hosts, and the ZIKV incubation time in both vectors and humans. The analyses are performed on two populations with real data from Rio de Janeiro State. Our results reveal that the outbreak is sensitive to the first three parameters while human incubation period has only marginal impact.

We examine four containment strategies: reducing biting rate, increasing vector mortality rate, reducing larvae carrying capacity, and reducing vector population. All four strategies are effective (in varying degrees) in containing the outbreak and reducing the overall infection. While findings for reducing biting rate and increasing vector mortality rate are similar for both populations (both are superior to other strategies), results for the larvae carrying capacity and reduction in vector population differ. These findings suggest environmental and demographic information should be considered when determining proper containment strategies. Our study also shows that reducing vector population early on can help delay the onset of the outbreak.

Combination strategies are both promising in practice and cost-effective in achieving early containment. The model provides a decision support framework for policy makers to estimate the cost-effectiveness for each prevention
measure. Public health departments should select a strategy portfolio compatible with their local environment and regional demographics. In addition, the public should be educated and informed of ZIKV status. Population behaviors (protecting themselves by reducing biting, cleaning water ponds to rid of larvae, etc.) have demonstrably significant impact on containing and mitigating the outbreak.

The multiple components involving the dynamics of human and vector populations in this model allow flexibility in characterizing disease spread and performing strategic analysis. However, obtaining/determining all essential input parameters for this to be practical may prove difficult. The model can be simplified without diminishing its quality and rigor in disease dynamics and infection/containment outcome prediction\(^5\). Such a model may be desirable when detailed input data are not readily available.

For example, the natural human population can be assumed to be constant throughout the outbreak since the magnitude of natural population growth is relatively small within the pandemic period. The mosquito population lifecycle can also be condensed to a simple birth-death process. In Lee et al 2016\(^5\), we propose a simplified model with constant human and mosquito population to study the ZIKV outbreak. The study predicts the disease trends and characterizes containment strategies for Brazil and Puerto Rico. The model has accurately predicted ZIKV outbreak trends for these two countries. It predicts the number of infectious pregnant women in Puerto Rico within 5% of the actual documented numbers (as of July 2016)\(^5\). Although the simplified model is statistically useful and usable, additional components and parameters presented herein should help decision makers better understand the details of ZIKV outbreaks. It may also provide them with more analytic-based options in deciding the proper containment strategies when such input data are available.

Modern information technologies which are capable of tracking disease spread and vector activities play an indispensable role in supporting disease modeling and in mitigating and containing epidemiology outbreaks. Informatics applications such as social media and internet-based participatory surveillance systems have already demonstrated their capability in helping us understand and prevent disease outbreaks like Dengue and influenza\(^2,5\). Software and hardware such as ArcGIS platform and mobile DNA sequencing lab are also designed to help track the current ZIKV outbreak. These technologies capture valuable inputs for our model, which is very flexible and can be easily adapted in real-time as real data feeds arrive. With the support of these technologies, the model parameters can be estimated accurately and updated on a regular basis. The model output can then be used to predict the status of the outbreak in a timely manner. It also reflects any changes in the environment, policy, and human and social behavior. Conversely, the model can also serve as a guideline of the application of these decision technologies such that they are deployed and utilized optimally by policy makers. Informatics can help us understand the underlying mechanism of the pandemic spread. It also enables decision and policy makers to understand/update the planning and response strategy in real time to maximize the containment effect while minimizing the overall infection / mortality and the associated costs and health burden.

There are limitations to our study. We assume a homogeneous human population in the model, which may not hold in practice. The possibility of contacting mosquitoes and the chance of getting infected from an infectious vector may differ among individuals and the environment. This can be overcome by creating additional compartments for each homogeneous subgroup. We have incorporated this subgroup concept in our vaccine prioritization analysis with great success\(^5\). However, this requires even more parameter estimation and may lead to over-fitting. In addition, our conclusions are strongly influenced by results from a particular demographic and geographic profile. Local decision makers should input proper (best estimate) parameters into the model in order to conduct accurate analyses.

The current model does not include any treatment or vaccination effects since they are currently under developed. With deeper understanding of ZIKV and the presence of medications and vaccines, these factors can also be incorporated under our modeling framework.

Abstract

In this study we developed a Fast Healthcare Interoperability Resources (FHIR) profile to support exchanging a full pedigree based family health history (FHH) information across multiple systems and applications used by clinicians, patients, and researchers. We used previously developed clinical element models (CEMs) that are capable of representing the FHH information, and derived essential data elements including attributes, constraints, and value sets. We analyzed gaps between the FHH CEM elements and existing FHIR resources. Based on the analysis, we developed a profile that consists of 1) FHIR resources for essential FHH data elements, 2) extensions for additional elements that were not covered by the resources, and 3) a structured definition to integrate patient and family member information in a FHIR message. We implemented the profile using an open-source based FHIR framework and validated it using patient-entered FHH data that was captured through a locally developed FHH tool.

Introduction

FHH has been recognized as a powerful tool for diagnosis and risk assessment in clinical genetics, aiming to identify risk of a specific gene disorder for the purpose of ensuring appropriate primary care and specialist intervention. However, utilization of FHH information has been limited by the lack of tools implemented in the clinical workflow to perform the required analysis. Unlike other clinical data, FHH includes not just patient data, but also their family members, including all relationships, their disease history, and age of disease onset or death. Traditionally clinicians have relied on interviews or questionnaires to collect narrative-only FHH information from patients, but due to the limitation of time in clinical settings, this method does not ensure sufficient information or data quality to complete the analysis. FHH is still mostly captured and stored in narrative text form, summarizing only essential or a minimum of information for risk assessment (e.g. family history of ovarian cancer on maternal side).

With support of computerized tools, improved electronic health record (EHR) systems are now capable of capturing and storing detailed FHH information in a structured way. Such tools have been implemented not only to be used by clinicians, but also outside clinical settings, as it ensures enough time and a systematic way to enter pedigree based FHH data by patients. Based on the ideal features of the FHH tools that have been suggested by the American Health Information Community, recently implemented tools provide a web-based access environment and visualization of family pedigree diagrams to connect with healthcare consumers, and motivate them to enter accurate FHH information.

In anticipation of increasing adoption of these tools, there have been efforts to develop a standardized data model of FHH for exchange across systems. The Health Level 7 (HL7) Version 3 implementation guide for family health history and pedigree interoperability is a well-known standard to represent FHH as an extensible markup language (XML) and has demonstrated its ability to be used for genetic risk assessment services across systems in a case study. However, it has been true that in general, HL7 Version 3 based standards haven’t been as widely adopted as Version 2, because Version 3 was thought to be difficult to develop, expensive, and required too much project time to develop.

FHIR is a next generation standard framework created by HL7 which has an implementation focused approach. FHIR provides an alternative to document-centric approaches by directly exposing discrete data elements, which compromise a FHIR resource, as services. Because the benefits of using FHIR are pre-built and standardized resources which are easily extensible, and the ability to combine these into profiles for easier implementation in development, a complex data model like FHH will be handled more efficiently using FHIR. Yet existing FHH resources do not cover detailed FHH data model such as full pedigree to support genetic risk assessment, and a few published extensions still have limitations.

In this manuscript, we used CEMs as a baseline data model to develop FHIR profile to address the gap. Elements of CEMs have features to be transformed to FHIR profiles in a straightforward manner, as the CEM strategy defines generic structures which specify the data type of an element, its permissible values or range, multiplicity of value
sets of the element, and permissible qualifying information, etc. \textsuperscript{13,14} In our previous study, we developed CEMs that can cover essential of FHH information; its key features are to capture full pedigree of FHH, linkages of family members to their patient records in EHR, and social history and health behaviors \textsuperscript{15}.

We selected FHH related resources by conducting a gap analysis between existing FHIR resources and FHH CEM elements, and added CEMs were not covered by the existing FHIR as extensions. We developed a structured definition that can contain all the selected resources and extensions as a patient’s full pedigree based FHH in one FHIR message. We used an open source based FHIR framework to implement the profile and to create messages using empirical FHH data of Intermountain Healthcare, and validated it by analyzing the gaps. We assume the profile to be used to run an external web service of genetic risk assessment.

**Background**

Intermountain Healthcare is a not-for-profit, community-oriented organization based on Salt Lake City in Utah with more than 37,000 employees, about 1,400 employed primary care and secondary care physicians, and provides healthcare services based on Utah and southeastern Idaho. It operates 22 hospitals and more than 185 clinics throughout the regions \textsuperscript{16}.

Intermountain Healthcare provides a web-based FHH collection tool named OurFamilyHealth, which was initially developed in 2009 and has made available through Intermountain’s patient web portal: MyHealth \textsuperscript{17}. The purpose of OurFamilyHealth is to provide patients the ability to enter FHH data by building a graphical family pedigree and assign disease and conditions to specific member in their history (see Figure 1). Patients are given a basic family tree at their first access and can add their family members to the tree with detailed demographic, disease histories, and health behavior information such as height, weight, and smoking status.

**Figure 1.** Screen shot: a graphically represented immediate family consists of a patient, father, mother, spouse, and two children in OurFamilyHealth

In our previous study, we introduced the principle and strategy of developing OurFamilyHealth, and also analyzed its early usage patterns \textsuperscript{18}. Although OurFamilyHealth was designed to capture and store essential FHH data elements based on the AHIC recommendation, yet it was not integrated with Intermountain’s EHR. As groundwork of the integration, we developed CEMs as baseline logic and data model to cover the essential of FHH information in OurFamilyHealth, to be eventually stored into our clinical data repository (CDR).

We currently have two use cases of utilizing the CEMs at Intermountain. First, OurFamilyHealth currently only collects patient’s FHH data but does not provide any decision support function to clinicians for patients. We have a
plan to enhance the application connected to an external risk assessment service such as HughesRiskService. To do so, OurFamilyHealth should be able to transform its FHH data into a standard message to run against the service, but also to interpret outcome of risk assessment from the service and present it to patients. The other motivation is integration of FHH data into our new EHR based on Cerner. Since OurFamilyHealth is a locally developed tool, it does not yet interface with Cerner system and a standard message can be used to exchange OurFamilyHealth data with Cerner’s CDR and applications. The data model and logic of the CEMs can be used in the both use cases.

Limitation of current model

HL7 FHIR builds on previous data format standards from HL7, like HL7 version 2.x and HL7 version 3.x, and is the most enhanced standard to exchange healthcare data. It is easier to implement because it uses a modern web-based suite of Application Programming Interface (API) technology, including a RESTful (Representational State Transfer) protocol, a choice of JavaScript Object Notation (JSON) or XML for data representation. FHIR is currently on second stage of draft standard for use (DSTU 2) and provides an alternative to document-centric approaches by directly exposing discrete data elements as services. For example, basic elements of healthcare like patients, admissions, diagnostic reports and medications can each be retrieved and manipulated via their own resource uniform resource identifiers (URIs).

A resource in FHIR is a small logically discrete unit of data exchange and has a known identity by which it can be addressed. Among FHIR resources, FamilyMemberHistory resource in the clinical category is to represent a simple structure used to capture an elementary family history for a particular family member. Figure 2 depicts a diagram of the data model of FamilyMemberHistory.

Figure 2. UML Diagram of FHIR Resource: FamilyMemberHistory (DSTU2)

Since FHH information consist of disease history of a patient and family members, ideally a combination of a Patient resource and a set of FamilyMemberHistory resources with appropriate linkages between resources can represent a FHH. The problem is that a FamilyMemberHistory only describes “a relationship of a family member to a patient” using the HL3 v3 relation codes, but it does not describe relationships between family members. For example, a FamilyMemberHistory resource instance with relationship code “PCOUSN” implies that a patient has a paternal cousin. But merely the relationship code does not examine who is parent of the cousin out of uncles and aunts, unless the patient has only one paternal uncle without aunts or one paternal aunt without uncle. Similarly, if a patient has multiple spouses and multiple children, a list of FamilyMemberHistory does not inform a child is from which of the spouses. As a result, we are unable to render a full pedigree from a set of FamilyMemberHistory.

FHH CEMs

The FHH CEMs are developed using Constraint Definition Language (CDL). CDLs were originally developed by GE Healthcare and are syntax for expression of constraint models that are key features of CEMs, with extensions including additions of new constraints to the modeling language, formalization of the model specialization capabilities, and a concrete reference object model. Based on our previous project, we have 126 CDLs to cover FHH including full pedigree, disease and conditions, and social history, such as smoking status, alcohol consumption status, and physical activity. Table 1 describes the key CDLs and their attributes.

**Method**

A FHIR profile is a set of base resources and is to author and publish a customized and more specific resource definition, by specifying a set of constraints and/or extensions on the base resource. Therefore concrete FHIR resources can express their conformance to a specific profile, and a FHIR server can to programmatically validate a given resource against the associated profile definition.
Our first step of profiling is to identify the base resources covering essential information of FHH, and then find extensions to cover rest of the information. We conducted a gap analysis between the FHH CDLs and current FHIR resources. The FHH CDLs are categorized by four meaningfully related groups: patient, family relationship, disease and condition, and health behavior. For every data elements in each category, we investigated if there is a match of FHIR resources, and then compared details with value sets in data elements in the two domains.

**Patient**

In a family pedigree represented based on the FHH CEMs, all the persons in the tree are recognized as patients and they are flat. However, we can also specify one person in the tree as a proband: a term used in genetic counseling to refer a patient describing his/her FHH to a counselor. In this case, a proband is a node locates in the center of a family pedigree, and relationships of all family members may be described as a set of “relationship to proband” (e.g. paternal father of patient). Data elements in this category cover mainly patient’s demographic information such as name, age, sex, and race / ethnicity, etc. Table 2 presents gap analysis between the data elements of proband category.

**Family relationship**

The family relationship structure in FHH CDLs is described by the Family Panel contains three items: parent1, parent2, and child (See Figure 3), which means a unit family basically consists of two parents and one child. The model of the three items is Patient, which implies every family member in the Family Panel is considered as patients and also identified by PatientExternalIdentifier that may be linked to patient records in EHR systems. AdministrativeMaritalStatus and Consanguinity represent marital information of parent1 and parent2. If a person has relationships with multiple spouses, Family Panels may be needed as many as the number of the spouses. For example, if person A has married twice with spouses B and C, and has had children D and E from with spouse, the relationship will be presented with two Family Panels consist of the following items: {A,B,D} and {A,C,E}.

Disease and condition

Disease and condition history of proband and family members is essential information to assess risk of genetic diseases. Not all disease and condition concepts are captured; the FHH CEMs may bind consumer-facing disease concepts or family history. These concepts are mapped to SNOMED concepts. When a FHIR message is created, local disease code should be transformed to a SNOMED code to ensure interoperability with external systems.

Health behavior

The FHH CEM also contains data elements of health behaviors, which are potentially related to genetic risk assessment as environmental factors (e.g. smoking history of family with lung cancer). We mapped Observation resource to represent health behaviors as they may cover a diagnosis, monitor progress, baselines and patterns, and demographic characteristics.

</tr>
</tbody>
</table>
From the gap analysis in four categories, we identified five types of gaps to address between the two models.

- **Exact match**: concepts of data elements are same with their data types and value sets (e.g. first / last name, date of birth).
- **Mapping required**: race and ethnicity in the two domains have same concepts but different value sets and need to be mapped. For example, OurFamilyHealth captures “Ashkenazi Jews” particularly in ethnicity, as they statistically have more BRCA1 and BRCA2 genes that imply higher risk of breast, ovarian, and prostate cancer [25], however HL7 ethnicity code does not support it.
- **Reasoning required**: e.g. inferring a family member’s adoption status in his/her family from a HL7 relationship code of the person and proband.
- **Type conversion**: age in years can be calculated from date of birth. However date of birth can be only estimated as a range from age in years.
- **No match**: existing FHIR resources or HL7 value sets do not cover consanguinity. It should be added as a new Observation or extension.

**FHIR structure**

In addition to selecting the base resources and extensions, we built a model of structure to integrate them in one FHIR message. We used two infrastructure resources: Bundle and List. Bundle refers to a container for a collection of resources, particularly to gather a collection of resources into a single instance with containing context. List is to contain a set of information summarized from a list of other resources and is a flat, possibly ordered, collection of records. Resources supported by the List resource can be homogenous – consisting of only one type of resource or heterogeneous – containing a variety of resources. Here we used List to contain homogenous resources such as Condition and FamilyMemberHistory. Using the features of Bundle and List, a structure of a FHH FHIR message can be formed as Figure 3.

In the structure, a family pedigree of a patient can have 1) a HeaderList that contains information of message header such as identifier of a FHIR message, message created (or sent) date, language code, etc., 2) a PatientBundle that contains a patient’s conditions and observations, and 3) a FamilyMemberHistoryList that contains multiple FamilyMemberHistory resources and their conditions and observations. All resources in the structure have resource references to a patient that indicate who is proband in a family pedigree. In addition, all Observations and Conditions of family members have subject references that indicate whom in the tree this clinical data belongs to.
Implementation
We implemented the proposed profile using HAPI framework; an open source based library for creating and validating FHIR messages. HAPI is pure Java based, and licensed under the business-friendly Apache Software License, version 2.0. Developers can create a FHIR message reusing Java objects, methods, and value sets provided by the libraries. Using these components, we developed a composer to generate a FHH FHIR message based on the profile we created.

To validate the FHH profile with HAPI, we used empirical patient data from OurFamilyHealth. FHH data in the database of OurFamilyHealth is stored in form of XML. We developed a parser to extract the XMLs from the database and decompose them as Java objects at the level of the FHH data elements. We automated parsing each patient’s FHH XML into individual data elements then feed them into the parser to generate FHIR XMLs. In the process we de-identified the data prior to creating messages by eliminating the tags of personal identification including names, birthdates of patients and families. As a result, we successfully created 4594 XMLs of FHH FHIR message (See example message in Figure 4).

Conclusion and future research
Our approach of deriving the profile of FHH FHIR through gap analysis based on the CEMs was plausible. We successfully implemented the profile and created FHIR messages using an open source based FHIR framework and empirical patient data.

We have limitations in our study and future works to address them. First, although our FHH CEMs were developed to be a general data model for FHH, they were developed based on the local data model of OurFamilyHealth. In addition we used patient data from OurFamilyHealth for validating the profile. Because of this the profile should be more validated in outside Intermountain settings and use cases. Secondly, although we assumed that the profile would adopt the feature of the FHH CEMs that can link family members to patient records in EHRs, we have not validated the idea. In our use case, we assumed that all the patients are independent and don’t have any links each other.
There are ongoing efforts to validate and implement the created profile in real use cases. We are working with the team of HughesRiskApp to connect OurFamilyHealth to their risk assessment service through FHIR. Currently we are validating the profile based on the historical patient data to see it can properly be consumed and interpreted by the service. In the future we plan to run the service real-time. For example, at the end of a session that a patient enters FHH into the application, he/she will be presented risk analysis results given the information entered.

**Figure 4.** An XML of FHH FHIR message created based on HAPI. Two extension tags represent two parents of a patient (left), and their internal person Ids (Id = 1, 2) match person Ids of FamilyMemberHistory (right).

We are also working with Healthcare Services Platform Consortium (HSPC): a provider-driven organization of healthcare institutes, IT vendors, systems integrators, and venture firms, providing a collaborative platform to achieve the gold standard of semantic interoperability of healthcare applications. HSPC is working on general profiling of FHIR based on CEMs, and our FHH profile will be part of the process eventually to be validated, publicized, and standardized.

9. HL7 Version 3 Implementation Guide: Family History/Pedigree Interoperability, Release 1

Toward Medical Documentation That Enhances Situational Awareness and Learning

Leslie A. Lenert, M.D., M.S
Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC, USA

Abstract

The purpose of writing medical notes in a computer system goes beyond documentation for medical-legal purposes or billing. The structure of documentation is a checklist that serves as a cognitive aid and a potential index to retrieve information for learning from the record. For the past 50 years, one of the primary organizing structures for physicians’ clinical documentation have been the SOAP note (Subjective, Objective, Assessment, Plan). The cognitive check list is well-suited to differential diagnosis but may not support detection of changes in systems and/or learning from cases. We describe an alternative cognitive checklist called the OODA Loop (Observe, Orient, Decide, Act). Through incorporation of projections of anticipated course events with and without treatment and by making “Decisions” an explicit category of documentation in the medical record in the context of a variable temporal cycle for observations, OODA may enhance opportunities to learn from clinical care.

Introduction

Physicians and other healthcare providers write notes for a variety of purposes, including documentation of care, communication with other team members, and providing evidence of services for billing. There are a growing number of applications that help physicians write notes both for efficiency and to produce coded data as a by-product. Whether application generated, dictated, typed or (increasingly rarely) hand written. There is a substantial question as to whom physicians are composing notes for (billers, themselves, or other providers) and many notes by medical professionals go largely unread by others. (1) There is also a growing concern about the use of cut and paste actions and templates short circuiting clinical cognition (2) and about resident practices that separate note composition from clinical workflows pre-empting thinking during note writing. (3)

We believe that when physicians compose notes, they should be thinking about the patient and the task of composition should shape both the processes of care and the ultimate conclusions they reach about diagnoses.(4) Moreover, note writing should provide an opportunity to learn from a case both as it evolves and on retrospective review. This paper reviews predominant cognitive models that shape providers’ thinking during the process of documentation, and proposes an alternative model designed to promote situational awareness and learning from experience.

Background

Larry Weed is the father of structured recording of medical information to facilitate reasoning. His theories were first expounded almost 50 years ago in the seminal paper, “Medical Records that Guide and Teach.” (4) At the core of Weed’s theories is the use of checklists for clinical cognition that encourage medical providers to think systematically about their patients. A widely adopted structural innovation described by Weed—the Subjective, Objective, Assessment and Plan (SOAP) framework—reminds clinicians of specific tasks while providing a framework for evaluation of information and provides a cognitive framework for reasoning activities.

The “Subjective” header is a cue for documentation of data that comes from patients’ experiences. By labeling this data “subjective”, it encourages clinicians to reason using an objectivist view and to divide the world into the “subjective” experiences of patients (history of illness, symptoms experienced, pain and anxiety and other features as elicited by the clinician or other healthcare providers), and the more “objective” measures of the clinician (physical examination findings, diagnostic testing and radiological examinations) that govern the processing of subjective reports of illness into medical diagnoses. Donnelly critiques this division of the world into subjective and objective based on the perspective of the physician: “The fact that we cannot know the facts becomes obscured if one accepts the subjective-objective distinction in SOAP.” (8)

The Assessment section documents the synthesis of “subjective” and “objective” evidence to arrive at a diagnosis. The Assessment section details the differential diagnosis process and may include some risk benefit tradeoffs in decision making. The Plan section details the needs for additional testing and consultation with other clinicians to address the patients’ illnesses, in addition to the steps being taken to treat the patient.
Examining this framework, what is the operational task that it supports? This author would assert that task is capture and consideration of all relevant data with a view toward differential diagnosis. SOAP is probably not the actual framework that clinicians use in diagnostic reasoning (9), but it has probably served well as a guide to diagnostic reasoning for a variety of reasons. The framework is hypothetico-deductive one that is focused on the application of the scientific method to patient care and the disproof of competing hypotheses. This gives the approach a certain face value (that may be diminishing in light of “big data” methods of empiric assessment and treatment). In addition to being “scientific”, the approach is fundamentally Bayesian: the prior probability of different diseases is updated by elements personal history (the subjective). Physical exam findings and laboratory tests, further update the posterior probability, ruling in or out different diagnoses. The Assessment follows all this data, and thus is allows the clinician to review relevant data before reaching a conclusion. Thus, if differential diagnosis was the only task that providers performed, SOAP might be the ideal cognitive framework.

But what if the situation is more dynamic? Could hypothetico-deductive reasoning lead providers astray by anchoring them on past observations and conclusions? It is likely that more common task in medical environments than differential diagnosis of an unknown problem(s) is the active management of an evolving, known medical problem over time and the differentiation of change in a disease from acquisition of a new one. In many clinical situations, evidence changes over time, requiring providers to reconsider diagnoses and treatments or risk error. (10) The SOAP model does not explicitly integrates time into its cognitive framework and thus has an important gap.

This has not gone unnoticed. Nurse clinicians have proposed extensions to SOAP designed to address its temporal “blind spot.” For example, the SOAP, SOAPIE, and SOAPIER models add “Intervention”, “Evaluation” and “Revision” headers and, as a result, creates categories for linking a note to overall progress on treatment of the problem. (11) The “E” and “R” are important refinements to SOAP. “E” adds an explicit reminder to assess how well a plan worked. “R” creates explicit expectations that plans need to change over time.

Physician have also proposed changes to their SOAP notes to make it easier follow a problem over time. Proposed changes have focused frames designed to help providers look backward across prior notes may detect changes in a patient’s condition or failure of a medical plan to achieve its intended effects. To support these concepts, Meyers and Miller suggest adding an “orientation” step to SOAP (O-SOAP) based on retrospective review of records. (12, 13) Gensinger and Fowler suggest re-arrangement of SOAP as ASOP (14), focusing on Assessment at the beginning to provide more temporal orientation. An ASOP structured note would bear some similarity to a cognitive frame widely used handoffs between providers called SBAR (Situation, Background, Assessment, Recommendations) (15), with Assessments in ASOP playing a similar role to Situations in SBAR. While putting Assessment first has some advantages, it might also lead to faulty decision making, if performed in order of the acronym, by forcing conclusions prior to review of all the data, voiding the positive cognitive check list effects of SOAP.

Unfortunately, none of the proposed enhancements of the SOAP cognitive framework have gained wide acceptance as a way to document progress notes. One potential reason for the “stickiness” of the SOAP model is that it is cognitively “right-sized.” As Miller described in his seminal 1956 paper (16), there are limits on working memory capacity of the brain. Cowan Miller’s work arguing that the magic number of items is four (17). It is an interesting coincidence that SOAP has four steps—as does SBAR, which is also widely adopted (18-22), and that extensions to SOAP that add additional tasks have not received as wide acceptance. Alternatively, SOAP extensions may not offer sufficient advances as to warrant their adoption based on Rogers Theory of Diffusion. (23)

Where could we look to improve upon SOAP, borrowing from other fields, while also recognizing the importance of prior authors insights into the limitations of SOAP? Electronic health records systems (EHRs) offer the potential of re interpreting the SOAP approach to focus on the evolution of problems over time. As described by Meyers’ et al. (12), the problem with the SOAP is that “it does not recognize the crucial effect that the last assessment and plan and the returned plan results have upon the next visit.” Prototypes developed by Meyers et al. (13) and Bosen (24) , illustrate how EHRs could bring elements of SOAP notes related to specific problems over time together in context to improve reasoning. However, there might also be value in changing the frame all together.

An Alternative Framework for Reasoning

The discipline of human factors research provides alternative directions on how to reorganize note writing. The failure of a clinician to recognize change in manifestations of a hypothesized disease over time, or to recognize unexplained systems, might be characterized as a lack of situational awareness.(10) Endsley defines situational awareness as “the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future.” (25) For example, situational awareness might require that physicians retain unexplained observations in their working memory and to document these in their notes (for example, the fever that doesn’t resolve or the serum sodium that is too low), in addition to
documenting their diagnoses and their rationale. Or, situational awareness might require one discipline to be aware of the findings of another. For example, a physician might need to read a nurse's note to be aware of a patient's changes in cognition. Situational awareness might also include subtle observations of interactions between the patient and family members that give clues about how care for the patient occurs at how.

Similar to SOAP, there are cognitive models that outline steps that can help novices and experienced users maintain situational awareness and learn in rapidly changing environments. One such model, which was initially developed by Boyd to help Air Force pilots outthink their opponents in aerial combat but is now widely applied within the U.S. military, is the Observe Orient Decide Act (OODA) model.

OODA is an action-oriented decision making model is explicitly applied in a repeating loop. Completion of one cycle prompts the next. There are no fixed time intervals for OODA cycles—the rate of cycling depends on how fast circumstances are changing. The goal of the OODA Loop is “think” and “act” faster and better than the enemy (in this case the disease(s) afflicting the patient), and thereby utilize available resources to maximum effect. (26) This is an important concept that is rarely addressed in medical reasoning: unless the pace of medical assessments and interventions outpaces the disease, the patient will, at best, experience morbidity or at worst, mortality (27). Bad outcomes occur when medical treatments are not adjusted fast enough, based on current hypotheses about what the illness is, to outpace progression of the illness.

In addition, OODA loops emphasize recognition of mismatch between predictions and experiences and, also, automation of responses in specific settings, once a problem has been recognized. OODA and other models that formally integrate a predictive step enhance learning through observation. They force a projection on the learner and periodic (re) assessments to test that projection with reality.

The OODA Loop is a proven technique to speed cognitive adaptation to changing circumstances. It has been widely adopted within U.S. military doctrine and the success of operations such as the first Gulf War, attributed, at least in part, to its appropriate implementation. (26, 28) OODA loops have been successfully utilized in the field of medicine (29, 30) but not as a template for documentation or teaching reasoning. The specific elements of the OODA framework will be discussed in turn in following paragraphs.

The Observation step encompasses both subjective and objective elements found in the SOAP note avoiding the subjective-fallacy. The decision maker notes what facts are available at a particular time. Observations might be general or specific to a designated problem. They might come from more than one observer; for example, a nurse or a caretaker. Observations may reflect patient history or be abstracted from other elements of a clinical record such as laboratory and radiological tests. Observations are time stamped, reflecting the state of the world at the time of its examination by the reasoner. This is critical, because in retrospective review of decision making, for the purposes of learning, a learner would need to distinguish an error due to a lack of availability of key information (a failure of observation) from a failure to integrate that information into a decision process.

The next step in the OODA model is Orientation, which puts Observations in context and presents integrative hypotheses for causation or explanation (e.g., diagnoses and social contexts). To quote Boyd, “orientation is an interactive process of many-sided implicit cross-referencing projections, empathies, correlations, and rejections that is shaped by and shapes the interplay of genetic heritage (!), cultural tradition, previous experiences, and unfolding circumstances.” A frequent cause of decision-making error in complex, evolving environments is cognitive tunneling, which is a form of “expectancy-driven” thinking bias. (31) An explicit goal of the orientation step is the prevention of this mental tunnel vision and the mitigation of confirmation bias—that is, an excessive, self-convincing focus on a few details thought to be pertinent. Orientation includes noting which observations are missing and which are unexplained.

Boyd stressed iterative re-orientation as an essential means to correct oneself from perceptual “mismatches” with reality, as it “unfold[s] in an irregular, disorderly, unpredictable manner.” (32) This effortful act of sense making (33) would call upon the physician to apply the wholeness of his or her being, including his or her previous experience and innate talents, medico-ethical heritage, a holistic contextual view of his patient, and even his or her feelings in addition relevant guidelines and resources available in the environment in order to integrate across observations and problems to create a synthesis on the current patient state. Orientation might include updating probabilities of different potential diseases in the differential diagnosis. It could also include an assessment of the effects of treatment, but should always include the non-medical context of care. Problem list generation and, perhaps more importantly, problem list maintenance, are part of the Orientation step.

Endsley (a contemporary of Boyd, whose work includes best practices for safety in aircraft cockpit environments and has been adopted by medical safety researchers) expanded the initial concepts underlying the OODA Loop by proposing that situational awareness should include projection (prediction) of the effects of both action and inaction. (25, 34) In current documentation practices, providers rarely predict what will happen if they do nothing or expected the effects of a prescribed treatment. This is critical for subsequent comparison to observed
effects to ascertain if the cognitive model of the provider is correct. For example, predicting the effect of prescription of a blood pressure medicine (e.g., drop in systolic blood pressure of 10 mm/hg by the next visit, a decrease in potassium of 0.2 ug/mL after infusion, or an increase in uric acid concentration of 0.5 ug/mL). Documentation of the expected effect of actions (and non-actions) is important in assessing the correctness of decisions and the adequacy of actions. Understanding of the gap between predictions and observations is critical to learning from experience. To echo Boyd, who also made projection a major theme of his work, if your predictions were incorrect, your earlier observations (perceptions) or orientation (integration of information) were mismatched with reality. One must –(re) observe and (re) orient, quickly until predictions match reality. Or, in other words, one must learn.

The third step in the OODA model is to make and record decisions. Decisions include both interpretations of observations through the lens of orientating (e.g., diagnoses) and risk-benefit trade-offs that underlie Actions. Decisions, like Observations and Orienting hypotheses, should be time stamped. (3) Analyzing the effect of decisions provides the opportunity to assess and refine decision-making skills—to allow trainees to learn from their experiences and to see, potentially, what others decided to do in similar circumstances. Quality control efforts could benefit from individual and team performance reviews of decisions made during episodes of care. Tracing longitudinal decision pathways permits individual and team reflection and learning. It may also facilitate the identification of novel approaches, which could be leveraged across a healthcare organization in pertinent care settings, or inform guideline improvement efforts. For example, natural language process approaches might be applied to identify all the decision points in a case and bring those together for review. In SOAP formatted notes, medical decisions are often implicit in documentation, embedded in Assessments and Plans; there is no easy way to call these out of a health record and re-examine a provider’s reasoning vis-à-vis the state of evidence at any particular time and his or her rationale for decision making.

Advanced versions of OODA include implicit guidance and control operations as an alternative to explicit decision-making. In note writing and clinical care, this might take the form of instructions for “what if” cases that are expected. For example, a standing order for use of acetaminophen with a fever over 39 C, followed by obtaining a blood culture. These bits of “compiled” knowledge of how to respond to a patient’s illness shorten the time to implementation of orientating insights and potential enable quicker control of progression of disease.

The final element in an OODA cycle is to specify Actions. The OODA framework specifies Actions rather than the SOAP note’s Plans: this is because it is one thing to plan and another to act. While the difference is semantics to some degree (Webster’s defines a “plan” as “a detailed formulation of a program of action”), specifying actions removes ambiguity. For example, a list of actions might clarify which team members have responsibility for execution of the different actions that comprise “the plan” (including the patient). Action specifications should include predictions of their effects, potentially aided by predictive analytics models. Observations in subsequent cycles should address the effectiveness of implementation of proposed actions.

The OODA Loop has the advantage of being applied in a cyclic fashion, clarifying thinking over time, with the most recent Observations challenging Predictions and Actions from the previous period. Iterative diagnostic reasoning helps prevent errors by encouraging the review of assumptions of prior decisions and aiding to assess the degree to which the operational model fits observed effects. (35) A failure to reconsider initial diagnosis in the face of mounting evidence supporting an alternative is a frequent cause of error. (36) The Decide step, in a temporal frame, allows revisiting of the choice, model, and actions, and a reconsideration of assumptions. In contrast to SOAP, OODA prompts the documenter to refine his or her thinking based on how prior actions correspond to current observations. (See Figure 1.) It prompts the note writer to contemplate, “What was I thinking yesterday and was it correct? How should I think differently today? What is important to focus on at this juncture? What is relevant? What warrants action? What will happen if I do nothing?” (37) While the OODA cycle includes prediction in two of the steps, we would argue that prediction is not an independent action. Rather one cannot/should not complete the tasks of Orientation or Action selection without the context provided by a prediction of the outcomes of inaction and action.
As clinicians increasingly “cut and paste” content from prior patient encounters into notes, (38) the decision support opportunities provided by note writing are in jeopardy. It is time we (once again) recognize note writing as a cognitive task that helps clinicians think better and thereby avoid errors. But, in order to better reflect what we know about clinical cognition after 50 years, perhaps it is time to advance the mindset that guides notes. There is probably not a single cognitive frame that is valid for all types of notes. The cognitive frame of note writing should match the predominant task in management of the patient. The POMR/SOAP format is well adapted to the initial medical encounter. In an initial evaluation of a patient, the sequential evaluation of symptoms, signs and evidence to formulate a differential diagnosis may be the most important task. Further, a reductionist approach, focused on identifying specific problems and solutions, may be highly adaptive. But, in the subsequent management of patients, particularly in dynamic environments or the ongoing management of patient conditions, it may be more important for the cognitive frame of the note to aid the author in maintaining situational awareness, and in detecting change and errors in diagnosis. In this setting, integrating lessons from OODA-style thinking may be preferable. An OODA-style note would also improve communications by explicitly documenting a clinician’s reasoning and decisions, much of which is not transparent in SOAP notes.

What would an OODA note look like in an electronic medical records system? To better understand this, working with a student in my laboratory, we adapted from the initial visit of a patient with colorectal cancer to the OODA format. In Figure 2a is the description of the patient visit in a more traditional SOAP and problem oriented format. Figure 2b is the description in the OODA format. The OODA note is not comprehensive in order to illustrate its differences.

While the first note focused on the process of coming to the diagnosis of colorectal cancer and the evidence for an against this diagnosis, the OODA equivalent focused more on developing an action plan that both executable and acceptable to that patient. The consequences of inaction are also made explicit. The OODA note is more conceptual and combines subjective and objective data elements in one category and orientating information that places the patient in a human context. The explicit predictions with and without treatment help assess both the
correctness of the diagnosis and the impact of care. In a SOAP note, it is relatively easy for the note to focus the note on the disease (colorectal cancer) rather than the patient. The note, a documentation of the findings of the physician, goes into great detail on the history suggestive of cancer, the findings that confirmed it, and emphasized the amount of time it took for the physician to perform the careful history and examination required to make the diagnosis. It is an excellent logbook entry (15) of the care of this patient. But, beyond careful documentation, what did does the log do? In this case, the diagnosis was virtually certain (and would be absolutely certain with obvious diagnostic tests.) What was uncertain that needed to be managed? It was the patient’s response to learning the diagnosis and the plan for controlling his symptoms. OODA may help focus documentation and as a result clinical thinking on the uncertain—on the parts of care that are not obvious—that need attention and future care. The differences are illustrative and should not be considered the target for OODA implementation rather than the definitive instance.

**Subjective** - A 65 year old male presenting to address the following issue(s):
Patient presents with a 2 month history of weight loss, blood in stool, and diarrhea. Also has moderate to severe LLQ pain for which he is taking very large amounts of acetaminophen (3-4 grams per day) and had been taking excessive amounts of naproxen (750 mg BID). Pain is in the LLQ and RLQ. Keeps him up at night in addition to diarrhea. Was using some sort of fiber-bulking agent colon “cleaner” for about 2 months (March to April) prior to onset of diarrhea.

**Problem 1: Loss of Weight**
Eating a regular diet with good appetite but has had diarrhea and a 20 lb. weight loss over the past 3 months. Easts everything without pain or discomfort. No fever chills or night sweats. Moderate LLQ and some RLQ pain, mostly at night.

**Problem 2: Blood in Stool**
Ongoing over past several months. Small amounts of blood in stool. No bleeding between bowel movements.

**Problem 3: Chronic Diarrhea**
Floating smelling stools with blood on occasion 4 to 20 times per day without fever or chills

**Past medical history**
No problems

**Family history**
Father with brain tumor
Brother with some sort of heart trouble

**Medications**
OTC naprosyn and tylenol for pain as described

**Social History Narrative**
- Married
- Smokes between 5 and 20 cigarettes per day
- No alcohol or other substances
- Delayed access to care until he was eligible for Medicare despite symptoms because of costs/lack of insurance

**Review of Systems**
Constitutional: Positive for fatigue and unexpected weight change.
Gastrointestinal: Positive for abdominal pain, diarrhea, blood in stool, anal bleeding and rectal pain.
Musculoskeletal: Positive for back pain
Skin: Positive for rash
Psychiatric/Behavioral: Positive for sleep disturbance.

**Objective**
BP 106/65 | Pulse 77 | Temp 98.4°F | Resp 16 | Ht 5’11” | Wt 146 lb 14.4 oz | BMI 20.49 kg/m2 | SpO2 92%
Constitutional: He is oriented to person, place, and time. No distress observed. Thin white male.

Normal HEENT examination
Normal Pulmonary examination
Normal Cardiovascular examination except for S4
Normal Abdominal examination, including liver and spleen size
Genitourinary: Penis normal. Gualac positive stool. Rectal:
Exophytic hardish rough mass about 3 cm beyond anus. Felt like it was very prominent and at least 2X2 cm. Very painful to touch (deep pain).
Unable to get around for complete rectal exam. Opposite wall smooth and without lesion. Unable to palpate prostate due to mass. Pink tinged heme positive fluid on glove after exam
Lymphadenopathy: Right side:
inguinal adenopathy present. No supraclavicular and no epitrochlear adenopathy present. Left side: inguinal adenopathy present. No supraclavicular and no epitrochlear adenopathy present. Small shotty nodes.
Extremity examination: Normal
Neurological examination: Normal

**Assessment/Plan**
Rectal mass: rule out rectal carcinoma
Chronic diarrhea/to infection
Weight loss due to malignancy or malabsorption
CT scan with contrast of abdomen and pelvis
Hydrocortone for pain, diarrhea-caution about maximum safe dose of acetaminophen
Labs: CBC, Chemistries, LFT’s, PT, stool culture, UA
Referral to colorectal surgeons to evaluate patient
Follow-up on Friday

Figure 2a. Description of an initial visit of a patient with colorectal cancer in the traditional format.
Other Medical Applications of OODA documentation

In addition to using OODA as a documentation template, there are many other potential applications that could take data from an OODA framework and make it more available to clinicians. If data in OODA format were coded and if appropriate meta data were available, then it might be possible to re-present notes created in the OODA format in the more traditional SOAP format. In fact, there is probably not a strong reason to align note creation frameworks supporting cognition with the framework used for display for a viewer. Informatics tools could allow readers to view notes in the templates most aligned to their own thinking using metadata to order and organize the display.

OODA may be an important tool in medical education. Notes labeled in an OODA format allows a different type of chart review of a case more akin to “replay” of the clinical state of thinking. At each point where a decision was recorded, the learner could review the observed data, the orientations of the decision maker, the projects and the decisions. In current EHRs, review of a case occurs primarily through the retrospective lens of the discharge summary. While many authors write discharge summaries as historical records or “captain’s logs”, this is probably not the highest use of these documents, which should be focused on care coordination post discharge.(15) The ability to record decision points and to review decisions over time might be one of the most important advances afforded by OODA approaches.

OODA may also have a roll in coordinating care across disciplines. One way it could do this is by providing an interdisciplinary “blackboard” for recording observations, orienting facts and hypotheses, decisions, and actions that are transdisciplinary. One reason that physicians, nurses and other providers might not view each others documentation as often as they should (1), might be the orientation of that documentation around SOAP models targeted at diagnosis specific to their own discipline. Medicine (and even subspecialties of medicine), nursing, dentistry and other disciplines all make diagnoses of that often may be of limited relevance to other disciplines. But what if as each discipline were writing their note, they could mark up observations, orientations, etc. as being important for the

Figure 2b. Same note in OODA format.
situational awareness of other providers. This might not take re-entry of data—rather in a coded data environment, one might mark up a fact for sharing. The OODA model might be very good for organizing data sharing as a neutral framework. A transdisciplinary blackboard might also allow providers to identify facts that are unexplained or request help from other disciplines in confirming predictions.

Conclusions

While the SOAP model has served practitioners well for over 50 years, the nature of the tasks that physicians perform has evolved over that time, its limitations are well known. The purpose of this article is to introduce OODA, a tested cognitive framework that has potential lessons for how doctors should write notes to improve the clarity of their thinking and to make their reasoning more transparent so that the writer and subsequent readers of notes can learn from care. OODA reflects the evolution of SOAP over time but also introduces new concepts related to temporality and explicit decision cycles for clinical care. This paper does not address the issues of how to link OODA notes together or the potential medical-legal issues of having every decision open for review in a medical record. These are complex issues; however, pragmatic issues, should not be allowed to thwart strategies to improve patient care. Small improvements in cognitive aids for note writing used many times a day by hundreds of thousands of physicians might have large impacts. Research is needed to identify the optimal framework for cognitive support during note writing. OODA is an example of a proven framework that may have important implications for medicine and which could potentially serve as a replacement for SOAP.

Abstract

Predictive analytics can provide valuable support to the effective management of pathology facilities. The introduction of new tests and technologies in anatomical pathology will increase the volume of specimens to be processed, as well as the complexity of pathology processes. In order for predictive analytics to address managerial challenges associated with the volume and complexity increases, it is important to pinpoint the areas where pathology managers would most benefit from predictive capabilities. We illustrate common issues in managing pathology facilities with an analysis of the surgical specimen process at the Department of Pathology and Laboratory Medicine (DPLM) at The Ottawa Hospital, which processes all surgical specimens for the Eastern Ontario Regional Laboratory Association. We then show how predictive analytics could be used to support management. Our proposed approach can be generalized beyond the DPLM, contributing to a more effective management of pathology facilities and in turn to quicker clinical diagnoses.

Introduction

The introduction of new tests and technologies in anatomical pathology is bringing at once new opportunities and challenges for diagnostic pathologists. For example, the onset of personalized medicine requires that new methods for the detection of oncogenic pathways in tumors be integrated in routine diagnostic pathology [1]. This shows an increasingly important role for pathology in management of surgical patients; however, it also implies a much higher volume of surgical specimen to be diagnosed, along with pathology processes more complex than what is currently the norm in pathology facilities. Given that timely pathology diagnostics are required to provide optimal patient management, changes in terms of the clinical complexity of pathology processes create challenges at the managerial level. Indeed, clinical and operations managers of these facilities need to ensure that pathology processes continue to run safely, efficiently and effectively despite their growing size and complexity.

The use of advanced information technologies and analytics in pathology – otherwise known as pathology informatics – has grown in response to these challenges [2]. In healthcare, predictive analytics have now matured sufficiently to be used in addressing major issues, such as preventing early post-discharge readmissions, facilitating patient engagement, and detecting insurance and billing fraud [3]. These techniques now extend visual analytics systems such as dashboards that allow users to access relevant data through graphical and tabular displays, drill down in the data and form hypothesis about root causes. However, dashboards often lack the capability of predicting events [4]. In this paper, we discuss how advanced predictive analytics can be integrated at key points in pathology processes in order to facilitate workload, throughput planning, and intervention by managers of pathology facilities. For the purpose of this paper, we define predictive analytics rather broadly as a set of techniques such as data mining, statistics, modeling, and machine learning to analyze current data and make predictions about future events. In that sense, we accept that predictive analytics is based on a fundamental assumption that patterns observed in the past are sufficiently stable for predicting future behavior. While this assumption is sometimes contested, its limitations can be mitigated by creating predictive models that can adjust to changes in past patterns through a feedback loop. However, it is important to stress that despite these limitations, the use of predictive analytics in healthcare is being recognized as a reliable approach to improving outcomes, enhancing patients’ experience, and reducing the costs of delivery of health services [5].

We illustrate the potential contributions of predictive analytics using the problem and solution domains at the Department of Pathology and Laboratory Medicine (DPLM) at The Ottawa Hospital (TOH), Ottawa, Ontario,
Canada. TOH is a teaching hospital affiliated with the University of Ottawa. The DPML houses grossing, histology and cytology laboratories, and processes all pathology specimens for the Eastern Ontario Regional Laboratory Association (EORLA), a newly established association of all the laboratory and pathology departments of Eastern Ontario that currently includes facilities from eight hospitals in the region. The rapid growth of volume of surgical and cytology specimens resulting from this centralized structure has created many challenges in insuring smooth workflow and processing of cases and diagnostic reports in a timely fashion. A number of research projects are underway to address these challenges and provide solutions that support decision-making for managers of the DPML, including the development of optimized pathologists’ scheduling models [6], a real-time visual dashboard tracking the inventory to be processed by the DPML [7], and predictive analytics algorithms for workload and throughput planning. We focus here on the latter.

The remainder of the paper is organized as follows. First, we describe the pathology processes currently implemented at the DPML, and identify three key points within the surgical specimen process workflow where predictive analytics would generate the greatest benefits. We then present the systems architecture currently in place at the DPML, and situate the use of predictive analytics within this architecture. We elaborate on the use of predictive analytics that is the most appropriate for each point within the specimen process flow. We conclude with future work and contributions.

Pathology processes at the DPML

We briefly present the pathology process for surgical specimens implemented at the DPML at TOH. The process revolves around pathology-specific entities being managed at the DPML: cases, specimens, blocks, and slides. A case groups all specimens received from one patient-physician encounter. A specimen is one or more tissue fragments removed from an organ or specific site. A block is a container of one or multiple tissue fragments from the same specimen. A slide is a thin slice of tissue cut from the block and stained with a specific set of reagents. These elements thus form a hierarchy of the inventory to be processed by the DPML.

The first step in the DPML process is the accessioning of specimens, where specimens and clinical orders from physicians arrive and are given a uniquely identifying case code. Each specimen is also associated with a pathology subcode that determines how many blocks and slides will need to be created for this specimen. The second step is the grossing of specimens, where blocks are created from the tissue and automatically processed in a manner suitable for creating slides later on. In the third step, blocks are sent to the Histology laboratory, where each one is manually embedded in paraffin and then sliced and stained as required by the pathology subcode attached to it. In the fourth step, called dispatch, finished slides are checked to ensure that they are matched with the correct specimen and case. They are then organized by case and assigned to pathologists. The last step is the diagnosis, where pathologists receive complete cases to examine. During this diagnosis process, a pathologist may order additional slides or blocks. The process ends when the pathologist makes a definite diagnosis for a case and writes a report.

Figure 1 shows a simplified business process model developed for surgical specimens at the DPML. As can be seen in the model, the process requires interactions among four key entities (Grossing lab, Histology lab, Immuno lab, and Pathologist) in order to be completed. This is not a fully linear process, since requests for additional slides or tests can originate from pathologists when they start to interpret slides, preventing the diagnostic process to be completed until these requests have been fulfilled and quality controlled. Key challenges in ensuring the timely completion of diagnostic reports are (i) the variability in the amount and type of cases being received at any point in time; (ii) the optimal allocation of cases to individual pathologists given the variability in cases as well as the variability in their availability and sub-specialties; and (iii) the variability in levels of complexity across similar cases, which can only be ascertained once the diagnostic process has been initiated. These challenges highlight the potential benefits of predictive analytics at three specific point in the surgical specimen flow shown in Figure 1: predicting the number of cases and case types that will be received by the pathology facility, predicting the workload that will be generated from this volume, and predicting the actual diagnostic throughput of pathologists based on case volume and complexity.
The DPLM currently uses the commercial laboratory information system PowerPath® by Sunquest [8] to record and track individual cases. PowerJ, a dashboard application developed in-house, pulls data from this system in order to monitor key phases in pathology processes at the DPLM, namely: i) number of pending and grossed cases; ii) number of pending and cut blocks; and, iii) number of pending and routed slides. The application also records and presents individual pathologists’ workload, and overflow slides by sub-specialty. A business intelligence (BI) tool providing a fine-grained overview of the performance of the DPLM in terms of cases that are within or that exceed predetermined processing targets has been developed and is planned to be deployed in the near future. The latter combines data from PowerPath® with business rules that specify target processing times per specimen types and process steps. The BI tool supports monitoring, analysis, and reporting. It does not, however, offer the ability to predict future events. Therefore, a predictive analytics capability needs to provide this added level of support. Figure 2 relates these current and upcoming capabilities as a proposed system architecture for the DPLM.

**Current and upcoming information systems at the DPLM**

The DPLM currently uses the commercial laboratory information system PowerPath® by Sunquest [8] to record and track individual cases. Facilitating effective management in pathology through predictive analytics

The transition of pathology diagnosis into a context of digital pathology where slide analysis is conducted using computer-based tools represents a significant step forward in the pathological diagnosis process. This transition also creates new opportunities for the production, capture and use of large volumes of accurate data. In the DPLM, data capture is currently confined to selected stages of the process illustrated in Figure 1. Namely, data are collected at the start and completion of some, but not all, of the steps. With the advent of digital pathology, additional events can be captured, allowing for example to determine the amount of time a pathologist actually spends on each slide during the diagnosis step. Once laboratory information systems have been adapted to capture these new data, they can be leveraged to provide pathology facilities managers with a more accurate picture of their facilities’ operations. Our current project with the DPLM is designed to take advantage of such emerging opportunity.

The real-time use of operational data has the potential to increase the quality of diagnosis and to reduce the costs of the diagnostic process, contributing both to an increase in facility performance and effective management [9]. However, the contribution of pathology informatics to effective management has received less attention in the academic community; given the growing complexity of pathology processes and the resulting challenges to the management of pathology facilities, applying predictive analytics to support managerial decision-making is timely and relevant. This is the focus of this paper and we explain here the benefits of using predictive analytics at three key points within the DPLM surgical specimens process flow: predicting the number of incoming cases by type (and associated diagnostic complexity), predicting the workload of the pathologists, and finally predicting the throughput of the facility. Next, we describe our proposed solutions for each of these areas.
Predicting the number of incoming cases per type

The DPLM operates in a constantly changing and seemingly unpredictable environment. The arrival of surgical cases is driven by a surgical schedule, the allocation of operating room blocks to surgical specialties (thus determining types of the surgeries), and the complexity of patients’ cases. In most hospitals, there is a disconnect between the information infrastructure designed to support patient management and surgical services (patient registration, EHR, surgical information system) and the one supporting pathology services. Hence, pathologists and managers of pathology facilities are typically not aware of the surgeons’ schedules and changes to block scheduling of the surgeries. This situation makes it difficult to correctly allocate resources within a pathology facility, for example in terms of scheduling the optimal number of laboratory technicians on a given day.

In our research, a long-term objective is to address this disconnect by developing an application that will capture relevant data about surgeries and store this information in a relational database (bottom of Figure 2) to be accessible by the pathology BI tools. While this will give access to reliable data on the number of surgical cases to be processed on any given day, it will not give a complete understanding of the level of complexity of incoming cases. However, historical data about past surgeries and types of incoming cases will allow us to develop predictive models using statistical techniques. Namely, we will use case complexity as the dependent variable and develop logistic regression models to predict the behavior of this variable in the future. Simultaneously, we will be mining pathology data in order to develop associations between case complexity and pathology specific attributes such as number of slides, stains used, etc. In this stage of our work, we expect to rely on unsupervised data mining methods such as association rule learning [10].

Predicting pathologists’ workload

The need to measure workload in a pathology facility is critical for management in order for appropriate service levels to be maintained. The Canadian Association of Pathologists advocated an approach to workload measurement that is based on the L4E system [11]. The L4E system was developed from survey data collected from 27 pathology centres; the results suggest that a full-time pathologist working in a facility such as the DPLM should generate about 7560 L4E equivalents annually. While this measure can be used to evaluate individual pathologists’ performance, it is not very useful for predicting the workload of pathologists working in a teaching hospital; indeed, such predictions need to take into account their academic, teaching, research, and administrative responsibilities – which can account for up to 75% of their time -, as well as dimensions such as each pathologist’s sub-specialties and the impact of each case’s complexity on the time needed for diagnosis.

Our research thus takes a different approach; specifically, the association rules for case complexity used to process historical surgical will allow us to translate purely surgical information into data annotated with the complexity of pathological diagnosis. In turn, we will be able to use the annotated data as an input to a stochastic optimization model for predicting pathologists’ workload taking into account their availability, sub-specialties, prioritization of the cases, and sessional variations. Having such predictive power should allow managers of pathology facilities to better plan human resource allocation by sub-specialties, to develop flexible work schedules (including “floating” resources when available), and to prepare contingencies for unexpected events.

Predicting throughput

As Figure 1 shows, there are a number of potential bottlenecks in a pathology process, from the time cases are received to the time the pathology report is submitted. In order to help manage the process, and take full advantage of digital pathology, it is important to capture fine-grained data at each input and output point in each process step. This may however require a change in practices and equipment. For example, at the DPLM, data about each case, specimen, block, or slide is usually captured when the element arrives at a workstation, and at the time that the work is completed, but not necessarily at a fine-grained level. For example, when a pathologist receives slides to be interpreted for a case, data is captured at beginning of the step (by scanning one of the slide), and again at the end of the process, once the report is finalized; however, events such as interruptions do not generate data. Hence, data about the duration of some steps does not differentiate between active work and waiting time.

Capturing data at the times when an element leaves one station and moves to another would give more precise information from which to predict future throughput. Moreover, while processing times in some instances are fixed and cannot be really manipulated (thus act as fixed parameters), there are some that can be influenced by adding...
additional resources to processing. The resulting real time throughput prediction model could monitor the actual volume of cases that are in a process, that are waiting for processing, that are being diagnosed, or that are waiting for a diagnosis, hence representing a general performance measure for a pathology facility. Going beyond performance measurement, simulation models could simulate different strategies of dealing with changes in incoming cases and workload parameters, and be associated with the throughput prediction model. Once a model would detect deviation from predicted throughput (for a given context described as day of a month, etc.), it would automatically consult one of the scenarios and apply it (or present it to a manager) in order for the detected anomaly to be addressed.

Implementing the solution

Deployment of the proposed predictive analytics solution will be part of a multi-layer architecture that clearly separates data from a host of analytics tools, and user interface. The logical, hence application-neutral architecture is illustrated on Figure 2. The advantage of such a multi-layer architecture includes the ability to combine varied components, for example a hospital-wide data infrastructure in the data tier with a business intelligence application specifically developed for a pathology facility. While the proposed architecture can be implemented in a number of different (and customized) manners depending on the data infrastructure and suite of analytics solutions ultimately chosen, the DPLM implementation will involve using one of the industry predictive engines (such as those developed by IBM, SAS, or SAP). We are planning for the data tier to include stream data coming from, for example, laboratory information systems such as PowerPath® and historical pre-processed data, for example surgical block schedules updated occasionally. This tier will also include the association rules for determining case complexity and the business rules describing the processing of the specimens in case of the unexpected events (developed as a result of the simulation described earlier). Pragmatic issues regarding the integration of these data streams, for example variations in data structures, will have to be addressed.

Application and presentation tiers will act as an interface between data and end-users. The application tier will include a host of modeling services together with a set of BI applications. The presentation tier is where the reports, alerts, etc. are to be configured. We will use ontology-driven design to create a repository of presentation widgets for easier re-use and customization. Finally, a client tier will implement a web portal that will represent a “one point entry” to all the functions our system offers to the DPLM managers. Access to the portal will be governed by role-based principles, with different levels of granularity of information being accessible to different types of the end-users. We are currently working on finalizing the general architecture of the system, on identifying the relevant software tools, and on eliciting a final set of system requirements from different groups of potential end-users and other stakeholders.

Preliminary results of a user study conducted to evaluate a prototype of the business intelligence layer illustrated in Figure 2 shows that pathology managers find the proposed solution relevant to their work and plan to use the final system to support daily decision-making when it will be implemented in DPLM. Moreover, the preliminary version of the proposed solution had a positive impact on DPLM operations, allowing for example for more effective scheduling of pathology assistants and adjustments to pathologists’ schedules [7]. Given these positive results, it is expected that a fully implemented solution will increase managerial efficiency and effectiveness at the DPLM, allowing the facility to face new challenges in terms of the volume and complexity of cases to be processed.

Conclusion

At a time of growing complexity in pathology processes, it is of great importance that the management of pathology facilities be adequately supported in order to ensure that processing times and quality of provided services remain within acceptable standards. Indeed, unresolved managerial issues could trump the benefits of the new tests and technologies that are currently being introduced to support new patient management paradigms such as personalized medicine. In this paper, we have shown that predictive analytics could usefully be applied in a pathology facility to address issues of variability in case volume and complexity that make it difficult to adequately plan resource allocation over short and long time horizons. Specifically, we proposed the use of techniques such as logistic regression models, data mining, and simulation models to predict the amount of incoming cases per type, complexity, workload requirements, and facility throughput. These techniques could provide novel and timely solutions to the managers of pathology facilities beyond the DPLM, contributing to a quicker processing of pathology specimens and in turn of clinical diagnoses.

Comparing lagged linear correlation, lagged regression, Granger causality, and vector autoregression for uncovering associations in EHR data

Matthew E. Levine, BA1, David J. Albers, Ph.D.1, George Hripcsak, M.D., M.S.1
1Department of Biomedical Informatics, Columbia University, New York, New York, USA

Abstract

Time series analysis methods have been shown to reveal clinical and biological associations in data collected in the electronic health record. We wish to develop reliable high-throughput methods for identifying adverse drug effects that are easy to implement and produce readily interpretable results. To move toward this goal, we used univariate and multivariate lagged regression models to investigate associations between twenty pairs of drug orders and laboratory measurements. Multivariate lagged regression models exhibited higher sensitivity and specificity than univariate lagged regression in the 20 examples, and incorporating autoregressive terms for labs and drugs produced more robust signals in cases of known associations among the 20 example pairings. Moreover, including inpatient admission terms in the model attenuated the signals for some cases of unlikely associations, demonstrating how multivariate lagged regression models’ explicit handling of context-based variables can provide a simple way to probe for health-care processes that confound analyses of EHR data.

Introduction

With the increasing collection and storage of patient electronic health data around the world comes a proportionally growing impetus to use that information to improve clinical care. These improvements can range from workflow and operations optimization to pharmacovigilance studies, but the central feature for effectively exploiting the electronic health record (EHR) is our ability to learn from the data collected. We hope to move towards reliable high-throughput methods for determining adverse drug effects that can be applied to large clinical data repositories, like that collected by Observational Health Data Sciences and Informatics (OHDSI), which contains over 600 million patient records [1].

Many research inquiries can be satisfied with simple determinations of whether a patient ever had a particular condition, and it is often sufficient to consider events that occur over relevant time windows with respect to a condition of interest [2]. However, it can be useful to consider methods with the potential to reveal fine temporal structure in EHR data, and recent advances in such methods have been applied to machine-learning approaches during phenotyping [3,4], pattern discovery [5–7], temporal abstraction over intervals [8], and dynamic Bayesian networks [9].

Many of these approaches to time-series analysis rely on assumptions of stationarity (roughly, having consistent mean and variance through a time window of interest) that are frequently broken by clinical data—this is to be expected, even desired, since the primary goal of medicine is to drive patients from problematic to healthy states. This issue is compounded by the simple fact that patients are sampled with greater frequency when they are ill [10]. In fact, it appears that clinicians sample patients at rates proportional to their health variability, effectively inducing stationarity by indexing the time series not by clock-time, but rather by mere measurement sequence with single units of time imposed between each measurement [11].

Our past work has revealed informative results about temporal processes in the EHR by applying lagged linear correlation to time series constructed using linear temporal interpolation and intra-patient normalization of clinical signout note and laboratory test data [12]. These results indicated temporal processes that were definitional (e.g. low potassium levels associated with hypokalemia), physiologic (e.g. a potassium-sparing diuretic preceded increases in potassium levels), or intentional (e.g. a potassium-sparing diuretic was ordered in patients with low potassium levels), and used clock-time as the lagged time variable. Similarly, time-delayed mutual information reveal lagged linear structure as well as nonlinear dynamical processes related to physiology [13,14] despite EHR-data complexities and homo- or heterogeneity among patient populations [11,15–17].

Our most recent efforts to characterize temporal processes in the EHR are motivated by our previous findings that 1) temporal clinical and physiologic processes can be described through lagged linear correlation of concepts extracted from signout notes and laboratory values [12], 2) time series data, under some clinical circumstances, are better parameterized by their raw sequence than their clock measurements [11], and 3) health-care process events such as inpatient admission are systematically correlated with concepts and laboratory values [18].

779
In this study, we used multivariate distributed lag models to incorporate additional context-related variables in lagged linear analysis of temporal processes to better characterize both intended and unintended physiologic effects of drugs. In order to broaden the applicability of the method, we designed a time series preparation methodology that can use drug-order records as inputs, which are readily available in more contexts than physician notes. In order to evaluate these methods, we applied them to twenty pairings of drugs and laboratory measurements. As part of optimizing time series construction methods, we also investigated the effects of two pre-processing steps: intra-patient normalization of laboratory tests and different data preparation strategies.

Because our goal is to minimize bias and confounding, we employed two techniques to minimize bias. We used a particular form of lagged regression, known as Granger causality [19], to assess the effect of one variable (drug) over another (laboratory measurement) beyond that accounted for by the target variable’s autocorrelation. We used an extension of Granger causality, vector autoregression [20], to also account for a third variable (inpatient admission) as an example of a health care process confounder.

Methods

Experimental design

We used the 27-year-old clinical data warehouse at NewYork-Presbyterian Hospital, which contains electronic health records for over 3 million patients, to examine pairwise relationships between drug order records and laboratory measurements. We considered five drugs—simvastatin, amphotericin B, spironolactone, and warfarin—and four laboratory tests (total creatine kinase (CK), creatinine, potassium, and hemoglobin), and a patient cohort was identified for each of the 20 drug-lab pairs in the experiment. We identified eight drug-lab pairs for which clinical evidence suggested significant physiologic associations (shown in Table 1); we did not find conclusive evidence for associations between the remaining 12 drug-lab pairs. Patients were included in a drug-lab cohort if they met the following criteria: 1) at least 2 of the laboratory measurements of interest on record, 2) at least 1 order for the drug of interest, and 3) more than 30 combined data points between laboratory measurements of interest and total drug orders (any drug). No attempts were made to remove or correct outliers.

Building a time series from clinical data

Laboratory measurements, drug orders, and inpatient admission events for each patient in each cohort were extracted from the clinical data warehouse. A piecewise-defined linear drug-lab timeline was constructed for each patient as described by Hripcsak et al. using linear temporal interpolation (see Figure 1 in Hripcsak et al. for an example) [12]. Laboratory values were continuous, and orders for the drug of interest were represented as 1 (present), whereas orders for other drugs were represented as 0 (absent). Although orders for other drugs do not necessarily indicate cessation of a drug of interest, such orders were treated as evidence of absence to avoid incorporating external domain knowledge about drug administration that might produce artifact associations. Inpatient admission timelines were defined with a 1 at the time of admission, and zeros at 24hrs before and after admission, effectively creating spikes at times of admission. Smoothness and differentiability of the admission spike are unimportant when using discretized convolutional approaches, and there are many ways of constructing the spike such that it has mass to contribute during the convolution. For every time point where there was a concept (lab, drug, or inpatient admission), the values of each other variable at that time point were interpolated as the clock-time weighted mean of the preceding and succeeding value of each respective variable (or as the closest measurement if there was no value on one side). Clock-time weighting is computed by weighting the 2 bordering values by their temporal distances from the time-point at which we interpolate. Thus, all concepts, whether from categorical or real-valued sources, took on rational values that were paired at each time point. Because each time-point typically has only 1 reported event, each time-tuple is comprised of 1 true data point and 2 interpolated values.

Pre-processing of time series data

Two types of pre-processing of interpolated time series were designed and evaluated. First, each patient’s time series of laboratory values were normalized to have 0 mean and 1 variance by subtracting the mean and dividing by standard deviation [12]. This operation removed inter-patient effects. Second, we replaced each interpolated value in the time series with its difference from the immediately preceding interpolated value, such that time series values represented changes in values. This was an important means of reducing dependence between lagged variables in our novel application of multivariate lagged regression models to interpolated clinical data. As such, we effectively considered 4 time series construction methods—1) no pre-processing, 2) intra-patient normalization, 3) differences, and 4) normalization and differences.
**Sequence time**

Although clock-time was used for weighted interpolations and pre-processing steps, it was discarded in favor of raw sequence time for subsequent lagged linear analyses due to recent examples that demonstrated greater information and greater stationarity in clinical time series data that are parameterized by their sequence [11]. Real-time may prove to be a more sensible choice in other circumstances, especially when data is stationary. All time intervals between interpolated, pre-processed values were set to unit 1 length, effectively converting from clock-time to sequence time.

**Univariate lagged linear regression (ULLR)**

We compute lagged linear regression coefficients, $\beta_\tau$, for the following distributed lag model [20], where $y_t$ represents a laboratory value at sequence time $t$ and $x$ represents the interpolated drug value at time $t-\tau$. This model performs the same computations as our previous lagged linear correlation experiment [12], but supplies a different statistic, namely the lagged drug coefficient $\beta_\tau$.

$$y_t = c + \beta_\tau x_{t-\tau} + \epsilon_\tau$$  

(1)

**Multivariate lagged regression (MLLR)**

We aim to leverage the relationship between the context of each data point and the variables they predict by including context-dependent factors in multivariate autoregressive models. In general, a multivariate distributed lag model for $L$ lags and $N$ variables (for which the $i^{th}$ variable is denoted $u_i$), can be used to define the lagged coefficient for each variable $u_i$ at each lag $\tau$ (denoted as $\beta_{u_i,\tau}$), and is written as [20]

$$y_t = c + \sum_{i=1}^{N} \sum_{\tau=1}^{L} \beta_{u_i,\tau} u_{t-\tau}^i + \epsilon$$  

(2)

where $\beta_{u_i,\tau}$ is the coefficient for lag $\tau$ of the variable $u_i$. Because the parameters of these models are estimated jointly, adding explanatory variables that are related to both the predicted variables and variables of interest can change the values of coefficients of interest. Concretely, we considered a simple multivariate lagged regression that only incorporates lagged drug values, and jointly estimates all lagged drug coefficients $\beta_\tau$, with $L=30$, according to the following model, which we refer to as the “multivariate lagged drug model”

$$y_t = c + \sum_{\tau=1}^{L} \beta_\tau x_{t-\tau} + \epsilon$$  

(3)

We then evaluated how adding lagged terms to represent previous laboratory values affects drug coefficients by fitting the following “autoregressive drug and lab” model with $L=30$; this is in the form of Granger causality [19].

$$y_t = c + \sum_{\tau=1}^{L} \beta_{y,\tau} y_{t-\tau} + \sum_{\tau=1}^{L} \beta_{x,\tau} x_{t-\tau} + \epsilon$$  

(4)

We also introduce an additional context variable, $z$, to represent the inpatient admission timeline, and fit a further augmented “autoregressive drug, lab, and context” model with $L=30$; this is in the form of vector autoregression [20].

$$y_t = c + \sum_{\tau=1}^{L} \beta_{y,\tau} y_{t-\tau} + \sum_{\tau=1}^{L} \beta_{x,\tau} x_{t-\tau} + \sum_{\tau=1}^{L} \beta_{z,\tau} z_{t-\tau} + \epsilon$$  

(5)

Intuitively, this model uses the last 30 interpolated laboratory values, the last 30 interpolated drug values, and the last 30 interpolated admission values from the constructed time series to predict a present measurement. This alignment of previous data is performed for each laboratory measurement, and is aggregated within each patient, then across patients, creating a matrix with 91 columns (90 explanatory values and 1 predicted value) and a length equivalent to the number of qualifying laboratory measurements in the cohort. We did not perform any feature selection procedures, such as Bayesian information criterion, as this was out of the scope of our case study for...
method comparison—employing such selection criteria is a key step in determining true Granger causality, which we did not attempt.

Bootstrap

After cohort identification, timeline construction, and pre-processing, we aggregated pairs of lagged interpolated values across patients to construct a sparse model matrix for each drug-lab pair that conformed to the specified dimensionality of each model. Coefficients for each model were estimated by performing sparse linear least squares regression with Cholesky factorization from the MatrixModels package in R [21]. One hundred iterations of a bootstrap were performed for each matrix by sampling patients with replacement [22] in order to obtain empirical estimates of statistical significance. Coefficient estimates were labeled as statistically significant if zero was not included in their 95% Confidence Interval (CI) as computed by the bootstrap, which was defined as

\[
\left( \mathbb{E}[^\beta] - 1.96 \sqrt{\text{var}(\beta)}, \mathbb{E}[^\beta] + 1.96 \sqrt{\text{var}(\beta)} \right)
\]

In our evaluation, we focus on the estimates of lagged drug coefficients, and evaluate the effect of additional variables not by examining their coefficients directly, but rather by evaluating how their presence affected the drug coefficients.

Results

Intra-patient normalization in univariate lagged linear regression

Univariate lagged linear regression (ULLR) with intra-patient normalization was performed for each of the 20 drug-lab pairs of interest, eight of which we hypothesized, based on clinical literature, to have a significant directional (i.e. increasing or decreasing) effect. The number of significantly positive and negative lagged drug coefficients are compared with results that could be expected from the literature in Table 1. Analysis of normalized data with ULLR detected 4 out of 8 expected signals correctly with appropriate directionality (3 positive relationships and 1 negative), and reported all other cases to have statistically significant relationships. While this demonstrates real statistical correlations between variables, it does not necessarily implicate a physiologic association. The many biases in EHR data can be misleading when drawing statistical conclusions, so it is important to find ways of systematically focusing the analysis to reveal only the effects of interest—in this case, ones rooted in physiology.

In Figure 1, we show that univariate LLR analysis of normalized data reveals clinically characterized trends, such as amphotericin B’s tendency to decrease potassium levels and increase creatinine. It shows an overall trend linking spironolactone to increases in creatinine levels (a known phenomenon), but also finds a statistically significant negative relationship at lag of 1 in sequence time. Figure 1 also indicates a significant association between simvastatin and increases in hemoglobin levels, for which we do not have a particular biological interpretation. This result is characteristic of the significant signals detected by ULLR in the 12 drug-lab pairs for which we did not expect a physiologic association. The many biases in EHR data can be misleading when drawing statistical conclusions, so it is important to find ways of systematically focusing the analysis to reveal only the effects of interest—in this case, ones rooted in physiology.

In Figure 1, we show that univariate LLR analysis of normalized data reveals clinically characterized trends, such as amphotericin B’s tendency to decrease potassium levels and increase creatinine. It shows an overall trend linking spironolactone to increases in creatinine levels (a known phenomenon), but also finds a statistically significant negative relationship at lag of 1 in sequence time. Figure 1 also indicates a significant association between simvastatin and increases in hemoglobin levels, for which we do not have a particular biological interpretation. This result is characteristic of the significant signals detected by ULLR in the 12 drug-lab pairs for which we did not expect a physiologic association. These results suggest that univariate LLR analysis, like other analytic approaches to clinical data, is vulnerable to health-care process effects in EHR data. For example, the short-term negative relationship of spironolactone and could be attributed to a treatment pattern in which patients first prescribed the drug are likely to be sick (possibly with high creatinine) and subsequently improve due to treatment. Creatinine elevation due to the drug, then, would be on a longer time scale than creatinine-lowering treatments. Table 1 shows that the multivariate models remove this effect, likely by jointly considering previous orders of the drug.
Adding autoregressive terms: multivariate lagged linear regression

We adopted a multivariate LLR model in order to address the confounding effects of health care process when tasked with detecting true physiologic effects of drugs. We first considered a model that estimates all lagged drug coefficients jointly (equation 3, “multivariate lagged drug model”) with the intent of incorporating drug timeline history into each prediction. We also evaluated an augmented version of this model that adds autoregressive terms of previous laboratory values as well as drug orders (equation 4, “autoregressive drug and lab model”)—this formulation is very similar to the autoregressive model used in Granger causality, although we do not perform model selection to choose the number of lags, nor do we address potential unit root issues as is typical in Granger causal analysis [19]. We used intra-patient normalization and applied the differences pre-processing step described earlier (replacing values of the time series with their difference from the previous value) in all multivariate LLR analyses to reduce dependence between interpolated values (independence of lagged variables is an important requirement in multiple regression).

The multivariate lagged drug model showed statistically significant relationships with correct directionality between 6 of the 8 drug-lab pairs with known biological activity and rejected 3 of the 12 uncharacterized pairings. The autoregressive model of drug and lab histories detected the same 6 of the 8 known pairs, and also rejected 3 uncharacterized pairings. Moreover, in cases of true associations, drug and lab autoregression revealed, on average, more significant coefficients with greater magnitude. This finding suggests that the multivariate drug and lab model will have better sensitivity than the lagged drug model without sacrificing specificity.

Figure 2 shows how univariate LLR, multivariate LLR with drugs, and multivariate LLR with drugs and labs describe two cases: 1) ibuprofen predicting creatinine levels, and 2) simvastatin predicting changes in hemoglobin. It is known that ibuprofen can cause acute renal failure, for which high creatinine is a common symptom, and indeed we see that multivariate LLR (and not ULLR) predicts the correct directionality of the effect, with larger and more significant coefficients produced when using autoregressive terms of lab and drug values. An effect of simvastatin on hemoglobin levels, however, was not supported by evidence from our literature search, suggesting that apparent effects are attributable to non-biological phenomena. Figure 2b shows that the MLLR drug model predicts a significant negative effect, whereas the lab and drug model indicates no significant relationships. This implies that previous hemoglobin measurements helped to explain future drops in hemoglobin (i.e. this model may account for the number of anemic patients on simvastatin). The univariate model, however, showed a positive effect during early time points, indicating something more likely related to health care processes that were accounted for by the multivariate models through joint parameter estimation.

The performance of multivariate LLR methods was dependent on both intra-patient normalization and taking differences of the time series data sets. Omitting both pre-processing steps resulted in 0 correctly identified signals for the drug-only model, and 1 correctly identified signal for the drug and lab model. Using normalization without differences allowed the drug and lab model to detect 1 additional signal (2 in total), while using differences without normalization restored performance closer to levels seen with both pre-processing steps. The drug-only model detected the same 6 of 8 hypothesized drug-lab pairs, and had 10 apparent false positives. The lab and drug model significantly underperformed without both differences and normalization, detecting half the number of expected associations when used without normalization.

Furthermore, the combination of normalization and differences yielded more robust signals. Figure 3 illustrates that the combination of both pre-processing steps produces the most robust signal for predicting creatinine elevation by
amphotericin B, as measured by the number and magnitude of correctly oriented significant coefficients. In this, example both differences and normalization are required to identify a positive signal with confidence.

**Adding context-related variables to multivariate lagged linear regression**

We evaluated lagged drug coefficients for a multivariate autoregressive model that incorporates patients’ admission timelines as well as drug and lab measurement histories for all 20 drug-lab pairs using intra-patient normalized time series of differences. This allowed us to consider the extent to which contextual information, like inpatient admission, can recalibrate estimated effects of drugs on physiologic measurements. Using this method, we detected the same 6 known drug effects that were captured using the autoregressive drug and lab model. Little difference was seen in number or magnitude of significant drug coefficients between the autoregressive drug and lab model and the context model in cases of expected physiologic drug effects. However, the context model did produce significantly different results for some of the uncharacterized drug-lab pairs.

Figure 4a demonstrates that autoregressive context terms “explain away” the effect of simvastatin on creatinine, potassium, and hemoglobin (hemoglobin has only 1 significant coefficient in the context model) by adjusting the lagged drug coefficients to insignificant quantities, while keeping intact simvastatin’s propensity to increase Total CK via muscle damage. Figure 4b shows that admission does not, however, contribute additional information toward studying the effect of ibuprofen on the four considered lab tests. This result is striking, and suggests that inpatient admission is an important confounding variable to consider when analyzing temporal effects of simvastatin, but is largely unimportant for analyzing the effects of ibuprofen. While the significant relationships for ibuprofen may in fact be legitimate, it is equally possible that they are explained away by other process-related context variables.

**Discussion**

By developing a method for constructing time series of continuous and categorical variables, we were able to compare univariate and multivariate lagged regression models that incorporate lab measurements, drug orders, and inpatient admissions. All lagged methods showed highest specificity and sensitivity, overall, with intra-patient normalized laboratory values, and multivariate methods performed best in these metrics when differences were used during pre-processing stages. All multivariate methods identified the same six physiologic effects documented in clinical literature. Adding variables that describe patient context (lagged lab measurements and lagged admission events) increased the number and magnitude of significant drug coefficients in the expected cases and improved discrimination against unlikely
associations. We found that adding context-based variables to autoregressive models allowed for explicit handling of confounding variables and provided a simple way to evaluate the temporal effects of ordered drugs on physiology.

It is useful to note that the inpatient admission variables did not affect drug coefficients for warfarin or ibuprofen for most labs. This simply indicates that there is little correlation between admission, the drug, and each lab that cannot be explained by the drugs and labs alone. In this study, we are not interested in confounder coefficient magnitude or their relative explanatory contributions—rather, we are looking for the co-linearities that eliminate or enable rightfully significant drug coefficients (i.e. explaining away). Adding context-variables to autoregressive models appears to be a simple way to probe for confounders in EHR data without biasing the analysis. Selecting other possible confounders, like surgery, is a worthwhile exercise in better explaining the trends we observed with little physiologic interpretation. However, adding multiple new variables effectively adds new time points for interpolation in the time series, making each lag represent less average clock-time. It is unclear how many variables can be included in the timeline construction without detrimental distortion of results.

It is difficult to discuss the detected positive associations that are not reported in clinical literature. On one hand, data from the EHR are liable to bias, and confounders can only be accounted for explicitly in our formulation. On the other hand, subtle drug effects are likely to be unstudied, yet omnipresent in medical practice. For this reason, we do not formally compute specificity or sensitivity metrics. We were also unable to detect drops in hemoglobin to implicate ibuprofen and warfarin in bleeding events. Our results suggested that warfarin and ibuprofen increase hemoglobin levels, which contradicts strong clinical evidence that they are causative agents of intestinal bleeding as defined by low hemoglobin levels [23]. It may be that physicians are very careful to maintain normal or even high hemoglobin levels when concerned about bleeding. This is an open question that merits further investigation, and we hypothesize that introducing relevant context variables (e.g. surgery, other labs) in the autoregression could help untangle this problem. In general, different data sources may impose different limitations on inference. It is unclear why we did not observe a drop in hemoglobin, but it may be a natural limitation of the data we used, which may lack the measurement frequency necessary to capture short-term fluctuations in hemoglobin levels.

More broadly, we wish to better understand how temporal dependence between lagged variables (even after taking differences) manifests in the coefficient estimation. We found that changing the number of estimated lags often does not significantly alter the trend of coefficients. Specifically, similar trends for amphotericin B predicting elevated creatinine persist whether estimating 10, 30, or 60 lags. The plots, not shown, are all close to zero at their endpoints and peak in the middle. This is clearly an effect of co-linearity between lags of a particular variable, and it may be important to employ model selection methods, like Akaike information criterion [24] and Bayesian information criterion [25], to reduce the number of variables and their co-dependencies. These and other methods may assist in automating and optimizing feature selection (we hand-selected drugs and labs that are consistently taken across large patient cohorts at our center). Model selection criteria are also important for formally evaluating Granger causality between correlated variables, and we hope to have a method that rigorously evaluates causality.

We seek a reliable high-throughput method that produces meaningful and interpretable results that will allow us to uncover new associations—we can only build the methodology for detecting known associations de novo, but it is hard to know if such a methods will be as good at detecting previously hidden associations. Moreover, given that drug coefficients are lagged by sequence, it is difficult to map results back to actual clock-time. In principle, each lag $\tau$ is associated with a distribution of time lengths across all patients, and the summary statistics for those distributions may provide sufficient insight into the unique time-scale of each temporal process we detect.

Linear and non-linear distributed lag models have been used widely to study the temporal relationships between environmental factors and rates of health-related incidents, like suicide, mortality, and infectious disease [26,26–29], but their adoption in work with EHR data has been less common. These methods offer the advantage of explicit handling of confounding variables by including their autoregressive terms in the regression. More complex approaches also exist for removing confounders in distributed lag models, and Bahadori and Liu have proposed a methodology for applying Granger causality to medical data that is designed to learn the effects of unobserved confounders [30]. Ghassemi et al. used multi-task Gaussian process models for multivariate time series modeling of data collected in intensive care units (ICU) [31], and Joshi and Szolovits have applied novel unsupervised data mining techniques to characterize severity of patient physiology in ICUs [32]. Other noteworthy approaches for temporal pattern discovery have been applied to EHR data [5–7,33]. Jung and Shah evaluated the effect of non-stationarity in EHR data on different machine learning models, and found suboptimal performance of complex methods that ignore non-stationarity [34]. In addition, Lasko et al. have demonstrated machine learning methods that evaluate sampling rates and biases in laboratory measurements [35] and model temporal effects for both
continuous and categorical variables from the EHR [3,36]. While machine learning and pattern recognition methods can uncover complex relationships in high dimensional data, the lagged linear regression methods we use are advantageous due to their simplicity of implementation and interpretability.

This study was limited to EHR data from one medical center, and was limited to eight hypotheses based on review of clinical literature. However, there does not exist a ground truth for these hypotheses. Similarly, the twelve drug-lab pairs that were not found to be significantly linked in clinical literature cannot be verified and were thus exploratory, rather than formal negative controls.

### Conclusion

By comparing univariate and multivariate lagged regression models, we established methods for timeline construction that yielded consistent results across model implementations. We found that drug effects were best characterized, as compared to clinical literature, by multivariate lagged models that incorporate drug orders, laboratory measurements, and inpatient admission events for 20 example drug and lab pairs. These results suggest that simple autoregressive models of commonly available EHR data can be used to detect real physiologic drug effects in the presence of confounding health-care processes, and a more thorough study with a larger feature set is warranted.

Abstract

Classification of drug-drug interaction (DDI) from medical literatures is significant in preventing medication-related errors. Most of the existing machine learning approaches are based on supervised learning methods. However, the dynamic nature of drug knowledge, combined with the enormity and rapidly growing of the biomedical literatures make supervised DDI classification methods easily overfit the corpora and may not meet the needs of real-world applications. In this paper, we proposed a relation classification framework based on topic modeling (RelTM) augmented with distant supervision for the task of DDI from biomedical text. The uniqueness of RelTM lies in its two-level sampling from both DDI and drug entities. Through this design, RelTM take both relation features and drug mention features into considerations. An efficient inference algorithm for the model using Gibbs sampling is also proposed. Compared to the previous supervised models, our approach does not require human efforts such as annotation and labeling, which is its advantage in trending big data applications. Meanwhile, the distant supervision combination allows RelTM to incorporate rich existing knowledge resources provided by domain experts. The experimental results on the 2013 DDI challenge corpus reach 48% in F1 score, showing the effectiveness of RelTM.

Introduction

Potential drug-drug interactions, defined as the co-prescription of two or more drugs that are known to interact, are one of the primary causes of medical error¹². Some studies estimate that medical errors result in around 44,000 to 98,000 deaths per year in the United States³, and that 7,000 of those deaths are due to medication-related errors⁴. Therefore, it is significant to prevent or reduce such errors in order to improve the clinical diagnosis quality and thus save thousands of patients' lives. The Institute of Medicine has noted that a lack of drug knowledge is one of the most frequent proximal causes of such errors⁵. A report in Australia⁶ mentioned that 75% of hospital admissions related to medication errors are preventable, which implies that drug-drug interactions are a preventable cause of morbidity and mortality. Yet, the consequences of drug-drug interactions in the community are not well characterized⁶. Indeed, health care providers often have inadequate knowledge of what drug interactions can occur, of patient specific factors that can increase the risk of harm from an interaction, and of how to properly manage an interaction when patient exposure cannot be avoided⁷⁸.

One of the primary reasons for this knowledge gap is the lack of complete and authoritative source of DDI knowledge⁹. Rather, there are multiple sources, including DrugBank, DailyMed, National Drug File, Express Scripts DRUG DIGEST and Medscape for WebMD4, each tasked with extracting, evaluating, and staying up-to-date with pertinent DDIs reported in the literature, and drug product labeling¹⁰. However, the inconsistency of information found in these resources is a serious issue. A manual review by a clinical pharmacologist of 100 randomly selected potential interactions out of more than 300,000 automatically extracted interactions revealed that 40% were genuinely inconsistent¹¹. The dynamic nature of drug knowledge, combined with the enormity of the biomedical literature, makes the task of collecting and maintaining up-to-date information on drug-drug interactions extremely challenging and time-consuming.

There is a strong need to approach this task with automated methods, supplemented with human efforts. Natural language processing (NLP) and information extraction methods for identifying and extracting DDIs have been increased attention in the last few years, and several attempts have already been made to develop methods for this task, showing good potentials for success. In 2011, the first shared task challenge for DDI extraction,
DDIExtraction-2011 invited participants to develop automatic methods to extract DDIs. Most of participants developed binary classification models to handle this task. In the 2013 challenge, the organizers further classified the DDI categories and correspondingly, participants expanded their binary classification work into multiple classifications. Some of them took two steps to do the classification, first, detecting whether there is a relation among a pair of drugs and second, assign specific category to it. In general, those approaches yielded results ranging from 40% to 68%. However, all those approaches deployed supervised machine learning frameworks and focused more on feature engineering. Nonetheless, at the time when the data is growing exponentially, the supervised approaches cannot meet the needs of real-world applications. In particular, the dependency on annotated corpus forms a bottleneck for those methods since human annotations are expensive and time-consuming. Besides, the model will easily become over-fitted due to limited annotated corpus. On the other hand, if we only use unsupervised methods, like K-means, the results will be hard to interpret and therefore arduous to cluster into consistent categories.

In light of this, we conjecture that using semi-supervised or distant-supervised approach to detect and classify drug-drug interactions from biomedical text can be a better alternative because it can address limitations of both supervised and unsupervised methods. Specifically, we design, implement and evaluate a Bayesian model complemented with knowledge-driven distant supervision. In alignment with the term topic modeling for text mining, we call it relation topic modeling (RelTM). This approach attempts to make assumptions on the generative process in discourses and uses Gibbs sampling and Expectation-Maximization to infer the model parameters. Unlike supervised models such as support vector machines, or logistic regression, unsupervised Bayesian methods do not require human efforts such as annotation and labeling in data preparation stages, which is its advantage in today’s trending big data applications. Meanwhile, the distant supervision combination allows us to incorporate rich existing knowledge resources provided by domain experts.

Related Work

In this section, we discuss techniques related to both the DDI challenges and to our proposed framework. The state-of-art techniques for the DDI challenge participation in 2011 are from Segura et al. They used a hybrid method that combines supervised machine learning, shallow parsing and syntactic simplification with pattern matching. The UMLS MetaMap tool (MMT) was used to provide shallow syntactic parsing and a set of domain-specific lexical patterns were developed to extract DDIs. The experimental results showed that they achieved a precision of 0.51, a recall of 0.72 and an F1 score of 0.60 using SVM classifier. In the 2013 challenge, the system with the highest F1 score was proposed by the FBK-irst team. Their system is a multi-phase relation extraction system. They used two separate phases for DDI extraction and classification. For DDI extraction, they removed less informative sentences and instances, and then trained a system on the remaining instances. A hybrid kernel classifier that contains a feature based kernel, a shallow linguistic kernel, and a Path-Enclosed Tree kernel was used in the first step. For classification of DDI, they trained four separate models for each class (one vs. all the other classes). The innovative part of this system is detecting less informative sentences, where a sentence is considered less informative if all drugs in a sentence fall under the scope of a negation cue (such as not). A negation detector system (focused on a limited set of negation cues, such as no, n't and not) is used to identify and filter the less informative sentences. The remaining sentences are classified with the SVM Light-TK toolkit, utilizing the Charniak-Johnson reranking parser, a self-trained biomedical parsing model, and the Stanford parser. On the DDI-DrugBank test dataset, they obtained an F1 score of 0.68 and on the DDI-Medline test dataset, an F1 score of 0.40. Other high-performance systems usually took similar approaches with differences in the use of machine learning model and feature selections. All of them employed gold-standard labels for supervised learning besides the utilization of rich features and knowledge resources. Their model developments and especially their efforts in feature engineering provide us food for thought and allows us to directly explore those resources for our usage.

As mentioned in the introduction, in order to reduce the dependency on human annotations, we plan to develop semi-supervised models. Our proposed method is inspired by research in areas other than DDI classification. The work which is most relevant to us is the study of relation discovery from news domain using generative models. They proposed rel-LDA and type-LDA, the latter of which is quite similar to ours. Specifically, their type-LDA composed of a probability graphical model where each document comprises N pairs. Each pair consists of relation features, entity features for source argument and destination argument. This framework takes dependency path, trigger words, part-of-speech features and named entity tags as features. The pair here refers to a relation in the
document. Their relations include authorOf, bornIn, founder, parent and so on. Similarly, we have a generative graphical model to generate DDI, relation features and drug features.

Nonetheless, there are a few important differences in our work. First, our approach is a combination of generative model and clustering method. A similarity function is integrated into the relation sampling. This is inspired by Blei et al’s correlated topic models\textsuperscript{35} and distance dependent Chinese restaurant process\textsuperscript{36}, Ghosh et al’s spatial distance dependent Chinese restaurant process\textsuperscript{37} and Chang et al’s relation topic models for document networks\textsuperscript{38}. All of these techniques share the common point that they attempt to accommodate random partitions of non-exchangeable data by taking distances or similarities between topics into consideration. We notice that DDI pairs of same categories share correlated features, many of which are implicit. Consequently, methods based only on co-occurrence may miss clustering them together while the introduction of similarity functions may make up for this weakness. This is an innovative extension of type-LDA. With this extension, we can add rich knowledge resources and further we can flexibly experiment diverse similarity measures to discriminate relations more accurately.

Second, our work borrows the concept of distant supervision\textsuperscript{39}. Distant supervision for relation classification is based on the assumption that if two entities, which are relevant, are mentioned in one sentence, that sentence may imply a relation and thus can be used as evidence for that relation\textsuperscript{40}. Based on this assumption, we employ two knowledge sources, Drugbank and DailyMed, which are the two main resources of drug-drug interactions all over the world to boost the performance of our framework. Accordingly, our work shares some similarities with the work of Riedel et al\textsuperscript{11}, in which, they employ Freebase to train a semi-supervised graphical model to extract relations from New York Times corpus. Their semi-supervised graphical model is essentially an undirected factor-graph model, which makes use of Gibbs sampling to update confidence on a group of expressions involving two entities. With the confidence learning, a ranked list of expressions extracted from Freebase is used as evidence for relation extraction in New York Times corpus.

One more related work is our latest work on coreference resolution with non-parametric topic modeling. In that work\textsuperscript{42}, the proposed infinite mixture model integrates definite sampling with maximum likelihood estimation of mention similarity to estimate the cluster of coreferring entities in clinical notes. That system achieves an F measure of 0.847 on i2b2 2011 coreference dataset. Our current work shares two common ideas. First, both works attempt to handle relation classification (one for identity relation, the other for drug-drug interaction) under the framework of Bayesian topic modeling; second, similarity functions are utilized to guide the sampling of the objective functions. The difference lies in that our current work is not non-parametrical and distant supervision is employed. In addition, the generative process of our previous work is mention-entity sampling and the observed variable is the mention while our current work is feature-entity-relation sampling. More complex sampling is involved in our current approach.

Methods

The task of relation extraction can be abstracted as mapping surface textual relations to underlying semantic relations. There are several components to a coherent relation type, including a tight small number of textual expressions (two drug mentions, or called relation pair) as well as constraints on the entities involved in the relation. Often, the textual expressions themselves may not include sufficient information for us to model the relation type and thus make reasonable predictions. Hence, the constraints will play quite a big role in constructing discriminant predictors. For supervised approaches, those constraints are utilized as features to learn classifiers. Differently, in our work, we deploy them as observed variables for our Bayesian model plus the textual expressions for entities. Through this way, we can assume that multinomial distributions exist among those observed variables and further we can set Dirichlet priors for relation pairs. In addition, we notice that drug mentions, constraints and relation features belong to different semantic space where relation pairs depend on both relation features, such as trigger words and relation constraints, like negation tagger and drug mentions while drug mentions depend on constraints related to them, such as syntactic roles. Therefore, they should be modeled at different levels.

Based on above observations, we present relation topic modeling (RelTM), a semi-supervised probabilistic generative model for inducing clusters of relation types and recognizing their textual expressions. The set of relation types is not pre-specified but induced from observed unlabeled data. The relation induction will be augmented with distant supervision by incorporating external resources-based similarity functions.

We know that relations can only hold between certain entity types, known as selectional preferences (Ritter et al., 2010; Seaghdha, 2010; Kozareva and Hovy, 2010). This model can capture the selectional preferences of relations to their arguments (drugs in our context). In the mean time, it clusters pair into relational clusters, and arguments into
Instead of using the relations types from the labeled data, we suppose the data consists of more clusters, which is called latent relations in the following sections. In other words, we expect a specific relation type may have more than one pattern of feature set. This allows each relational cluster to have several sub-clusters. These sub-clusters (latent relations) are merged in the categorizing step.

Our observed data consist of a corpus of sentences and each sentence is represented by a bag of relation pairs. Each pair represents an observed drug-drug interaction between two drugs and consists of three components: the relation features, the source drug and the destination drug. The relation pair is the primary observed random variable in our model and we construct our models so that clusters consist of textual expressions representing the same underlying relation type. Since unlike classical LDA where observed words are independent and shared by the whole collection of documents, it will be reasonable to assume that each word may be generated by some specific topic. In our framework, a set of drug mention features supports one drug and relation features and mention features jointly support one relation. Therefore, the generative process is somewhat different. Namely, all of its features are only sampled under one specific relation and all of mention features are only sampled under one specific drug entity as well.

**Generative Process**

Before we start to introduce the generative process, some notations are explained. The symbol $\sim$ stands for drawing the sample given a specific distribution. For example, the notation $x \sim \text{Multi}(\theta)$ represents sampling variable $x$ from

**Figure 1 The Plate Diagram of DDI-LDA**
the multinomial distribution given parameter \( \theta \).

Correspondingly, 
\( x \sim \text{Dirichlet}(\alpha) \) stands for sampling variable \( x \) from the multinomial distribution given parameter \( \alpha \). Table 1 shows other notations used in this paper. Following the convention of NLP community, the real world objects mentioned in a discourse by noun phrases or pronouns are usually called entities, in our context, drugs, and the phrases or pronouns appearing in discourses are called mentions, namely drug instances. Mentions may consist of several words in free texts and each of such words is called a token. Each relation is composed of two drug mentions.

The plate diagram of graphical model of RelTM is illustrated in Figure 1. The generative process of relation features, drug entities and their entity features are described in Figure 2. Formally, there are \( N \) numbers of possible relations \( (N \) is a random variable) in each sentence. Each relation is represented by three distributions, namely, relation feature distribution, features of drug entity 1 and features of drug entity 2. When we detect the relations between two drugs, we first choose a relation type based on a relation type distribution, composed of \( |R| \) number of distribution with summation 1. Then we generate a bag of relation features one by one based on the chosen latent relation type as well as generate a pair of drug entities. Sequentially, drug entity 1 and the drug entity 2 are employed to generate mention features for specific drugs, namely, instances of entities. Essentially, we do all sampling with Dirichlet for priors and multinomial for their conjugate posteriors. Namely, each multinomial distribution is governed by symmetric Dirichlet distribution.

The features of a relation pair consist of relation level features and mention level features. Relation level features include part-of-speech, dependency path, trigger, drug-bank indication (indications of drug-drug relations from the drug-bank database\(^{13}\)), lexicon and POS features, mention level features include the drug mention itself, its named entity tag, \( i.e. \) the type of drug and its Unified Medical Language System (UMLS) concept unique identifier (CUI) and type unique identifier (TUI).

**Strengthened Model with Similarity Measures**

Although the current framework takes both relation features and mention features into considerations, it is found that co-occurrences hypothesis, the foundation of topic modeling, may lead to poor performance while evaluated by DDI evaluation metrics. Therefore, similarity measures are introduced to improve the system performance. We use Simple Matching Coefficient (SMC)\(^2\) as the similarity measure of two different relation pairs, which is widely used in data mining and statistics for quantifying the similarity of two binary vectors. The SMC of two different pairs can be simply represented by:

\[
SMC(w, v) = \frac{\text{Number of matching features of } w \text{ and } v}{\text{Number of total features of } w \text{ and } v}
\]

Equation 1

Specifically, after each sampling of relations for one pair of drugs is done, we selected high-discriminate features to compute similarity scores between current relation pair and previous relation pairs, instead of between two large feature sets. In this study, the trigger words in Drugbank and DailyMed are used. In other words, if two drug entities

      iii. For each entity feature \( n = 1, \ldots, N_n^w \)
          1. Draw \( \varnothing_y \sim \text{Dirichlet}(\beta_y) \)
          2. Draw \( y_{w,t} \sim \text{Multi}(\varnothing_y) \)
   c. For entity \( i = 1, \ldots, N_e \)
      i. Draw \( \varnothing_v \sim \text{Dirichlet}(\beta_v) \)
      ii. Draw \( v_t \sim \text{Multi}(\varnothing_v, r) \)
      iii. For each entity feature \( n = 1, \ldots, N_n^v \)
          1. Draw \( \varnothing_z \sim \text{Dirichlet}(\beta_z) \)
          2. Draw \( z_{v,t} \sim \text{Multi}(\varnothing_z) \)

**Figure 2** The generative process of DDI-LDA
are mentioned with the same trigger verb in these two corpora, the similar feature count is incremented by one. After the count for each pair is obtained, it is divided by the size of the union of the entity feature sets. This step performs normalization to the co-occurrence feature count. Then the normalized feature counts of given relation assumptions are added to the probability vector in the inference stage.

Inferences

For simplicity and clarity, we omit the likelihood functions and their detailed derivations in this paper. We use collapsed Gibbs sampling to perform model inference. In collapsed Gibbs sampling, the distribution of a relation for its related features and two drug mentions are based on values of mention features is computed. For the simplicity of the equation, we first define the following function:

$$\Gamma(x, K) = \frac{n^i_{t-i} + \beta^i_t}{\sum_{i=1}^{\|F\|}(n^i_{t-i} + \beta^i_t)}$$  \hspace{1cm} \text{Eq. 2}

where $x = \{y, z, w, v, f\}$ and $K = \{|F|, |F|, |R|, |R|, |R|\}$ respectively. Then we have:

$$pp(r_t|r_{-t}, x, \alpha, \beta^x) \propto \frac{n^p_{m,i} + \alpha_m}{\sum_{m=1}^{\|P\|}(n^p_{m,i} + \alpha_m)} \prod_{x=(y,z,w,v,f)} \Gamma(x, K) \cdot \text{SMC}(w, v)$$  \hspace{1cm} \text{Eq. 3}

In this Eq., $n^p_{m,i}$ is a count of how many features are assigned to relations in sentence $s$, excluding the count of current relation $i$. The first term is the distribution of current relation $i$ sampled from the prior $\alpha$. The second term is the product of distributions of a series of supporting feature vectors. They include the proportion of the mention features for drug entity 1 and for drug entity 2, the proportion of the drug entity 1 and drug entity 2 and the proportion of relation features in current relation $i$ sampled from the prior $\alpha$. And the third term is SMC term. For the simplicity of the derivations of Gibbs sampling, we separate the RelTM term and the SMC term in inference stage. That is to say, the RelTM is optimized during the inference stage, while the SMC term remains constant in Gibbs sampling.

$$p(w_t = j|w_{-t}, r, \tilde{y}) \propto \frac{n^i_{t-i} + \beta_{t1}}{\sum_{i=1}^{\|W\|}(n^i_{t-i} + \beta_{t1})} \frac{n^j_{t-i} + \beta_{w_t}}{\sum_{i=1}^{\|W\|}(n^j_{t-i} + \beta_{w_t})}$$  \hspace{1cm} \text{Eq. 4}

$$p(v_t = j|v_{-t}, r, z) \propto \frac{n^i_{t-i} + \beta_{t2}}{\sum_{i=1}^{\|W\|}(n^i_{t-i} + \beta_{t2})} \frac{n^j_{t-i} + \beta_{v_t}}{\sum_{i=1}^{\|W\|}(n^j_{t-i} + \beta_{v_t})}$$  \hspace{1cm} \text{Eq. 5}

The above two equations compute the distribution of the two drug entities. Similar to Eq. 2, the distribution of drug entity 1 is based on the counts of features assigned to all entities in sentence $s$, excluding the count of current entity $i$ (term 1) and based on the distribution of all drug entities in sentence $s$ (term 2). Similar is the distribution of entity 2.

Categorizing topics

For the DDI Drugbank dataset, because the ground truth relations have been manually labeled, intuitively, if an inferred latent relation is associated with many pairs in a particular category, the relation is likely to belong to that category. To capture this intuition, we match the inferred latent relations to category $q$ where $q = arg\max_p p(q|r) = arg\max_q p(r|q) * \frac{p(q)}{p(r)} = arg\max_q p(r|q)$, assuming that all categories are equally important. We can estimate the probability of inferred latent relation type given category $q$ as,

$$p(r|q) = \frac{\sum_{s \in S_q} p(r|s)}{|S_q|}$$  \hspace{1cm} \text{Eq. 6}

where $p(r|s)$ denotes the learned probability of relation $r$ given sentence $s$ and $S_q$ denotes the subset of sentences in the DDI drugbank data collection that are labeled as category $q$.

Experimental Results

As a gold standard for all experiments in this task, we used DDIExtraction-2013 corpus provided by the challenge organizer, for development. It contains 142 Medline abstracts on the subject of drug-drug interactions, and 572 documents describing drug-drug interactions from the DrugBank database. The corpus includes 6976 sentences that were annotated with four types of pharmacological entities and four types of DDIs. The DDIs types are: advice, effect, mechanism, and int.

The four types of drug-drug-interactions are defined as follows.

- Advice: the sentence notes a recommendation or advice related to the concomitant use of the two drugs. For example, "... UROXATRAL should NOT be used in combination with other alpha-blockers."
- Effect: the sentence states the effect of the drug interactions, including pharmacodynamic effect or mechanism of interaction. For example, "Quinones may enhance the effects of the oral anticoagulant, warfarin, ..."
- Mechanism: the sentence describes a pharmacokinetic mechanism.
- Int: the sentence mentions a drug interaction but doesn't provide any additional information.

To demonstrate the effectiveness of our proposed model, we conducted a series of experiments on DDI Drugbank dataset. In our problem setting, we assume that all drugs are provided and sentences are the place all interaction among drugs take place. Any two drugs among sentences are potential relation pairs. Yet, we do not suppose relation labels between any two drugs in a sentence of the training data are known. Namely, we target to develop semi-supervised framework to assign labels to those unlabeled DDI pairs with the four categories introduced in Table 2.

Since we are using an unsupervised method in model development, we did not divide our dataset into training set and testing set. That is to say the experiments are carried out in the corpus described in Table 2. There are two models evaluated in this section: baseline RelTM model and the RelTM with similarity measure (SMC) model. The performance metrics is computed with the package provided by DDIExtraction 2013 Challenge organizers. The performance of the two models mentioned above is shown in columns 3 to columns 5 and columns 6 to columns 8, respectively. Comparing these results, we can draw the conclusion that the combination of RelTM and distant supervision together improves the overall performance, which is indicated in the micro-average F1 score, from 0.3624 increasing to 0.480.

Since we are using a model with pre-specified number of latent relations, the same as other finite mixture model like LDA, the number of latent relations (topics) will also influence the system performance. Figure 3 demonstrates the relation between number of specified latent relations of our model and the micro-average F1 score. From the curve there are three trends worth mentioning. The first trend is when the number of latent relations is smaller than 15, the F1 score will increase with the increase of number of latent relations. This is because when the number of latent relations is less than the optimal number, the model may fail in splitting some similarity patterns of different DDI pairs. The optimal number of latent relations observed in the dataset is 15, based on experiments. The second trend is, after the optimal latent relation number, the F1 score will decrease with the number of relations increasing. This is due to the decreasing effectiveness of Gibbs sampling method we are using for the model inference. A similar pattern can also be found in conventional LDA model. However, as we continually obtained finer and finer clusters of DDI pairs, which applies after the relation number is larger than 50, the F1 score will slightly increase. This trend...
is because of the greedy manner of how we do the cluster labeling. As the clusters become smaller, the accuracy of cluster labeling will benefit the F1 score.

**Discussion**

Due to the characteristic of Bayesian inferences, all the clusters are generated as random variables. It means they are generated according to the predicted probabilities of random variables in each category, instead of being directly assigned a label as in supervised methods such as support vector machine or random forest. The output results show our system can detect most of the strong category patterns, like the existence of the word “should” in *advise* and “effective” in *effect* in given sentences. However, while sampling the category label using category probabilities, most of the elements in the probability vectors are not strictly zero. Consequently, there is still possibility that DDI pairs with these strong patterns are not correctly classified, but the possibility of this kind of errors is within a low and acceptable range.

Another issue impacting the overall performance is the unbalanced category, in our study, *int*. In Table 2 we can find that there are only 188 instances of *int* pairs, which is much smaller than the second smallest category, which has 827 instances. Without any prior knowledge of category proportion, it is difficult for an unsupervised model to generate this small cluster, compared with other tunable supervised methods. As a result, our system generated more false positives in *int* categories than the other relatively large clusters. Therefore, the precision is lower that other categories, and it further impairs the micro-average F1 score. If we can utilize the prior knowledge of expected category proportion, this can be avoided by using unbalanced vector $\alpha$ as Bayesian prior of RelTM instead of a scalar value we are currently using.

Although the performance of our system is not as good as the state-of-art supervised approaches, it does induce promising results, which shows that the utilization of distant supervised machine learning methods like LDA is promising in relation classification, even in challenging tasks as DDI classification. With the augmented similarity measures, which use domain knowledge in medical corpora, the results are improved. It is reasonable to believe that if more prior knowledge is used in the proposed model, then it has a potential to detect relations more accurately. This paves the way for us to deploy and extend our current system on large-scale unlabeled medical literatures and thus reduce the dependencies on the corpus annotations.

**Conclusion and Future Work**

In this paper, we proposed a topic modeling based distant supervised approach for the task of drug-drug interaction from biomedical text. Specifically, we proposed to design, implement and evaluate a Bayesian model complemented with knowledge-driven distant supervision. Under the assumption that the relations of drug-drug interaction are generated from proposed generative process, an inference algorithm using Gibbs sampling was also designed. A similarity measure was also introduced to strengthen the model and its effectiveness is proven by the experiments. The proposed approach does not require human efforts such as annotation and labeling in data preparation stage, which is its advantage in today’s trending big data applications. Meanwhile, the distant supervision combination allows us to incorporate rich existing knowledge resources provided by domain experts.

In future, we will address problems found in error analysis. In addition, we will extend the similarity function by incorporating updating rules and correlation between latent relations. One direction of exploration includes the release of symmetric Dirichlet prior to non-symmetric considering the unbalanced numbers of relation categories.

Abstract

Atrial fibrillation (AF) is a common cardiac rhythm disorder, which increases the risk of ischemic stroke and other thromboembolism (TE). Accurate prediction of TE is highly valuable for early intervention to AF patients. However, the prediction performance of previous TE risk models for AF is not satisfactory. In this study, we used integrated machine learning and data mining approaches to build 2-year TE prediction models for AF from Chinese Atrial Fibrillation Registry data. We first performed data cleansing and imputation on the raw data to generate available dataset. Then a series of feature construction and selection methods were used to identify predictive risk factors, based on which supervised learning methods were applied to build the prediction models. The experimental results show that our approach can achieve higher prediction performance (AUC: 0.71–0.74) than previous TE prediction models for AF (AUC: 0.66–0.69), and identify new potential risk factors as well.

Introduction

Atrial fibrillation (AF) is one of the most common clinical arrhythmias, affecting approximately 4 million adults in China¹. AF significantly increases the risk of ischemic stroke and other thromboembolism (TE). Moreover, compared to non-AF ischemic stroke, AF related ischemic stroke is more fatal and disabling². Oral anticoagulation (OAC) including warfarin has shown great efficacy in preventing ischemic stroke and TE for AF patients³. However, because OAC may have severe side effects such as warfarin bleeding, it is normally only recommended to AF patients with high risk of TE in clinical guidelines⁴. Besides, though radiofrequency ablation (RFA) is an effective procedure to treat AF and then reduce the risk of TE, it is still a scarce medical resource in present day China and increases economic burden on AF patients. Therefore, it is critical to accurately predict the risks of TE for AF patients and identify those truly high risk patients that should be treated by OAC and/or RFA.

Current ischemic stroke and TE risk models for AF, such as CHADS²⁶, CHA²DS²-VASc⁷ and Framingham Score⁸, were developed to stratify AF patients into categories of high, intermediate, and low risk. The risk factors used in these models, such as age, gender, prior ischemic stroke and TE, hypertension, diabetes, congestive heart failure (CHF), etc., are grounded in previous known evidence and experience, which are well understood and easy to apply. However, these risk models have only moderate prediction performance⁹ (the area under the receiver operating characteristic curve (AUC) is usually less than 0.7¹). It is mainly because that some potential risk factors that are highly related to TE occurrence for AF patients were not previously identified and involved in these risk models.

The objective of this study was to build 2-year ischemic stroke and TE prediction models for AF with high prediction ability and interpretability, based on the Chinese Atrial Fibrillation Registry (CAFR) data. The CAFR study started from the year of 2011, and has enrolled more than 17,000 AF patients from 32 hospitals in Beijing, China. The study collected the patients’ demographics, symptoms and signs, medical history, results of physical examination and laboratory test, details of treatments at baseline, and followed up the patients every 6 months. At every follow-up visit, the clinical events such as ischemic stroke and TE were collected.

Many previous works used statistical inference and machine learning methods to build high accuracy risk prediction models for patients with cardiovascular, diabetes and other diseases¹⁰,¹¹,¹²,¹³. However, it is still a challenging problem to build accurate and clinically interpretable TE prediction models from CAFR data. The first challenge is from the dataset, which is heterogeneous, non-standardized, incomplete and redundant. Much elaborate data curation work has to be done to remedy the data before analysis. Also, feature engineering should be performed to transform data types...
and reduce the redundancy of features. Another challenge is from the requirement of interpretability. Since we wanted to build human understandable and applicable prediction models, the dimensionality reduction and learning algorithms in which resulting models are difficult to interpret (e.g., principle component analysis and support vector machine) were not preferable.

In this paper, we address these issues by using integrated machine learning and data mining approaches to build TE prediction models for AF patients. We first performed data cleansing and imputation on the raw CAFR dataset to standardize the features and fill-in missing entries. Then a series of feature construction and selection methods were used to identify predictive risk factors and reduce redundancy. Finally, we applied different categories of supervised learning methods that have good interpretability, including generalized linear model, Bayes model and decision tree model, to build TE prediction models for AF. The experimental results show that our approach can achieve higher prediction performance than previous TE risk models, and also identify new potential risk factors that have not been previously identified or commonly used.

Methods

Figure 1 shows our approach pipeline of building ischemic stroke and TE prediction models for AF patients from CAFR data. We first selected and constructed the patient cohort of interest. Then data curation, including data cleansing and missing data imputation, were performed to generate available dataset. After that, we applied a series of feature engineering methods, including feature construction and feature selection, to identify the potential risk factors for predicting TE in AF. Finally, we trained prediction models using different supervised learning algorithms, and evaluated their prediction performance in terms of AUC and the area under the precision recall curve (AUPR) by cross validation and train/test splitting.

**Cohort**

The purpose of TE prediction models is to help clinicians identify AF patients with high risk of TE, and then decide to whom relevant interventions such as OAC and RFA should be used. Therefore, in this study the patients of interest are those who had not been treated with OAC (mainly warfarin in our data) or RFA at baseline. From the CAFR data, we identified 1864 AF patients who meet this criteria, where 193 patients (10.4%) are cases who had TE within 2 years after baseline, and 1671 patients are control instances who completed 2-year follow-ups and did not have TE within 2 years. The features used in our analysis include demographics, symptoms and signs, medical history, vital signs, laboratory test results, life styles and treatments.
Data Curation

In the raw CAFR data, more than half of the features have non-standardized and dirty values, and this percentage for the numeric type is particularly higher. Besides, the raw data has significant omissions due to the questionnaire structure, unknown values or errors in data collection. The workload of manually correcting these dirty and missing values could be enormous. Therefore, we performed automatic data curation, including data cleansing and missing data imputation, before predictive analysis.

1) Data Cleansing

The raw data is heterogeneous and includes different types of data items: binary type (e.g., hypertension history), nominal type (e.g., AF type) and numeric type (e.g., systolic blood pressure, SBP). For different data types, we designed sets of cleansing rules to remedy the non-standardized and dirty values in batch. These cleansing rules can be used to standardize data formats, correct input errors, or discard the values that cannot be recognized as the target types.

For the numeric features, some values in the raw data are not standardized (e.g. the full-width Chinese character “。” in Figure 2(a.1)), so we first defined a set of cleansing rules to standardize these values (e.g., Figure 2(b.i) that transforms “。” to the half-width character “.”). Besides, because the dataset was collected from different hospitals, a numeric feature may have different units (e.g., mg/dL and µmol/L for serum creatinine in Figure 2(a.2-3)). Therefore, we defined cleansing rules to unify these units (e.g., Figure 2(b.ii) that transforms mg/dL to µmol/L for serum creatinine). Finally, we discarded the numeric values that are out-of-range (e.g., the SBP greater than 200 mmHg in Figure 2(a.4)) and the non-numeric values (e.g., the values in Figure 2(a.5-6)) in numeric columns. Figure 2(c) shows the cleansed numeric values of the examples in Figure 2(a). For the binary features and nominal features, we also defined corresponding cleansing rules to standardize the formats and discard the unstructured values.

2) Missing Data Imputation

Data imputation is the process to remedy missing data, which is usually necessary for building a reasonable prediction model. Since the dataset is derived from questionnaire and the features have interrelationships, we first built a set of imputation rules to infer the missing values from the other relevant features. For example, if a patient’s SBP was greater than 140 mm Hg, then his/her hypertension history can be replaced with “true”. For another example, if the value of a parent question “having heart failure symptoms” is “false”, then all its children questions, such as “cantering rhythm”, can be imputed with “false”.

After that, we statistically imputed the remaining missing values that cannot be inferred from other features. We first discarded the features with too many missing entries, because their distributions are difficult to estimate, which may lead to inaccurate imputation results. Concretely, if a binary feature has more than 80% missing instances, or a numeric/ multi-value nominal feature has more than 60% missing entries, then this feature was removed from the dataset. For the remaining features, every missing value of a numeric feature (e.g., SBP) was replaced with the mean of the feature’s observed values, every missing value of an ordinal feature (e.g., NYHA level) was replaced with the median of its observed values, and every missing value of an unordered nominal feature (e.g., AF type) was replaced with the mode of its observed values. These methods can statistically minimize the impact of the imputed values in predictive modeling.
Risk Factor Identification

Risk factors for ischemic stroke and TE in AF have been previously studied\(^{6,7,8}\). These knowledge-based risk factors are grounded in previous evidence and have good interpretability. However, many other risk factors that are highly related to TE occurrence for AF patients were not previously identified and involved, and the models built from the previously known factors may not have adequate predictive power.

On the other hand, feature selection methods in machine learning\(^14\) can be used to automatically test and select predictive features from a large number of candidate features, and discover new risk factors that have not been previously identified. The prediction models built from the automatically identified factors can represent more complex disease progressions, and usually have higher predictive performance than the models derived from the knowledge-based factors\(^{10,12}\). The disadvantage of the data driven methods is that the resulting models may usually be difficult to interpret or apply in real clinical practices, because the original features in the data are not as easy to understand as the knowledge-based factors. To address these problems, we first performed feature construction to transform the original features and combine knowledge-based features. Then feature selection algorithms were applied to identify potential risk factors from the original and knowledge-based features.

1) Feature Construction
We first preformed feature transformation to split each multi-value feature to a set of binary features. After that, a set of formulas provided by clinicians were used to generate knowledge-based combination features, which can also be used as candidate features in feature selection. These knowledge-based features describe high-level clinical concepts, and each of them maps to multiple original features in the CAFR data. For example, in this study, “CHF” is defined by four features: “NYHA level” > 2 or “left ventricular ejection fractions” < 40% or “having heart failure history” or “having heart failure symptoms”. Similarly, “diabetes mellitus” is defined as “glycated hemoglobin (HbA1c)” ≥ 6.5% or “fasting plasma glucose” ≥ 7.0 mmol/L or “having diabetes history”.

2) Feature Selection
Before feature selection, we first performed pre-selection to remove the unreasonable features. We asked the clinicians to select the feature categories of interest, and discarded the uninteresting features (e.g., all subjective features about quality of life were discarded in order to avoid bias). The close-to-constant features, in which 99% of the instances have identical values, were also be removed.

In machine learning, there are three main supervised feature selection strategies: filter, wrapper and embedded optimization\(^{14}\). In this study, we employed and compared these methods in identifying predictive risk factors.

- **Filter.** This category of methods calculates a score to represent the relevancy of a feature (or a group of features) against the outcome, and then filters the features based on the score. In this study, we applied two univariate filter methods, which respectively use the p-value from chi-squared test and the information gain as the relevancy score to filter each feature independently. We also used the correlation-based feature subset selection method\(^{15}\) (CFS), which is a multivariate filter method that evaluates features in a batch way, to obtain the subset of features that are highly correlated with the outcome while having low intercorrelation between the features.

- **Wrapper.** This type of methods utilizes a specific classifier (e.g., logistic regression) to select the subset of features that provides the best performance for a specific metric (e.g., AUC). In this study, we applied the wrapper subset selection method\(^{16}\). This method evaluates a subset of features by the prediction performance of the classifier using cross validation, and uses the best first search strategy to search the subset of features that can achieve optimized performance.

- **Embedded optimization.** These methods incorporate feature selection directly into the learning process of a model. In this study, we used Lasso\(^{17}\) to introduce L1-norm regularization to generalized linear models (e.g., logistic regression), which can achieve feature selection by shrinking the coefficients of low relevant features to zero during model training.

Predictive Modeling
In this study, we applied and compared different categories of machine learning models that have good interpretability, including generalized linear models, Bayes models and decision tree models, to build TE prediction models for AF.
• **Generalized linear model (GLM).** GLM generalizes ordinary linear regression by allowing the linear model to be related to the response variable via a link function. We used logistic regression, which is a GLM with a logit link function and a binomial distribution. It was widely used in both medical statistics and machine learning due to its good performance and interpretability. We also applied Cox proportional hazards model\textsuperscript{18} in this study, which is a statistical model commonly used in survival analysis. Cox is a semi-parametric GLM that takes into account the time of observations.

• **Bayes model.** Naive Bayes model\textsuperscript{19} is a probabilistic classifier based on Bayes theorem with strong independence assumptions between the features. Naive Bayes models can be trained very efficiently, and have decent prediction performance and interpretability as well.

• **Decision tree model.** The classification and regression tree (CART) method was applied to build tree-based prediction model, which is very easy to interpret. We also employed random forest\textsuperscript{20}, which constructs a multitude of decision trees and outputs the mode of the classes of the individual trees. Compared to other decision tree learning methods, random forest generally has greater performance by reducing the problem of over-fitting, though having worse interpretability.

**Results**

We evaluated the performance of our approaches, including data curation, feature engineering and supervised learning, in building 2-year TE prediction models for AF patients from CAFR dataset. Figure 3 demonstrates the proportions of dirty and missing data in our dataset before and after data curation. In the 221 original features of the raw data, 116 features (55.0%) have non-standardized and dirty values, and 211 features (95.5%) have missing values (Figure 3(a)). After data cleansing, the dirty data in 91 features were standardized and/or corrected (Figure 3(b)). And after data imputation, the missing data in 155 features were filled-in, while 54 features with dirty values and/or missing values that cannot be remedied were discarded (Figure 3(c)). Finally, 167 available features were produced to the following feature engineering step.

Two standard metrics, AUC and AUPR, were used to evaluate the prediction performance of models. We used AUPR in addition to AUC because in our case of imbalanced dataset, AUC may provide an overly optimistic view of performance, while AUPR can provide a more informative assessment under this situation\textsuperscript{21}. Note that the baseline of AUPR for our dataset is 0.104, which is the average precision of randomly predicting the risk (i.e., an AUPR of 0.208 means the average precision is doubled than that of random prediction).

To compare the performance of the feature engineering methods, we built logistic regression models on different feature sets generated by different feature construction and feature selection methods, and evaluated the mean and standard deviation of AUC and AUPR of each model on 5 different 10-fold cross validation partitions of the data. As shown in Table 1, all the feature selection algorithms can significantly improve the AUC and AUPR of logistic regression, where the multivariate filter method (CFS) and the wrapper method achieved better prediction performance than the univariate filter and embedded methods on our dataset. Besides, when using multivariate filter, wrapper and embedded selection methods, combining knowledge-based features in predictive modeling can also improve the prediction performance to some extent.

To evaluate the performance of different supervised learning algorithms, we built different learning models on various feature sets (the combination of original and knowledge-based features were used as candidate features in this and the following experiments). As shown in Table 2, GLM methods (logistic regression and Cox) achieved the best performance on our dataset after performing feature selection. Naïve Bayes also got decent AUC and AUPR and their trends are similar with GLM. The decision tree method CART did not work well on our dataset. In comparison, random forest achieved the best performance when applied on all candidate features, but its performance cannot be stably increased by feature selection (except wrapper).

We also compared the performance of our approaches to the state-of-the-arts risk models: Framingham and CHA₂DS₂-VASc scores. We randomly split the dataset to a training set with 60% instances and a testing set with remained instances, and selected feature engineering and supervised learning algorithms based on the above experiments to train our prediction models on the training set. Then we applied both previous models and our trained models on the same testing set, and computed the AUC and AUPR of each model. This process was repeated 5 times, and the means and standard deviations of AUC and AUPR of the models were compared. As shown in Figure 4, the prediction performance of our models outweigh the Framingham and CHA₂DS₂-VASc models.
Discussion

In this study, we compared several feature selection and supervised learning methods in building TE prediction models for AF patients. The GLM (logistic regression and Cox) and Naïve Bayes methods did not work well on the whole feature set, but their prediction performance can be significantly improved by appropriate feature selection. This is probably because both GLM and Naïve Bayes have the assumption of no multicollinearity between the features, but the whole feature set is highly redundant and intercorrelated, which negatively affects the prediction performance of GLM and Naïve Bayes. The feature selection algorithms, especially the CFS algorithm that minimizes the intercorrelation and the wrapper algorithm that directly optimizes the AUC, can reduce the redundancy of features and therefore increase prediction performance. As a whole, the decision tree methods (CART and random forest) did not achieve satisfactory performance on our dataset, probably due to the problem of over-fitting. However, by implicitly embedding feature selection, random forest worked relatively well on the whole feature set with high intercorrelation. Besides, in this study, the wrapper selection method achieved the best prediction performance in terms of AUC and AUPR, because the method directly optimizes the performance metric of the specific learning models. However, the time complexity of wrapper selection is very high, which is not practicable for larger datasets. In addition, because the knowledge-based combination features provided by clinicians can describe high-level clinical concepts, adding them during feature engineering can increase the prediction performance while reducing model complexity, when appropriate feature selection is performed.

In addition to achieving higher predictive performance than existing TE prediction models for AF patients, our approach also identified potential risk factors that had not been commonly used. Table 3 shows the risk factors in the previous Framingham and CHA2DS2-VASc models, as well as the factors that were most commonly selected by multiple feature selection methods in this study. The identified risk factors and their odds ratios in logistic regression were verified by clinicians, concluding that the majority of new risk factors, including cardiovascular problem histories, disease durations, relevant electrocardiography and laboratory tests, as well as medications, are interpretable and reasonable to clinicians.

Despite the promising results in building TE prediction models for AF patients, there are still several aspects of the approach that could be improved. First of all, in this study, we combined knowledge-based features in feature construction, improving the performance of the resulting models. Besides this, there are also other forms of domain knowledge could be used to enhance the predictive power and/or interpretability of models. For example, clinicians have some knowledge and common sense about the impact of features on a target outcome, from their experience or literature. These knowledge could be built as constraints in the modeling algorithms, which could reduce the bias of a specific dataset and then improve the applicability of the models.

Secondly, we applied the state-of-the-arts feature selection algorithms in machine learning to identify risk factors and used performance metrics AUC and AUPR to evaluate their performance. However, the statistical significance (p-value) of the factors, which is critical for a model to be published and adopted in real clinical practices, was not considered. Though the traditional stepwise selection methods can ensure the significance of selected factors, their prediction performance is usually not good enough. Therefore, a new wrapper-based algorithm that optimizes both prediction power and statistical significance would be a practical method to build more interpretable models.

Thirdly, in this study, we only used original features of CAFR data and knowledge-based combinations as candidate features for building prediction models. There are some frequent pattern mining and pattern abstraction methods could be used to discover more complex co-occurrence or temporal patterns, which could be used as combination features in building more effective and interpretable prediction models.

Lastly, in order to use our prediction models in practice, we are also developing a mobile phone app which is named Health Risk Advisor. The TE prediction models can be integrated into the app to provide risk assessment to AF patients, and alert physicians once their patients’ risk levels are changed. A clinical pilot trial for the prediction models could also be conducted in the future based on Health Risk Advisor.
Conclusion

AF significantly increases the risk of ischemic stroke and TE, and accurate prediction of TE for AF patients is critical for early intervention and prevention. In this study, we used integrated machine learning approaches, including data curation, feature engineering and supervised learning, to build TE prediction models for AF patients from CAFR data. The experimental results show that our approach can achieve significantly better prediction performance than previous TE risk models for AF, and identify new potential risk factors as well.

Data-Driven Prediction of Beneficial Drug Combinations in Spontaneous Reporting Systems

Ying Li, PhD, Ping Zhang, PhD, Zhaonan Sun, PhD, Jianying Hu, PhD

Center for Computational Health, IBM T.J. Watson Research Center, NY, USA

Abstracts

Post-market withdrawal of medications because of adverse drug reactions (ADRs) could result in loss of effective compounds which are effective for treating a specific disease but have unfavorable benefit-to-harm ratio. Recent therapeutic successes have renewed interest in drug combinations, which could work synergistically to improve therapeutic efficacy or work antagonistically to alleviate the risk of the ADRs. However, experimental screening approaches are costly and often can identify only a small number of drug combinations. Spontaneous reporting systems (SRSs) routinely collect adverse drug events (ADEs) from patients on complex combinations of medications and provide an empirical and cost-effective source to detect unexpected beneficial drug combinations. In this paper, we proposed a novel data-driven method for the prediction of drug combinations where one drug could reduce the ADRs of the other, based on data from SRSs. The predictive model was shown to be effective using a commonly used evaluation approach in pharmacovigilance by constructing a known drug-drug interaction (DDI) reference standard. The method was applied to perform large-scale screening on SRS data for drug-ADR-drug triples where polypharmacy could potentially reduce the ADR. Analysis of the top ranking candidates showed high level of clinical validity.

Introduction

Combinatorial drug therapy is useful for combating complex and refractory diseases such as acquired immune deficiency syndrome (AIDS)\(^1\), cancer\(^2\) and Type 2 diabetes mellitus (T2DM)\(^3\). Two main reasons for using combinatorial drug therapy are that the combination of drugs could work synergistically to improve therapeutic efficacy or work antagonistically to alleviate the risk of adverse drug reactions. A prominent example is the combined use of aspirin and dipyridamole has been shown to be more beneficial and safer than using either of the drugs alone for secondary prevention of stroke in the United States\(^4\).

Despite the increasing number of drug combinations in use, there is significant challenge in discovering beneficial drug-drug combinations (DDCs) in a scalable manner. To date most of them were found in the clinic through experience, or experimentally derived by dose-response curves for each pair of drugs against a protein target\(^5,6\). In recent years, various sources of large-scale data on drugs are emerging, which involve detailed chemical, pharmacological, and pharmaceutical data along with sequence, structure, and pathway information about drug targets\(^7-9\). The systematic identification of novel DDCs is expected to contribute to the development of combinatorial drug therapy\(^6,10,11\). However, the aforementioned studies are based on in-vitro experimental data, data collected from limited number of participants in clinical trials, or from limited well-known drug combinations extracted from FDA orange book\(^12\). Spontaneous reporting systems (SRSs) routinely collect drug-induced adverse drug events (ADEs) from patients on single medication or complex combinations of medications, which provide an opportunity to discover unexpected beneficial drug combinations for ADE reduction.

Many researchers have used SRSs to identify drug combinations that lead to unanticipated harmful adverse events, hereinafter referred to as drug-drug interactions (DDIs), and developed methodologies to effectively mine this database. For instance, Noren et al.\(^13\) implemented a three-way disproportionality measure to identify suspected DDIs, and evaluated the method using empirical examples among the 20 highest predictions. Harpaz et al.\(^14\) used association rule mining to identify multi-item ADE associations from the FDA adverse event reporting systems (FAERS), and 4% of results were characterized and validated as DDIs by an expert. Tatonetti et al.\(^15\) mined FAERS reports for side-effect profiles related to glucose homeostasis and uncovered a novel interaction between pravastatin and paroxetine that causes a potentially hazardous increase in blood glucose levels. Theoretically, we should be able to identify not only adverse drug combinations (DDIs) but also beneficial drug combinations (DDCs) for ADE reduction from SRSs. Zhao et al.\(^16\) proposed the first of its kind to identify DDCs based on FAERS. Specifically, they utilized difference-in-differences estimators\(^17\) to look for drug pairs in which Drug B, when taken with Drug A, could reduce reports of adverse events from patients taking Drug A. Consequently they discovered that the
combined therapy of *rosiglitazone* and *exenatide* was able to reduce the reported incidences of *myocardial infarction* associated with the use of *rosiglitazone* alone. One known issue with SRS data is that selection biases resulting from the nonrandom selection of subjects exposed to the drug and experiencing adverse events could lead to many false positive associations between the drug and the ADR when a causative covariate (for instance, a patient’s disease state or other medications) is not accounted for. In order to alleviate such bias, Zhao *et al.* 16 conducted an extensive post-hoc analysis based on stratification of the data on predefined covariates such as the use of *metformin* and Type 2 diabetes. However, such a stratification requires significant domain knowledge and sometimes enumeration of important covariates, which is intractable for any large-scale analysis. The propensity score matching (PSM) is the most developed and popular strategy for causal analysis in observational studies 18 that yield an unbiased estimate of treatment effects. Tatonetti *et al.* 5 successfully applied the PSM for single drug-ADR detection and results showed that PSM can reduce selection bias associated with drugs reported in the case reports and therefore decrease the false positive associations.

In this study, we propose a novel data-driven method, which incorporates PSM, for large-scale prediction of drug combinations where one drug could reduce the ADRs of the other, based on FAERS data. We denote Drug A as a medication that could cause a specific ADR and Drug B as a medication that could reduce the reported rate of Drug A-induced ADR. We hypothesize that Drug B can alter the chance of developing Drug A-induced ADR based on two mechanisms: the additive or subtractive individual effect of Drug B itself, and the interaction effect with Drug A. Our method is able to predict the combined effect, which takes both mechanisms into consideration. In addition, since both beneficial and harmful drug interactions have gained much interest within the research community, we also report results associated with the interaction effect alone. The knowledge (ground truth) of beneficial drug combinations in terms of ADR reduction is scarce if not nonexistent, we therefore follow a common practice in pharmacovigilance and evaluate the proposed method based on a reference standard of known DDIs and their related ADRs in our experiments.

**Materials and Methods**

**Data sources**

FAERS: FDA adverse event reporting systems

FAERS is a spontaneous reporting system maintained by U.S. Food and Drug Administration (FDA) 19. FAERS contains case reports of suspected ADRs, which are either obligatorily submitted by pharmaceutical companies, or are voluntarily reported by healthcare professionals and consumers. Drugs are entered in a report using free text, which can be brand or generic names, while suspected ADRs are coded using MedDRA terms 20. In addition, the reporters sometimes link the medications to their indications, which are also coded using MedDRA terms. In order to gain statistical power, we normalized drug names to their chemical compounds using the STITCH database 21, which maintains synonym lists for chemicals, and relationships between drugs and their chemical compounds. For example, *quinapril hydrochloride* and *hemokvin* are mapped to the main ingredient *quinapril*.

SIDER: a Side Effect Resource

The SIDER (SIDe Effect Resource) 22 is a publicly available resource that relates the medications to their known side effects, or ADRs. The relationships are extracted by an automatic method from the FDA Structured Product Labels. Presently, the medications are coded using STITCH and the ADRs are coded using MedDRA terms. For instance, the medication *lansoprazole* (CID000216416) is described to cause the MedDRA-coded side effect *gastrointestinal pain*. For this study, we utilized the latest version SIDER 4.1.

DrugBank: a comprehensive knowledgebase for drugs, drug actions, and drug targets

DrugBank 23 is a knowledge base that contains detailed biomedical and pharmacological information about drugs, their mechanisms and their targets. In addition, DrugBank provides a set of 12,128 ingredient level drug- drug interactions (DDIs), and most of which are along with a brief textual description of the interaction. For example, an interaction between *nalidixic acid* and *warfarin* is described as “*nalidixic acid* may increase the anticoagulant effect of *warfarin*”. Another example is “the combined use of *amiodarone* and *lovastatin* increase the risk of severe myopathy/rhabdomyolysis”, which links the DDI between *amiodarone* and *lovastatin* to its ADRs of myopathy or rhabdomyolysis that can be mapped to MedDRA.
terms. The version of DrugBank used in this study is 4.0.

Methods

The overall workflow of the study is shown in Figure 1, which consisted of three steps: (1) Identify and filter potential candidate triples of Drug A-ADR-Drug B. (2) Compute propensity scores for individual drugs. (3) Determine the associations for each specific Drug A-ADR-Drug B triple.

![Figure 1. An overview workflow of the study.](image)

Step 1. Filtering of potential candidate triples of Drug A-ADR-Drug B

Three criteria in combination with a statistical method were used to limit the search space of the set of Drug A-ADR-Drug B triples. From all pairs of Drug A-ADR that were reported in the FAERS case report data for more than 200 times (Criteria 1), we identified the candidate pairs of Drug A-induced ADR based on the observed Odds Ratio (OR). Let Drug denote a Drug A, the OR of Drug developing an ADR is defined as follows:

$$
\text{OR}_{\text{drug}} = \frac{\text{odds}(\text{ADR} = 1|\text{drug} = 1)}{\text{odds}(\text{ADR} = 1|\text{drug} = 0)}
$$

(1)

where \( \text{odds}(X) = \frac{\Pr(x)}{1 - \Pr(x)} \).

An OR greater than 1 indicates the chance that Drug develops the ADR is higher than the expected background rate, and an OR smaller than 1 indicates the chance that Drug develops the ADR is lower than the expected background rate. By replacing the probabilities in (1) with empirical probabilities, we obtained the observed OR for each Drug A-ADR pair. We then used Chi-Square test to determine whether the observed OR for a drug-ADR pair was significantly greater than 1. Any pair with p-value less than 0.05 were selected into the initial set of Drug A-ADR pairs. We further filtered out those pairs of Drug A-ADR that were not mentioned in the SIDER 4.1 (Criteria 2).

For each Drug A-ADR pair, we selected medications as Drug Bs that are co-prescribed with Drug A for a minimum of 500 case reports, regardless of the association between a Drug B and the ADR of interest (Criteria 3). We denoted the set of all candidate Drug A-ADR-Drug B triples as \( C = \{(\text{Drug A, ADR, Drug B})\} \), and elements in \( C \) is denoted as \( C_i \). The associations between Drug B and the ADR in each \( C_i \), when
patients are prescribed with Drug A will be our interest throughout this paper.

Step 2. Compute propensity scores for individual drugs

The propensity score is the conditional probability of being exposed to a drug, given a set of baseline characteristics. Using propensity scores, potential bias due to treatment selection could be mitigated and the response being evaluated is conditionally independent given the measured baseline characteristics. To adjust potential selection bias, we calculated propensity score for each individual drug that is either Drug A or Drug B in C.

For each individual drug, we selected the baseline characteristics as the top 200 most relevant medications and indications. The relevance of a medication or an indication to a drug is measured by the phi correlation coefficient. We use Rx and Dx to denote the relevant medications and indications respectively.

To obtain the propensity score, a logistic regression is performed for each drug, which is expressed as the following.

\[
\logit(P(Drug = 1)) = \alpha + \sum_{i=1}^{200} \delta_i Rx_i + \sum_{j=1}^{200} \gamma_j Dx_j
\]

(2)

Where \(\logit(x) = \log(x/(1-x))\), \(\alpha\), \(\delta\) and \(\gamma\) are the coefficients in the logistic regression. Once we obtain the estimates of the coefficients, the propensity score is estimated as the predicted probability of receiving the drug for each case report, i.e. predicted value of \(P(Drug = 1)\).

Step 3. Determine the association for the Drug A-ADR-Drug B triple

Within each triple \(C_i = (\text{Drug A}, \text{ADR}, \text{Drug B})\), it has been established in Step 1 that the chance that Drug A develops the ADR of interest is higher than the expected background rate. By adding the second medication - Drug B, the chance of developing the ADR of interest would possibly alter.

Specifically, we are interested in two predicted scores. First, given that the patient is prescribed with Drug A, whether adding Drug B will modify the chance of developing the ADR of interest. Second, given that the patient is prescribed with both Drug A and Drug B, whether Drug B will interact with Drug A to alter the chance of developing the ADR of interest. These two predicted scores can be generated by a regularized logistic regression as follows:

\[
\logit(P(ADR = 1)) = \beta_0 + \beta_1 DrugA + \beta_2 P_1 + \beta_3 DrugB + \beta_4 P_2 + \beta_5 DrugA * DrugB + \lambda |\beta|_1
\]

(3)

Where \(P_1\) and \(P_2\) are the propensity scores for Drug A and Drug B, respectively. \(\beta_i\) for \(i = 0, \ldots, 5\) are the coefficients, \(\beta = (\beta_1, \ldots, \beta_5)\) denote the vector of linear coefficients, and \(|\beta|_1\) denote the L-1 norm. The last term on the right hand side of Formula (3) is the least absolute shrinkage and selection operator (LASSO) regularizer, which could enforce estimates of \(\beta\) to be sparse, and \(\lambda\) is the tuning parameter of the regularizer. In this paper, for each \(C_i = (\text{Drug A}, \text{ADR}, \text{Drug B})\), we selected an optimal \(\lambda\) by 3-fold cross-validation. \(P_1\) and \(P_2\) are obtained from Step 2. The purpose of adding propensity scores in the logistic regression is to mitigate the drug selection bias given other patient characteristics such as medications that patients on and underlying diseases that patients have.

The value of \((\beta_1 + \beta_2)\) is referred to as predicted beneficial score for taking Drug B. The predicted beneficial score specifies the degree that a patient who is on Drug A could benefit or suffer from taking Drug B for the ADR of interest. A predicted beneficial score smaller than 0 indicates that patients who are on Drug A could benefit from taking Drug B in terms of reducing the ADR of interest, and a predicted beneficial score greater than 0 indicates that patients who are on drug A cannot benefit from taking drug B in terms of reducing the ADR of interest. The value of \(\beta_5\) is referred to as predicted interaction score. A predicted interaction score smaller than 0 indicates an antagonistic interaction between Drug A and Drug B which decrease the chance of developing the ADR of interest, while a predicted interaction score greater than 1 signifies a synergistic interaction between Drug A and Drug B which increase the chance of developing the ADR of interest. The later scenario is also referred to as DDIs.

Evaluation

The aim of this study is to identify a set of Drug Bs that could reduce the reporting rate of Drug A-induced ADRs. The appropriate evaluation of the proposed system should be based on a reference standard
consisted of a list of Drug Bs that are known to or not known to reduce the Drug A-induced ADRs, however, this kind of knowledge is scarce if not nonexistent. In order to demonstrate the effectiveness of the proposed method quantitatively, we assessed the predicted interaction score ($\beta_S$) against a set of known DDIs and their ADRs. Following common practice in pharmacovigilance\textsuperscript{25,26}, we constructed a reference standard, which consisted of DDIs known to cause or not known to cause either of two serious ADRs: rhabdomyolysis and QT prolongation. The DDIs, known to be associated with either rhabdomyolysis or QT prolongation, were extracted from DrugBank knowledgebase that comprise positive controls in the reference standard. For negative controls, we randomly paired drugs in the FAERS, excluded those that are known to interact with each other for any ADR, and then randomly selected the same number of negative controls from the rest of drug pairs. The rationale of selecting equal representation of positive and negative controls is to avoid class imbalance that can bias performance metrics to favor a method that is calibrated towards true positive rates when a reference set predominantly contains positive controls or specificity (1-\text{false positive rate}) when negative controls predominate\textsuperscript{27,28}. To quantitatively assess the performances of the proposed method, we generated receiver operating characteristic (ROC) curves, which are graphical plots of true positive rate vs. false positive rate. The whole ROC curve can be plotted by varying the threshold value or prediction score, above which the output is predicted as positive and negative otherwise. We also calculated the area under ROC curve (AUC) in our experiments.

Results

Data characteristics

FAERS data were collected from January 2004 to September 2015 accounting for 6,434,615 case reports, which contain 9,315 unique STITCH coded drugs and 18,159 MedDRA coded unique ADEs. On average, each report contains 3.5 different generic drugs, 2.2 different indications and 3.4 different ADEs.

System Evaluation

Table 1 shows statistics of and examples of positive and negative controls in the reference standard for DDIs and their ADRs. The reference standard was based on DrugBank knowledgebase. For instance, according to DrugBank knowledgebase, the concurrent use of cisapride and tacrolimus may result in increased risk of QT-interval prolongation. In total, 50 positive controls and negative controls were generated for rhabdomyolysis, and 61 positive controls and negative controls were created for QT prolongation. We further defined the relevant MedDRA preferred term for two ADRs, which were rhabdomyolysis and electrocardiogram QT prolonged respectively.

Figure 2 shows the resulting ROC curves for the classification of 100 drug pairs for rhabdomyolysis and 122 drug pairs for QT prolongation as true/false DDI using the proposed method. The AUC is 0.80 and 0.70 for rhabdomyolysis and QT prolongation respectively (1 indicates perfect classifier and 0.5 indicates random classifier), which indicates that the proposed system is effective for identifying DDIs and their ADRs. We then utilized the method to identify drugs (Drug Bs) that could reduce the ADRs of the other drugs (Drug As).

Large-scale prediction of novel drug combinations and their ADR reduction

After establishing the effectiveness of the approach as described above, we proceeded to perform comprehensive predictions of Drug Bs that can decrease the reporting rates of the ADRs induced by Drug As. A candidate set of 694,957 Drug A-ADR-Drug B triples was selected in Step 1 of the method, which involves 449 Drug As, 895 ADRs and 947 Drug Bs. Among them, 322,417 Drug A-ADR-Drug B triples have predicted beneficial scores smaller than 0 indicating that polypharmacy could potentially reduce the ADR.

As mentioned in the method section, the predicted beneficial score ($\beta_3$+$\beta_5$) indicates the degree that a patient who is on Drug A could benefit or suffer from taking Drug B for the ADR of interest, and the predicted interaction score ($\beta_5$) specifies the degree that the interaction effect between Drug B and Drug A on the ADR. By using the cutoff of 0, Table 2 shows the statistics of drug effects on the ADRs of interest computed from the regularized regression model. After adjusting for patient characteristics, 95.6% of Drug A-ADR pairs were positively associated indicating that Drug A increases the reported rate of ADRs, 3.3% of Drug A-ADR pairs were not associated indicating that Drug A does not either increase or decrease the reported rate of ADRs and 1.1% of Drug A-ADR pairs were negatively associated indicating that Drug A decreases the reported rate of ADRs. Moreover, among all Drug A-ADR-Drug B triples, 46.4% of predicted beneficial scores were smaller than 0 indicating that taking Drug B could decrease the chance of developing the ADR induced by Drug A; and 38.5% of predicted interaction scores were smaller than 0 signifying that Drug B could interact antagonistically with Drug A to reduce the ADR.

We are more interested in negative values of predicted beneficial score, and negative values of predicted interaction score (both of them are highlighted in bold in Table 2). Figure 3 (a) shows the histogram of
numbers of beneficial Drug Bs per Drug A-ADR pair. In total, the reporting rates of 4,950 drug A-induced ADRs can be reduced by at least one Drug B. On average, the reporting rate of a specific Drug A-induced ADR can be decreased by 65 Drug Bs. Figure 3 (b) shows the histogram of numbers of Drug Bs that could interact with Drug A antagonistically to reduce Drug A-induced ADR. In total, the reporting rates of 4,825 drug A-induced ADRs could be reduced by at least one Drug B’s antagonistic interaction with Drug A. On average, the reporting rate of a specific drug A-induced ADR could be decreased by 55 Drug Bs.

F: FDA approved drug combination; III: phase III clinical trial; IV: phase IV clinical trial
We further analyzed top 15 predictions for two scores. Table 3 displays a list of the top 15 Drug A-ADR-Drug B triples sorted with our predicted beneficial scores wherein the Drug B most dramatically reduced Drug A-induced ADR. In parallel, Table 4 presents a list of the top 15 Drug A-ADR-Drug B triples sorted with our predicted interaction scores wherein the drug B results in the best reduction of drug A-induced ADR. We investigated whether the predicted Drug B were prescribed with Drug A for the same disease using ATC code. Twelve Drug A-Drug B pairs in Table 3 and nine Drug A-Drug B pairs in Table 4 shared at least one ATC code signifying that the predicted drug combinations are useful in clinical practice since drug combinations are usually prescribed to treat or manage the same disease. Finally, the FDA orange book and clinical trials were interrogated to check clinical validity of the top ranked drug combinations. Nine drug combinations in Table 3 and two drug combinations in Table 4 have been validated in the orange book or investigated in the clinical trials, indicating their clinical validity.

III: Phase III clinical trial

**Discussions**

Results in Figure 2 demonstrated that the proposed method is effective in identifying and prioritizing DDIs with their ADRs. By comparing Table 3 with Table 4, more clinical evidences were found for drug pairs when the overall beneficial effect of Drug B was considered. Typically, drug combinations are developed to aim at a more effective treatment than the monotherapy for a single disease such as the combined use of benazepril and amlodipine besylate, ranked 1 in Table 3, for treating hypertension. And the combined use of atovaquone and proguanil, ranked 2 in Table 3, for treating or preventing malaria. However, very few clinical trials focus on evaluating the reduction of the Drug A-induced ADRs that the Drug B is able to achieve. Our method, in combination with a spontaneous reporting system, showed that the use of amlodipine besylate reduced benazepril-induced ADRs such as angioedema, cough and dizziness, with the most reduction in dizziness. Similarly, results showed that the use of proguanil reduced atovaquone-induced ADRs such as diarrhea, vomiting and pyrexia, with the most reduction in pyrexia. Cisplatin-acute renal failure-mannitol triple in Table 4 is an example that mannitol is used to reduce the chance of acute
renal failure (ARF) with the use of cisplatin. Although a couple of studies have reached to different conclusions about additional use of mannitol, either leads to reduction in the incidence of nephrotoxicity or is associated with the null result \(^{29,30}\). Our results showed that mannitol could reduce ARF through an antagonistic interaction with cisplatin.

Similar to DDI detection task wherein very few of publicly available data sources linking the potential DDIs to their ADRs \(^{31}\), very few of mined DDC data sources that link DDCs to their beneficial clinical effects. For example, the study conducted by Iwata et al. \(^{11}\) only predicted that the combined use of adrenaline and chloroprocaine was beneficial without relating them to a specific clinical effect. Our predicted data set is capable to relate DDCs to their clinical effects.

**Limitations and Future Research**

In Table 2, the use of Drug B may sometimes increase the reporting rate of Drug A-induced ADRs (34.3% of all triples). Specifically, there is a scenario where a Drug B that could decrease some Drug A-induced ADRs while increase the other Drug A-induced ADRs. For example, although additional use of sulfamethoxazole decreased trimethoprim-induced pyrexia, ranked 6 in Table 4, it also increased trimethoprim-induced hypersensitivity. In future work, a more comprehensive assessment should be conducted to evaluate the comprehensive effect of Drug B among patients who are on Drug A.

More legitimate cutoff values for the predicted beneficial and interaction scores, rather than 0 used in the study, could make our proposed approach more practical for supporting domain experts. Due to the heterogeneity in the mechanism of drug combination, as well as the heterogeneity in the sample sizes, a universal cutoff value may not be available. In our future research, we will explore statistical methods to determine specific cutoff values for different drug combinations.

The full database screening of FAERS to identify all Drug Bs to reduce the reporting rate of Drug A-induced ADRs are very time consuming simply because they are severely dependent on the searches of a vast space of possible drug pairs and relevant ADRs. In order to reduce the search space, we utilized the following criteria in the study: (1) Drug A should have more than 200 reports with the ADR; (2) Drug A-ADR signals should have been corroborated in SIDER 4.1 and (3) Drug A and Drug B are mentioned for a minimum of 500 case reports. The values in criteria (1) and (3) were also utilized in Zhao et al.’s study \(^{16}\). In future work, we plan to implement the algorithm in the high performance-computing environment so that we can relax these values in criteria to obtain more beneficial drug combinations and their clinical effects.

**Conclusion**

In this study, we proposed a novel data-driven method for large-scale prediction of drug combinations where one drug could reduce the ADRs of the other, based on FAERS data set. We validated the method against a known DDI reference standard, and applied the method to perform large-scale screening on FAERS data for drug-ADR-drug triples where polypharmacy could potentially reduce the ADR. Analysis of the top ranking candidates demonstrated high level of clinical validity and the usefulness of the approach.

Abstract

Time is an important aspect of information and is very useful for information utilization. The goal of this study was to analyze the challenges of temporal expression (TE) extraction and normalization in Chinese clinical notes by assessing the performance of a rule-based system developed by us on a manually annotated corpus (including 1,778 clinical notes of 281 hospitalized patients). In order to develop system conveniently, we divided TEs into three categories: direct, indirect and uncertain TEs, and designed different rules for each category of them. Evaluation on the independent test set shows that our system achieves an F-score of 93.40% on TE extraction, and an accuracy of 92.58% on TE normalization under “exact-match” criterion. Compared with HeidelTime for Chinese newswire text, our system is much better, indicating that it is necessary to develop a specific TE extraction and normalization system for Chinese clinical notes because of domain difference.

Introduction

Time is one of the most important aspects of information as information is usually event-centred and organized in order of time. To understand progress of events, people have to capture temporal information related to them, including temporal expressions (TEs) and temporal relations. Because of this, temporal information extraction as a fundamental task of natural language processing (NLP) has been always attracting a great deal of attention. A large number of systems using various methods, including rule-based and machine learning (ML)-based, have been developed to extract temporal information in text in different languages (e.g., English, Chinese, French, etc.) from different domains such as newswire and social media. In the clinical domain, there also have been a few temporal information extraction systems. However, most of them are designed for English clinical notes from electronic medical record (EMR) systems, and very limited studies have been carried out on Chinese clinical notes.

In recent years, with the rapid growth of EMRs in China, information extraction from Chinese clinical notes has attracted more and more attention of Chinese researchers. In this study, we developed a temporal expression (TE) extraction and normalization system for Chinese clinical notes, assessed its performance on a manually annotated corpus of Chinese clinical notes, and published our system online. To the best of knowledge, this is one of the earliest studies on TE extraction and normalization for Chinese clinical notes, our system is the first publicly available system, and we believe it will provide valuable insights into NLP research in Chinese clinical text.

Background

TE extraction and normalization are integral parts of information extraction and have been extensively studied in multilingual text in multiple domains. The development of related technology was mainly driven by several public challenges such as the TE recognition and normalization (TERN) challenge1 in 2004, the automatic content extraction (ACE) challenges2 in both 2005 and 2007, and a series of TempEval challenges: TempEval-13 in 2007, TempEval-24,5 in 2010 and TempEval-36 in 2013. In the early challenges (e.g., the 2004 TERN challenge and the 2007 ACE challenge), only English text in newswire domain was considered. Subsequently text in other languages such as Chinese was also gradually included, and the text was not limited to newswire text. For example, extracting and normalizing TEs in Chinese text from broadcast news, newswire and weblogs was added as a new subtask of the 2005 ACE challenge. In these challenges, both rule-based and ML-based approaches have been investigated, and the rule-based ones almost always showed better performance than the ML-based ones. For example, in the 2010 TempEval-2 challenge, the best TE extraction and normalization system (i.e., HeidelTime7-9) was a rule-based system which significantly outperformed other state-of-the-art ML-based systems such as two conditional random

* Corresponding author; Email: tangbuzhou@gmail.com
fields (CRF)-based systems: TIPSem\textsuperscript{10} and TRIOS\textsuperscript{11}. In the rule-based system, not only word, but also syntactic and semantic information such as part-of-the-speech and semantic role of words were used for rule design\textsuperscript{10, 12, 13}.

In the clinical domain, with the development of clinical NLP, a number of attempts have been proposed for English clinical notes. The early representative clinical NLP systems such as ConText\textsuperscript{14}, CNTRO\textsuperscript{15, 16}, MedLEE\textsuperscript{17}, CTakes\textsuperscript{18}, etc. usually include an individual rule-based module for TE extraction and normalization. As there was no benchmark corpus available for TE extraction and normalization system evaluation, it was difficult to compare them. In 2012, the i2b2 (Center of Informatics for Integrating Biology and Bedside) organized a clinical NLP challenge\textsuperscript{19} of temporal information extraction in clinical text, including a subtask of TE extraction and normalization. This challenge provided a benchmark corpus to evaluate different systems developed by researchers all over the world. In this challenge, both rule-based and ML-based methods were proposed for TE extraction and normalization, and finally the rule-based system developed by Sunghwan Sohn et al\textsuperscript{20} achieved the best performance, slightly better than the CRF-based system developed by Yan Xu et al\textsuperscript{21}. Subsequently, the SemEval challenge in 2015 included a clinical TempEval task\textsuperscript{22, 23} including a subtask of TE extraction and normalization in clinical text. Most of systems were rule-based. The information used to design rules included word, pos, clinical entity, etc.

In recent years, with the rapid growth of EMRs in China, the need of information extraction from Chinese clinical notes has become more and more strident, including temporal information extraction. However, very limited studies have been proposed for TE extraction and normalization in Chinese clinical text. Zhou et al\textsuperscript{24} proposed a simple rule-based method to extract and normalize TEs in Chinese clinical text and evaluated the method on a very small manually annotated dataset with only 1,207 TEs from 147 medical records. Despite the important contributions of previous studies on TE extraction and normalization in Chinese clinical text, none has systematically analyzed the difference of the TE extraction and normalization systems for clinical text in Chinese and English, and the difference of the TE extraction and normalization systems for Chinese clinical text in the newswire domain and clinical domain, which is very important for system porting from English clinical text or Chinese newswire text to Chinese clinical text.

In this paper, we analyzed the characteristics of Chinese clinical notes, developed a rule-based TE extraction and normalization system for Chinese clinical text (available at http://icrc.hitsz.edu.cn:8096/CMedTEX), and analyzed which cases were the new cases in Chinese clinical text compared to English clinical text and Chinese newswire text. To the best of our knowledge, this is one of the earliest comprehensive studies on TE extraction and normalization for Chinese clinical notes, and our system is the first publicly available TE extraction and normalization system for Chinese clinical notes, whose source code was also released for application at: http://icrc.hitsz.edu.cn/Article/show/147.html.

**Methods**

**Dataset and annotation**

A real world dataset of 1,778 de-identified clinical notes of 281 hospitalized patients were collected from the sixth people’s hospital of Shenzhen, Shenzhen, China. Two master students with computer science and medical informatics background were recruited to annotate TEs in the clinical notes by following annotation guidelines designed for this study. When creating the annotation guidelines, we referred to the TE annotation guidelines of TimeML\textsuperscript{25, 26} for English newswire text and the 2012 i2b2 NLP challenge\textsuperscript{27} for English clinical text, and defined the same three attributes for each TE, i.e., type, value and modifier, where there were four types (DATE, TIME, DURATION and FREQUENCY) and seven modifiers (APPROX, START, END, MIDDLE, MORE, LESS and NA (default value)), and the value attribute is the standard temporal value defined in ISO8601. Some examples were shown in Figure 1.

To calculate the inter-rater annotation agreement of the two annotators, we asked them to annotate 300 out of 1,778 notes at the same time. When there was any disagreement between the two annotators, a third judge was brought in to select or confirm the different annotations. Following the 2012 NLP challenge\textsuperscript{29, 30}, the inter-rater annotation agreement of the two annotators was calculated under two criteria: “exact-match” and “partial-match”, where “exact-match” and “partial-match” denote that two time expressions are correctly matched if and only if their text spans are exactly the same and overlap with each other respectively. Based on these 300 notes, inter-rater agreements of TE span, type and modifier using Kappa statistics\textsuperscript{29} were 0.9035, 0.9681 and 0.9195, the inter-rater annotation agreements of type value and modifier using accuracy were 0.9756, 0.8773 and 0.9879 under the exact-match criterion (see Table 1), indicating that our annotation was reliable. The remaining 1,478 notes were annotated by one annotator only.
Figure 1. Examples of TEs with attributes. ‘x’ denotes the missing information needing to be determined during normalization.

Table 1. Inter-annotator agreement under both “exact-match” and “partial-match” criteria. “/” denotes there is no available value.

After annotation, we obtained 46,508 TEs. The annotated dataset was randomly divided into training and test sets. The training set consisted of 1,076 records with 28,442 TEs of 170 hospitalized patients, while the test set consisted of 702 records with 18,066 TEs of 111 hospitalized patients. The statistics of the dataset were shown in Table 2 in detail, where “#*” denotes the number of ‘*’. Among four types of TEs, dates accounted for the highest proportion of 36.56% (17,005/46,508), and times accounted for the lowest proportion of 15.84% (7,368/46,508).

TE extraction and normalization

Although a large number of both machine learning-based and rule-based methods have been proposed for TE extraction, experiments in TempEval-2 and 2012 i2b2 NLP challenges demonstrated that the rule-based methods obviously outperformed the machine learning-base methods, and the best systems of the two challenges were all rule-based4, 19. For TE normalization, almost all systems were rule-based. Therefore, in this study, we investigated the rule-based methods for TE extraction and normalization. In order to develop our system conveniently, we analyzed the characteristics of Chinese clinical notes and classified them into three categories: direct, indirect and uncertain, which denoted complete and exact TEs, incomplete or implicit but exact TEs, and inexact TEs. Figure 2
listed some examples. For each category of TEs, we designed specific rules, which were presented in the following paragraphs in detail.

**Figure 2.** Examples of TEs in the three categories: direct, indirect and uncertain.

1. Direct TEs

It is easy to extract and normalize direct TEs in clinical text as they usually appear in common patterns explicitly and do not need further processing for normalization. For each type of direct TEs, we defined a large number of rules. Taking dates for example, they are calendar dates in three patterns as shown in Figure 3, where “YearDigit”, “MonthNumber” and “DayNumber” are sets of regular expressions for year, month and day numbers respectively (including Chinese numbers such as “零” (zero), “一” (one), “二” (two), etc.), ‘年’, ‘月’ and ‘日/号’ are the units of year, month and day, and “NormYear”, “NormMonth”, “NormDay” are mapping functions from “YearDigit”, “MonthNumber” and “DayNumber” to their standard forms respectively.

**Pattern 1**

- **Extraction rule:** `YearDigit[-一零]+MonthNumber[-一月]+DayNumber[日号]?`
- **Normalization rule:** `NormYear(NormDigit)-NormMonth(NormMonth)-NormDay(NormDay)`
- **Examples:** 2011/6/21, 2011年6月21日 (June 21, 2011), 二零一一年六月二十一日 (June 21, 2011)

**Pattern 2**

- **Extraction rule:** `YearDigit[-一零]+MonthNumber`
- **Normalization rule:** `NormYear(NormDigit)-NormMonth(NormMonth)`
- **Examples:** 2011-6, 2011年6月 (June, 2011), 二零一一年六月 (June, 2011)

**Pattern 3**

- **Extraction rule:** `YearDigit季`
- **Normalization rule:** `NormYear(NormDigit)`

**Figure 3.** Extraction and normalization rules for direct date expressions.
2. Indirect TEs

Compared to direct TEs, indirect TEs are also exact but incomplete or implicit. There are two cases: 1) incomplete temporal expressions missing some parts such as year and month. For example, “6月21日” (“June 21”) is a date expression missing year; 2) implicit temporal expressions representing relative time such as “3天前” (“three days ago”) and “手术前一天” (“the day before surgery”). To exact indirect TEs, we modified rules for direct TEs. To normalize indirect TEs, we need further inference to complete the missing part of them or to calculate the absolute time of them. For example, we need to complete the year information for “6月21日” (“June 21”), and to calculate the absolute time of “3天前” (“three days ago”) and that of “手术前一天” (“the day before surgery”). The key of indirect TE normalization is to find out the baseline time of them which may be a calendar time or the occurring time of some event such as “手术” (“surgery”) in “手术前一天” (“the day before surgery”). In this study, we tried the following three strategies gradually to determine the baseline time of indirect TEs:

1) The baseline time of all indirect TEs in a note is the admission/discharge/create time (for admission notes, discharge summaries and progress notes respectively.) mentioned in the note, which is easy to determine as it usually appears at the beginning of a note.

2) The baseline time of an indirect TE is the nearest TE in front of it in the same sentence or a previous sentence.

3) The baseline time, which is the occurring time of some events (e.g., surgery, operation, transfer, etc.), is determined by the previous two strategies when they first appear.

Figure 4 gave some examples using different strategies for indirect TE normalization, where there was a fragment of an admission note with two direct TEs and five indirect TEs enclosed in square brackets. It is clear that the five indirect TEs were wrongly normalized except the last one when only using strategy 1 mentioned above. When strategy 2 was added, the first three indirect TEs were correctly normalized but the last two TEs not. Nevertheless, strategy 3 corrected the last two TEs normalized by strategy 2 since they were times relative to “手术” (“the operation”) and “入院” (“admission”) with baseline times: 2011-10-18 and 2012-02-03T15:00, respectively. It should be noted that the time of “手术” (“the operation”) is “2011-10-18” not “2011-10-19” since the nearest TE in front of “手术” (“the operation”) that first appears is “18日” (“18th”) not “一天后” (“one day later”).

3. Uncertain TEs

There are two types of uncertain TEs: direct/indirect TEs modified by fuzzy adjectives or adverbs, and fuzzy temporal phrases (e.g., more than, about, in the morning, etc.). For the first type of uncertain TEs, rules for extraction were also modified from direct/indirect TEs by adding fuzzy adjectives or adverbs; and the key of their
normalization lies in a list of modifiers and in which way an uncertain TE and a modifier should be combined together. For the second type of uncertain TEs, we needed to collect a list of fuzzy temporal phrases with modifier attribute. Figure 5 listed some examples of uncertain TEs with modifier value.

**Experiments and evaluation**

We developed our system on the training set, and then evaluated its performance on the independent test set. In order to investigate the effects of the three categories of TEs, we started with the baseline system only considering direct TEs, and then progressively added indirect TEs and uncertain TEs.

The micro-averaged precision, recall, and F-measure under exact/partial-match criteria were used to evaluate system performance for TE extraction, and the micro-averaged accuracy for TE normalization. Under exact-match criterion, an entity is correctly predicted if and only if its text span is exactly the same as that of one entity in the gold standard, while, under partial-match criterion, an entity is correctly predicted if it overlaps with any entity in the gold standard. We developed an evaluation tool based on the official evaluation program provided by the 2012 i2b2 NLP organizers.

**Results**

Table 3 showed the performance of our system on the test set when different categories of TEs were considered. The number in columns 2 and 6 were F-measures followed by corresponding precision and recall in parentheses for TE extraction under exact-match and partial-match criteria, while the numbers in other columns were accuracies for identifying corresponding attributes such as numbers in columns 4 and 8 for TE normalization under two criteria. Under exact-match criterion, our system (“direct”) achieved a precision of 79.46%, a recall of 59.57% and an F-measure of 68.09% on TE extraction, and an accuracy of 57.88% on TE normalization when it only considered
direct TEs. When indirect TEs were added (“direct + indirect”), the precision, recall and F-measure of our system on TE extraction were improved to 87.00%, 77.62% and 82.04%, and the accuracy on TE normalization was improved to 74.04%. When further considering uncertain TEs (“direct + indirect + uncertain”), our system achieved highest precision of 90.83%, highest recall of 96.11% and highest F-measure of 93.40% on TE extraction and highest accuracy of 92.58% on TE normalization. These results demonstrated that both indirect and uncertain TEs played an important role in TE extraction and normalization.

The detailed results of the best system for each type of TE are shown in Table 4. On TE extraction, F-measures ranged from 88.45% to 97.92% under exact-match criterion. Among four types of TEs, our system performed best for times and worse for durations. On TE normalization, accuracies ranged from 87.69% to 96.48% under exact-match criterion, and our system performed best for times and worse for frequencies.

Discussion

In this paper, we comprehensively investigated the rule-based methods for TE extraction and normalization in Chinese clinical notes. We manually created an annotated dataset of 1,778 clinical notes in Chinese for system development and test. Experiments on the dataset showed that our system achieved the highest F-measure of 93.40% on TE extraction, and the highest accuracy of 92.58% on TE normalization under exact-match criterion. We published our system online (http://icrc.hitsz.edu.cn:8096/CMedTEX), which is the first public available TE extraction and normalization system for Chinese clinical notes and will be useful for future Chinese clinical NLP studies. The source code of our system was available for application at: http://icrc.hitsz.edu.cn/Article/show/147.html.

It is clear that our system performance is progressively improved when gradually adding specific rules for direct, indirect and uncertain TEs as shown in Table 3. The main reason lies in that when the rules for direct TEs are deployed to indirect and uncertain TEs, parts of indirect and uncertain TEs will be recognized as direct TEs, which will cause some errors. For example, when applying rules for direct TEs to “2011 年 6 月 21 日下午” (“afternoon of June 21, 2011”), an indirect TE, and “3 天以前” (“3 days ago”), an uncertain TE, we will only obtain two direct TEs: a date of “2011 年 6 月 21 日” (“June 21, 2011”) and a duration of “3 天” (“3 days”), which are two errors. Therefore, we designed specific rules for indirect and uncertain TEs, respectively, which are derived from the rules for direct TEs, to correct these errors.

Compared to TE extraction and normalization systems in other domains (e.g., newswire) or other languages (e.g., English), our system is promising. For example, the best system on the Chinese corpus of TempEval-2 in newswire domain (i.e., HeidelTime) was rule-based and achieved an F-measure of 89.30% on TE extraction and an accuracy of 87% on TE normalization under exact-match criterion. In the 2012 i2b2 challenge about temporal information extraction for English clinical text, the highest F-measure and accuracy on TE extraction and normalization were 91.44% and 73.13% respectively. Our system showed better performance than the best systems of those two challenges even though the comparison between them is not very fair as they were not evaluated under the same conditions.

In order to investigate the effect of domain difference on TE extraction and normalization systems, we compared HeidelTime, a state of the art TE extraction and normalization system for Chinese newswire text, with our system on the test set. Under exact-match criterion, the F-measure and accuracy on TE extraction and normalization of HeidelTime were only 38.35% and 8.60%, much lower than those of our system, indicating that TEs in clinical text are much different from TEs in other domains (especially newswire domain). Therefore, it is necessary to design...
new rules and systems to extract and normalize TEs in clinical text. The reasons why HeidelTime performed so bad for Chinese clinical notes may lie in the following two aspects: 1) there are a large number of proper TEs in clinical text such as qid (“一天四次”, four times per day), which cannot be recognized by HeidelTime; and 2) many indirect TEs in clinical text are relative to clinical events such as operation and transfer, which are not considered by HeidelTime.

Furthermore, we analyzed the errors caused by our system, and found that most of the errors were related to word ambiguities. For example, “9-10” can be either a date “9月10号” (“September 10”) or a duration “9至10” (“from 9 to 11”), “9.10” can be either a date “9月10号” (“September 10”) or a number, “10个月” (“10 months”) can be either a duration or a child’s age, “夜间” (“at night”) is usually a duration, but not a separate TE when it is a part of problem “夜间盗汗” (“night sweats”), and “一周” (“one week”) is usually a duration, but not a TE when it appears in problem “脐带绕颈一周” (“a nuchal cord”) with another meaning “one round” in Chinese. Among these errors, the first three are common problems in both English and Chinese clinical text and the last two are special problems in Chinese clinical text. To tackle these problems, we may need to take other information, such as syntax and clinical entities, into account. However, it is not easy to obtain these information as the studies on Chinese clinical NLP has just began.

In the future, we plan to focus on the following two aspects for further improvement: 1) consider more information, such as syntactic and semantic information, to fix current errors; and 2) attempt machine learning-based methods to enhance our system.

Conclusion

In this study, we developed a rule-based time expression extraction and normalization system for Chinese clinical notes. The time expressions were summarized into three different categories: direct, indirect and uncertain expressions, which facilitated the construction of rules more easily and clearly. Our system achieved a span F-measure of 93.40% and a value accuracy of 92.58% under “exact-match” criterion. The online system is publicly available and its source code is released for application.

Interpretable Topic Features for Post-ICU Mortality Prediction

Yen-Fu Luo, MS, Anna Rumshisky, PhD
University of Massachusetts Lowell, Lowell, MA

Abstract

Electronic health records provide valuable resources for understanding the correlation between various diseases and mortality. The analysis of post-discharge mortality is critical for healthcare professionals to follow up potential causes of death after a patient is discharged from the hospital and give prompt treatment. Moreover, it may reduce the cost derived from readmissions and improve the quality of healthcare.

Our work focused on post-discharge ICU mortality prediction. In addition to features derived from physiological measurements, we incorporated ICD-9-CM hierarchy into Bayesian topic model learning and extracted topic features from medical notes. We achieved highest AUCs of 0.835 and 0.829 for 30-day and 6-month post-discharge mortality prediction using baseline and topic proportions derived from Labeled-LDA. Moreover, our work emphasized the interpretability of topic features derived from topic model which may facilitates the understanding and investigation of the complexity between mortality and diseases.

1. Introduction

Post-discharge management is one of the important aspects in current healthcare system. For high-risk patients, and especially for the intensive care unit (ICU) patients, it is critical to understand and prevent possible complications and problems which may lead to a patient’s death after being discharged from the hospital. The present work focused on mortality prediction of high-risk ICU patients. In our patient cohort, the post-discharge mortality for 30-day and 6-month are 3.4% and 9.5% respectively. There has been a lot of recent interest in mortality prediction in general and post-ICU mortality prediction in particular\(^1\)\(^-\)\(^3\). However, many of the state-of-the-art methods use “black box” predictive models which can not provide any explanation for practitioners as to why a particular patient may be at risk after discharge. In this paper, our goal is two-fold: develop novel methods that can both accurately predict mortality and at the same time create a transparent predictive model that can be easily understood and therefore actionable by the providers.

SAPS-II\(^4\), APACHE-II\(^7\), and SOFA\(^6\) scores are commonly used in ICU mortality prediction\(^1\)\(^-\)\(^2\), \(^7\)\(^-\)\(^10\). In addition to structured data and derived severity scores, we build a mortality prediction model that incorporates features derived from unstructured medical notes. We use Multiparameter Intelligent Monitoring in Intensive Care (MIMIC II)\(^11\) database. The narrative provider notes from MIMIC II give detailed descriptions of symptoms, diagnosis, surgery, medicine, and treatments. It is highly informative but in the form of free-text. Our goal is to capture clinically relevant information and patterns identified and summarized by healthcare providers in order to leverage them in transparent prediction.

There have been recent attempts to use Bayesian topic modeling techniques to improve mortality prediction using narrative notes\(^1\)\(^-\)\(^5\), \(^7\). In topic modeling, each document is represented as a probability distribution over a set of topics and each topic is modeled as a probability distribution over a set of words. Although topic-based features have been used in literature to improve outcome prediction, the topics themselves are flat word collections that need to be examined by domain expert in order to assign a clinical interpretation.

Although the derived topics show some degree of interpretability\(^12\), human annotators are prone to assigning meaning to topics or word clusters even in cases when such word collections are not coherent. In this work, we propose a method to automatically define interpretable topics. To make a topic itself interpretable and clearly definable based on domain knowledge, we used the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes as topics namely labels in Labeled-LDA to guide topic model learning and extract understandable topic feature representations from medical notes. In addition, we examined the feasibility of using topic features derived from Labeled-LDA for post-discharge mortality prediction.

2. Related Work

One of the common approaches to using narrative notes for clinical outcome prediction is to extract clinically-relevant concept and relations using information extraction techniques and use them as features in predictive models. A number of medical concept extraction systems, including rule-based systems (MetaMap\(^13\), MedLEE\(^14\)
cTAKES\textsuperscript{15}, etc.) and machine learning-based systems (Clien\textsuperscript{16}, RapTAT\textsuperscript{17}) have been used for this task\textsuperscript{15-23}. However, such systems require a substantial amount of human labor in order to produce accurate results, either for rule construction and keyword selection, or for text annotation and feature engineering required for the supervised machine learning. As a result, shifting between different types of clinical notes, or between different institutions, requires a substantial overhead in order to achieve domain adaptation. This is additionally compounded by continuous changes in medical terminology, introduction of new medication brands, and so on.

There has been a number of recent attempts to bypass this problem by using unsupervised methods that rely on topic modeling to extract topic features from clinical narrative text in order to improve the prediction of in-hospital and post-discharge mortality for ICU patients. Ghassemi et al.\textsuperscript{1} reported AUCs of 0.754 and 0.781 for 30-day and 6-month post-discharge mortality prediction. Ghassemi et al.\textsuperscript{2} also reported an AUC of 0.818 for 30-day post-discharge mortality prediction using retrospective topic + derived features model. Lehman et al.\textsuperscript{7} combined medical concepts extracted from medical notes with topic model for ICU in-hospital mortality prediction. Jo et al.\textsuperscript{3} used state-transition topic model for incorporating temporal information and reached an AUC of 0.792 for 6-month post-discharge mortality prediction.

Ideally, predictive models for mortality should be customized for different patient groups, based on primary diagnosis and other patient characteristics. Nori et al.\textsuperscript{24} combined the hierarchy of ICD-10 into mortality prediction and divided the general prediction model into multi-task/multi-disease learning problem. Makar et al.\textsuperscript{25} also incorporated ICD-9-CM codes for short-term mortality prediction of elderly patients.

Topic models such as the Latent Dirichlet Allocation (LDA)\textsuperscript{26} and Hierarchical Dirichlet Process (HDP)\textsuperscript{27} are widely used to explore coherent topics within large text corpora. HDP is a nonparametric Bayesian approach which does not require specifying the desired number of topics. Arnold et al.\textsuperscript{12} showed the interpretability of topic model from a physician’s perspective. Although their conclusions support using topic features in a prediction task, identifying high quality topics may also require a labor-intensive topic evaluation by domain experts, in order to determine the optimal parameter settings (i.e., the number of topics in LDA or the concentration hyperparameter in HDP). Incorporating domain knowledge into the topic learning in the way implemented in the present work helps to address both the problem of customizing predictive models for different patient categories and to improve topic interpretability.

3. Methods

In the present work, we propose to incorporate domain knowledge into topic learning using Labeled-LDA\textsuperscript{28} with ICD-9-CM codes as labels. Labels are equivalent to topics or ICD-9-CM codes in our setting, and each document may be assigned multiple labels. In LDA, all documents contribute to all topics in the learning of the topic model. In Labeled-LDA, a subset of documents with the corresponding label is used to infer word distributions for a topic. The benefit of using ICD-9-CM codes as labels in Labeled-LDA is two-fold. First, the clinical notes from a given patient’s record contribute only to a subset of topics corresponding to the ICD-9-CM code assignments for that patient. Second, topic interpretability is achieved through a combination of the ICD-9-CM code definition and the top words for a given topic. At the training stage, we incorporate ICD-9-CM codes to guide the Labeled-LDA model learning. However, since ICD-9-CM codes are not available at the time of discharge, they can not be included as features in the predictive models directly. Using Labeled-LDA approach allows us to bypass this issue, since at the prediction stage, inferring topic proportions corresponding to different ICD-9-CM codes does not require one to have the ICD-9-CM codes available.

3.1 Patient Selection

We used MIMIC II database. The database contains physiological signals, vital signs, medical notes, and other structured data from several ICUs, including medical, surgical, coronary care, and neonatal. This data was collected between 2001 and 2008 at Boston’s Beth Israel Deaconess Medical Center (BIDMC). The database contains over 25,000 patients including around 20,000 adults and 5,000 neonates.

Since the factors related to mortality differ substantially for neonates, only patients in the adult age group were selected. The patients without discharge summary were excluded from the cohort, since discharge summary is essential for building the prediction model for post-discharge mortality. We also excluded patients without the first SAPS II score. All available clinical notes, including nursing, physician, radiology, and the discharge summary of the patient’s first hospital stay were collected. We identified and removed 11% duplicate medical notes. The resulting cohort consisted of 18,412 patients with 400,494 notes. The patient data was randomly split into 80% for training set and 20% for testing set.
3.2 Preprocessing and Tokenization

Each note was processed by using the SPECIALIST Lexicon LRABR table to preserve medical abbreviations and acronyms; this was followed by whitespace-based tokenization, and the removal of stopwords from the Onix stopword list. Term frequency was generated by aggregating word frequency for each patient. The top 500 most informative words were selected for each patient, based on the TF-IDF score29 for each patient included in the training data. This resulted in the overall vocabulary containing 151,772 words.

3.3 LDA and Labeled-LDA

Knowledge Based Topic Models (KBTM) were developed to guide topic model learning by incorporating domain knowledge. Andrzejewski et al.30-31 demonstrated the use of Dirichlet forest priors and first-order logic in order to create must-links and cannot-links between words which encode domain knowledge during model learning. This solution requires domain experts to encode knowledge used to create constraints. We propose using Labeled-LDA as an alternative. Labeled-LDA was designed to analyze the text of the web pages that may be annotated by users in a community portal. Each page may have multiple labels associated with the topics of the page (such as arts, politics, physics, religion, alaska, etc.), assigned by the readers. In Labeled-LDA, word distribution of a topic is inferred based on a subset of the corpus with the corresponding label. Therefore, the inferred top keywords of a topic are associated with the subject of the label.

We adapted this model to the task of transparent outcome prediction, using the ICD-9 diagnostic codes assigned to each patient as labels, with the two-fold goal of guiding the topic learning and improving interpretability of the resulting topics. ICD-9-CM is based on the World Health Organization’s Ninth Revision, International Classification of Diseases (ICD-9). Until October 2015, diagnoses and procedures associated with hospital utilization in the United States were recorded using official ICD-9-CM codes. Based on multiple procedures and treatments during a patient’s hospital stay, multiple ICD-9-CM codes are assigned by trained healthcare professionals. Although there is some disagreement on the viability of using ICD-9 codes in predictive tasks due to the diagnostic codes being assigned exclusively for billing purposes, they do provide an expert-generated authoritative source of annotation for each record, which can be reasonably assumed to represent high-level domain knowledge. The topics obtained by applying Labeled-LDA to medical notes of ICU patients with ICD-9-CM codes as labels may be interpreted as providing a description of sorts to the corresponding code, which can be easily verified against the ICD-9 code definition. Under this interpretation, the topic proportions also represent the extent to which a particular diagnosis or procedure is associated with the given hospital stay.

Rather than using the raw ICD-9-CM codes, we used the ICD-9-CM hierarchy with 180 upper-level codes in order to reduce the sparsity of ICD-9-CM code assignments. Comparing to the LDA model that uses all documents to infer topic proportions and word distributions, the Labeled-LDA model only uses a subset of documents for each topic inference. Since training a topic model requires sufficient data to produce coherent topics, we only considered labels with minimum frequency 50, 100, 200, and 400. The resulting number of labels are 111, 94, 79, and 59 respectively. Following Ghassemi et al1-2, we used 50 topics for training a regular LDA model. We sampled topic proportions for each patient in the training data after using 2,500 iterations during model learning, and the resulting model was used to obtain topic proportions for each patient in the test data. We used default hyperparameter settings in both LDA and Labeled-LDA models.

3.4 Mortality Prediction

We retrieved age, gender, SAPS-II scores, Elixhauser Comorbidity Index32, the text of the medical notes, and the ICD-9-CM code assignments for each patient’s first hospital stay recorded in the MIMIC II database. The topic model was used to infer topic proportions for all medical notes in a patient’s record at the time of discharge. This information, together with the obtained topic proportions, were used as real-valued features in a predictive model. A Support Vector Machine (SVM) model33 with radial basis function (RBF) kernel was trained and used to predict 30-day and 6-month post-discharge mortality.

For 6-month post-discharge mortality prediction, we used three feature settings: (1) baseline features included age, gender, SAPS-II score at admission, minimum SAPS II score, maximum SAPS II score, and 30 Elixhauser Comorbidities, (2) baseline features and 50 topic proportions derived from regular LDA, and (3) baseline features and topic proportions derived from Labeled-LDA. For the 30-day prediction model, we excluded minimum SAPS-II score, maximum SAPS-II score, and ICD-9-CM derived 30 Elixhauser Comorbidities from the baseline features.
The reason is that the assignment of ICD-9-CM codes is usually finalized within 2 weeks after a patient is discharged from the hospital, and therefore is not available at the time the prediction needs to be made.

In our patient cohort, 3.4% and 9.5% of the patients died within 30-day and 6-month post-discharge respectively. Because of the highly imbalanced data, we subsampled negative class to generate dataset with 20% positive and 80% negative class for training. In addition, we penalized misclassification of positive class by assigning higher class weight in SVM. The optimal cost and gamma parameters were determined in 5-fold cross-validation over the training data against ROC-AUC.

4. Results

4.1 Topic Interpretability

Baseline + Labeled-LDA with 111 labels achieved highest AUC in both 30-day and 6-month mortality prediction. To illustrate the topics derived with this Labeled-LDA model, we show 10 most and 10 least frequent ICD-9-CM codes in Table 1, along with their definitions, and top 20 words. The results suggest the consistency between ICD-9-CM code’s definition and the corresponding keywords. For example, the top words for the “hypertensive disease” topic include ‘chest’, ‘cabg’, ‘artery’, ‘coronary’, etc. Another example topic, labeled “complications occurring mainly in the course of labor and delivery” is associated with the words ‘uterine’, ‘bleeding’, ‘vaginal’, ‘delivery’, ‘abd’, and ‘hct’.

Table 1. List of top 20 words learned from Labeled-LDA and its corresponding ICD-9-CM definition. Top 10 and bottom 10 entries are most and least frequent ICD-9-CM code in our dataset. Frequency of 111 ICD-9-CM codes are listed in Table 3.

4.2 Mortality Prediction

Table 2 shows mortality prediction results, with AUC, sensitivity, and specificity shown for baseline features, baseline + LDA topics, and baseline + Labeled-LDA topics with four label settings. The model using baseline + topic features from Labeled-LDA with 111 labels achieved an AUC of 0.835 for 30-day post-discharge mortality prediction. For 6-month post-discharge mortality prediction, baseline + Labeled-LDA with 111 and 94 labels performed closely with AUCs of 0.829. While both topic model derived features outperform the baseline in both 30-day and 6-month prediction model, baseline + LDA topics achieves somewhat higher AUCs than baseline + Labeled-LDA topics.

4.3 Topic Mortality

We applied probability of mortality defined by Marlin et al. for each topic to investigate correlation between topics and mortality. Table 3 depicts ICD-9-CM codes with corresponding probability of mortality for 30-day and 6-month post-discharge periods. The results suggested “viral diseases accompanied by exanthem” (050-059), “dislocation” (830-839), and malignant neoplasm of “other and unspecified sites”, “respiratory and intrathoracic organs” (190-199 and 160-165), and “other diseases of skin and subcutaneous tissue” (700-709) are the potentially important causes of death for 30-day post-discharge. For 6-month post-discharge mortality, malignant neoplasm of “other and unspecified sites”, “respiratory and intrathoracic organs” (190-199, 160-165, and 200-208), and “other diseases of skin and subcutaneous tissue” (700-709) are the potentially important causes of death. On the other hand, one can see that “open wound of limb” (880-887 and 890-897), “superficial injury” (910-919), “complications of labor and delivery” (660-669), “complications mainly related to pregnancy” (640-649), “injury to blood vessels” (900-904), “homicide and injury purposely inflicted by other persons” (E960-969), and “suicide and self-inflicted injury” (E950-959) were ranked high in both 30-day and 6-month post-discharge survival.

5. Discussion

Our results confirm previous findings that LDA-derived topic features provide a promising boost to mortality prediction\(^1\). Although the features derived from the "vanilla" LDA achieve slightly higher AUC than Labeled-LDA, the “vanilla” LDA topics require domain experts to interpret the topics and associate them with the underlying disease representation. At the same time, our proposal of using Labeled-LDA model with ICD-9-CM codes as labels suggest a feasible way to achieve direct interpretability of topic features. Specifically, the top words of a topic derived with Labeled-LDA tend to be strongly associated with the corresponding definition of ICD-9-CM code. Note that expert evaluation of topic quality is also made easy by virtue of associating topics with ICD-9 definitions.

Our transparent predictive model effectively provides the ability to tailor mortality prediction to the particular diagnosis, with the Labeled-LDA topic model supplying an association score for each ICD-9-CM code via topic proportions. Several cancers are notorious causes of death as can be seen in Table 3. Likewise, the largest proportion of our patient cohort are cardiac patients, and Table 3 shows low average probability of mortality for the corresponding topics. On the other hand, dislocation was surprisingly ranked high in topic mortality. We examined the patients with dislocation and found that more than half of the patients were over 50 years old. It might suggest the poor recovery from dislocation of the elderly which causing following complications after they were discharged from the hospital.

We expect that using different methods of label selection to supplement frequency thresholding we used in this work may lead to improved prediction for the labeled LDA model. This may entail, for example, selecting the ICD-9 codes from specific levels of the ICD-9 hierarchy. This can be seen as similar to the topic granularity experiments in which the number of topics is changed in the regular LDA model.

Interestingly, the Labeled-LDA topic model can potentially be used to uncover relations between different diagnostic labels by virtue of examining the associated terms. As an example, some of top words in the topic associated with “Other metabolic and immunity disorders” such as ‘chest’, ‘artery’, ‘coronary’, ‘cabg’, and etc. may reflect the relationship between cardiac and metabolic diseases as described in Alvarez et al.\(^35\) and Naschitz et al.\(^36\). This suggests that using labeled LDA models which factor in the label frequency and interdependence, such as the ones proposed by Rubin et al.\(^37\) can potentially be used to explore the correlation between different labels.
6. Conclusions

We demonstrated the promising predictive power for 30-day and 6-month post-discharge mortality prediction using Labeled-LDA derived topic features. Because of the diversity and complexity of the diseases, our approach incorporated ICD-9-CM codes as knowledge input to guide topic model learning. Given an ICU record, the derived model could be used to determine the likelihood of post-discharge mortality and provide the physician with a justification for this assessment in the form of a combination of diagnostic codes associated with derived high-risk topics. In addition, ICD-9-CM topic features may be interpreted directly by healthcare professionals and patients for understanding the specific results of mortality prediction. In future work, different ICD-9-CM hierarchy and Labeled-LDA variants may be explored to improve the topic interpretability and prediction model.

A First Step towards a Clinical Decision Support System for Post-traumatic Stress Disorders

Sisi Ma, PhD, Isaac R Galatzer-Levy, PhD, Xuya Wang, MS, David Fenyö, PhD, Arieh Y Shalev, PhD
New York University School of Medicine, NY, NY, USA

Abstract

PTSD is distressful and debilitating, following a non-remitting course in about 10% to 20% of trauma survivors. Numerous risk indicators of PTSD have been identified, but individual level prediction remains elusive. As an effort to bridge the gap between scientific discovery and practical application, we designed and implemented a clinical decision support pipeline to provide clinically relevant recommendation for trauma survivors. To meet the specific challenge of early prediction, this work uses data obtained within ten days of a traumatic event. The pipeline creates personalized predictive model for each individual, and computes quality metrics for each predictive model. Clinical recommendations are made based on both the prediction of the model and its quality, thus avoiding making potentially detrimental recommendations based on insufficient information or suboptimal model. The current pipeline outperforms the acute stress disorder, a commonly used clinical risk factor for PTSD development, both in terms of sensitivity and specificity.

Introduction

Chronic PTSD is distressful and debilitating\(^1\), following a non-remitting course in about 10% to 20% of trauma survivors\(^2,3\). The early response may provide sufficient information to identify individuals at high risk\(^4,5\) as multiple studies to date have identified numerous risk indicators of chronic PTSD, many of which are retrievable shortly after trauma exposure including early symptoms of PTSD, depression or dissociation, physiological arousal (e.g., heart rate), early neuroendocrine responses, gender, lower socio-economic status, the early use of opiate analgesics, the occurrence of traumatic brain injury, and a progressively growing number of genetic and transcriptional factors\(^6-10\). Despite these discoveries, the individual prediction of PTSD remains elusive, thereby leaving a major gap between scientific discovery and practical application.

One reason for such a gap is the current use of computational models that do not match the disorder’s inherent complexity in etiology. As attested by its numerous risk factors, the etiology of PTSD is multi-causal, multi-modal and complex. As such, the longitudinal course of PTSD reflects a converging interaction of numerous, multimodal risk factors. Moreover, specific risk markers and their relative weight can vary between individuals and traumatic circumstances. For example, head injury increases the likelihood of developing PTSD\(^11\) but does not occur to many survivors. Similarly, the contribution of female gender to the risk of developing PTSD varies between traumatic events\(^12\) and with specific genetic risk alleles\(^13\). One other challenge faced by practitioners is that the risk of developing PTSD often has to be determined based on incomplete data, due to the constraint of clinical resources. Thus, to accurately predict PTSD in individuals, one must account for complex and variable interactions between putative markers and develop a method that is robust to missing data.

Machine learning techniques are well suited for knowledge discovery and outcome prediction for diseases that have complex etiology and multifaceted manifestation like PTSD. Machine learning methods, especially supervised learning methods, can discover structures and interactions that are informative for prediction from high dimensional, multi-modal data\(^14-16\). However, the implementation of machine learning methods to clinical observations for individual level prognostics and diagnostics is limited in psychiatry.

In the current study, as an effort to bridge the gap between the existing academic knowledge about PTSD and individual level diagnostics and prognostics, we designed and implemented a clinical decision support pipeline to provide clinically relevant recommendation for trauma survivors. To meet the specific challenge of early prediction, this work uses data obtained within ten days of a traumatic event. The current pipeline outperforms the acute stress disorder, a commonly used clinical diagnostic criterion, both in terms of sensitivity and specificity. The decision support pipeline is interactive in nature. When the quality of the predictive model is unsatisfactory, the pipeline recommends more information to be collected for re-evaluation rather than making a potentially detrimental decision based on insufficient data.
Methods

Data

This study used data collected for the Jerusalem Trauma Outreach and Prevention Study (J-TOPS\textsuperscript{2,17}, ClinicalTrial.Gov identifier: NCT0014690). Participants were adults admitted to the emergency department (ED) following potentially traumatic events. Eligible participants were screened by short telephone interviews, and those with confirmed PTEs as per DSM-IV PTSD criteria A1 and A2 received structured, telephone-based interviews approximately ten days (9.6 ± 3.9 days) after trauma exposure. Participants with acute PTSD symptoms in the first assessment were additionally invited for clinical interviews, 29.5 ± 4.6 days after trauma exposure. Participants of the first clinical assessment were re-evaluated five, nine, and fifteen months after the traumatic event. For detailed procedures, see Shalev et al\textsuperscript{17}. Participants provided oral and written consent for all phases of the study. The study’s procedures were approved and monitored by the Hadassah University Hospital’s Institutional Review Board.

For the purpose of this study, we included individuals who had initial data available at ten days and at least two additional time points (n = 957). The initial traumatic event exposure included motor vehicle accidents (84.1%), terrorist attacks (9.4%), work accidents (4.4%) and other accidents (2.0%). Participants included in this study did not differ from those who were not included in gender distribution, age, general distress, initial PTSD symptoms and the frequency of exposure to new traumatic events during the study\textsuperscript{2}.

To characterize the stress response after the exposure to the traumatic events, PTSD symptom trajectory was constructed with latent growth mixture modeling (LGMM) on PTSD symptom severity measured at different times after the trauma (see figure 1 in reference 5). The LGMM identified three distinct stress response types/trajectories: non-remitting (17% of the participants), slow remitting (27% of the participants), and rapid remitting (56% of the participants). The goal of the study is to predict whether an individual will display a non-remitting stress response or a remitting stress response and recommend appropriate course of action using data collected in the ED and 10 days following the trauma.

To predict whether an individual will display a non-remitting stress response, 20 features measured in the ED and at 10 days after the trauma were selected as predictors. These variables were selected because they were shown to contain predictive information (measured by the area under the ROC curve) regarding PTSD symptom trajectory in a previous study\textsuperscript{5}. All the selected features can be measured at low cost during emergency room visits and through follow-up interview by phone, therefore, ideal for a clinical decision support system. The features used in the current study are listed in table 1.

The Decision Support Pipeline
The goal of the proposed decision support pipeline is to assist practitioners in assigning proper treatment options for individuals who are recently exposed to a traumatic event. More specifically, upon receiving relevant information collected from an individual, the proposed decision support system would provide one of the following three recommendations: (r1) High clinical risk, recommend clinical monitoring or treatment. (r2) low clinical risk, no clinical monitoring or treatment recommended (r3) insufficient information to determine clinical risk, recommend more information to be collected.

The decision support pipeline consists of three components, illustrated in figure 1. The first component is a database containing data collected from individuals who were exposed to a traumatic event and followed for a period of 14 month such that their long-term stress response trajectory could be determined. In our implementation, we used data collected for the Jerusalem Trauma Outreach and Prevention Study (J-TOPS) as the database. Since the goal is the early detection of high risk individuals for PTSD, we included data collected in the emergency department and within 10 days after the trauma. The second component of the decision support pipeline is a prediction algorithm that models the relationship between the stress response trajectory and other information (demographic, clinical, psychiatric, etc.) in the database. The prediction algorithm produces a predictive model as well as quality metrics associated with the predictive model. In our implementation, upon receiving the information (features) about an individual, the database was queried such that the data for all individuals that have the same features measured were returned. The predictive model was built on this subset of the database. We used the support vector machine with radial basis function kernel as the predictive algorithm, and sensitivity and specificity computed from leave-one-out cross validation on the validation set as the quality metrics of the model. We consider predicting the individual would display remitting stress response when he/she would actually display non-remitting stress response ten times as costly as predicting the individual would display non-remitting stress response when he/she would actually display remitting stress response. This cost information was taken into account by the prediction algorithm when building the predictive model. The third component of the decision support pipeline is a recommendation generator. The recommendation generator generates recommendations based on the prediction and quality metric(s) computed by the predictive model. In our implementation, we used a simple decision rule: if the leave-one-out cross validation sensitivity (the first quality metric) is greater than or equal to and the leave-one-out cross validation specificity (the second quality metric) is greater than or equal to , make the recommendation according to the prediction made by the predictive model, otherwise make the recommendation that more information is needed to determine the stress response. . The quality metrics and the decision rule are critical in our pipeline. The quality metrics estimate the performance of the predictive model built for individual patients (consists of different features). And, the decision rule produces clinical recommendations only when the predictive model is determined to be high quality. This allows the algorithm to recommend potentially detrimental clinical decisions based on predictions that have low quality. The decision support pipeline was implemented in Python.

Figure 1: The workflow of the decision support pipeline. 1) A subset of data from the database is retrieved according to what features are available for the individual to be predicted. 2) A predictive model is built on the subset of the data by the predictive modeling algorithm. 3) Quality metrics is computed for the predictive model. 4) PTSD trajectory membership is predicted by the predictive model. 5) The decision generator generates recommendation based on the quality metric and the predicted trajectory.

Evaluation of the Decision Support Pipeline
Leave-one-out cross validation was implemented to evaluate the performance of the decision support pipeline, i.e. each individual’s PTSD trajectory membership was predicted using the model built with data collected from the rest of the individuals as the database. Three metrics were computed to evaluate the performance of the pipeline: (1) Percent of decisive decision: the percent of individuals that the pipeline is able to make a decisive decision on, i.e. recommending (r1) or (r2); (2) Sensitivity; and (3) Specificity. We evaluated the performance of the pipeline with 143 different sets of thresholds for the quality metrics (leave-one-out cross validation sensitivity and specificity computed with the data in the database).

We also calculated the predictive performance of acute stress disorder (ASD, defined according to the DSM-IV\textsuperscript{21}) measured around 10 days after trauma exposure. ASD is commonly used in the clinical setting to identify people who are at high risk for PTSD development in the initial period of time following trauma exposure.\textsuperscript{22}. ASD is a binary variable computed from ASD symptom measurements. The predictive performance of ASD was compared to the predictive performance of our pipeline. Sensitivity and specificity obtained from leave-one-out cross validation computed from the entire cohort was reported.

Results

Predictive Performance of ASD

In the current patient cohort, 17\% of the individuals developed non-remitting stress response. Predicting the post-traumatic stress response trajectory membership using 10-days’ ASD results in a sensitivity of 0.527 and specificity of 0.695.

Predictive Performance of the Decision Support Pipeline

The predictive performance of the decision support pipeline was evaluated with 143 sets of different threshold values (leave-one-out cross validation sensitivity and specificity computed on the validation set) for the quality metrics. The sensitivity, specificity and percent of decisive decisions of the pipeline corresponding to the 143 different threshold values were shown in figure 2. Not surprisingly, the percent of decisive decision decreases as the thresholds for the quality metric increases. On the other hand, sensitivity and specificity do not change linearly as the thresholds increase. In figure 2, the performance corresponds to sets of thresholds that result in more than 60\% of decisive decisions were highlighted with dashed line. Within that same threshold region, the range of sensitivity on the testing set is 0.616-0.667, and the range of specificity on the testing set is 0.697-0.726 (see figure 3 for sensitivity and specificity for individual threshold values, with the Pareto front highlighted). The performance of the decision support pipeline outperforms that of the ASD both in terms of sensitivity and specificity within this threshold region.

Figure 2: Model performance evaluated at different sets of quality metric (validation set sensitivity and specificity) thresholds. Three panels show percent decisive decisions, sensitivity and specificity on the testing set. Each square shows the performance of the pipeline under a particular threshold setting. The color of the square (different shades of red) represents the performance, with red mapped to the best performance. Black dashed line encloses threshold region where the model makes decisive decision for more than 60\% of the individuals. The most stringent threshold settings (top right corner of individual panel) did not result in any decisive decisions. These results were left blank in the figure.
Discussion

The main contribution of this study is the design and implementation of a decision support pipeline that automatically generates clinical recommendations for individuals who have recently been exposed to trauma. To the best of our knowledge, this pipeline is the first to provide individual level and personalized prognostics for trauma exposure with special consideration for the quality of the predictive model. The current pipeline outperforms the ASD, a commonly used clinical diagnostic criterion, both in terms of sensitivity and specificity. One distinctive characteristic of the decision support pipeline is the inclusion of quality metrics for the predictive models. The main purpose of the quality metric is to evaluate the quality of models constructed with different predictors, since in the clinical setting, not all predictor are available for all patients. If the quality of a predictive model (constructed with a subset of features) is inadequate, the pipeline recommends more information to be collected for re-evaluation, rather than making a decision based on the prediction generated by a suboptimal model. Some of the features used for prediction are routinely obtained in the emergency department, whereas other features can be obtained through phone interviews around 10 days after trauma exposure at low financial cost. Therefore, this decision support pipeline can be readily incorporated into a clinical setting with minimal modification of the existing clinical workflow. We are currently working on implementing software based on the proposed pipeline. The software would automatically integrate clinical observations from sources including the EHR, diagnostic questionnaires and clinical interviews, to generate appropriate recommendations. When the information regarding a patient is not sufficient for prognosis, the software would generate a list of additional information to be collected and re-evaluate when new information is available. We believe the current pipeline and the aforementioned software could be a valuable addition to a clinician’s toolkit, especially when insufficient information is available.

One direction to expand the current work is to test the performance of the pipeline in a different population. In the current study, the predictive model was constructed with the J-TOPS population and the evaluation of pipeline is conducted on the same population. This may result in optimistic performance estimation of the pipeline. Furthermore, a certain percentage of the J-TOP patients only have data collected in less than 2 time points and were exclude in the study, which might result in bias of the performance estimation. To address these issues, we are currently collecting data in the Bellevue hospital center in New York as an independent test set.

In the proposed decision support pipeline, all three components can be modified to further improve the predictive performance. The first component of the pipeline, the database for building the predictive model, can be constructed to suit specific diagnostic purposes. For example, if the goal is to predict stress response trajectory in the general population, including individuals from a diverse demographic and socio-economic background would likely increase the predictive performance of the algorithm. On the other hand, if the goal is to predict stress response trajectory in a specific population, for example, war veterans, it is more appropriate to restrict the database to the target population. Moreover, other variables that are potentially predictive of PTSD trajectory could be included in the database as potential predictive features of PTSD to improve the predictive performance and robustness of the prediction. Similarly, for the second part of the pipeline, any predictive algorithms can be implemented to generate the predictive model. If the database consists of predictive features for distinct domains (e.g. demographic, psychiatric measurements, clinical measurements and physiological measurements) utilizing ensemble methods might result in better predictive performance. In addition, the current implementation builds the predictive model based on subset of the database where the features present in the testing set are available. Exploring different data imputation methods may result in better utilization of information contained in the database, thus resulting in improved performance. Also, different methods for model performance estimation can be implemented. Instead of leave-one-out cross validation, cross validation or cross indexing can be utilized as performance estimation with limited computational resource. Lastly, for decision generator, the last component of the pipeline, one can expand the possible recommendations and design customized functions to convert the prediction of the predictive algorithms to actionable recommendations.

Conclusion

841
The current study demonstrated the feasibility of early individual level prediction for chronic PTSD. As a first step towards a decision support system for chronic PTSD, the proposed pipeline provides clinically relevant recommendations based on personalized predictive models. To avoid making potentially detrimental clinical recommendations based on insufficient information, the quality of the predictive model was computed and integrated into the decision support pipeline. The pipeline outperforms ASD, a criterion often used in the clinical setting.

Reusable Filtering Functions for Application in ICU data: a case study

Vincent Major, ME1, Monique S. Tanna, MD1, Simon Jones, PhD MSc1, Yin Aphinyanaphongs, MD PhD1

1NYU Langone Medical Center, New York, NY

Abstract

Complex medical data sometimes requires significant data preprocessing to prepare for analysis. The complexity can lead non-domain experts to apply simple filters of available data or to not use the data at all. The preprocessing choices can also have serious effects on the results of the study if incorrect decision or missteps are made. In this work, we present open-source data filters for an analysis motivated by understanding mortality in the context of sepsis-associated cardiomyopathy in the ICU. We report specific ICU filters and validations through chart review and graphs. These published filters reduce the complexity of using data in analysis by (1) encapsulating the domain expertise and feature engineering applied to the filter, by (2) providing debugged and ready code for use, and by (3) providing sensible validations. We intend these filters to evolve through pull requests and forks and serve as common starting points for specific analyses.

1.0. Introduction

1.1. Motivation

Randomized-controlled trials are considered the gold standard in clinical research to determine the efficacy and adverse effects of an intervention. However, there are many limitations to performing a randomized-controlled trial, including financial and personnel resources as well as patient recruitment, especially if the condition or outcome being studied is not common. Similarly, prospective observational studies can be used to characterize a condition and its associated outcomes, but are time-consuming and require large populations when studying uncommon conditions. Well-conducted retrospective database analyses circumvent many of these issues given the large population of data available for research. Broader exploration of infrequent conditions and outcomes, or of specific cohorts is enabled by big-data analysis tools and retrospective analysis of databases such as MIMIC-III.

MIMIC is an openly available database developed by the MIT Lab for Computational Physiology1. MIMIC recently released an updated version, MIMIC-III, which contains de-identified patient records for >40,000 critical care patients between 2001 and 2012. MIMIC-III is a 26 table relational database connected by a combination of unique identifiers and dictionary tables that link each identifier’s definition and the corresponding data. For additional information on the data and tables contained within MIMIC-III please refer to the detailed documentation at http://mimic.physionet.org/gettingstarted/overview/.

Using MIMIC-III for analyses is challenging due to the complexity of the input data and the complexity of the imperative preprocessing steps. The complexity of the input data can require significant feature engineering and domain knowledge to get data into a state of analytic readiness. The complexity of the preprocessing steps can also require engineering efforts to reproduce and may lead to profuse bugs as others attempt to reproduce the work.

In this paper, we reduce this complexity by describing and open sourcing code functions which allow other researchers to apply sensible filters toward putting specific data types into analytic form. The functions reduce complexity. First, the functions aggregate domain expertise and feature engineering for each specific data type. Second, the functions are debugged and in active use in our analytic projects.

We expressly aim to publish functions according to several engineering standards. Our intent is to encourage modular sharing through our code and to promote reuse. Publishing functions, such as the ones we propose, have several advantages. First, they promote reuse. Other researchers may easily use our code. Second, the steps are justified. Researchers may examine our feature engineering choices in detail and make sensible choices for their own analyses. Third, they encapsulate domain knowledge by practitioners. This will allow researchers who do not have access to domain experts to apply sensible filtering to clean ICU data. Fourth, the functions are validated. We provide evidence that the filtering is reasonable. Fifth, they are debugged. The code is in active use for our ICU projects and has been tested. Sixth, they provide a baseline starting point for applying different kinds of preprocessing toward optimizing objectives. For example, researchers may use our filters as a baseline and then from these tweak and build their own filters.
1.2. Background – Sepsis-Associated Cardiomyopathy

We motivate our overall approach with a clinical example. This example drives the design choices that we have made along the way. Acute left ventricular dysfunction has been reported to occur in one third of critically ill patients\(^2\). The inflammatory state associated with severe sepsis and septic shock can lead to dysfunction of multiple organ systems, including myocardial depression resulting in sepsis-associated cardiomyopathy. Also known as septic cardiomyopathy, this condition is characterized by acute left ventricular dysfunction, reduced ejection fraction and normal or increased cardiac output. By definition, sepsis-associated cardiomyopathy is reversible with resolution of the acute septic state with early studies reporting resolution of left ventricular dysfunction in 7-10 days\(^3\).

Although cardiovascular dysfunction is known to increase mortality, the prognostic implications of sepsis-associated cardiomyopathy remains controversial. Whether these patients should be managed any differently from patients with sepsis without associated cardiomyopathy is also unknown. Data on the pathophysiology, management and outcomes of this entity are limited and the literature on this topic consists mostly of small observational cohort studies.

2.0. Methods and Results

2.1. General Approach

The general approach to this case study investigation was to sequentially filter a large, diverse ICU cohort to one that reflects patients indicative of a particular condition, in our case sepsis-associated cardiomyopathy. Simple, modular functions are written that can be modified and assembled in countless ways. We will present six functions in this case study that (1) describe identification of sepsis, (2) discern severity of cardiomyopathy, (3) identify sepsis manifestations on admission, (4) exclude CHF/cardiomyopathy in past medical history, (4) calculate volume of intravenous fluids administered, and (6) calculate a severity of illness score. The six functions fit broadly into filtering of the dataset or calculating clinically significant parameters. For each function, we describe our method and approach and provide a simple chart review or graphical validation.

MIMIC-III uses subject, hospital admission, and ICU stay identifiers to distinguish individuals and their distinct inpatient admissions to the hospital and ICU respectively. These identifiers serve as a key in the majority of tables within the database but cases of repeated admission within the database were observed, i.e. individuals were admitted to the hospital/ICU more than once. The decision to use HADM_ID as the primary identifier and translate into the others only when necessary was made since sepsis-associated cardiomyopathy is an acute but reversible condition and distinct hospital admissions are unlikely to be affected by previous admissions.

2.2. Filtering database to target cohort

2.2.1. Sepsis Identification

**Method:** The MIMIC-III database contains great depth and breadth of ICU data. In order to filter the database down to patients relevant for a sepsis-associated cardiomyopathy study, the first step was ICD-9 requirements for severe sepsis. Patients with severe sepsis, defined as evidence of the systemic inflammatory response syndrome, source of infection, and at least one organ function dysfunction, were selected using the discharge ICD-9 codes indicative of infection\(^4\) concurrent with ICD-9 codes indicative of new onset organ dysfunction\(^4,5\). The complete list of ICD-9 codes with the function are available at the project page: [https://github.com/vjm261/MIMIC-ICU-filter-modules/wiki](https://github.com/vjm261/MIMIC-ICU-filter-modules/wiki).

**Validation:** The ICD-9 codes were independently reviewed in 30 final cohort individuals. The raw discharge summary was reviewed and compared to the ICD-9 codes to determine if the ICD-9 codes truly reflect a severe sepsis cohort. In three of the 30 randomly selected patients, there was no identified infection during the hospitalization despite the presence of ICD-9 codes indicative of infection. This accuracy met the criteria for our study and we did not pursue further refinements of the coding.
2.2.2. Cardiomyopathy Identification (extracting ejection fractions)

**Method:** In addition to ICD-9 codes, for a patient to be included, at least one echocardiogram report must be contained within the database and contain a valid left ventricular ejection fraction (LVEF). LVEFs are searched for from the raw, unstructured, free-text echocardiogram reports in both numeric (e.g. LVEF > 55% or LVEF = 60-80%) and ordinal (e.g. normal or severe) formats. LVEF is characterized by four ordinal values (Table 1).

Table 1. Clinically defined values of left ventricular dysfunction and the associated numeric ranges of LVEF.

<table>
<thead>
<tr>
<th>LVEF numerical range (%)</th>
<th>Ordinal value</th>
<th>Text string examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>LVEF &lt; 30</td>
<td>Severe</td>
<td>severely depressed, severe LV/left ventric. systolic dysfunction, severe hypokinesis</td>
</tr>
<tr>
<td>30 ≤ LVEF &lt; 45</td>
<td>Moderate</td>
<td>moderately depressed, moderate LV/left ventric. systolic dysfunction, moderate hypokinesis</td>
</tr>
<tr>
<td>45 ≤ LVEF &lt; 55</td>
<td>Mild</td>
<td>mildly depressed, mild LV/left ventric. systolic dysfunction, mild hypokinesis</td>
</tr>
<tr>
<td>55 ≤ LVEF</td>
<td>Normal</td>
<td>low normal EF, LV function normal, normal LV/left ventric./biventricular systolic function, LV/left ventric. systolic function grossly preserved</td>
</tr>
</tbody>
</table>

Numeric values of LVEF are binned into the four ordinal values as there is no way of back-calculating the numeric LVEF from the ordinal value and the ordinal values are relevant to clinical decision-making.

Searching through the raw, unstructured, free-text notes to find the echocardiogram reports is one of the more computationally expensive tasks of the analysis. All of the free-text notes are included in one, 4 GB .csv file. A python-based command line tool called csvkit was used to extract only the echocardiogram reports and circumvent problems arising from a comma-delimited file containing commas within the text field. The echocardiogram reports were later searched in R using regular expressions.

**Validation:** Over 150 distinct echocardiogram reports were independently reviewed and compared to the LVEF value extracted. Several examples of various text phrases used to describe left ventricular dysfunction were identified and amended to the list (Table 2). Otherwise, we excluded all cases of failure to extract an LVEF. These reports either had no mention of the LVEF or were transesophageal echocardiograms (TEEs).

2.2.3. Admission diagnosis inclusion/exclusion

**Method:** Given that our ICD-9 inclusion criteria were derived from discharge ICD-9 codes, and there is no other way of determining the time of onset, we also incorporated admission diagnosis consistent with a manifestation of severe sepsis into our inclusion criteria. After this step, we assume that admission is a consistent zero-time point from which temporal data is linked and comparable among the cohort. The admission diagnosis is a free text-based field in the database that clinicians were required to populate. Unfortunately, as a result the quality of this field is often poor.

All admission diagnoses were split into basic components (separators of commas and semicolons) and each component with frequency ≥ 3 were independently reviewed to generate a list of inclusion and exclusion terms. Patients were included if their admission diagnosis field could be a manifestation of sepsis but excluded if it also contained any of an exclusion list (Table 2). The exclusions remove patients that are admitted primarily for a non-sepsis condition and includes accidents, fractures, heart failure, gastrointestinal bleed, stroke, trauma, and others. A group of patients failed to meet the requirements of either the inclusion or exclusion lists and were excluded for lack of information about their presenting diagnosis. Of the 7984 patients with severe sepsis and an interpretable echocardiogram, 4044 pass this admission diagnosis filtering step. The remainder were either actively excluded, n = 6, or do not have an admission diagnosis that resembles a manifestation of sepsis, n = 3934.
We chose to be strict in our inclusion criteria for admission diagnosis in order to achieve a more specific cohort at the expense of possibly losing some patients who may in fact have been admitted with severe sepsis. Furthermore, the use of text-based admission diagnosis could be greatly improved by restricting this field to pre-defined diagnoses rather than allowing a free text field, as there was a very skewed count distribution of admission diagnosis with hundreds of strings occurring only once or twice which were automatically excluded.

Table 2. Inclusion and exclusion lists for admission diagnosis.

</tr>
</tbody>
</table>

Validation: The resulting cohort’s raw admission diagnosis were independently reviewed in a random sample of 30 patients. Each individual’s discharge summary was read to determine whether the inclusion/exclusion criteria used adequately identified patients with severe sepsis. In three of the 30 randomly selected patients, patients had a condition other than sepsis on admission, but this was not discernable based on the admission diagnosis field. For example, one patient was admitted with a diagnosis of shortness of breath and initially thought to have possible pneumonia, but the clinical presentation was later thought to be consistent with volume overload without infection. All three of these patients were included in the cohort based on the ICD-9 inclusion criteria because they did in fact develop an infection later during the hospitalization. This accuracy met the criteria for our study and we did not pursue further refinements of the coding.

2.2.4. Past medical history

Method: The last cohort filtering step was inspecting the past medical history (PMH) within the discharge summaries for any mention of past heart failure, hypokinesis, ventricular dysfunction, or depressed LVEF. Patients with pre-existing heart failure and/or reduced LVEF cannot be reliably diagnosed with further sepsis-associated cardiomyopathy in addition to their pre-existing left ventricular dysfunction in this retrospective study. Identical to the echocardiogram reports, the discharge summaries are extracted from the raw table with csvkit and the PMH section of each semi-structured report searched with a list of heart failure related terms and then the aforementioned numerical LVEF algorithm (Table 3).
Table 3. Text strings and numerical LVEF used to exclude patients with past medical history of reduced LVEF.

<td></td>
</tr>
</tbody>
</table>

Validation: The past medical history was independently reviewed in the discharge summaries of 30 final cohort individuals. The presence or absence of pre-existing heart failure, both systolic and diastolic, was accurately identified in all 30 randomly selected patients.

2.2.5. Resulting filtered cohort

At this stage, each patient in the cohort: 1) has severe sepsis, defined by ICD-9 codes for both major organ dysfunction and systemic infection, 2) had an echocardiogram during their admission with a recorded, and interpretable, LVEF measure, 3) is admitted to the hospital with an admission diagnosis consistent with a manifestation of sepsis, and 4) has no known history of heart failure or reduced LVEF. Patients that were not admitted to the ICU within 24 hours of their hospital admission (that is, they spent time on a ward before the ICU) were also excluded as their sepsis-associated cardiomyopathy was unlikely to be the cause of admission (n=795). Patients with zero records of fluid ins were also removed from the final cohort (n=48). This resulted in a cohort of n = 2350 patients without a prior history of heart failure who were admitted to a medical intensive care unit with severe sepsis and had an echocardiogram during their hospitalization. Figure 1 describes the number of patients in the cohort at each filtering step.

Figure 1. Summary of the filtering steps from the whole database to the final cohort.

2.3. Calculation of Clinical Parameters

2.3.1. Fluids

Methods: Given the lack of evidence on the best fluid management strategy in patients with sepsis-associated cardiomyopathy, one of our clinical questions was to describe the differences in volume of fluids administered among patients with varying degrees of left ventricular dysfunction and its association with mortality. To address the effects of fluid management on patient outcomes, the fluids given to the cohort must be calculated. MIMIC-III contains tables of the various enterally and parenterally administered products (“ins”) including intravenous saline, intravenous blood products, intravenous and oral nutrition and intravenous medications. Tables of “outs” include outputs such as urine and drain output. In this analysis, fluids are restricted to items with volume units (fortunately all recorded ins were consistently measured in mL, verified by manual inspection). For each patient, all ins were extracted and summed for the first 72 hours following admission to the ICU. Evidence behind early goal-directed therapy for sepsis supports
aggressive fluid resuscitation in the first six hours after admission\textsuperscript{7}, however, given that patients requiring continued ICU stay likely remained acutely ill, we analyzed fluids administered over the initial 72 hours to examine physician practices in this setting.

The fluid ins and outs are categorized by unique item identifiers (MIMIC-III: ITEM_ID), that arose from combining two systems, one of which allowed manual naming during data collection. An attempt was made to limit the fluid analysis to the fluid types most commonly administered for fluid resuscitation purposes, excluding nutrition for example, but the same type of fluid was listed in various different text strings, and the decision was made that fluids of any kind should have the same effect on fluid balance and therefore all types of intravenously or orally administered fluids were included.

Information from many different database tables is combined into one table that is then used for the analysis. The final table includes patient identifiers, length of stay in the ICU and hospital, gender, age, date of echocardiogram, LVEF, mortality flags, volume of fluids in and out over 72 hours, and the OASIS score.

**Validation 1 - Descriptive:** The validity of the fluids calculation is dependent on the accuracy and reliability of the individual recordings in the database. Some patients have zero or very few recorded fluid ins or outs over several days. Many patients do not appear to have been administered substantial fluids. These same patients are likely to be those who are less severely ill or ill in a manner where strict fluid management is less important, and it is likely that these patients’ ins were not being strictly recorded. The histogram of Figure 2 illustrates this highly skewed distribution with a large peak near zero representing the 55 (2.3\%) of patients with zero and 101 (4.3\%) of patients with less than 1000 mL of fluid ins recorded over 72 hours. Note that 48 patients with zero fluid records have already been removed for lack of information.

![Figure 2. Histogram of the fluids administered over 72 hours.](image)

**Validation 2 - External Cohorts:** In order to address the potential invalidity of the recorded fluid ins, comparison of the distribution of fluid ins and outs between patients with sepsis-associated cardiomyopathy and several other cohorts was made. Even if the absolute values of fluid do not reflect the actual quantity of fluids administered, if the relative fluid quantities are appropriate between cohorts, the analysis outcomes should remain valid.

The final filtering step of excluding patients with a past medical history of heart failure or reduced LVEF removes 736 patients that would otherwise be eligible for the main cohort. These patients will be the first group compared to the main cohort. Patients with previous left ventricular dysfunction will likely be administered less fluid to avoid fluid overload and pulmonary edema, despite their severe sepsis.

By considering the excluded group at each of the other filtering steps, three other cohorts are found. Severe sepsis patients, by ICD-9 diagnostic code, but without an echocardiogram or no recoverable LVEF (n = 6702), heart failure with no systemic infection, by ICD-9 codes (n = 6042), and systemic infection without major organ dysfunction, again
by ICD-9 code, \(n = 7079\). Finally, a completely unrelated cohort of active dialysis patients is included as a lower limit of fluid requirements \(n = 2417\).

Each patient’s fluid ins and urine output are summed over the first 72 hours of their ICU admission. An empirical cumulative distribution function is calculated for each group and overlaid in Figure 3.

![Figure 3](image)

**Figure 3.** Empirical cumulative distribution function of (a) fluids administered, and (b) urine output over 72 hours for each of six independent cohorts.

As expected, dialysis patients receive the least amount of fluid ins, and the least amount of urine output given that many are unable to produce urine. Similarly, heart failure patients without infection also receive a relatively small amount of fluid ins given their increased risk of volume overload and pulmonary edema. Patients with pre-existing heart failure and concomitant severe sepsis, however receive more fluid ins than their counterparts with heart failure without infection given that the management of sepsis includes fluid resuscitation despite the risk of volume overload. Patients with severe sepsis and no history of heart failure (main cohort) have the largest amount of fluid ins, again as expected given that fluids are the mainstay of sepsis management. These findings validate that, in aggregate, the fluids reflect our expectations in the various cohorts.

By a Mann-Whitney test, all fluids in medians are significantly different \((p < 0.05)\). For the fluids out medians, most comparisons are significantly different except comparisons between the heart failure with no infection, infection without organ dysfunction, and severe sepsis with no echocardiogram groups that have similar medians \((p > 0.05)\).

### 2.3.2. OASIS

**Methods:** Unfortunately, the absence of a reliable ICU severity of illness score in the database requires the analyst to calculate their own. APACHE II or IV require variables that are not easily obtainable or ubiquitous in MIMIC including numerous lab results. In addition, several parameters are difficult to address with limited retrospective data such as whether the patient has acute renal failure, other chronic organ insufficiency or is immunocompromised. Although these questions could be addressed with a combination of ICD-9 codes, DRG codes and text-mining through the discharge summaries, any attempt to address these factors would not be robust without significant optimization.

In order to control for differences in severity of illness amongst the cohort, we implemented the Oxford Acute Severity of Illness Score (OASIS)

As opposed to comorbidity scores, such as the Elixhauser score, which are often derived exclusively from ICD-9 diagnosis codes, the OASIS score is a severity of illness score optimized for predictive strength with the fewest, and easily obtainable, subset of APACHE IV data elements. OASIS includes the heart rate, mean arterial pressure (MAP), respiratory rate, temperature, pre-ICU length of stay, patient age, Glasgow Coma Score (GCS), urine output, if the patient is ventilated on day 1, and if the patient was admitted following an elective surgery. Similar to APACHE,

OASIS is implemented with the most extreme values of each variable and the total urine output over the first 24 hours in the ICU which reflects the time within which clinical decisions regarding fluid resuscitation are made.
Many of the required variables for OASIS were recorded and time-stamped in the database (MIMIC-III: CHARTEVENTS). Age is given (MIMIC-III: PATIENTS), pre-ICU length of stay was calculated as the difference between ICU and hospital admission (MIMIC-III: ICUSTAY and MIMIC-III: ADMISSION) tables, urine output was calculated similarly to fluid ins, ventilation was addressed by the existence of an FiO₂ value (MIMIC-III: CHARTEVENTS) and given our inclusion criteria there were no patients in our cohort who were admitted following elective surgery. This was validated by manually reviewing the discharge summaries of 50 randomly selected final cohort patients, none of whom were admitted after elective surgery.

The item identifier (MIMIC-III: ITEM_ID) for each OASIS variable was manually searched in the dictionary table (MIMIC-III: D_ITEMS), and then extracted from the very large, 29GB table (MIMIC-III: CHARTEVENTS). Searching through and extracting chart records (from MIMIC-III: CHARTEVENTS) in order to calculate the OASIS score was the most computationally expensive component of the analysis. Bash scripts were used to extract the manually derived item identifiers (MIMIC-III: ITEM_IDs) for each relevant parameter separately which were then further processed in R and later combined. Similar to the admission diagnosis or fluid in identifiers, the chart item identifiers are not systematically organized. Numerous codes for each parameter are included in the database, most of which are infrequently used but all are included. Please refer to the project page at https://github.com/vjm261/MIMIC-ICU-filter-modules/wiki for the complete list of ITEM_IDs used for each OASIS parameter.

The OASIS score is a sum of component weights for each parameter. That is, each parameter falls within a weighted bin and the combination of parameter scores is the resulting OASIS score sum. The maximum and minimum of each parameter were extracted for each patient and the greater OASIS score component was used to calculate the total OASIS score.

Several problems arose in the combination of OASIS components:

- Temperature existed in both Fahrenheit and Celsius; given that temperatures were usually recorded in Fahrenheit, that was searched for first and if no record existed, Celsius was converted to Fahrenheit.
- MAP was uncommon in CHARTEVENTS. Instead, MAP was calculated from blood pressure measurements that exist for every patient using MAP = (DBP*2/3) + (SBP*1/3), where DBP and SBP are the diastolic and systolic blood pressures respectively.
- GCS was recorded as a total score or in its components (eye, verbal and motor response); this was thought to be an artifact due to the change in the clinical information system during the data capture period, and the component scores were summed to result in a total GCS score. Although most patients had either the GCS total or all three GCS components recorded in the first 24 hours in the ICU, 17.2% of patients did not.
- No records of urine output existed for 11.0% of patients.
- No record of body temperature existed for 0.1% of patients.

The patients with missing GCS, urine or temperature were imputed with k-nearest neighbors (kNN) with k = 5. All of the OASIS parameters, including the min, max, and median of the repeated chart variables were used to impute total GCS, total urine and temperature min, max, and median. The percentage of patients with missing GCS scores who were also missing urine outputs was 12.1% (108 of 888 patients), which is similar to the percentage of patients missing urine outputs among the entire cohort (11%) and suggests that the missingness of data is uniform and not limited to a specific group of patients.

Validation: The OASIS score has been previously validated in a very large ICU dataset; however, we used logistic regression to validate our function used to calculate the OASIS score. The OASIS score was used with age and gender to predict ICU mortality. Age was factored into 10 year bins, referenced to the ≤ 30 years group, whereas OASIS was factored into five equal-population quintile bins with the least severe factor, OASIS ≤ 30, used as a reference point. Quintile bins were used as the proportion of patients that died and is consistent within each bin but different between bins. The odds ratio (OR) with a 95% confidence interval (CI) is presented with the corresponding p-value (Table 4).

Increasing OASIS score is significantly associated with an increased mortality rate among our cohort of severe sepsis patients, as expected. Relative to the lowest quintile of OASIS score (≤ 30), the odds ratios of the four higher quintiles are 1.79 [1.21, 2.67], 2.33 [1.62, 3.37], 2.72 [1.88, 3.99], and 5.87 [4.14, 8.46] respectively, supporting that OASIS calculated from the MIMIC-III database reflects the increased risk of death for more severely ill patients and validates the use of OASIS in both this database and others.

3.0. Discussion

3.1. Function Design

We applied several software design principles laid out in *Clean Code*\(^1\) such as input parameter reduction, descriptive parameter naming, and data abstraction to create simple and reusable functions. We also built functions at multiple levels of granularity. At the first level is to assume that the database input structure is fixed and then the filters are applied. At the second level is to have functions that only accept data primitives (i.e. strings). For example, two simplified functions in each category are:

```plaintext
extract_echoreports_from_notes_mimic_dbase(<MIMIC-III database>)
extract_ef_from_echos(<echo report>)
```

3.2. Generalization

In this report, we describe and publish several filters on ICU data. These functions are customized toward our specific example. However, we see our filters as routine data processing steps for producing features on a given output type. These filters may also serve as building blocks that may be customized to other examples. These other examples may cite and fork our work to build their own filter functions.

3.3. Data Structure Changes

Some of these functions are sensitive to changes in the underlying data structure. If the MIMIC tables change, then the code will need to be updated to take into account the modified structure.
3.4 Validations

For each filter, we provided a validation by either chart review or further analysis. For some cases, the accuracy metric was less than 100%. We could have iterated further in refining our criteria. However, our validations met our error tolerances and in the context of the sepsis-associated cardiomyopathy, we were able to continue our clinical analysis. Our validation methods are also biased toward charts that meet the filter requirements. For example, we do not consider patients that may have had sepsis but the ICD-9 simply wasn’t recorded. In analyzing these huge retrospective databases, we felt that missing these uncommon occurrences was acceptable for our clinical question.

Chart review validation focused exclusively on minimizing false positives (i.e. optimizing precision) to improve the quality of the filtered cohort. Further work is required to broaden each filter to improve recall and specificity. The optimal operating point, balancing precision and recall, is likely to be highly problem. For our use-case, maximizing the recall was not a priority, instead the filters presented ensure all patients meet all filtering conditions.

4.0 Conclusion

We open-sourced a series of filters and validations on complex medical ICU data. These functions encapsulate the domain expertise and feature engineering of the medical authors and serve as a starting point for other researchers to apply to their own modeling work. Through pull requests and fork processes through git, we expect these functions to evolve and serve as common starting points for analysis. We demonstrate filters for cohort selection, fluids, and calculation of an ICU severity of illness score. We also validate each filter through chart review and sensible graphs. The code repository is available at https://github.com/vjm261/MIMIC-ICU-filter-modules/wiki.

Abstract

The heterogeneity of clinical data is a key problem in the sharing and reuse of Electronic Health Record (EHR) data. We approach this problem through the combined use of EHR standards and semantic web technologies, concretely by means of clinical data transformation applications that convert EHR data in proprietary format, first into clinical information models based on archetypes, and then into RDF/OWL extracts which can be used for automated reasoning. In this paper we describe a proof-of-concept platform to facilitate the (re)configuration of such clinical data transformation applications. The platform is built upon a number of web services dealing with transformations at different levels (such as normalization or abstraction), and relies on a collection of reusable mappings designed to solve specific transformation steps in a particular clinical domain. The platform has been used in the development of two different data transformation applications in the area of colorectal cancer.

Introduction

Electronic Health Record (EHR) systems are called to play an increasingly important role in health information technology. The quantifiable benefits mentioned in a 2006 AHRQ report include: savings from data capture and access; information connectivity for stakeholders; and decision support, improving efficiency, safety, and quality of healthcare. In many cases (e.g. information exchange, and interoperability with decision support systems), a key issue is dealing with the heterogeneity of clinical data. As a matter of fact, clinical data sources may differ in the data models, schemas, naming conventions and level of detail they use. Several works define some sort of virtual health record (VHR) to bridge these differences. In order to achieve standardization, a number of works base their VHR on a standard EHR architecture. Some authors take a step further and use clinical information models based on EHR standards for this purpose. These models could come in the form of openEHR archetypes, CEN/ISO EN13606 archetypes, Clinical Document Architecture (CDA) templates, or Detailed Clinical Models (DCMs). An important role of such models is providing structure and terminology-based semantics to data instances that conform to some EHR model.

Beyond this, the semantic web has been proposed as the natural technological space for the integration and exploitation of biomedical data. The semantic web describes a new form of web content meaningful to computers, in which the meaning is provided by ontologies. In the context of EHR systems, ontologies enable the formal representation of the entities and relationships involved in an EHR extract, and of the associated background knowledge. Linked Open Data (LOD) is the most prominent semantic web initiative to develop the Web of Data, in which datasets would be semantically connected over the Internet. LOD principles propose semantic publishing and sharing of data using RDF and OWL languages. Based on these contents, automated reasoners can be used to infer new information or to check logical data consistency.

In line with the above ideas, in a previous work we solved an EHR-driven phenotyping problem by means of a data transformation pipeline to convert EHR data stored in a proprietary database, first into information models based on openEHR archetypes, and then into RDF/OWL extracts which could ultimately be combined with an OWL domain ontology for automated reasoning. In the case study, an abstraction phase including certain calculations (e.g. counting, negation) was done at the archetype (or data) level, while the classification tasks were performed at the
ontological (or knowledge) one. The separation of concerns between the archetype and the ontology levels was identified as a key factor in achieving the interoperability goals for the project at issue. The decision will depend on the project itself as well as on the features of the clinical information models used and/or the ontology language chosen. On the other hand, we concluded that a wide range of interoperability scenarios could be envisaged. For example, in a particular clinical domain, different information models may be under consideration. As another example, the transformation to the ontological level may not be required at all, or it may be limited to a set of RDF triples representing the EHR extract.

In this context, this paper describes a proof-of-concept platform to explore alternative solutions to a range of clinical data transformation problems. The platform is built upon a number of web services dealing with the transformation at the different levels. For this purpose, it relies on a collection of reusable fine-grained mappings designed to solve specific transformation steps (e.g., openEHR archetype to RDF) in a particular clinical domain (e.g., colorectal cancer). The paper is structured as follows. First we elaborate on the services offered by the platform, which we have classified according to the kind of operations they perform on the data: normalization, abstraction, semantic publishing, and reasoning services. Next we describe the web-based platform that we have implemented based on these services to evaluate the feasibility and utility of the idea, and explain how it has been used in two different data transformation scenarios in the domain of colorectal cancer. Lastly, we present some concluding remarks and outline future work.

Web services for clinical data transformation

Normalization service

Dual model EHR architectures (EHRA) encompass a reference model and set of archetypes for modelling EHRs. The reference model represents the generic and stable properties of the EHR. Conversely, archetypes are used to define domain-specific information models such as blood pressure recording, discharge report or a lab result. Notice that any reference model, such as ISO 13606-1, openEHR reference model or HL7 CDA, may be used as basis for defining archetypes.

The normalization service deals with one of the main problems when adopting EHR standards: how to standardize existing data. This involves transforming EHR content into a data structure compliant with both reference models and archetypes. We face a problem known in the literature as the data exchange (translation or transformation) problem. This problem is a difficult one, since it deals with differences and mismatches between heterogeneous data formats and models. In the case of the EHR this problem is even more complex. On the one hand, we have the legacy data that conform to a particular schema, and with local semantics. On the other hand, we have EHR reference models and archetypes that have been defined without any regard to the internal architecture or database design of EHR systems. The main requirements on the target instances are that they shall be compliant with the target archetype, be non-redundant and be an accurate representation of the source data (EHR data to be normalized).

The output of this kind of services is an XML instance of the target schema (archetype). Our normalization process requires the source schema expressed as an XML Schema, the target archetype and a declarative mapping relating both schemas. The mapping language is based on tuple-generating dependencies (tgds). They are expressive enough to represent, in a declarative way, many of the schema mappings of interest. The tgds basically specify how to compute a value for an atomic attribute of the target schema (archetype) by using a set of atomic elements from the data source. In our setting these value correspondences are defined by a set of pairs, consisting of a transformation function and a filter. The simplest kind of transformation function is the identity function which copies an atomic source value into a target atomic attribute. This is the most common transformation function in normalization scenarios since often they only involve restructuring source data to make them compliant with the target schema. In those cases where it is necessary to transform source atomic values, a wide range of transformation functions are supported. As an example, Table 1 contains a simple mapping transforming gender codes. It transforms the local gender code in the source path /patient/gender into a normalized code (0 for male, 1 for female and 9 otherwise). Note that the order of the filter-transformation function pairs is relevant and only the first applicable function is executed, consequently the last filter acts as a ‘default’ condition.
Table 1. Example of mapping expression normalizing local gender codes.

</tbody>
</table>

Value correspondences allow us to hide much of the structural complexity of archetypes and reference model. Users do not need to thoroughly specify the logical relations between all the entities of the source and target schemas. It is only necessary to specify the navigation path of the attributes used in the mapping. The semantics of the data transformation is complemented by a default grouping semantics which can be customized in different ways to cope with complex mapping scenarios. Finally, taking into account the mapping specification, the archetype constraints, and the source schema, an XQuery script is generated. The script takes as input an instance of the source EHR data and generates an XML document that is compliant both with the archetype and the underlying reference model. As a main advantage, this approach makes possible to separate the mapping specification from its implementation.

For the specification of the mapping and the generation of the normalization XQuery script we rely on the LinkEHR platform\textsuperscript{12,13}. The normalization service has been implemented as a web service that takes as input the XQuery script and the source data. The actual data transformation is performed by an XQuery engine.

Abstraction service

While the normalization service focuses on the transformation of EHR data according to a standardized information structure, without significant modifications, the abstraction service deals with the transformations required when recorded data must be interpreted before use on the basis of clinical considerations. These transformations are generally based on specialized domain knowledge, and are often substantial in nature (e.g. the notion of severe comorbidity can be inferred from the existence of a total of 19 specific problems, but may not be recorded as such). This is what has been called inferential abstraction by some authors\textsuperscript{14}, and terminology abstractions or abstract definitions by others\textsuperscript{1}. Interoperability of EHR systems and decision-support systems is a typical scenario with such abstraction requirements.

This service, as the normalization one, deals with data transformations. The main difference lies in the fact that target instances do not need to be an accurate representation of source data. For instance, the target data may not be expressed at same granularity level as in the source data. As a consequence a wide range of data transformation functions are required such as arithmetical or string functions, type conversion, and especially aggregation or terminology abstraction functions.

This service has three inputs: the source schema expressed as an XML Schema or as an archetype, the target archetype (not necessarily based on the same reference model as the source schema) and the mapping relating both schemas. The mapping formalism is the same as in the normalization service; the only differences are the support for a broader set of functions in value correspondences (such as aggregation), and that archetypes can be the source schema of the mapping.

For instance, to obtain the value for the attribute “severe comorbidity”, assuming that the presence/absence of a number of morbidities affecting the patient can be obtained from the source schema, we could perform an abstraction based on the Charlson comorbidity score of those morbidities. Note that this is a rather complex example because the attribute “Charlson score” may not be included either in the source schema. The mapping expression for “severe comorbidity” will produce the value \textit{true} if the Charlson score is above a certain threshold, and \textit{false} otherwise. The filter part of the mapping will contain an adequate comparison expression whereas the transformation function will be a constant (either \textit{true} or false).

For the specification of conceptual abstractions over SNOMED CT we support the SNOMED CT Expression Constraint Language\textsuperscript{15}. This language, recently developed by IHTSDO, can be used for the definition of computable rules that define sets of clinical meanings represented by either pre-coordinated or post-coordinated expressions. For instance the constraint:
is satisfied only by disorders of lung which have an associated morphology of edema (or a subtype thereof). This constraint may be used to abstract from acute pulmonary edema or toxic pulmonary edema to pulmonary edema. Note that in contrast to mappings between raw EHR data and archetypes, mappings between archetypes have the potential of being reused as they are, since they often encode domain knowledge. We have extended the Archetype Definition Language (ADL) with support for this language for terminology binding.

The result of the mapping specification is again an XQuery script which takes as input an instance of the source schema and generates an XML document that is compliant with the target archetype. The LinkEHR platform is used both for the specification of the mapping and for the automatic generation of the XQuery transformation script. The abstraction service has been implemented as a web service and the data transformation is performed by an XQuery engine. We additionally use an execution engine for the SNOMED CT Expression Constraint Language (available at http://snquery.veratech.es) which is invoked by the XQuery scripts to perform the abstractions required.

Semantic publishing service

The objective of the semantic publishing service is to represent EHR data in RDF or OWL. The input to this service must be data coming from relational databases or XML EHR extracts. In the present work, we focus on the second case, so this service takes normalized XML EHR extracts as input, that is, the outputs of the normalization and/or abstraction services. By normalized we mean that the data must have been captured using archetypes and expressed in XML conforming to such archetypes. At this stage there are two possible output formats for the EHR data, RDF and OWL. The choice depends on the expected data exploitation use case. If the user desires to obtain a LOD-oriented representation, RDF will be the output format. RDF is oriented to semantic data representation, but with reasoning possibilities limited by the triple store used. OWL is the output format of choice for those scenarios in which automated reasoning is required. OWL is oriented to knowledge representation and its OWL DL level permits to use DL reasoning over the knowledge base.

The XML EHR extracts may not be sufficient to generate their semantic representation because they generally lack domain knowledge. Our transformation engine also uses (1) the OWL ontology that is used for creating the semantic content and acts as knowledge schema; and (2) the mappings between the archetypes used for representing the extracts and the OWL ontology, which define how the EHR data are transformed into OWL individuals. The mapping rules ensure that the EHR data are correctly transformed into the semantic format and prevent redundancy in the output dataset.

For instance, the mapping rules would describe how the information about an adenoma in an EHR extract should be represented in the OWL ontology. In this example, a rule could map the attribute size of the adenoma in the archetype to the corresponding datatype property in the OWL ontology that is associated with the class representing adenomas. Such rule would be systematically applied to all the EHR data instances to create OWL individuals of the adenoma class. This is an example of a basic mapping rule. Our approach includes three types of basic mapping rules, which permit to link archetype entities with OWL classes, datatype properties and object properties, respectively.

Our experience in semantic transformation reveals that the basic rules are not sufficient to get semantically rich datasets. Sometimes, we need to define rules that involve multiple input entities and one or more ontology classes. Besides, the data sources do not always include all the content that is needed to obtain a semantic representation of the data or, at least, such meaning is not made explicit either in the XML schema or in the corresponding table. Therefore, we need to provide additional information in the mapping rules to enrich the EHR data. This is solved in our approach by means of transformation patterns, which will generate additional OWL axioms. These patterns can be regarded as a set of OWL axioms that provides the semantics required and missing in the data source. The patterns are linked to archetype entities, allowing for a semantic transformation of data. Finally, the patterns are expressed in OPPL2 (http://oppl2.sourceforge.net). It should be noted that once the mapping rules are defined, they can be stored and reused in similar transformation processes. The function used in most of these mapping rules is identity, since the atomic values are not changed. The exception to this is the function to create URIs from atomic values. Besides, rules may have filters associated, which would only transform the data instances for which the conditions defined in the corresponding filter hold true.

The semantic transformation method is also able to prevent the duplicity of OWL individuals in case different XML extracts represent the same OWL individual. For this purpose, identity conditions are used, which define the properties that make an OWL individual unique. OWL semantics is applied in the transformation process, which
permits to ensure that only data consistent with the ontology constraints are transformed. Besides, when RDF is the output format, the process ensures that an RDF dataset consistent with the OWL ontology is produced. In our approach, the semantic publishing service is provided by the semantic web integration and transformation engine SWIT\textsuperscript{17} (http://sele.inf.um.es/swit).

Reasoning service

The previous services provide means for data transformation and abstraction, and their outputs are datasets that correspond to EHR extracts in formats like XML, RDF and OWL. The secondary use of EHR data is becoming increasingly important in clinical scenarios, because it enables the exploitation of EHR content with different healthcare-related purposes. One example of secondary use is the classification of patients (e.g. according to levels of risk). This involves applying a series of classification rules which partitions the patients in the groups of interest defined by the rules.

The input to this service is an EHR extract. The reasoning service also uses a set of classification rules, which are applied to the EHR extract. The reasoning service is able to produce two different outputs, which depend on the way it is invoked: (1) an EHR data extract in OWL format, which contains all the information inferred by the reasoner; and (2) the OWL classes to which the patient described in EHR data extract belongs. Hence, the first option returns the whole OWL content whereas the second one targets very concrete RDF triples. As an example of the latter, in the case of a colorectal cancer screening protocol, only the level of risk of a given patient would be returned.

Currently, our reasoning service has been implemented for EHR extracts in RDF/OWL format, that is, the result of the semantic publishing service. However, the solution is generic in the sense that the reasoning service could be implemented for EHR data coming in other formats such as XML. The current service deals with classification rules expressed in OWL. This decision is motivated by the possibility of applying DL reasoning over OWL content, so that state-of-the-art tooling can be reused for this purpose.

This service imposes two major requirements on the OWL ontology used for data classification. The first requirement is that it must contain one class per group of interest. Each group is implemented as an OWL class with equivalenceClass axioms, because they define the sufficient conditions for an OWL individual to be classified as a member of the class. This enables a DL reasoner to automatically partition the clinical data into the desired groups of interest. The second requirement is that the classification ontology must be aligned with the domain ontology used for representing the EHR data in OWL. The simplest way to achieve this is to define the groups of interest based on the domain ontology. Otherwise, the reasoner is still able to infer the corresponding classifications if equivalenceClass or SubClassOf axioms are established between the classes of the two ontologies.

Finally, this service has been implemented as two web services: one returns the OWL ontology with the inferred information, and another one returns the classification of a given individual. The reasoning of the input ontologies and the classification is obtained by applying the Hermit reasoner\textsuperscript{18}.

A proof-of-concept platform

In this work we have implemented a web-based platform that can be used to explore different alternatives for a clinical data transformation problem using the above web services. The platform works on a collection of reusable mappings designed for specific data transformation steps in a particular clinical domain. Based on the mappings, the platform offers a number of transformation alternatives or paths, made up of one or possibly more transformation steps, which can be then executed on sample data (see below for more details). The platform deals with this execution, by making the appropriate calls to the services involved (normalization, abstraction, etc.) and passing the output of each step to the input of the next one. Note that the possible transformation paths will vary depending on the available mappings. Also note that the mappings will determine the scenarios that can be explored (normalization only, normalization plus semantic publishing, etc.). The design of the platform is highly generic, so that new mappings can be easily added to explore different data transformation problems. At the time of this writing the platform includes a series of mappings related to the domain of colorectal cancer (see http://cliniklinks.upv.es/demoAMIA2016.html).

The following paragraphs detail the main steps when solving a data transformation problem with the platform, including the user interaction steps. They also describe the additional web services that have been implemented to support each step. The overall process and components are shown in Figure 1.
1) The platform displays automatically a list of all possible targets or destinations. These are retrieved from the currently available mappings through a specific-purpose web service. This action is performed in real time which facilitates the inclusion of new schemas and schema mappings. The user chooses the desired target.

2) Once the target has been established, another web service computes all possible transformation paths based on the mappings, in order to retrieve all the paths ending in the selected target. The mappings that define transformations between schemas and the schemas themselves may be distributed among servers in different organizations. The mappings and schemas can be interpreted as a directed acyclic graph, where the vertices are the schemas, and the edges are the mappings. A recursive in-depth search is performed which returns all the transformation paths from a source schema to the target one. The user selects which transformation paths to execute.

3) The user input for the execution of a transformation path is a clinical data instance based on the clinical data source schema. The instance may be provided directly from an EHR system or manually by clinicians by using digital data forms. Our proof-of-concept platform provides a web form based method to generate the input instance on the fly. The forms have been manually pre-designed according to the clinical data source schema. An additional web service automatically serves one form (each form is identified by the name of the first vertex in the selected transformation path) to the platform. The user fills out the displayed form to generate the source instance. In case multiple transformation paths are selected, the process would be much the same except for using multiple source instances (with different forms involved).

4) The platform includes a management web service that operates on the transformation paths and the data form contents. First, the management web service invokes another supporting web service that creates a valid source instance based on the form contents. With this instance, it then executes the corresponding web services for clinical data transformation (normalization, abstraction, semantic publishing, or reasoning transformations) in the required order. The management web service retrieves the output of each transformation step and hands it as input to the next one until the desired target is obtained, which is returned as result. It is also worth noticing that a single normalization or abstraction transformation may return a set of instances (e.g. in case the original source data contains information from more than one patient). This implies that all possible generated instances must be transformed so that further transformation steps are applied to each one of them.

**Figure 1.** Overview of the platform architecture along with the main steps to execute a data transformation scenario

**Application to the colorectal cancer domain**

We have used our platform for the development of two different data transformation applications in the area of colorectal cancer. Colorectal cancer is an important cause of death in developed countries. Screening for colorectal cancer serves to identify people who may be at risk of developing the disease. Concretely, the framework of our work is the colorectal cancer screening program of the Region of Murcia (Spain), which uses screening protocols standardized in Europe and America to classify patients according to their level of risk. As a result of the application
of these protocols, a database with data on more than 20,000 patients has been produced. Our goal is to demonstrate that the platform allows us to readily develop data transformation applications for different purposes, using EHR standards and semantic web technologies. In the first place, this requires a careful design of the different transformation steps, as well as of the models (archetypes, ontologies, etc.) to be used in each step, all this taking into account the needs of the project. Secondly, appropriate mappings must be defined for each transformation step, given the source and target of the transformation. Having defined the mappings, the platform will deal with the execution of the transformation pipeline, as described before. It should be noted that the mappings making up an application can be reused in other applications with similar transformation requirements.

In the rest of the section we describe the implementation of two applications using as starting point the database of Murcia’s colorectal cancer screening program. The first application corresponds to a basic normalization scenario, while the second is a more complex scenario implementing a colorectal cancer screening protocol. All the resources mentioned in the scenarios are available online (see http://cliniklinks.upv.es/demoAMIA2016.html).

Scenario 1: normalization to the CKM archetype for histopathology lab test results

This scenario corresponds to a single-step transformation performing a normalization. The input is the above database with the EHR extracts of the patients, and the output is a normalization of the previous database in terms of a standardized clinical information model. For this purpose we have chosen the openEHR-EHR-OBSERVATION.lab_test-histopathology archetype from the openEHR CKM repository.

Normalization

As stated before, the normalization service requires at design time the specification of a high-level mapping between the source schema and the target archetype. The source schema is a nested schema describing anatomic pathology studies with their findings. There is a top-level set of studies, and each study record has a nested set of test records. Tests have an additional nesting where each test has a set of findings. Studies and test records include context information such as dates and performers. Finally, findings contain the details of the microscopic findings such as size or pathological staging. In the target schema (archetype), there is a top-level record that represents a test. Each test has a set of microscopic findings and a set of macroscopic findings along with other information items such as specimen details or test status. Since the source schema has an additional nesting level (study), a single source instance might produce several target instances.

The mapping specification was created using the LinkEHR mapping capabilities. Since our purpose was to make public the available data in the form of an XML document compliant with the openEHR reference model, we did not employ any transformation function neither normalized the local terminology. It was not necessary either to define a mapping for all the atomic data elements in the archetype since a great part of them are not present in source data. Note that archetypes are defined to be as generic as possible in order to accommodate any relevant piece of information.

Scenario 2: implementation of a colorectal cancer screening protocol using abstraction, semantic publishing and reasoning

In this scenario we have used the platform to implement the case study of a previous work. The input to this clinical data transformation problem is the above-mentioned database with the EHR extracts of the patients, and the desired output is the level of risk for each patient. To take advantage of the platform’s capabilities for reasoning with OWL content, the EHR data will have to be transformed into OWL, to obtain the level of risk through classification reasoning. For this purpose, the semantic publishing service will be required.

Both the European and the American screening protocols define the level of risk by taking into account aspects like the amount of adenomas or the size of the largest adenoma, information which can be obtained from histopathologic findings. If this specific information is not included in the database, it will have to be calculated in terms of the services offered in the platform, that is, by means of either abstraction or reasoning services. For efficiency reasons, we consider more appropriate to perform operations like count or maximum as part of an abstraction step.

Hence, abstraction, semantic publishing and reasoning are the three services required in this scenario. Next, we describe the requirements and the inputs and outputs of each transformation step, including which inputs correspond to outputs of previous steps.

Abstraction
In the same vein as the normalization service, the abstraction one requires at design time the specification of a high-
level mapping between the source and target schemas, the only difference is that the source schema can be also an
archetype. In order to determine the patient’s risk level, we need to use concepts at two different levels of
granularity: at finding and at test levels. For the representation of finding-level concepts, we defined a specialization
of the archetype openEHR-EHR-OBSERVATION.lab_test-histopathology, named openEHR-EHR-
OBSERVATION.lab_test-histopathology colorectal_screening. This specialized archetype includes information
about adenoma findings such as the type or maximum size of the recorded dimensions (width, breadth and height),
the dysplasia grade and whether they are sessile and/or advanced. These information items are not stored directly in
the database but can be calculated by performing different types of abstractions. In order to represent test-level
concepts, concretely the maximum size of all adenomas and the number of adenomas, we developed a new
archetype from scratch called openEHR-EHR-EVALUATION.colorectal_screening.v1.

Two mapping specifications were necessary, the first one between the database and the finding-level archetype and
the second one between the finding-level archetype and the test-level archetype. The required abstractions were
codified in the mapping specification and therefore are performed by the resulting XQuery script. As explained
before, in our mapping formalism a value correspondence comprises a set of filter-transformation function pairs that
allows complex conditional expressions (if-then-elseif …). Value correspondences proved to be powerful enough
for defining the concept abstractions required in the first mapping (e.g. advanced adenoma). The second mapping
required additionally the use of aggregation functions: max for the calculation of the maximum size of all adenomas,
and count for the calculation of the number of adenomas. The archetypes and the mapping specifications were
created using the LinkEHR archetype editing and mapping capabilities, respectively.

Semantic publishing

The semantic publishing service uses the mapping designed to transform the EHR data conformant with the
archetypes of the previous step into the colorectal-domain OWL ontology, which provides the specific domain
knowledge. The ontology itself is also used in this transformation step. The service takes as input the EHR extract
produced by the abstraction service, and produces as output an OWL representation of that extract in terms of the
colorectal-domain ontology.

Reusing an OWL ontology from the NCBO BioPortal (http://bioportal.bioontology.org) was our first option to
promote the interoperability of the OWL content generated. We were not able to find any appropriate OWL
ontology, so we had to develop one specifically for this use case. The development of the colorectal-domain OWL
ontology was a manual process guided by the entities identified in the source database, in order to represent the
domain knowledge that would be required to express the meaning of the EHR extracts in OWL format. This
ontology includes classes for histopathology reports, types of findings, types of results of anatomical pathology
tests, etc., and properties and axioms that define precisely the meaning of these entities. The ontology consists of
102 classes, 47 object properties, 42 datatype properties and 1693 logical axioms.

The mapping file specifying the correspondences between the archetypes and the colorectal-domain ontology was
created using the SWIT tool. This mapping includes a transformation rule for each of the entities included in the
archetypes resulting from the abstraction step. Note that we have only defined the transformation rules for those
entities which we believe to be of interest for a semantic exploitation. Given that the mapping is defined between
archetypes and the domain ontology, it is independent of the source database.

Reasoning

The reasoning service takes as input the EHR extracts in OWL format resulting from the application of the semantic
publishing service. It operates by using the OWL classification ontology which contains the logical definition of the
levels of risk according to the European and American protocols. The output of the reasoning service is the level of
risk inferred based on both the input EHR extract and the classification ontology.

The OWL classification ontology was developed as an extension of the colorectal-domain one. Basically, the
classification ontology defines five classes, which correspond to the risk groups specified in the protocols. The
European protocol distinguishes high risk, intermediate risk, and low risk, whereas the American one only
differentiates between high risk and low risk. The five classes are modeled in a similar way. First, each class is
defined as a subclass of HistopathologyReport, which is a class of the domain ontology. Second, equivalentTo
axioms are associated with each class, which define sufficient conditions for membership of the class. For example,
the condition associated with both the LowRiskAmericanProtocol and LowRiskEuropeanProtocol classes is the
same, and is described as follows: “A histopathology report that only contains at most 2 normal adenomas, but does
not contain any advanced one". This is implemented in the OWL classification ontology as follows: HistopathologyReport and (hasAdenoma only NormalAdenoma) and (max_size some integer[< 10]) and (number some integer[< 3]). The classes of interest were mainly defined by using the properties and classes of the domain ontology. The classification ontology introduces 16 new classes and 62 new logical axioms, but no additional object or datatype properties.

Conclusion

In this paper we introduce the proof-of-concept platform that we have implemented to explore different alternatives for a clinical data transformation problem. It is built upon specialized web services dealing with data transformations which work at different levels, namely: normalization, abstraction, semantic publishing and reasoning. More importantly, the platform uses a series of reusable mappings that might be distributed across servers in different organizations and supports multiple EHR information standards (such as HL7 CDA, ISO 13606 or openEHR). In principle the mappings restrict the range of transformation applications (and hence scenarios) that can be configured using the platform. However, the design is rather generic, so that new mappings can be easily added allowing for a wider range of scenarios.

We also describe two different data transformation applications that have been implemented using our platform and web services. It is important to stress that the different models (archetypes, etc.) to be used along the transformation process, and specially the mappings defined taking into account the source and target of each transformation step, are essential in this kind of implementations.

Mappings involve local (XML) schemas, archetypes and ontologies as source or target elements. Concretely, mappings can be defined between: (a) an XML schema and an archetype, (b) an XML schema and an OWL ontology, (c) two archetypes, and (d) an archetype and an OWL ontology. As described earlier, we follow a “specify and generate” approach for all types of mappings. In this approach, developers are responsible for defining high-level mappings using specific-purpose tools, namely LinkEHR for mappings resulting in archetypes ((a) and (c)) and an ontology alignment format for mappings to RDF/OWL ((b) and (d)). These definitions are then automatically compiled into an executable script that will be used to perform the actual transformation. With mapping reuse in mind, it becomes necessary to pay attention to quality assurance aspects.

In our platform, automated reasoning supports both the semantic publishing and reasoning services, that is, the generation of the semantic dataset and its exploitation. State-of-the-art approaches do not use reasoning for guaranteeing the generation of consistent datasets, although reasoning has supported the transformation of clinical models into OWL. Those approaches mainly exploit reasoning as part of SPARQL queries or use specific rule languages such as SWRL, which are options more limited in terms of reasoning than OWL DL. Since we were interested in classification, OWL DL was deemed the preferred alternative. SPARQL and SWRL seem interesting options for other exploitation services that could be included in the future in our platform.

As future work we intend to extend our platform with different mapping management functionalities. Examples include the development of mapping operators, such as the merging of mappings, as well as of criteria (e.g. quality criteria in terms of the amount of information transferred) that can be used to compare mappings. Furthermore, we also foresee applications where the mappings (and/or models) listed in the platform are used in alternative ways. An example might be to use the mappings to determine the EHR data requirements for semantic publishing according to a given ontology. This will surely require including in the platform a precise characterization and/or a declarative description of the mappings. For instance, a formal description of the concept definition used in an abstraction mapping has proved very useful according to our previous experience. Finally, we plan to carry out the necessary developments with a view to the utilization of the data transformation applications built with our platform in a clinical setting.

Abstract

The U.S. Federal Government developed HealthData.gov to disseminate healthcare datasets to the public. Metadata is provided for each dataset and is the sole source of information to find and retrieve data. This study employed automated quality assessments of the HealthData.gov metadata published from 2012 to 2014 to measure completeness, accuracy, and consistency of applying standards. The results demonstrated that metadata published in earlier years had lower completeness, accuracy, and consistency. Also, metadata that underwent modifications following their original creation were of higher quality. HealthData.gov did not uniformly apply Dublin Core Metadata Initiative to the metadata, which is a widely accepted metadata standard. These findings suggested that the HealthData.gov metadata suffered from quality issues, particularly related to information that wasn’t frequently updated. The results supported the need for policies to standardize metadata and contributed to the development of automated measures of metadata quality.

Introduction

As part of the Open Government Initiative, the United States Federal Government published important datasets to the public using an online portal, HealthData.gov, to increase collaboration, transparency, consumer participation, and research. Despite the motivation to increase governmental transparency and accountability by publishing important healthcare datasets, there are considerable limitations to data access and retrieval. The lack of consistent standards to data storage and retrieval has been shown to inhibit citizen engagement in utilizing these resources for scholarly purposes. Martin, Foulonneau, and Turki conducted a study to examine if data that is considered open and public is actually accessible. They found limited openness of datasets advertised as open data, and considerable heterogeneity in the metadata elements that are intended to represent data sources. Shah and colleagues explained how publicly available biomedical data are annotated with unstructured text and are rarely described with ontology concepts available in the domain. The challenge is to adopt consistent metadata standards for public data to index the resources and allow for search methods that can identify the resource and related resources. Together, these issues challenge users in the discovery and access of public data. These limitations may be overcome with improvements to the quality of the metadata and adoption of standard annotation principles to index the publicly available data. Of particular interest is identifying the points of failure in the quality of the HealthData.gov metadata.

In HealthData.gov, metadata is used to summarize the available datasets and acts as the sole source of information for searching and retrieving relevant data. From 2012-2014, HealthData.gov metadata was maintained with the Comprehensive Knowledge Archive Network (CKAN), which is open-source data repository software. The CKAN platform requires federal agencies to submit specific metadata fields to describe a dataset (Table 1). Winn formally evaluated CKAN and found that there were limitations to the software including the inability to browse metadata history and workflow challenges around data storage and management. The advantages of CKAN include the flexibility for organizations to adapt the use of the platform with the opportunity to support data exchange using the Resource Description Framework (RDF) to facilitate data merging under a common schema.

Until now, the quality of storing publicly available healthcare data on HealthData.gov has not been formally evaluated. There are documented challenges around public participation of HealthData.gov, but the underlying causes of the challenges are not well explained. Therefore, the primary aim of this research is to formally examine the quality of the HealthData.gov metadata by assessing completeness, accuracy, and consistency to create standards and policies for publishing publicly available healthcare data.

### Methods

The quality of the HealthData.gov metadata was evaluated using automated methods to assess completeness, accuracy, and consistency. The quality of the metadata was compared across the years the metadata was created and whether the metadata had undergone modifications at any point after the metadata was created.

#### Data Extraction

In August 2015, the complete HealthData.gov metadata catalogue from datasets that were published from January 2012 through December 2014 was queried from the CKAN engine using an HTTP GET Script. There were a total of 1,632 metadata instances extracted.

#### Completeness Assessment

The percentage of primary fields in each metadata instance that contained a null value was calculated to identify the frequency of blank fields. Additionally, an aggregated measure of completeness was obtained for each metadata instance. Equation 1 expressed how this metric was determined.

\[
Q_{\text{comp}} = \frac{\sum_{i=1}^{N} P(i)}{N}
\]

Where \( P(i) \) is 1 if the \( i \)th field has a non-null value, 0 otherwise. \( N \) is the number of fields defined in the metadata standard. The maximum value of this metric is 1 (in the case all the fields contain information) and the minimum value is 0 (all metadata primary fields are empty).

#### Accuracy Assessment

Accuracy is the degree to which metadata values are “correct” (i.e. how well they describe the object). Accuracy was assessed based on the proportion of working URLs and a semantic distance assessment.

The URL metadata field was classified as working or broken using a Python package that checks the syntax and connection of HTML documents. The proportion of error response codes was calculated. Only metadata instances where a URL was provided were included in the analysis.

Another measure of accuracy was the semantic distance between the information from the metadata instance and the information the same user could obtain from the resource itself. Formula 2 presents the semantic distance calculation, which was adapted from Ochoa and Duval\(^1\). The text for the data source was derived from the information contained on the website at the URL specified in the metadata.

All of the text was transformed to lowercase, punctuation was removed, the resulting white space was stripped, and common English words (i.e., stopwords) were removed. Two vectors were created based on the distinct words that appeared in the text of the original resource and the text of the metadata instance. The vectors were preprocessed before measuring the distance by removing any words that were not found in biomedical text using the biomedical dictionary GSpell\(^2\). GSpell is a spelling suggestion tool that uses a variety of algorithms to retrieve close neighbors. Any word identified as a misspelling was removed from the vectors. The reason this was done is to remove aberrant
words that may have resulted from text that was embedded within URLs found on the source page (e.g., .html, https).

The semantic distance was determined based on the comparison of terms that appeared in the metadata instance that also occurred in the original resource text. In Equation 2 the distance formula is presented.

\[
Q_{\text{accu}} = \frac{\sum_i \text{source}_i}{\sum_i \text{metadata}_i}
\]  

(2)

Where \(\text{source}_i\) is the binary output that indicated whether a word appearing in the metadata text also appeared in the source text of the \(i\)th dataset and \(\text{metadata}_i\) is the relative frequency of terms of the \(i\)th dataset. \(N\) is the total number of distinct words in the metadata text. The minimum value (lower quality) is 0, meaning that the text in the metadata does not exist in the source text. The maximum value (higher quality) is 1, meaning that all the words from the metadata appear in the source text.

To validate the \(Q_{\text{accu}}\) scores, 2 human reviewers independently assessed the level of agreement between the metadata and source text using a manual review process based on a method described by Ochoa and Duval\textsuperscript{11}. The metadata and the content from the URL were presented to the reviewers and the reviewers were asked to rate their level of similarity. The ratings were captured on a 7-point Likert scale from absolutely inappropriate to absolutely appropriate. The reviewer’s responses were assessed for reliability using an intraclass correlation coefficient (ICC). The human reviewer and \(Q_{\text{accu}}\) scores were transformed to categories where a score greater than or equal to 0.5 indicated high accuracy and anything less was low accuracy. Precision, recall, and \(F_1\) scores for \(Q_{\text{accu}}\) was assessed relative to the manual human reviewers as a method of measuring \(Q_{\text{accu}}\) accuracy.

**Consistency Assessment**

The consistency of the metadata was estimated as the degree to which the metadata matched standard definitions. There were two consistency measures: 1) Whether the fields of the metadata instances followed the CKAN requirements for the data type; 2) Whether the fields of the metadata framework followed the Dublin Core Metadata Initiative requirements.

The first consistency issue was measured by determining if each metadata field met the requirements of the data type as specified by CKAN\textsuperscript{9}. There were five different data types included in the metadata fields including GUID, plain text, HTML text, URL, and array of text. Rules were established to assess compliance with CKAN requirements, which are shown in Table 2. With the exception of the ‘Plain text characters’, the rules were assessed using regular expressions (regex) in the R statistical software package to determine if the format of the metadata field followed the CKAN requirements. The ‘Plain text characters’ rule was assessed by identifying the metadata instances that raised an exception to UTF-8 encoding. A logical vector was returned (i.e., TRUE or FALSE) indicating whether the regex found a match in the corresponding element in the input vector. The total number and proportion of TRUE values were added across each metadata field and for each metadata instance.

The consistency metric was based on CKAN compliance and equal to 1 minus the average of the fraction of problems found. Equation 3 was adapted from Ochoa and Duval\textsuperscript{11} and presents the calculation for the first consistency measure.

\[
Q_{\text{cons}} = 1 - \frac{\sum_i \text{brokenRule}_i}{N}
\]  

(3)

where \(\text{brokenRule}_i\) is a binary variable where 0 indicates compliance with a rule and 1 indicates noncompliance with a rule for each \(i\)th metadata instance. \(N\) is the number of rules in the metadata standard. The minimum value for the consistency metric is 0 (all possible errors were made) and the maximum value is 1 (there were no consistency problems).

The second measure of consistency was determined based on compliance with the metadata requirements set forth by the Dublin Core Metadata Initiative\(^\text{13}\). The consistency measures evaluated the level of consistency between the HealthData.gov metadata field names and properties based on the Dublin Core standards. There were 9 rules evaluated and the frequency of compliance and violations was measured.

**Statistical Analysis**

The R Statistical Software package was used to carry out the statistical analyses. The proportion of URL errors that occurred in modified and unmodified metadata instances was compared using a two-sample Z-test of proportions. A three-sample Z-test of proportions was used to compare the proportion of URL errors across each of the three years the metadata instances were created. The Kruskal-Wallis statistical procedure with the Nemenyi post hoc test was used to test for differences in \(Q_{\text{comp}}\), \(Q_{\text{accu}}\), and \(Q_{\text{cons}}\) between each year the data was created. Between each year, the Mann-Whitney U test was used to compare differences in median values of \(Q_{\text{comp}}\), \(Q_{\text{accu}}\), and \(Q_{\text{cons}}\) based on the modification status.

**Results**

**Completeness**

When evaluating the frequency that required metadata fields included a blank entry, there were 0 for title, 19 (1\%) for author, 33 (2\%) for URL, 57 (4\%) for notes, and 157 (10\%) for tags.

As shown in Figure 1, the unmodified metadata had lower \(Q_{\text{comp}}\) scores compared to modified metadata (\(W = 154590.0\), p-value\(<0.001\)) and there were differences based on the year the metadata was created (Kruskal-Wallis \(\chi^2 = 13.5\); df= 2; p-value=0.002). Pairwise comparisons revealed that metadata created in 2012 had higher scores compared to 2013 (p=0.001) and 2014 (p=0.02). When comparing differences in \(Q_{\text{comp}}\) for each year the metadata was created and between each modification status, unmodified metadata had lower scores than modified metadata created in 2013 (W= 9924; p-value\(<0.001\)) and 2014 (W= 45750; p-value\(<0.001\)). Unmodified metadata created in 2012 had higher scores than unmodified metadata created in 2013 (W=641.5; p-value=0.006) and 2014 (W=2470.5; p-value=0.039). Modified metadata created in 2012 had higher scores than modified metadata created in 2013 (W=79062; p-value=0.005). Also, modified metadata created in 2013 had lower scores than modified metadata created in 2014 (W=144940; p-value=0.032)
Figure 1. Dotplot of the distribution and median values (red line) for $Q_{comp}$ scores by the year the metadata was created and modification status (n=1,632). Note: To prevent overplotting, the dotplot is presented with jitter. The scores do not exceed 1.

Accuracy

There were 1,601 metadata instances where a URL was provided and 71 (4%) resulted in an error. Of the 241 unmodified metadata instances, 32 (13%) had a URL error. There were 39 (3%) URL errors in the 1,360 modified metadata instances. There were significantly greater URL errors for the unmodified metadata compared to the modified metadata ($\chi^2=52.35$, df=1, p-value<0.001).

There were 29/290 (10%) errors for 2012, 6/579 (1%) errors in 2013, and 36/732 (5%) errors in 2014. The proportion of URL errors was significantly different across the three years ($\chi^2=37.38$, df=2, p-value<0.001).

The total number of 1,529 metadata instances were included in the semantic distance analysis. There were 103 instances removed due to invalid or missing URLs.

To validate the $Q_{accu}$ scores, 2 human reviewers independently rated metadata instances. The ICC statistic for reliability was 0.978, indicating strong agreement between raters. The precision of $Q_{accu}$ was 0.95 with a recall of 0.87 and an $F_1$ of 0.91. Together, these statistics verify strong accuracy of $Q_{accu}$.

As shown in Figure 2, unmodified metadata had significantly lower $Q_{accu}$ scores compared to modified metadata (W = 65899.0, p-value<0.001) and there were significant differences based on the year the metadata was created (Kruskal-Wallis $\chi^2$ = 368.04; df= 2; p-value=0.001). Metadata created in 2012 had a significantly lower $Q_{accu}$ scores compared to 2013 (p<0.001) and 2014 (p<0.001). The metadata created in 2013 had a lower scores than 2014 (p<0.001). When comparing differences in $Q_{accu}$ for each year between each modification status, unmodified metadata had lower scores than modified metadata for instances created in 2013 (W= 4457; p-value<0.001) and 2014 (W= 10308; p-value<0.001). Modified metadata that was originally created in 2012 had lower scores than modified metadata created in 2013 (W=24984; p-value<0.001) and 2014 (W=8062; p-value<0.001). Also, 2013 had lower scores than 2014 for modified metadata (W=75800; p-value<0.001).
Figure 2. Dotplot of the distribution and median (red line) of $Q_{accu}$ scores by the year the metadata was created and modification status (n=1,529).

Consistency

As shown in Figure 3, unmodified metadata had lower $Q_{cons}$ scores than modified metadata ($W = 162640.0$; p-value<0.001), but there weren’t differences based on the year the metadata was created (Kruskal-Wallis $\chi^2 = 6.11$; df= 2; p-value=0.05). Unmodified metadata had lower $Q_{cons}$ scores than modified metadata that originated in 2013 ($W= 8496$; p-value<0.001) and 2014 ($W= 50524$; p-value<0.001). The metadata created in 2012 had higher scores than 2013 for unmodified metadata ($W=633.5$; p-value=0.008) and lower scores for modified metadata ($W=721088$; p-value=0.031). Metadata created in 2012 had lower scores than modified metadata created in 2014 ($W=70961$; p-value<0.001). Unmodified metadata created in 2013 had higher scores than unmodified metadata created in 2014 ($W=3255.5$; p-value<0.001).

Figure 3. Dotplot of the distribution and median (red line) of $Q_{cons}$ scores by the year the metadata was created and modification status (n=1,632). Note: To prevent overplotting, the dotplot is presented with jitter. The scores do not exceed 1.
When comparing compliance with the Dublin Core standards, the metadata followed 3 of the 9 rules. Table 3 displays the rules that were confirmed and violated. The most common violations were related to the naming schema of fields.

**Table 3. Metadata compliance with Dublin Core standards.**

**Discussion**

The goal of this research was to investigate the quality of the HealthData.gov metadata. There was considerable growth in the number of datasets released each year, which suggested increased participation by agencies to publish important datasets in an open, accessible format. However, there was evidence of existing problems regarding the quality of the metadata representing the datasets, which is the foundational information of HealthData.gov. If problems exist in the metadata, this can impact the ability to search and retrieve data. To date, research has noted a lack of citizen participation in utilizing the public data, which has been attributed to inconsistent access standards. Until now research has not addressed the specific impact that inconsistent data standards have on the quality of the data.

Quality was measured based on the completeness, accuracy, and consistency of the metadata. These measures were chosen based on the recommendations of past research. Each measure of quality was compared between datasets based on the year the metadata was initially created and whether the metadata had undergone modifications at any point.

The $Qcomp$ was measured for all metadata instances and was calculated based on the proportion of fields that included data. There results of the analysis suggested growing issues around completeness. The $Qcomp$ scores were higher in 2012 compared to 2013 and 2014, suggesting more complete metadata in earlier years. Additionally, metadata that had undergone a modification at the time of the analysis had significantly higher scores (i.e., greater completeness) than the unmodified metadata.
Accuracy was measured by evaluating the frequency of broken links and the similarity of the metadata to the source data. About 5% of the URLs resulted in an error. Errors occurred more frequently in metadata that was left unmodified (13.28%) versus metadata that had undergone modifications (2.87%). Also, the metadata that was created in 2012 had the highest frequency of URL errors (10.0%) followed by 2014 (4.92%) and then 2013 (1.04%). The reason why there were more errors for 2014 when compared to 2013 is likely due to the greater number of unmodified metadata instances from 2014.

To better examine the accuracy of the metadata, an evaluation was conducted to determine how well the metadata represented the source data. The $Q_{accu}$ score is a quality metric that was calculated for each metadata instance and demonstrated how well the metadata represented the source data. When comparing the years the metadata was created and the modification status, it was found that $Q_{accu}$ scores significantly increased each year and the unmodified metadata had lower scores than the modified metadata. Together, these findings suggested that the modified metadata offered a better representation of the source data compared to unmodified metadata. Therefore, frequent updates to the metadata are recommended to ensure the metadata accurately represent source information.

Research supports this recommendation by showing improvements in the quality of the metadata with modifications$^{14,15}$. A final quality evaluation included a comparison of consistency. Consistency was measured based on the requirements specified by CKAN, the data portal where the HealthData.gov was published, as well as requirements defined by the Dublin Core, a standard for metadata design and infrastructure. The consistency metric, $Q_{cons}$, was calculated for each metadata instance based on the compliance the 9 CKAN. The observed trends suggested declining consistency overtime with unmodified metadata having significantly lower $Q_{cons}$ scores compared to the modified metadata.

The second consistency measure examined compliance with the Dublin Core standards for publishing metadata. Largely, the field names had violated the naming schema outlined in the Dublin Core, where only one of the six key metadata fields (i.e., title) complied with the standard. Regarding the formatting of the data, the metadata did conform closer to the Dublin Core standards. That is, the unique identifier and date were formatted appropriately. However, there was not a field representing the topic of the metadata using a controlled vocabulary. Together, these findings are concerning given the fact that the Dublin Core was developed to offer generic metadata standards and is the most widely adopted vocabulary for a Resource Description Framework (RDF). RDF is a family of World Wide Web Consortium (W3C) specifications originally designed as a metadata data model enabling resource discovery and cataloguing to enable users to deal with information with efficiency and certainty$^{16}$. Of particular interest is the role of a controlled vocabulary for representing the topic of metadata to help facilitate the search and retrieval of results. Although HealthData.gov included tags (i.e., keywords) as a required metadata field, these tags did not conform to a controlled vocabulary.

Given the evidence of quality concerns regarding the HealthData.gov metadata, there is greater need for open data policies to standardize a metadata framework and outline best practices for government participation. Following the publication of the Open Data Initiative, the U.S. Department of Health and Human Services (HHS) began to actively promote wide distribution of healthcare data through the Health Data Initiative (HDI). The Health Data Consortium (HDC) was developed to oversee the HDI and offer a structured approach to accelerate the availability and use of health data. The HDC is a public-private partnership that drives innovative uses of health information to improve health outcomes for individuals, enhance the effectiveness of the health care system, and build healthier communities. In October 2013, HDC created a strategic plan for the HDI, outlining the methods for advancing the distribution of health data$^{18}$. By making health data publicly available, the HDI intended to describe how the public can responsibly support healthcare innovations through creative, cost-effective, and efficient solutions$^{18}$.

Under HDC’s strategic plan, various metrics were developed to determine the level of achievement regarding established goals. The strategic plan suggested that if the results from these metrics were not meeting the set expectations, appropriate changes to the initiative would be put forth. Given the findings of this research, updated policies regarding standards for publishing metadata are required, which can include methods for assessing metadata quality.

In addition to updated policies, an updated metadata framework can help support greater quality, accuracy, and consistency. HealthData.gov uses a metadata schema called the “Project Open Data Metadata Schema”$^{19}$. This schema is extensible where metadata elements from Dublin Core can be included, however, Dublin Core is not the basis of the metadata schema. Rather, the Project Open Data Metadata Schema is based on the Data Catalog Vocabulary (DCAT), a hierarchical vocabulary specific to datasets$^{19}$. 871
An updated framework can be adopted to support higher quality metadata. To ensure complete metadata, a requirement can include mandatory fields. That is, a metadata instance cannot be submitted to HealthData.gov unless specific fields are completed. To address the accuracy concerns the metadata should be published using a standardized vocabulary for indexing purposes. In addition, the publisher of the dataset should verify the accuracy of the data at the time of the initial publication and on a quarterly basis. The system could incorporate a quality assurance process using an automated auditing tool to determine if submitted metadata meets a minimum quality requirement to ensure the information is complete, accurate, and consistent. Feasibly, the automated metrics used in this research could be adopted to assess metadata quality upon submission. To satisfy the consistency concerns, the metadata fields should follow the Dublin Core standards for the field names and formats. This includes not just the key metadata fields, but all metadata fields should abide by Dublin Core standards. An updated graphical user interface that offers contextual cues to support more complete and accurate data entry may help achieve greater consistency in adopting the aforementioned standards. ClinicalTrials.gov currently uses a quality audit where incomplete or inadequate submissions are denied and the submitter is informed of the identified issues. The submitter needs to address the issues with the submission before the data will be posted to the public.

At present, publicly available healthcare data is difficult to find and retrieve. The reason for such difficulties may be related to poor data quality and inconsistent use of standards. Policies and procedures regarding data storage that accompany the adoption of a data repository application may aid in addressing existing challenges. Future research should explore the application of a metadata schema that could facilitate greater quality of the metadata. Also, future research needs to be conducted to determine if higher quality metadata facilitates improvements in the retrieval and use of the publicly available healthcare data. Ultimately, this research can help to inform best practices for publishing metadata to inform policymakers and developers.

**Conclusion**

As part of the Open Government Initiative, the United States Federal Government published important datasets for use by the public. Health data is made available through an online data repository, HealthData.gov. Although there has been increasing participation by health agencies in disseminating data to the public, there has been very low public participation in the use of the data. A cause for the lack of public participation may be related to issues with the quality of the metadata that represents the health data. The metadata is the key source of information for storing and searching for datasets. Using automated methods of assessing data quality, clear issues regarding the completeness, accuracy, and consistency of the data were identified in HealthData.gov. There is a need develop policies that elucidate methods for publishing metadata to HealthData.gov that is complete, accurate, and consistent, which may include automated quality assessment, metadata standards, and terminology adoption.

Abstract

This work analyzes strategies for better allocation of surgeon resources in an elective surgical practice. Among the metrics considered to evaluate the assignment of tasks are OR-to-Clinic ratio per provider, OR-to-Clinic ratio per day, patient access to clinic, and patient access to surgery. In addition, a simulation model is used to evaluate the clinical and surgical capacity of the calendar to identify potential inefficiencies and propose strategic changes to the calendar.

Introduction

The challenge of optimal assignment of human resources is one that is universal across all industries where human capital is a primary resource. In the health care industry this is especially true as people are involved in all aspects of patient care. From the person coordinating appointments, to the medical assistant checking vital signs, the doctor evaluating the patient, the nurse caring for hospital patients; the management decisions related to these resources are critical to a well-running integrated practice. Too few or too many of any of these resources can have negative impacts that could include: wasted resources, long waiting times, and poor quality of care. Health Care organizations are constantly challenged with these questions of resource assignment and how to best deliver quality care in the most efficient/cost effective way possible.

This paper addresses resource assignment in a specialty surgical practice with specific focus on how surgeons are assigned. In a specialty surgical practice, a surgeon can be assigned in one of two ways: clinic or surgery. Clinic time will result in new surgical procedures to be performed; while time assigned to surgery will reduce the number of procedures in the surgeon’s queue, see Figure 1.

Figure 1. General patient flow for an elective surgical practice.

It is important to maintain a proper balance of clinic and surgery. At a high level, too many patients entering the practice through clinic could result in very long queues for surgery. On the other hand, too much time assigned to surgery results in poor clinic access and under-utilization of operating room (OR) resources. These concepts are true of any surgical practice.

Capacity planning in health care industry is a complex problem which has been analyzed in the literature. For example, queue theory is used in 1 to determine the number of clinic appointments needed per day by a specialty clinic. The authors in 2 study the planning of operating rooms, they formulate an optimization problem to built a master surgical schedule. In contrast with previous works, this paper focuses on the strategic assignment of both clinic and OR. The surgeon assignment is done in a way to maintain appropriate OR-to-Clinic ratios for the overall practice as well as for each day in the planning horizon. The work presented in 1 considers a one-surgeon practice, our work considers time-allocation of multiple surgeons and its effects on patient access. As in 3, we use simulation to evaluate the performance of the calendar. The reader is referred to 4,5, 6 for a literature review on capacity planning problems in health care.
Materials and Method

This section discusses, in detail, an approach for addressing the surgeon time-allocation problem in an elective surgical practice at Mayo Clinic.

Assignment of Clinical Resources: Individual Calendar Pattern

Individual calendar patterns are the foundation for how surgeon resources are allocated between OR and Clinic. Mayo Clinic uses a 12-week planning horizon to assign clinical resources, surgeon calendars are updated on a rolling monthly basis. This means that calendars are available for clinical and/or surgical services twelve weeks into the future. Surgeons are assigned using a calendar where the days of the week are either blue or orange – in an alternating pattern. There are an equal number of blue and orange days each calendar year. A “blue” surgeon operates on blue days and is in clinic on orange days. This calendar structure creates a natural every-other-day clinic/surgery pattern for surgeons. Table 1 illustrates a two-week pattern for a surgeon. It can be observed that the resulting pattern for surgeon 1 defines a 1:1 OR-to-Clinic ratio.

<td>5</td>
<td>5</td>
</tr>
</tbody>
</table>

Another scenario will illustrate a common calendar pattern for surgeons where non-practice time (A) is included, see Table 2. This time is generally related to research, education, or administration. The goal of the calendar patterns is to maintain a balanced practice for each surgeon where the number of new cases closely matches surgical capacity. For this to occur, the number of clinic days should be in the proper ratio to OR days. Therefore, non-practice time is added into the calendar pattern so that the resulting OR-to-Clinic ratio of the surgeon calendar is adequate. The placement of this time is based on the following criteria:

1) External requirements, such as, meetings/lab time on specific days
2) Surgeon clinic/OR flow
3) General practice clinic/OR flow.

Table 2 shows a calendar pattern of a surgeon with 20% non-practice time. The allocation of non-practice days into the calendar of surgeon 4 defines a 5:3 OR-to-Clinic ratio which is appropriate for surgeon 4 based on historical practice data.

Assignment of Clinical Resources: Aggregate Calendar Pattern

The aggregate calendar pattern is the combination of all of the individual calendar patterns together. When we combine the eight individual calendar patterns, the resulting aggregate calendar pattern should be appropriate for the whole practice. This means that the OR-to-Clinic ratio is appropriate for each surgeon and also for each day of the two-week pattern. For this eight-surgeon practice the aggregate calendar with non-practice time is shown in Table 3.

</tbody>
</table>
Of the 14 non-practice (A) days assigned, 10 displace clinic days and 4 displace OR days. This results in an aggregate calendar that has: 1) an OR-to-Clinic ratio of 6:5 (36 OR and 30 Clinic days); 2) an even distribution of (A) days - one surgeon on (A) time on seven of the ten days; 3) a well-balanced daily OR-to-Clinic ratio.

Assignment of Clinical Resources: Aggregate Calendar Pattern with Discretionary Time

The calendar in Table 3 would repeat every two weeks if no other non-practice time were added. However, in reality there is additional discretionary time (D) that is available to all surgeons. This (D) time is made up primarily of trip time and paid time off. In this practice of eight surgeons there are approximately 500 days per year of (D) time – an average of about 10 days per week. This discretionary time, especially if the OR-to-Clinic ratio is changed significantly, can have a major impact on the surgeon and/or aggregate calendar. One of the policies in place to govern (D) time ensures a minimum of 4 surgeons assigned to either OR or Clinic each day. This is to ensure a minimum level of access for both Clinic and OR.

</tbody>
</table>

For the two-week period illustrated in Table 4, the addition of 19 discretionary days has a disruptive effect. As compared to Table 3: 1) Surgeon 1 has a ratio less than 1; 2) Surgeon 2 no longer has OR time; 3) the overall ratio has dropped below 1 (23:24); 4) three days (M, Th, and F) have an imbalance of OR and Clinic. These disruptions can have some of the following consequences:

- **Patient access** – too few clinic/OR days will result in poor clinic/OR access.
- **Day-to-day variation** – imbalance of surgeons assigned to clinic and OR (see Th and F) will cause variation in access and case volumes. Thursday will have high surgical volumes and low clinic access; Friday the exact opposite would occur.
- **Capacity utilization** – The overall ratio below 1 could result in any of the following: low utilization of clinics, reduced OR throughput, or OR overtime.

The management team recognizes that there is a need to monitor and adjust the practice calendar in order to minimize the impact of calendar disruptions. The next section discusses the process to strategically adjust the calendar to maintain a proper balance between OR and Clinic time.

Aggregate Calendar Planning and Maintenance Process

The management team meets each month to review and finalize the aggregate calendar. At the time of the meeting the calendar is finalized (patients can be scheduled) twelve weeks into the future. At the meeting, the calendar for weeks 13-16 is reviewed and finalized. Major changes can be made to the 13-16 week calendar and minor changes for weeks 1-12. An example of a major change is to switch a surgeon from Clinic to OR. Minor adjustments include additional resources assigned to a surgeon. This process is illustrated in Figure 2.
Figure 2. Calendar finalization process

At the management team meeting the aggregate calendar with discretionary days is reviewed along with the following practice data:

1) OR access - number of days to the next available day a case can be listed by surgeon and division
2) OR cases listed - total number of surgical cases listed in the 1-12 week period by surgeon and by division
3) OR-to-Clinic ratio per day
4) Number of surgeons assigned to clinic each day
5) Number of surgeons assigned to OR each day.

This data provides insight into the current state of the practice. Table 5 has an example of the data that would be used at this point in the process.

Table 5. Assignment allocation and practice data for surgeon 2 (13-16 week period).

<table>
<thead>
<tr>
<th>Clinic Assignment</th>
<th>OR Assignment</th>
<th>OR-to-Clinic Ratio</th>
<th>Cases Listed</th>
<th>Next Available OR</th>
</tr>
</thead>
<tbody>
<tr>
<td>8 days</td>
<td>6 days</td>
<td>0.75</td>
<td>25</td>
<td>14 days</td>
</tr>
</tbody>
</table>

In Table 5, the cases listed and next available OR indicate that the OR schedule for surgeon 2 is currently busy with 25 cases listed and a 14 day wait for the next available OR. In addition, the OR-to-Clinic ratio is less than 1 for weeks 13-16 which is likely to further increase the queue for next available OR. This data suggests that major changes should be made to the schedule for surgeon 2; for example, a switch of one clinic to OR would increase OR capacity and bring the OR-to-Clinic ratio to 1. This analysis is done for each surgeon to identify opportunities.

The total number of surgeons assigned to clinic and OR on each day is also reviewed. As shown in Table 4, there can be imbalances in the number of surgeons assigned to clinic and OR on given days. In these instances, major changes are considered. The team looks for changes that can both positively impact the daily balance and improve the surgeon calendar(s). For example, in Table 4 for Surgeon 6 a major change from clinic to OR can be made on the second Friday. This change will balance the number of surgeons assigned to clinic and OR on that day. Also, it will change the surgeon 6 OR-to-Clinic ratio to be greater than 1. Any change to any calendar is allowed using this process as long as non-practice (A) time, approved discretionary (D) time, and more importantly, patient care are not impacted.

Performance of Calendars

This calendar management process has made a positive impact on the overall practice: OR capacity has been added with limited impact to clinic access (Figure 3). Anecdotally, we have seen reduced variation in the number of cases per day and per week, and the hospital census has become less variable. Table 6 shows the number of OR and Clinic days for the practice. The left columns reflect the calendar data before the above-described process was completed. For the same time period, the right columns reflect calendar data post-management process. Over this 9-month period, 24 additional days of OR capacity were added.
One of the counter-measures to the additional OR capacity is clinic access. The “third next available” metric is used to track the number of days from a given day to the third open clinic consult slot on the aggregate calendar. Figure 3 shows this metric for the same time period as Table 6. The average for this metric was 2 days which is considered acceptable clinic consult access.

In the process, there are a number of factors that are not considered that could yield more prospective and precise schedule changes. Patient arrival data, including variation of demand, is an important input to identify bottlenecks and periods of high variation. The performance of the schedule has many downstream impacts, for example, hospital census and staffing levels. The manual management process as described above can be automated to incorporate this additional data and metrics. The next section of this paper describes this more automated approach using simulation.

Data-Driven Analysis of Calendars

A model is used to evaluate various metrics into the decision making process of the calendar. The simple patient flow in Figure 1 is expanded to include metrics and downstream impact, for example, patient arrival and census. To this end, historical billing data of clinic appointments and surgeries performed by the practice were used to model patient flow, see Figure 4.
Four years of clinic appointment and surgical billing data were used to determine the surgical yield of the practice. The surgical and clinical data was linked by patient, then it was assumed that a clinic appointment within two weeks of the surgery date was the one which yielded surgery, more details can be found in 10. The estimated surgical yield of the practice is 68%. The proportion of inpatients, 70%, was estimated with billing data of surgeries performed in 2015. Patient arrivals were modeled with historical billing data on high-yield (HY) clinic appointments of 2015 since nearly 80% of patients of this practice are residents of other countries or other states of the US10. HY visits comprise clinic consultations of new patients (60 minutes visits) and comprehensive consultations (45 to 50 minutes visits) of established patients; these visits capture patients work-up/itineraries since early/mid week appointments are preferred to avoid weekend stays before surgery. Patients requiring short clinic visits (15 minutes) are not considered in the model In what follows, we provide more details of the parameters used in the simulation.

- **Patient demand (random)** – Daily patient arrivals were modeled as homogeneous Poisson processes11 with intensity parameters estimated from (HY) visits performed by the practice per day. The estimated patient arrival rates for the practice are shown in Table 7. The arrival rate per day shows that high-request days are Tuesday, Wednesday, and Thursday. The arrival rate of Fridays are low to accommodate travel patterns of national/international patients.

</tr>
</tbody>
</table>

- **Clinical capacity (deterministic)** – Clinical capacity of a surgeon is defined as the historical maximum number of HY visits seen per day; the parameters are listed in Table 8. The clinical capacity of the calendar depends on the combination of surgeons assigned to Clinic. For example, the calendar in Table 4 has a clinic capacity of 19 and 13 consultations on Thursdays which are high patient arrival days.

</tbody>
</table>

- **OR capacity (random)** – Historical data on surgeries performed in 2015 was used to estimate the number of cases that a surgeon can perform on an OR day. As illustrated in Figure 5, there exists a difference among surgeons, which implies that the surgical capacity on a given day depends on the combination of surgeons assigned to the OR.
• **Census (random)** - The length of hospital stay (LOS) of an individual post-surgery was estimated with admission/discharge data of 2014 and 2015. The staffing level for postoperative care for this practice is generally constant, therefore, staffing levels effects were ignored. The average length of stay is 5.04 days; the discrete LOS probability distribution is shown in Figure 6.

The simulation models the interaction between clinic and OR calendar days considering patient arrivals. For each calendar day the number of patients requesting a clinic visit is generated with its corresponding weekday-arrival rate parameter, and OR capacity is sampled from the distributions of the surgeons assigned in OR. It is assumed that patients prefer to have their clinic appointment close to their arrival date, then the following metrics are estimated: 1) access to clinic - the number of days patients need to wait for a clinic consultation; 2) patient seen – number of patient seen in clinic; 3) new surgical cases – surgical yield of each patient seen in clinic is 68%; 4) under/over-utilization – unfilled or fully utilized daily clinic capacity. The OR capacity and the number of patient seen in clinic are used to estimate: 5) access to OR - number of days a new surgical case needs to wait to access OR; 6) number of surgeries performed; 7) census – admission rate is 70% and length of stay is sampled from the LOS distribution.
Results

The simulation model was used to evaluate the performance of the aggregate calendar for the period of October 2015, November 2015, December 2015, and January 2016. The simulation was conducted after the placement of discretionary (D) days and changes to OR-to-Clinic ratio were made. Figure 9 shows the number of patients seen in clinic and their access to clinic. The left figure in Figure 9 shows the simulated patient seen in clinic, the dotted red line is the clinical capacity of the calendar and the percentile lines corresponds to the number of patient seen in clinic with probability 0.50, 0.75, and 0.90. It can be observed that the current clinical capacity is conservative resulting in unused appointments on several days. Most of the days with this clinic time waste have 3 to 4 surgeons assigned in clinic. The figure on the right shows the average time to access clinic (blue line) and worst-case time observed in the simulation (red line); the results show that third available clinic access of the calendar is at most three days.

Figure 9. Left figure: Simulated patient seen in clinic. Right figure: access to clinic.

The simulation results suggest that a clinical capacity level equal to the 75-percentile of patients seen in clinic could be an adequate level for the practice without compromising clinical access. To validate this, we compared the suggested clinical capacity level (75-percentile of Figure 9) with the historical number of clinic consultations of the period analyzed. Figure 10 shows that the suggested clinic capacity is an appropriate level for most of the days of the period. In December, the simulation model suggests a conservative clinical capacity level, this might be caused by demand seasonality. More historical data is needed to incorporate demand trends and improve the model.

Figure 10. Comparison of suggested clinical capacity and current capacity. Purple line is the actual number of patient seen.

Figure 11 shows the number of surgical cases that can be performed and the number of patients in post-operative care per calendar day. The OR capacity experiences periods of high variation, for example, January has sudden variations from week to week caused by the discretionary time allocated in that month. The variations in OR
capacity have an impact in the census, for example, the number of patients in post-operative care decreases during the last week of December, and it has a sudden increase in January. Census projections could help planning the allocation of post-operative staff for different risk-levels, for example, the orange line could be used for worst-case scenario planning.

![Figure 11](image1.png)

**Figure 11.** Left figure: Estimated number of OR cases performed. Right figure: Estimated census.

The demand for surgery is modeled with the projected number of patients seen in clinic multiplied with the probability 0.68 that a patient will require surgical treatment. Figure 12 shows the estimated number of days for OR access. The average time during the months of October and November is below two weeks. Discretionary days distributed in December have a negative impact on access to surgery, for example, patients seen after January 15 are likely to not be able to access an OR in January. Therefore, major changes are needed in January to increase the surgical capacity of the practice, in particular, within the first two weeks of the month.

![Figure 12](image2.png)

**Figure 12.** Access to OR. Blue line is the average scenario, and red dotted line is the worst case.

**Discussion and conclusions**

Balancing OR and Clinic days in the calendar has made a positive impact on the overall practice. Strategic changes were made to increase the operating room capacity of the practice with limited impact on clinic access. A simulation-based tool was implemented to address some areas of the planning process where improvements could be made. Calendar inefficiencies which may be difficult to identify in a manual process are highlighted by the simulation tool since useful performance metrics such as access to clinic, access to surgery, OR and clinical capacity, and census could be estimated. Most importantly, the simulation tool would help illustrate to the management team the impacts of any changes to the calendar and performed what if scenarios analysis before calendar finalization.

Further improvements are needed to improve the predictive measures of the simulation. The access to OR analysis was done only considering patients accessing OR through clinic, data on transferred patients to the practice will be incorporated to obtain a better model of patient flow. The simulation model currently handles demand seasonality by...
scaling the arrival rates, more HY visit data is needed for a statistical model of seasonality of patent arrival. Finally, an optimization model will be incorporated to determine the best possible allocation of resources.

Abstract

The objective of the study is to assess the predictive performance of three different techniques as classifiers for extra-intestinal manifestations in 152 patients with Crohn’s disease. Naïve Bayes, Bayesian Additive Regression Trees and Bayesian Networks implemented using a Greedy Thick Thinning algorithm for learning dependencies among variables and EM algorithm for learning conditional probabilities associated to each variable are taken into account. Three sets of variables were considered: (i) disease characteristics: presentation, behavior and location (ii) risk factors: age, gender, smoke and familiarity and (iii) genetic polymorphisms of the NOD2, CD14, TNFA, IL12B, and IL1RN genes, whose involvement in Crohn’s disease is known or suspected. Extra-intestinal manifestations occurred in 75 patients. Bayesian Networks achieved accuracy of 82% when considering only clinical factors and 89% when considering also genetic information, outperforming the other techniques. CD14 has a small predicting capability. Adding TNFA, IL12B to the 3020insC NOD2 variant improved the accuracy.

Keywords: Clinical Decision Support, Clinical research informatics, Data mining and statistical data analysis.

Introduction

The extensive clinical heterogeneity of Inflammatory Bowel Disease (IBD), and in particular of Crohn’s disease (CD), has stimulated several efforts to classify patients according to recognized criteria, from the international meetings in Rome (1991) and Vienna (1998) to the recent revision in Montreal [1]. The presence of extra-intestinal manifestation (EIM), among others, has important consequences for the clinical management of CD patients and relevant effects on the overall burden of the disease, the quality of life and the allocation of health resources [2]. Attempts have been made to weight the risk of EIM according to the patients’ conditions both at onset and during disease progression, and among the potential risk factors for onset of EIM the role of several genetic predisposing/modifier factors have been recently reviewed [3], even if their clinical usefulness is at present unclear [4].

This increase of information, usually in conjunction with the limited size of the analyzed samples, is posing several threats to the statistical procedures used for EIM risk stratification. Classical and most used tools, such as logistic
models, are known to have limits in such situations. In addition, the effect of some risk factors on the risk of EIM is known to be non-linear and to interact with other covariates [5, 6].

In a previous paper from Giachino et al. [7], six common statistical models (logistic regression model, generalized additive models, linear and quadratic discriminant analysis, artificial neural networks (ANN) and projection pursuit regression (PPR) were implemented to predict EIM using genetic data in addition of clinical factors, showing the impact that genetics, when appropriately modeled, can have in predicting EIM.

The aim of this paper is to further develop on that pathway, approaching the problem of “predicting” EIM by implementing three different Bayesian classifiers and by assessing its predictive capability in comparison with these, previous and current, results.

Several approaches have been proposed in the Bayesian framework to deal with classification (or prediction) in a clinical setting. Among them, of a heuristically increasing complexity, major groups include naïve Bayes, Bayesian Additive Regression Trees (BART) and Bayesian networks.

Naïve Bayes (NB) classifier applies Bayes’ theorem by assuming that the features are independent given class, regardless of any possible correlation between them. Studied intensively from 1950s, it has been widely adopted in automatic medical diagnosis, with convincing performances, often outperforming other sophisticated techniques, despite its sometime unrealistic independence assumption [8].

Bayesian Additive Regression Trees (BART), having been developed at the beginning for regression problems, is a nonparametric statistical approach making use of a sum-of-trees model and regularization prior on the parameters in order to approximate an unknown function. It has been extended by Chipman et al. [9] to the probit model setup to handle binary classification tasks.

Bayesian Networks (BN) have been introduced in the 1980s as a probabilistic expert system for representing and reasoning models of problems involving uncertainty. Since the beginning of the 1990s, they have been used for developing medical applications [10, 11]. Their success in this field is due to the fact they possess the quality of being both a statistical and an Artificial Intelligent knowledge-representation tool. Furthermore, they allow for structuring domain knowledge by investigating causal relationships among domain variables [12]. In many cases, Bayesian Networks have been proven to outperform other statistical methodology in classification tasks [13].

**Materials and Methods**

The present dataset derives from the larger series of CD and Ulcerative Colitis patients enrolled in our ongoing observational study of IBD genetics in collaboration with three gastroenterology Units in Torino, Italy. An association analysis of the three common NOD2 variants has been reported. Genomic DNA was extracted using a commercial kit (Promega). The nomenclature of the analysed polymorphisms is reported in Table 1, together with references to typing technique and relevant literature. Of the two polymorphisms in the 5' region of the TNFA gene we here consider only the genotype at -308, since all analysed samples were homozygous for the common G allele at the -238 SNP.

**Patients**

We decided to use for this work the same data set as in the previous analysis [7] in order to allow a direct comparison of the various statistical approaches. Detailed clinical and familiar information were acquired from each patient and encoded according to the Vienna classification that was in use at the time of enrolment. Extra-intestinal manifestations were defined as the occurrence of rheumatologic, dermatological, ocular, liver and biliary manifestations and amyloidosis. Patients form a retrospective cohort belonging to the Italian Population. They gave a written consent to the study, which was performed under permission of the Hospital Ethical Committee.

**Naïve Bayes**

A Naïve-Bayes classifier [14] is a simple BN that has the outcome variable as the parent node of all other nodes and no other connections between variables.

Over the BN’s they are easy to construct, since the structure is given a priori and thus no structure learning procedure is needed. They require the assumption that all the features are independent of each other. Despite this strong assumption, Naive-Bayes have proven to outperform many classifiers especially where the features are not strongly correlated [15].

The naïve classifier combines a probability model with a decision rule: it computes the conditional a posteriori probabilities of a categorical class variable given independent predictor variables using the Bayes’ theorem. The metric predictors are supposed to be distributed as a Gaussian. This technique is the simplest class of Bayesian Networks where all of the features are class-conditionally independent. Its simplicity makes it easy to use and it allows to get a good result especially in case of small databases [8]. Moreover, naïve classifiers can be extremely fast in comparison to more sophisticated methods of data mining.

Naïve Bayes classifier’s implementation during this studio takes advantage of the “e1071” R package [16].

**Bayesian Additive Regression Trees**

A Bayesian Additive Regression Trees is a nonparametric Bayesian approach to estimation which uses dimensionally adaptive random basis elements, the regression trees, to approximate an unknown function \( f(x) = E(Y|x) \), by imposing accurately the regularization prior. By weakening the single effects BART ends up with a sum of trees each of which explains a small and different portion of the function \( f \) [9]. Obviously, respect to single trees, models composed of sums of trees have a greater ability to describe into details \( f \), capturing interaction and non-linearity. Hence the information regarding \( f \) is partitioned into different trees, each contributing to the overall fit.

This technique was primarily designed to predict quantitative (continuous) outcomes from observations via regression, but an algorithm that extends BART for binary classification, written in the statistical R package “BayesTree”, is provided online by the original authors of BART [9].
In general, as anticipated, BART model consists of two parts: a sum-of-trees model and a regularization prior of the model’s parameters that keeps the individual tree effects small. Mathematically BART probit extension model for binary classification (coded with outcomes “0” and “1”) can be expressed as:

\[ P[Y = 1|X] = \phi[T_1^M(X) + T_2^M(X) + \cdots + T_m^M(X)] \]

where \( \phi[\cdot] \) denotes the cumulative density function of the standard distribution, \( T \) denotes a binary tree made of a set of node decision rules and a set of terminal nodes, \( M \) a set of parameter values associated with each of the terminal nodes of \( T \). The number of trees, \( m \), is fixed to 200 by choice as a good trade-off: the more this number increases the more the model is flexible, showing excellent prediction capabilities slowing down the computational time.

Through a Bayesian backfitting MCMC algorithm [17] that iteratively constructs and fits successive residuals, thanks to the data augmentation approach of Albert and Chib (1993) [18], the posterior information is extracted. MCMC chooses between different generated trees the one providing the best sum-of-trees model according to a posterior probability. This approach, because of the complex computations, is usually time consuming. However, BART has several appealing features such as the additive characteristic able to catch the variability of the function and the capability to conduct automatic variable selection.

BART approach releases the strong hypothesis of statistical independence of attributes making this technique more akin to real data.

**Bayesian Networks**

A Bayesian Network is a graphical representation of the joint probability distributions over a set of random variables. It consists of a series of nodes representing variables connected by arrows forming a graph that has no cycles. The arcs specify the independence assumptions that must hold between the random variables.

In general, they may be many arcs going into and out of each node, creating a complex network. The most important restriction is that the arcs must not create cycles within the network; the resulting network is known as directed acyclic graph (DAG) [19]. Each node of the network is associated with a set of probability tables. For those nodes without ingoing arcs, the probability distribution is a prior distribution which requires supplying a set of initial values. Both the structure and the numerical parameters of a BN can be learned entirely from data [20, 21].

There are a great number of algorithms for learning the structure and the parameters of Bayesian networks from data. Many of them are based on a scoring function and a search procedure. The algorithms based on a scoring function try to find a graph that best represents the data, according to a specific criterion. They use a scoring function in combination with a search method to measure the goodness of each explored structure from the space of feasible solutions. During the exploring process, the scoring function is applied to evaluate the fitness of each candidate structure to the data.

In this analysis, a variant of this scoring approach is the Greedy Thick Thinning algorithm [22], which optimizes an existing structure by modifying the structure and scoring the result, was performed. By starting from a fully connected DAG and subsequently removing arcs between nodes based on conditional independences tests [23], the Greedy Thick Thinning algorithm is able to isolate the best scoring network. One of the most usual scoring function is the Bayesian metric [24], which is a measure of how likely it is to observe the data given the network structure, i.e. the best network in terms of the Bayesian metric is that one with the highest probability based on the given data [24].

Given the structure of the network, conditional probability learning is done. Since conditional probabilities to be learned depend not just on the parent variables’ values but also on the other linked variable (local structure), usually the assumption each variable is discrete is made. In this way, each local distribution is a collection of multinomial distributions. Given this class of local distributions, probabilities can be efficiently computed when there are no missing data in the sample and assuming local parameter independence, i.e. the probability of each state is independent of the probability of every other state. The learning method performed in this analysis was Expectation-Maximization (EM) algorithm [25].

The EM algorithm performs a number of iterations. For each iteration, the logarithm of the probability of the case data given the current joint probability distribution is computed and the EM-algorithm attempts to maximize this quantity. The starting point of the EM algorithm is the conditional probability tables specified prior to calling the algorithm. As a priori distribution, the uniform distribution was assumed for each variable. The EM algorithm
terminates when the relative difference between the log-likelihood for two successive iterations is sufficiently small (less than $10^{-4}$).

To assess model performance, error rate and predictive value of the Bayesian Network were estimated using a 10-fold cross validation procedure.

Bayesian Networks implementation was carried out using GeNIe 2.0 [26].

**Results**

Basic characteristics of the sample, stratified by occurrence of EIM, are presented in Table 2. A more detailed description of the dataset is given in Giachino’s work [27]. The clinical and genetic characteristics were divided into three groups: (1) characteristics of the disease: age at onset, location, disease behavior and presentation of the disease; (2) known risk factors: sex, smoking behavior and familiarity of the disease; (3) genetic polymorphisms of the NOD2, CD14, IL12B, TNF, IL1RN genes.

**Table 2.** Data description. Median, I, III quartile, number, percentages as appropriate. N indicates the number of cases with a valid information for the given covariate.

Due to the high number of patients with missing values, two different datasets are considered: the first one (1) in which TNF and IL1RN genes were excluded and a second one (2) containing only patients for whom data on TNF and IL were available (Figure 1).

The Bayesian Networks were depicted in Figure 1. Arrows between nodes denoted probability dependencies among variables (bolder arrows pointed out stronger influences among variables).

![Figure 1. Bayesian Network for characterizing EIM: BN1 (left) and BN2 with IL and TNF genes (right).](image_url)

Sensitivity to finding for BN1 is shown in Table 3. As can be seen from the low value of mutual information and variance of beliefs and from the graph, the role of CD14, is negligible for predicting EIM.

Discussion

The aim of our study was to compare the performance of three Bayesian classifiers in predicting EIM. Among Bayesian classifiers, in this work we focused on NBs, BNs and BARTs, which are the most popular ones. NBs are often regarded as a benchmark and generally well performing models in spite of their simplicity. On the other hand, BNs can be seen as a more general extension of NB, since they can capture also the interaction between features. Finally, BART represents a full Bayesian classifier.
Our analyses showed that BNs outperformed NB and BART. All classifiers show enhancements when introducing the knowledge about IL and TNF genes, paying the price of a small sensitivity. This comparison is useful to understand the important role of this factor in classification tasks. Taking into account the simplicity and the unrealistic assumption of independence at the basis of NB the results obtained through this classifier are quite comparable to those of BART technique that is more complex and computationally heavier. Typically, the performance of Naïve-Bayes can be further improved by carrying out features selection or by relaxing the independence assumption. From a clinical view a potential explanation could be due to the fact the information about genes is very specific. The involvement in Chron Disease of the genetic polymorphism analyzed is not proved but only suspected. Since this disease has a multifactorial origin, the presence of the polymorphism is not necessarily linked to the presence of the extra-intestinal manifestation but the absence can help in excluding it.

This also specifically means that when the information about genes is known the positive predictive values are higher, since better specificity lead to less false positives.

Combining naïve Bayes with features selection is known as selective naïve Bayes [29]. The search strategies for features selection can be carried out following two different approaches: (i) the filter approach and (ii) the wrapper approach [30]. In the filter approach the search strategy is aimed at maximizing the accuracy of the classifier looking only at the discrimination power of the single variables. This is done considering the mutual information function, which is a function independent of the classifier, i.e. the variables already added to the classifier.

Relaxing the independence assumption is basically performed by constructing a tree augmented Naïve-Bayes (TAN), i.e. first learning a structure tree over the set of variables and then adding a link from the response variable to each node, similar to a Naïve-Bayes structure. However, as discussed in [31], NBs often performs well even when the assumption is violated [31].

Finally, NBs rely also on the assumption that continuous variables are Gaussian. The Gaussian assumption means that the conditional probability of each feature given the class is normal with class conditional mean and variance and then it uses maximum likelihood approach to estimate parameters. Since in our data all variables were categorical, the Gaussian assumption was indeed not required.

The present analysis showed that Bayesian Networks were able to provide a further improvement with respect to other statistical model in terms of predictive accuracy. In addition to these features, the graphical nature of BNs allows to display the links between variable. This can facilitate discussion of the model from different backgrounds point of view (clinicians and genetists, for example) and can encourage interdisciplinary. Another important feature of BNs is the ability to learn about the structure and parameters on the basis of observed data. Knowledge of the structure reveals the dependencies of variables and can suggest a direction of causation. However, when using learning algorithm, causal interpretation of dependencies can be a matter of concern and it is more appropriate referring to them as probabilistic relationships.

The assessment of the optimal BN structure is based on the highest probability score for possible candidate structures, given the data provided and eventually penalized for the level of complexity. Different score metrics can be used at this purpose, varying from entropy methods to genetic algorithms. In our analysis we considered a Bayesian metric. The choice of the Bayesian metric as scoring function may lead to have less prediction error compared with BNs suggested by other scoring metrics. However, on the other hand, it may suggest a model that is highly complex and more difficult to interpret with a large number of variables and a large number of links.

A sufficient number of observations is needed to enable a robust estimation of conditional probabilities, even if it has been shown that BNs can yield good prediction accuracy using learning algorithms, even if sample size is small.

As expected for previous studies, our analysis confirms the negligible role of CD14 and that adding the INF-308 and IL12B genotypes information improved the predictive performance of the model. Whereas, adding NOD2, only the variant 3020insC seemed to be associated to predictive accuracy of EIM.

The small sample size and the absence of an independent sample to perform an external validation represent the major limitations of this work, even if the study’s conclusions are strengthened internal validation performed with cross-validation procedure, in order to reduce overfitting bias.

Among non-Bayesian classifiers, Projection Pursuit Regression, Artificial Neural Network and Quadratic Discriminant Analysis outperform in AUC the other models. However, BNs resulted in a comparable accuracy with them. Furthermore, BNs has the advantage to provide an interpretable graphical model, which can be easily discussed and accordingly modified on the basis of medical knowledge of the problem.
In this work we did not focus on the impact of the prior distributions over the posterior probabilities. Usually, the Naïve Bayes approach assumes equi-probable classes as a prior or it uses an estimate for the class probability given by the number of samples in the class over the total number of samples. In absence of prior information from other independent studies, we chose the former strategy in order to use data only once, i.e. just in the training/testing step and not also for specifying the a-priori probability over the classes. Of course as the sample size tend to be large, the prior is forgotten and the data play the most important role is taken by the data.

Also the two BNs were learned in a non-Bayesian way using the K2 greedy search algorithm, which has been shown to outperform other algorithms (Comparison of the Bayesian Network Structure Learning Algorithms).

Regarding BART, [32] proposed a method for incorporating informed prior information about the predictors into the BART model by modifying the prior on the splitting rules as well as the corresponding calculations in the Metropolis-Hastings step. In particular, covariates believed to influence the response can be proposed a priori more often as candidates for splitting rules. Also for this classifier, we chose to use uninformative prior, considering to work in a total ignorance situation.

The presence of small datasets is a common situation in medical applications. BN has some interesting implications for clinical practice where the dataset is usually very small, affecting statistical analysis. BN, even if temporal knowledge is not considered explicitly, can be useful to make a prediction about what will happen in future. In fact the clinical available knowledges about the patients before the treatments is started influence the treatments actions and hence the final outcome. The prognostic Bayesian networks importance in health-care is a well-documented topic and the obtained results in terms of accuracy demonstrates their possible employment is automatic medical prediction.

**Conclusion**

Our study shows that BNs are a feasible and accurate tool for predicting EIM in CD patients. IL and TFN genes influence the classification and bring to a more reliable classification, increasing the accuracy of about 10%.

Abstract

Although hospital care is carefully documented and that information is electronically available to clinicians, few information systems exist for patients and their families to use while they are in the hospital. Information often appears trapped within the hospital room. In this paper, we present findings from three participatory design sessions that we conducted with former patients, their parents, and clinicians from a large children’s hospital. Participants discussed challenges they faced getting information while in the hospital, and then designed possible technological solutions. Participants designed technologies aimed at extending parents’ access to and involvement in patients’ care. Their designs showed opportunities for health informatics within and beyond the children’s hospital room: to allow parents and children to disseminate information from within, access information from the hospital room remotely, establish pervasive and collaborative communication with the clinical care team, and learn about their child’s care throughout the hospital stay.

Introduction

The hospital presents a challenging information environment for patients and their caregivers. When patients are active participants in information about their care, readmission rates are lower and errors are less likely to occur (1). Close family members, such as parents, can be essential to patients’ information management practices, helping patients get the information they need and participating in medical decision-making (2). However, getting the latest information about a patient’s condition and care usually requires physical presence in the hospital room waiting for often unpredictable clinical encounters.

Hospitals now have sophisticated information systems that document details of patient care. Yet, few hospitals have systems that provide patients or caregivers with electronic access to that valuable information (3). Electronic medical records (EMRs) are created primarily for clinician documentation, organizing care, and billing, and patient portals are optimized for outpatient needs. Although much information flows to and from patients and their caregivers, hospitals are set up for all that information transfer to occur verbally, within a patient’s room. For example, the primary time for communicating with physicians occurs during the daily rounds, which take place in each patient’s room. Otherwise, patients must rely on sporadic in-person clinician encounters or updates from their bedside nurse. From the patients’ and caregivers’ perspective, information often appears trapped within the hospital room.

In this paper, we present findings from three participatory design sessions that we conducted with former patients, their parents, and clinicians from a large children’s hospital. Participants discussed challenges they faced getting information while in the hospital, and then designed possible technological solutions. Participants designed technologies aimed at extending parents’ access to and involvement in patients’ care, providing more connection between parents, children, and clinicians, and helping parents and children learn throughout their hospital stay. We describe participants’ designs, show how these designs represent their desires for improving patient-centered information systems in the hospital, and explain how those desires translate into opportunities for future design and research.

Related work

Our study builds on related work in the HCI and Health Informatics communities in three areas: inpatient information technologies in the hospital room, technology designs for patients and families, and participatory design as a technique for health and health technology research.

Patient information technologies in the hospital room

In recent years, researchers have designed and evaluated technologies to improve hospital patients’ access to information and enhance their ability to participate in decisions about their care (3). These technologies have the potential to improve upon existing whiteboard and call button-based systems, which while simple to operate can often frustrate patients and easily get out of sync (3,4).
One particular area of focus has been digital displays within the hospital room, such as large wall-mounted digital whiteboards, bedside tablet-based interfaces, or mobile phone apps (5). These technologies have predominantly focused on improving patients’ ability to see information about their care. For example, Wilcox et al. developed a patient-centered large display that could be better kept up to date than manual technologies (6). Dykes et al. built a patient-centered bedside communication center (7) that provides information such as a schedule, test results, and discharge education, and have involved patient preferences in the design of their systems (8). Vawdrey et al. provided a tablet to patients that allowed them to track their progress (9), care plan, and clinical team, and Greysen et al. provided similar information in a mobile phone form factor (10). Kendall et al. show the potential for making background work—‘hidden’ tasks often performed by patients and their caregivers—more visible in the inpatient setting (11). These and other studies have shown the promise for patient-centered technology to improve access to information. However, there is still much untapped potential of information technologies to empower patients as participants and information providers.

**Designs for pediatric patients and families**

The pediatric hospital presents unique design challenges for patient-centered information systems. Patients in this setting have diverse developmental abilities and care decisions are made by or at least in collaboration with their parents or guardians. The primary caregiver (often referred to as informal or family caregiver) (12) often takes an active role in information about the child patient’s care, and in these settings ‘patient-centered’ designs often address parents directly. Chen et al. argue that ‘informal’ caregivers, such as parents, are key stakeholders in decisions about health care and therefore essential users of pediatric health information systems (12). Others have called for the importance of looking at patients and families as whole people, especially in the pediatric setting. Kaziunas et al. studied parent-caregivers of child bone marrow transplant recipients, showing the connections between caregivers’ emotion intertwined with information work and arguing for a focus on ‘transforming lives’ rather than ‘transferring information’ (13). Miller et al. showed the potential for information technology to support caregivers and patients in the inpatient setting, and identified design implications for future patient and parent-centered technologies (14).

Other researchers have worked on designing parent-focused information systems, with most of these studies based in the neonatal intensive care unit (NICU). This setting often requires both intensive parent involvement in care decisions and physical separation from their child (15). As a result, proposed technologies for the NICU involve parents as active participants, both generating information and communicating with health providers through the tools. Safran et al.’s *BabyCareLink*, for example, allows parents to access information about their child from home or work (16). Liu et al. designed a prototype system for parents of high-risk infants that integrated social network features (17). Yet outside of this specialized context, little is known about parents’ and children’s desires and values with respect to information systems that involve them as true participants.

**Participatory design for health**

Participatory design (PD), a technique in which the eventual users of a system co-create ideas and requirements, has been widely used in a variety of settings (18). Using PD, researchers and project leaders can understand the values and priorities of often marginalized or under-represented groups, and the resulting systems better reflect their experiences (18). Health informatics researchers have found PD to be especially useful as a technique for involving patients in the design of hospital technologies. PD has been used in traditional healthcare contexts, such as the design of operating theaters (19). It has also been used to surface the values and priorities of minority populations, such as women from the Caribbean diaspora living with chronic conditions (20) and as part of everyday life (21,22).

Participatory design is particularly useful when designing with and for children (23), and especially when designing health systems. Health-focused human-computer interaction researchers have extended PD techniques for the particular needs of children. Miller et al. worked with young adolescents to design fitness-related games, engaging participants in skits and storytelling (24). Lindberg designed with and for children with cancer (25), finding that designing in pairs was useful, and taking a comics-based approach to help focus on the positive. Others have reflected on the challenges for PD in pediatric healthcare settings, especially for inpatients. Robertson and Balaam questioned the ethics of involving current patients, and suggested working with proxies, such as former patients (26). Researchers have also demonstrated the benefits of involving other representatives, such as family members and clinicians. Bonner et al. co-designed with Child Life Specialists (27). Insights from these projects inspired the design of our study.
Methods

We conducted our study at Seattle Children’s Hospital, a pediatric care hospital in a large urban area in the US, serving patients from a multi-state region. The hospital admits over 15,000 inpatients each year, about half of whom are insured privately. Seattle Children’s Hospital is also a teaching hospital.

Design sessions

We held three participatory design sessions with former patients, parents of former patients, and clinicians at Seattle Children’s Hospital. Sessions were held in meeting rooms at the hospital and lasted between 90 and 120 minutes. The authors’ institutional review board and the hospital approved this work. In Session 1, we recruited only parents and children. In Session 2 and Session 3, both parents and clinicians participated. The same people participated in sessions 2 and 3, which were held one week apart. All sessions were video and audio-recorded; we also took photographs throughout.

In Session 1, parents and children identified barriers to information access in the hospital and worked in pairs to design potential solutions to those problems. The session lasted two hours. We first handed out index cards and asked participants to spend five to ten minutes writing down responses to the prompt “What are some big problems in getting information during a hospital stay?” We then invited participants to share their responses with the group, and summarized these responses on an easel. Participants worked in pairs to pick one of the problems discussed and design a solution for it. We invited participants to make use of a variety of craft supplies in their designs. During this design phase, facilitators circulated to both observe participants’ progress and help them if they were stuck. We then reconvened and each pair shared their design with the group.

Sessions 2 and 3 followed a similar protocol to Session 1, but broken into two 90-minute sessions one week apart, and had both parents and clinicians participating. We were cognizant of the power imbalance between clinicians, parents, and children, and we chose this different format to give parents and clinicians more time to get acquainted, build trust, and discuss issues in depth. In Session 2, we first asked participants to respond to the question “What are some big problems for patients and families in getting information during a hospital stay?” We then held an extended discussion about these challenges.

In Session 3, held one week after Session 2, we began by asking participants to share any relevant issues or thoughts that had occurred to them during the previous week. We then led a discussion of these topics and a review of the issues raised the previous week. We then divided participants into two groups: the two parents worked together, and the three clinicians worked together. We asked participants to pick one problem identified in the discussion and design a technological solution. The groups presented their designs to each other. We then assigned participants to new groups. One parent worked with the physician, and the other parent worked with the nurses. During this second design phase, we invited the new groups to ‘remix’ one of their previous designs, or to work on something new.

Analysis

Our research team met after each session to discuss the sessions and identify potential emergent themes. Once all three sessions were complete, we reviewed the transcripts and design artifacts and iteratively identified themes in the design, checking them against the discussions and making sure the themes were present across both participant groups.

Participants

Thirteen people participated in our sessions: eight parents, two children, and three clinicians. We collaborated with the hospital’s Patient Relations office to recruit parents and children, and recruited clinicians through word of mouth. Parent and child participants were eligible to participate if they had spent at least two days in the hospital within the last two years, felt comfortable engaging in a group discussion in English, and were between the ages of 7 and 75.
Clinicians were eligible if they were currently engaged in full-time patient care within the hospital. Two of the clinicians were nurses, and one was a physician.

**Summary of designs**

Participants in our study created 9 designs, each focusing on a problem identified during the brainstorming discussion. In this section, we provide a summary of each design. In the section that follows, we extract and describe themes across the designs. Designs 1 through 4 were created by parents and children in our first session, without clinicians present. Designs 5 through 9 were created by parents and clinicians during our third session; designs 8 and 9 from this session were inspired by designs 5, 6, and 7. We have given each design a descriptive label (with the exception of design 6, which the participants named themselves).

1. **About me (2 parents)**

These parents sought to address the burden of parents and children repeatedly providing the same information to clinicians and the corresponding danger of forgetting something important in the retelling. They designed a patient-centered website where children and parents can provide information in a centralized manner (see figure 2).

2. **Knowing me, knowing you (2 parents)**

These parents also focused on intake, when parents repeatedly answer similar questions. Their design is a tablet-based interface for capturing patient-generated data, including preferences. This design also includes a list of who has entered the hospital room, including name, photo and role.

3. **Parent-clinician watch (2 children)**

These two former patients focused on the challenge their parents had getting questions answered and connecting with specific clinicians. To solve this problem, they designed a smart watch, which would allow parents to quickly place a video call to a clinician. We asked them why they designed something for their parents and not for themselves. They responded that their parents were the ones who really needed to be active on their behalf, and they worried about children being overwhelmed.

4. **Asking and answering (2 parents)**

These parents focused on challenges parents face both gathering and providing information. Their solution, also tablet-based, allows parents and children to record their answers to common questions, and those answers would travel with the patient when he or she switched services within the hospital. The system would also allow parents to ask questions before or after daily rounds, and promote various ‘hidden’ services overlooked by parents unfamiliar with the hospital, such as volunteers who can look after children while the parent takes a break.

5. **Family-centered portal & communicator (3 clinicians)**

The three clinician participants designed a multi-platform system with three main components: an overview of the care team and the hospital, a patient-focused portal with up-to-date information in a way parents can easily understand, and a communication feature so parents can ask questions and have them answered during clinical team meetings.

Figure 2. **About me**, featuring patient-provided video, and medical as well as personal information.
The hospital overview portion gives parents information about amenities, and the name, photo, and role of clinicians who care for their child. The system’s patient-focused portal provides access to the official medical record but in a more interpretable and family-friendly way. This will also include an estimated schedule for the next day, so parents and children can plan ahead. The communication feature seeks to answer the question “what keeps me up at night?” Parents can submit questions 24 hours a day, in the hospital or from home or work, which will be answered by the clinical team and incorporated into the daily rounding activities of the team.

6. OneDocAway (2 parents)

The two parents who participated in the second and third workshops designed two systems. The first of these emerged during a discussion in the second workshop, in which the parents expressed their frustration at feeling ‘trapped’ in the hospital room waiting for clinicians to come by. This system gives an estimated arrival time of the rounding team, showing their progress from patient to patient. They called their solution OneDocAway, based on the transit app OneBusAway, which provides real-time estimates of public transit departure and arrival times.

7. Lab investigator (2 parents)

The parents’ second design addresses challenges understanding lab results and how those results change over time. The system functions as a sort of super-powered patient portal, with results for a particular lab graphed over time, with a high and low marker so parents could know when levels fall outside of normal ranges. Parents could also click on terms for detailed explanations backed by trusted sources vetted by the hospital.

8. Shared calendar (parent & doctor)

In this ‘remixed’ team, one parent and one clinician (a physician) collaborated on a system to improve coordination and collaboration through a parent-focused shared calendar. This system collects events from the medical record, such as medications, labs, rounding times, and specialist visits, and presents a month, week, or day view.

9. Hospital buddy (parent & 2 nurses)

In this second ‘remixed’ team, one parent and two clinicians (both nurses) extended Design 5 to encompass a child and family’s whole experience with the children’s hospital, across inpatient stays and outpatient interactions. The system works on a phone, computer, or hospital-provided tablet. The additions to the system focus on tracking patient/family-clinician communications, with an emphasis on patient and parent-provided information. Parents can also provide information that would persist across shifts and across hospital stays, such as preferences, habits or personality.

Bursting the bubble: opportunities from participants’ designs

Participants’ designs involved parents and children as active participants in the patient’s care—as producers, aggregators, communicators, and learners. They showed how information technology can burst the information bubble of the hospital room, using information and communication technology to move beyond the constraints of the physical room. In doing so, participants designed technologies that allow parents and children to disseminate information to
the care team from within the room, share and receive information while outside the room, stay in persistent contact with their care team, and learn about their condition and care throughout the hospital stay.

Sharing out: parent-initiated dissemination

All participants in our study were adamant in their support of parents and children as participants in their care, and several of the designs encouraged parents and children to take an active role in providing information to clinicians. These designs focused on giving parents and children the ability to pre-emptively share information, so clinicians arrive in the hospital room with a sense of the patient's expertise, priorities, and values.

Many participants spoke about this challenge of sharing out the same information with many clinicians. As one parent put it: “One of the big things…is that that 50 first dates thing that they do, where I think the shortest ER visit we ever had was nine hours. You have just this constant cavalcade of people that come in and ask you the exact same questions.” Clinician participants also recognized this issue; one of the nurses reported it as a very common concern, but said some overlap was inevitable as patients were transferred between specialties. Four of the designs tackle this theme directly, addressing parents’ concerns at being asked the same questions over and over again by allowing them to proactively tell their stories in a way that clinicians would all be able to see. About Me even includes ‘read receipts’ so that parents will know that their messages and updates have been received by specific clinicians. The parents who designed Knowing me, knowing you and Asking and answering both specified that clinicians would ideally view patients’ answers before entering the hospital room, thus arriving informed and ready to ask the important questions. Hospital buddy allows parents to proactively share information such as their child’s personality or routines.

Clinicians in our study were receptive to this kind of approach, although with some caveats. As the doctor in our study put it: “If it’s something critical and important I want to hear it firsthand from the parent. I don’t want to depend on documentation; there’s room for error there. For other things, like, I think family history, social history, other things are important but I’d love if that kind of stuff was better automated and documented and I could say ‘hey I see this’ just ran it real quick by the family and not waste as much time on certain things that potentially are very easy to transfer.”

Designs for ‘sharing out’ also encourage clinicians to regard the patient as a whole person, allowing parents and children to share information that would not be included in standard clinical questions, to share information in a way that makes sense to them but may cut across medical boundaries, and to emphasize certain preferences. For example, About Me includes questions such as “what makes me feel better,” and Knowing Me, Knowing You allows patients to specify preferences, such as an aversion to certain flavors. Those systems also both incorporate parent and child-generated video responses, which add a personal touch by recording information literally in the patient’s own words.

Looking in: accessing the hospital room remotely

Parents, children, and clinicians all designed technologies aimed at extending parents’ access to and involvement in patients’ care, allowing them to keep up to date without trapping them in the patient’s room. Some designs allow parents to virtually peek into the hospital room from afar. In both Knowing me, knowing you and Asking and answering, parents can see a list of who visited the hospital room while they were away. In Family-centered portal & communicator (the clinicians’ design), parents can see a calendar view of visits to the hospital room, as well as a tentative schedule for the upcoming day. The clinicians’ design also incorporates a parent-focused summary of each day, so even remote parents can keep up to date more easily.

Several designs focus on allowing parents to contribute to discussions and care decisions that take place in the hospital room. For example, the Family-centered portal & communicator design allows parents to asynchronously send updates to the clinical care team during clinical rounding. At Seattle Children’s Hospital these rounds are done in or just outside of the hospital room and typically include parents or caregivers who are present at the time of rounding. The Family-centered portal & communicator extends this participation to include parents who cannot be physically present. Clinicians also felt this type of design would help them do their job more effectively. As one nurse put it: “If a parent can’t make rounds then it’s my responsibility as a bedside nurse to relay all that information that happened and I could be prioritizing something different than the parents wanted to hear. And then one provider relaying to another, another nurse relaying something, is difficult.” A technology and ritual in which parents can ‘look in’ to daily rounding even from afar would allow this nurse to focus on other aspects of the patient’s care, secure in the knowledge that the families were well informed and able to provide important information. She would also be able to get a better understanding of how parents were making sense of the information surrounding their child’s care, and the kinds of input they valued.
Other designs focus on giving parents more freedom within the hospital. Several parents spoke about these issues. As one parent put it: “There are many times where I’m like sitting in the hospital room for like hours, like waiting for rounds, although you do kind of know – there is like a four hour time period generally, but that’s a long time, right? And they’re not in your room for very long, so 5-10 minutes, that’s the time that you rush down to grab something to eat because you couldn’t wait any longer.” Another put it more succinctly: “You’re basically held captive in your room unnecessarily.” OneDocAway, which helps estimate the timing of upcoming clinician visits to the hospital room, allows parents to feel confident that they can leave the hospital room and not miss an important conversation with a clinician who stops by the room while they are out.

Connecting across the hospital

Information technology can also improve communication and coordination among parents, children, and clinicians throughout the hospital. Several of the designs enable such pervasive contact throughout the day, allowing parents and clinicians to communicate when they have time, even if both parties cannot meet in the hospital room itself. Parents, children, and clinicians all mentioned the value of transparency and coordinated communication, and several of their designs incorporated ‘anytime’ contact options.

For example, the two child participants in our study designed a smart watch (Parent-clinician watch) for their parents to wear that would support video calls to clinicians, allowing parents to get answers from clinicians without requiring the parents or clinicians to be physically present in the hospital room.

Several participants designed pervasive contact features to ensure their peace of mind at times when clinician encounters were unlikely, especially late at night. Parents in our study seemed keenly aware of the design tension between providing parents with pervasive access to clinicians and overwhelming those clinicians. In the design sessions, parents and clinicians discussed this issue directly:

Parent: “One of the things we started realizing was that you think of something at 11 o’clock at night and you send an email off and then at 11:15 you’re getting an answer back…I learned that I write the email and I save it and I give myself a little reminder that like at eight in the morning or 8:30 I send it to her, because I know she’s going to look at it and I don’t want to disturb her when I shouldn’t be disturbing her.”

Doctor: “That’s very considerate of you to do that.”

Parent: “She’s so amazing.”

The designers of Knowing me, knowing you added an ‘email a clinician’ button. “There’d be a way to email your doctor in the middle of the night (laughs), whether or not they check it. Just sometimes you need to do that, to sleep.”

Other designs focused on another aspect of pervasive contact: proactive awareness. Shared calendar, designed collaboratively by a parent and clinician, allows parents to see a timeline view of their previous and upcoming procedures, labs, and clinician visits, but it also allows parents to add their own schedules to the calendar, which would then be visible by everyone on their clinical team. As the doctor on this team described it, “the parent/caregiver schedule…could automatically go through to the medical team, so the parent just has to say all right, mom’s leaving here, dad’s coming here, then it would automatically be sent over.”

Promoting learning for partnership

Parents can become more effective partners in care as they gain expertise in the medical issues related to their child’s care. Several of the designs reflect this theme by improving parents’ understanding of terminology and helping them interpret test results, so they can better understand and participate in decisions around care.

Parents and clinicians saw the potential of clinical information tools to promote greater understanding. For example, the Lab investigator design allows parents to learn not only whether their child’s values are in the expected range, but lets them drill down into more detailed explanations whenever they wish. As the doctor in our study put it: “It would be nice if the medical records system was built for families and patients to understand as well too. A lot of times we’re saying let me print out the labs for you, explain to you what the labs or the radiology shows but if those labs and the radiology results were written in a way that could be easily understandable and interpretable that’d be nice to have a point of reference for families and patients.”

These tools are especially necessary after an initial diagnosis, when information is flying at parents at high speed while they are trying to cope with the emotional aspects of their child’s condition. As one parent put it: “Education is a very
good point, because we all come in knowing nothing, and we leave with more knowledge than we ever wanted to have but getting from point A to point B can be a long process, a painful process. It would be good to facilitate the learning curve on the early part of it so you’re more participatory. Then you have a certain base level of knowledge that you’re applying to all these results.”

Others specifically noted the potential for technology to help them record clinical information and process it later when they had more time and were better able to cope. “I imagine had there been some sort of video recording or something of some key meetings or things of that sort, where it’s like okay, then I could go back and play what was said by the doctor, that sort of thing, not just relying on my memory, my husband’s memory of what they were saying as I’m sobbing.”

Participants also began to explore the potential for child patients as learners about their own bodies and the teams that care for them. Hospital buddy becomes a totem carried by the child and is used by both the child and parent throughout the hospital experience. The design involves children as participants and learners about their own care, within the inpatient setting and beyond.

**Lessons learned from participatory design with children, parents, and clinicians**

*Parents and clinicians designing together*

When it comes to caring for children, parents and clinicians do not always see eye to eye. In the hospital, parents cede a certain level of control over their child and rely on clinicians’ knowledge and ability. Likewise, clinicians sometimes see parents’ advocacy for their child as a barrier to providing the most effective care. With these issues in mind, we carefully considered the flow and approach of our parent/clinician design sessions. In the end, parents and clinicians worked together quite well. Both sets of participants were accommodating, and frequently expressed their willingness to see things from each others’ perspective. In several exchanges, the two parents in these sessions discussed their worry about overburdening clinicians. Likewise, clinicians frequently expressed their desire for transparency and involving parents actively in decisions about their child’s care.

Much of this considerate attitude is attributable to the participants themselves; both parents and clinicians clearly came to the design sessions ready to collaborate. In addition, we carefully crafted our approach to foster collaboration and a democratic attitude. We began with an icebreaker exercise in which everyone—participants and facilitators alike—created a simple design and shared it with the rest of the group. We did not ask participants to design until the following session, giving them time to build trust and mutual understanding through discussion in their first session together. Only after participants had discussed problems and designed solutions to those problems did we ask parents and clinicians to collaborate. The resulting designs truly were cooperatively designed; parents and clinicians took turns designing and sharing their designs.

Based on our experiences, we are optimistic about the potential for collaborative patient/provider design for the hospital. Through their discussions and designs, parents and clinicians brought out design tensions and learned more about each others’ perspectives, and the designs are all the richer for doing so.

*Sharing video with clinicians*

All the designs created during Session 1 allow parents and/or children to communicate with clinicians via video. In particular, the parents’ designs from this session intend for clinicians to watch the videos before entering the hospital room. As one of the parents who designed *About me* put it, a clinician enters the hospital room “and asks you 25 questions, it gets videotaped and then everyone can watch them before they come in and ask you the same 25 questions!” However, clinical members of our research team quickly pointed out the pragmatic challenges to such an
approach. Clinicians operate in a highly text and graph-driven information workflow with little room to add additional tasks, and the idea of a clinician watching even a brief video before entering each hospital room seems impractical.

What, then, are we to make of parents’ and children’s use of video in their designs? Video-recorded information has definite advantages from a patient’s perspective. Participants felt it would be easier for parents and children to record information by just speaking, which seems like a natural response given that clinicians often ask them to verbally recount medical issues or histories. Low-literacy patients and young children would undoubtedly benefit from a verbal communication tool. Second, allowing patients and their caregivers to share information with clinicians in a naturalistic manner also frees them to express themselves as whole people and communicate across and beyond clinical information categories. Finally, in analyzing the data from our design sessions, we came to understand that parents and children believed because they find video easier to create and consume, that clinicians would also find it easier. These considerations will be crucial to keep in mind in designing interfaces that allow patients to easily express information but also support clinicians’ workflow and need to quickly review text-based information sources.

Limitations and future work

In this study, we worked with parents, children, and clinicians to identify design opportunities for patient-centered information systems in the hospital. However, our study has several limitations. We worked primarily with ‘expert’ parents and children who had extensive experience in the hospital. Despite extensive outreach and recruitment effort, only two children participated in our study. Participants were not demographically representative of the hospital’s patient pool, and Seattle Children’s Hospital is not necessarily representative of all pediatric hospitals. In the future, we hope to verify and extend these findings in other contexts and with different participant groups. Furthermore, participants’ designs significantly extend the ‘status quo’ and challenge existing modes of patient-provider interaction, which may inhibit the successful introduction of such technologies into hospital care. To address this, we plan to design and deploy technology probes based on participants’ designs. Many of the designs are technically feasible, and mainly require canny interaction design and institutional buy-in to be tested in realistic settings.

Conclusion

In this study, we asked participants to answer a simple question: how can technology alleviate big problems patients face in getting information about their care? Through their designs and discussions, participants showed the potential for information technology to allow parents and children to share information to clinicians from within the hospital room; for parents and other loved ones to look in on the hospital room from afar; for parents, children, and clinicians to stay in touch throughout a hospital stay; and for parents and children to learn within the hospital room and beyond. The designs show that patients and their caregivers can be more than recipients of information about their care; they can produce, aggregate, and learn information throughout a hospital stay. The values expressed in these designs will be important to explore in other contexts, such as adult hospitals and chronic condition management as well. While the hospital room will remain the hub for information about a patient’s care, it doesn’t have to be a bubble.

Abstract

A group of informatics experts in simulation, biomedical informatics, patient safety, medical education, and human factors gathered at Corbett, Oregon on April 30 and May 1, 2015. Their objective: to create a consensus statement on best practices for the use of electronic health record (EHR) simulations in education and training, to improve patient safety, and to outline a strategy for future EHR simulation work. A qualitative approach was utilized to analyze data from the conference and generate recommendations in five major categories: (1) Safety, (2) Education and Training, (3) People and Organizations, (4) Usability and Design, and (5) Sociotechnical Aspects.

Introduction

EHR adoption has increased dramatically in the last decade, primarily as a consequence of the Health Information Technology for Clinical and Economic Health (HITECH) Act of 2009. The widespread implementation of EHRs has resulted in both benefits and unintended consequences, with the latter linked to the potential of causing significant adverse outcomes and patient harm, in part due to poor implementation strategies and EHR customization as well as lack of user training.

There has been a growing realization that improving EHR use may reduce some of these issues, and EHR development, implementation and training have been identified as key areas of research to improve healthcare quality and safety. With this aim in mind, simulation activities, particularly high-fidelity, EHR-specific simulation training, afford an attractive potential solution that directly addresses some of these issues due to the fact that they can create realistic, reproducible environments without any chance of patient risk.

In contrast to a majority of simulation-centric research activities in which the EHR was a tool used by participants as they completed the activity, our prior research has utilized the EHR as the focus of the simulation. We have also developed a model for collaborative intelligent case and simulation design to facilitate EHR training. Having worked on an EHR safety simulation project funded by AHRQ for almost three years, our research team was about to embark on a second project, and the timing was right to gain input from experts regarding the way forward. In order to achieve this, a conference was organized.

Methods

A. Goals of the Conference

The main goals of the conference were to 1) develop a consensus statement on best practices for the use of EHR simulation in education and training, as well as utilizing the EHR to improve patient safety, and 2) outline a strategy for future EHR safety simulation work. The objective was to develop a consensus statement utilizing the input of expert representatives who would bring multiple perspectives to bear, thus providing guidance for practice in the specific area of EHR simulation.

A team of Oregon Health & Science University (OHSU) investigators organized the conference, played a supporting role during the two days when events were ongoing, and subsequently analyzed the data. An experienced facilitator (JA) managed the large group discussions. Small group discussions were led by a volunteer expert (VM, JG, JA) with a research team member assisting.

The agenda was developed so that an international group of experts in simulation, informatics, patient safety, medical education, and human factors (representing each of the five perspectives we hoped to capture) could first assess the state of the art in EHR safety simulation and then recommend a path forward. After reviewing what the
OHSU team had learned during the three years of their research project, the group discussed each of the specific thematic questions detailed in the "Conference Activities" section below from multiple perspectives. Discussions occurred in both large as well as small group formats, and conclusions were reached.

B. Pre-Conference Activities: Planning

Six months prior to the conference, potential participants were identified through literature searches, citation analysis, and by the purposive identification of known experts in the field. Categories of representatives included experts in simulation, critical care clinicians, experts in EHR safety, EHR usability experts and representatives of EHR vendors (see Appendix for a list of participants and their affiliations). Geographic and gender diversity was desired as well as representation from different healthcare systems (university-based healthcare systems, community medical centers, and federal institutions) as well as different EHR types (commercial and home-grown clinical information systems). Many of these attendees were able to represent more than one of the stakeholder groups involved in either EHR usability, ICU management, or simulation.

Participants were provided a number of papers, as well as a copy of the grant used to support the conference, as background material so that a certain level of shared knowledge could be assumed. The plan was to maximize on-site time to enable the sharing of expertise and experiences, generate narratives, and develop consensus statements. Attendees were asked to come prepared to discuss the role simulation could play in understanding and optimizing EHR use and design. In addition, participants were asked to provide insight for future directions and research questions to better develop the role for simulation in clinical informatics.

C. Conference Activities: Discussion

After an initial orientation, participants were tasked with answering the question “what have we learned about simulation for improving EHR safety?” Subsequent to an initial large group discussion on findings and the state of the art, participants broke into three groups, each of which addressed the question “how can we best use simulation to improve EHR safety?” Each group subsequently reported back to the large group.

Next, the group engaged in a large group discussion centered around the theme "what is the role of the EHR in collaborative rounding?", followed by small group discussions to answer the question “how can we best use the EHR for communicative activities (rounding, signoffs, consultations)?” After reporting out to the large group, we held an informal evening reception to expound on the most provocative topics of the day.

The second day began with a large group brainstorming session designed to answer the question “how can we ensure scalability of EHR simulation beyond the ICU to multiple locations and for multiple disciplines?” We ended with a prioritization exercise to identify the most important strategies for moving forward.

D. Post-Conference Activities: Analysis

The research team debriefed at the end of each day of the conference and in the days immediately afterwards. As the qualitative analysis progressed, the team met several times in the months after the conference to discuss insights and construct a consensus of expert considerations.

A total of 1,738 minutes of audio were recorded and transcribed into 25 individual transcripts. Five hundred and sixty-two pages of transcripts were qualitatively analyzed utilizing computer assisted qualitative data analysis software (NVivo, QSR International, Melbourne, Australia). Statements were coded by topic and cluster analysis diagrams employing Jaccard’s coefficient similarity metric were generated to ensure consistent coding between members of the research team. Utilizing a grounded theory approach, the research team identified five major themes: (1) Safety, (2) Education and Training, (3) People and Organizations, (4) Usability and Design, and (5) Sociotechnical Aspects.

Results

Theme: Safety

The expert group addressed issues surrounding EHR safety and the lack of effective tools to address this. One prevailing sentiment was that errors were ubiquitous and universal.

"EHR patient safety technology-based errors, they’re pretty much the same kind of errors around the world.”
It was felt the generation and perception of errors had changed substantially since the advent of the EHR, and that simulation was a prime tool to address safety issues. There is also a paucity of strong epidemiologic data on EHR errors and the true frequency of those reported; the dependence of incident reports probably vastly underestimates the frequency and nature of the spectrum of EHR use errors.

Additionally, significant silos exist within hospital systems between personnel undertaking safety, quality and informatics projects. Simulation can serve as a means to help identify errors in EHR system design and use. Specifically, including informatics expertise in EHR simulation activities could potentially help to identify and correct safety issues, especially those related to errors generated from the use of copy-and-paste techniques, voice recognition, and team-based workflows.

Vendors could also utilize EHR simulations to deliver products that enhance patient safety. Participants felt that the development of specific EHR safety-related standards might provide significant impetus for vendors to incorporate more safety-specific features within their products.

“Vendors want standards because somebody else sets them. It doesn’t favor one vendor over another, and the nice thing is, they don’t have to be responsible for it.”

Experts also emphasized the need to look at more than just the design of the EHR and data structure when identifying potential hazards to patient safety. How the EHR is used and by whom are also critical factors.

“...if you’re talking about HIT safety, you can’t approach this as a technical problem alone.”

**Theme: Education and Training**

The conference emphasized the need to utilize simulation for the purposes of research and education. As the healthcare industry has embraced widespread EHR use, training requirements have shifted away from current models of point-and-click usage to the need for scenario and case-based instruction.

It was also felt that the EHR should be used in simulations in a way that replicates real-world clinical scenarios, with attention to reproducing both realistic workflows as well as the ability to replicate the cognitive complexity of clinical decision-making.

“If the EHR is a tool to help delivery of care, you need to be able to practice using that tool with the functionality you expect it to be used within the real clinical setting. And unless you practice using it that way, you’re never going to know.”

Experts discussed ways to effectively use simulation to improve EHR design as well as optimize the use of the EHR in actual practice. They also discussed utilizing simulation to better train different types of clinicians. This resulted in an examination of the EHR functionality needed to achieve learning objectives.

"There’s a whole series of...strategies how to integrate the EHR into simulations depending on the learning objective. That’s training that I think the vendors could be able to supply to their trainers as well that’s not even part of the normal training."

It was felt that simulation-centric EHR training could be used to identify weaknesses of the system and in user practices, to train for common or rare events, and for formative or summative assessment. Simulations could be used to foster lifelong learning, both in individual and team environments.
"The purpose of simulation is to train people to work together with technology in an environment."

The expert group also appreciated the need to conduct simulations in an interprofessional environment, utilizing levels of complexity that would replicate team-based healthcare delivery, medical student and resident training, and also assist in training other members of the clinical team such as medical assistants, scribes, pharmacists, and nurses.

"...you can't really separate the technology from the environment in which you're training and you can't separate the interprofessional team-based education from the technology use."

The group placed emphasis on the post-simulation debriefing process, and on developing incentives for participation in simulation-based training such as continuing medical education (CME) credits.

It was also felt essential that simulation activities involve clinicians from environments that do not possess the ability to conduct simulations. This could be achieved by using a central simulation center that would act as a resource for multiple organizations and clinicians.

**Theme: People and Organizations**

Participants noted that the current EHR design paradigm still does not match the reality of how EHRs are used by healthcare professionals. Care is delivered by interdisciplinary and interprofessional teams of clinicians; however, EHRs are still designed with the individual user in mind.

“The EHR is designed for a single person when really it should be designed for the team.”

In addition, healthcare professionals serving in different roles use the EHR differently, and often visualize data on EHR screens that display information featuring distinctly different designs.

“...it’s important that simulations can really show how important these different views are, how important the trade-offs between safety and efficiency are.”

While the EHR might be useful in team-based clinical care, its limitations also need to be recognized by end users as well as information system designers.

“The EHR can be a part of the team, but we need to realize what it can and what it cannot also do.”

The experts felt that the EHR might play a crucial role in inculcating a culture of systems-based practice.

“...[the EHR] teaches each member of the team how to interact with each other member of the team and how they can work together to better accomplish the goals than they would individually.”

**Theme: Usability and Design**

EHR system usability and interface design were regarded as key factors in facilitating EHR education and training, and were also seen as crucial elements in ensuring patient safety.
Several factors that have been well described in the literature, such as cognitive overload and user distraction, continue to be a source of EHR-related errors, which suggests that despite attempts to improve EHR interface design and usability, EHR features may still contribute to errors. There is a delicate balance between features which add value and those that distract from completing necessary tasks.

“I will argue that we still have tons of medication errors, even though we have all the alerts that come in the system.”

It was expressed that EHRs need to better support team-based communication and decision-making, and facilitate group decision-making during group rounding.

“…there are a set of tasks that the team assembles to do. And the first tasks have been done by the computer, then you wouldn’t need that team to be there. So it’s all the things that they’re doing that they must converse about that are independent of whatever the computer does. It may be the computer gets smarter and their job gets smaller, but the question is how do you support whatever happens in there.”

While EHR safety features such as alerts are intended to facilitate collaborative clinical care, they can sometimes impede team-based work.

“If an alert comes up and you’re trying to do something, an alert comes up and then I got to deal with that, it stops the conversation.”

Experts grappled with how the user interface should be optimally designed to support education, training, and safety, while still affording for variability in individual users’ performance. One source of inconsistency which may negatively impact patient care is the process of entering data into the EHR. The reliability of data stored within the EHR is affected by the disconnect between the perception of the real-time nature of EHR data and the reality of EHR data entry, which is often delayed due to fragmented clinical workflows. Furthermore, the differences in how each provider uses the data also factors into the overall usability of the system. Incorporating an EHR design model that would account for variability in user tendencies (such as differences in information-finding behavior) could also be a useful EHR feature.

“…each different type of provider uses the data differently, they go to different areas, they look for different things, so we need to build the EHRs so it actually works with whatever the workflow design.”

Participants expressed dissatisfaction over the incongruence between the vendors’ values that guide EHR design (“they’re designing it for efficiency”) and the users’ values that govern EHR usage (“for safety”).

There was extensive discussion about the potential role of simulation in helping guide EHR design to enhance usability. Participants described the potential for developing and deploying a common, standard, simulated patient record that could be EHR-agnostic and contribute to training in different clinical and technological environments.

One major area of unrealized potential for the EHR that was discussed was its role in facilitating handoffs. It was felt that EHR interfaces could be better designed to facilitate provider handoffs that occur not only in person but also remotely (via phone). Clinical decision support tools could be developed to help prioritize the data to convey urgency or clinical severity.
“If we had a decision support tool that helped us synthesize the information better, that’s fantastic. That really helps. If we had a decision support tool that then prioritized it [data]... then all of a sudden you’d have an automatically generated handoff, prioritized handoff note, that actually made sense because it used the same rules to generate itself as the decision process...”

A particular EHR feature that could be helpful to facilitate group communication would be to enable collective situational awareness by sharing EHR screens. This could help others understand what information a user is drawing from to make a decision or to ask a question.

“If you got to design the EHR, it’s got to be designed in the understanding it’s part of a team environment and the person operating the keyboard may not be the person who is actually making the decisions and they might not even be seeing the right screen.”

**Theme: Sociotechnical Aspects**

The expert group felt that the use of EHR simulations in health care was best described within the context of a sociotechnical framework as an interaction among technology, organizations, and individuals. EHR technology is facilitating changes in how clinicians work, and changes in clinician training and work patterns are in turn changing how the EHR is used. We examined this in four contexts: interdisciplinary rounding in an inpatient setting, handoffs, working with a consultant, and providing team-based care in an outpatient setting.

As a consequence of the ubiquitous use of the EHR, the roles of team members have changed while engaging in interdisciplinary rounds.

“...once upon a time the role of the resident was to gather the data, and the attending to provide expert knowledge...Now the resident goes to the EHR where the data is already gathered, and they are doing more of a curation role...The attending’s role is becoming first of all a verification role...Is the right data being gathered and then are they applying it correctly.”

Our experts believed simulation can help develop workflows and processes that balance this shift in clinician roles. The interaction among people in a zero-risk simulation environment can potentially help build interpersonal relationships and assist in the development of trust among clinical care team members. It can also foster systems thinking that allow individuals to better interact with other members of the team and work together to better accomplish group goals.

“...Simulation offers the opportunity I think not only to break down the traditional barriers that exist for data but the traditional barriers that exist for roles.”

There is also a potential for simulation to assist in improving EHR design to better support rounding processes. EHRs have fundamentally changed the way clinicians interact with information. Simulation may help examine this paradigm shift and allow researchers to test new ways that data can be represented to clinicians. Simulation may also help clinicians discover hitherto unidentified errors, and improve safety by preventing patient harm. This requires the acquisition of appropriate tools, both technological as well as cognitive, to facilitate the process.

“This model of simulation training can be extended to a more ideal EHR design with the understanding it is part of a team environment...”
Participants also felt a need to use simulation to test and improve EHRs as part of the collaborative process, especially with respect to consultations, the nature and scope of which have also changed as a consequence of widespread EHR use.

“You don’t physically send your patient. You just simply send a message saying ‘Dr. X, I’ve got this patient I’m concerned about, could you take a look at their chart and give me a recommendation.’ … is it actually a very exhaustive process for the specialist to actually identify their role”

The experts also highlighted new trends that are developing in the use of the EHR to support team-based primary care.

“[In primary care] we don’t round on the patients of the day, we round on 5,000 patients all week. We use population health and reporting tools, but the same paradigm of communication is needed. We need to identify the gaps in care, we need to do something about it, and we need to let the person who is going to carry it out and the patient know about it. So that whole communication tools is needed in different views.”

Interprofessional simulation allows team-based activities to be evaluated, thus promoting improvements at both the individual as well as the group level. It was noted that the EHR was a tool that merely supported clinical workflows and processes, as opposed to defining the activities themselves.

“…decision-making is one team process or function…EHR doesn’t support rounds, it supports the processes and functions…”

Discussion

EHRs were primarily developed to improve workflow efficiency and capture billing in an optimal fashion, and while the explosive increase in EHR implementation has seen unprecedented growth in EHR use within the clinical environment for clinical decision-making, this phenomenon has not been accompanied by an equivalent growth in ensuring patient safety.

“…the vendors are not designing their systems for safety. First, they’re designing them for efficiency and billing, also we’ve got to have a huge paradigm shift that they’re not interested in at all because the people that are buying their systems are chief financial officers, not doctors.”

Recommendation: Simulations should be used to design systems and protocols explicitly to improve usability and patient safety.

Participants clearly felt that EHR safety could be promoted by the use of simulations. Simulations are likely to have a significant salutary effect on team-based care, and utilizing the EHR within simulations in a manner that mirrors real-life clinical scenarios allows the reproduction and modeling of cognitive burden and uncertainty in a way that replicates real-life conditions. Simulations can also assist in optimizing EHR design and functionality; however this advanced use of simulation in health care will also require an equivalent paradigm shift in operational culture.

However EHRs do have the potential to significantly improve safety. In order to achieve this goal, participants felt that a cultural paradigm shift in EHR training was also required.
“So the EHR can facilitate a lot of these[safety-related] things through check-listed tools, but you have to have the appropriate culture change and training to go along with it, as well as a needs assessment, to make sure that you’re creating the right tool.”

**Recommendation: Simulations should be central to clinician training and used to improve clinical team communication.**

Currently simulations are used to some extent in clinician training, but their role is marginal; a paradigm shift that brings simulation front and center in the process of clinician training is also warranted. The emphasis in this new model of training needs to be on the delivery of team-based care, with an equivalent stress on team-based, information-driven decision-making.

“...if you could change the paradigm of the simulation so that it is case-based instead of all of us...in a classroom setting. Just turn it around so that we are all part of a team and attacking the same problem, and that’s our [EHR] training.”

**Recommendation: Simulations should be part of a sociotechnical solution involving a broad spectrum of stakeholders and organizations.**

The effectiveness of the EHR within the context of communication was a theme that arose commonly during deliberations by the participants. Simulation offers the potential of improving communication processes through training and ideas for improved design, although the process will require the involvement of people with multiple skill sets.

“We need to break down these silos, and that includes involving people who understand the many factors, quality, and informatics. Most of the training activities focus on the EHR as a tool, but that doesn’t mean you still don’t need people who understand that tool and [the need to] get the information out.”

The interdisciplinary nature of the expert participants in the conference allowed them to examine potential solutions from an equally interdisciplinary perspective.

In order to achieve this goal, participants believed that it would be necessary to reach beyond the leaders of healthcare systems to engage diverse stakeholders including informaticians, quality improvement groups, EHR vendors, standards organizations, and payors.

“...we have multiple major stakeholders here within this group. We have industry, we have informaticians, we have clinical champions, quality, safety, and education leaders...What does each group need to bring to the table for each of these domains so that we make sure we keep it inclusive, so this doesn’t become just purely something in the value for the informatician or the hospital QI specialist or the hospital trainer?”

**Recommendation: Simulations should be part of a comprehensive incentive program to promote patient safety.**

How can we implement this new model of clinician training? The solution might perhaps require us to define a combination of incentives and penalties - incentives to achieve significant milestones in improving patient safety, and penalties when patient harm cannot be sufficiently eradicated.

“Incentives and penalties work together, you get the political will there, get the leadership to do it, and I think you can do it again and create a market. Vendors aren’t going to do this. If they are going to do it, it’s not because it’s the right thing. They are going to do it for an incentive.”
Of course, any incentive program to promote patient safety utilizing simulations would require the commitment of substantial resources, both to build the technical framework and infrastructure and to develop training and evaluation programs to engage end-users. Since lapses in patient safety are typically associated with costs, both with respect to the care subsequently delivered as well as the costs due to medicolegal repercussions, it might benefit both the risk management and medical malpractice community, as well as health insurance providers to bring resources to bear in order to facilitate the use of simulations to promote patient safety.

“So this...suggestion you made about the medical malpractice companies sponsoring this in some way sounds like the most reasonable approach, and maybe a coalition of vendors and the actual health insurance companies because they’re also going to benefit from fewer use of resources, and fewer costs...I just don’t see the EMR vendors doing this unless somebody’s going to step up and pay for it, you know, and I think that those two groups are going to benefit the most.”

Conclusion

The conference brought together authorities from different disciplines with extensive expertise in simulation, biomedical informatics, patient safety, medical education, and human factors. Their deliberations during the two day meeting were extensive and fruitful. Using a grounded theory approach, data analysis revealed five broad themes that could effectively be used to inform the deployment of simulations to improve clinical education, training, and patient safety.

The themes developed in this paper are intended to act as a framework to develop a comprehensive simulation plan, and assist in decision-making that will place simulation within an appropriate context, and assign a role for simulation-related activities within the infrastructure developed and utilized by organizations to educate and train clinicians and other EHR end-users.

More importantly, the themes also help to underscore the importance of using simulations in today's clinical environment, where the old paradigm of how end users engage with the EHR is rapidly changing not only because of advances in technologies and alterations in clinical workflows, but also notably because of the inexorable advent of the data-driven age of healthcare delivery.

“...how we actually engage with the EHR is antiquated...simulations offer an opportunity to test new modalities of engagement with data...”

Abstract

Determining the main topics in consumer health questions is a crucial step in their processing as it allows narrowing the search space to a specific semantic context. In this paper we propose a topic recognition approach based on biomedical and open-domain knowledge bases. In the first step of our method, we recognize named entities in consumer health questions using an unsupervised method that relies on a biomedical knowledge base, UMLS, and an open-domain knowledge base, DBpedia. In the next step, we cast topic recognition as a binary classification problem of deciding whether a named entity is the question topic or not. We evaluated our approach on a dataset from the National Library of Medicine (NLM), introduced in this paper, and another from the Genetic and Rare Disease Information Center (GARD). The combination of knowledge bases outperformed the results obtained by individual knowledge bases by up to 16.5% F1 and achieved state-of-the-art performance. Our results demonstrate that combining open-domain knowledge bases with biomedical knowledge bases can lead to a substantial improvement in understanding user-generated health content.

Introduction

Online resources are increasingly used by consumers to meet their health information needs [1]. According to recent surveys, one of three U.S. adults (35%) looks for information on a medical condition online¹, 30% found online health information helpful for them or someone they know, while only 3% found online information harmful². The same study showed that 15% of Internet users posted questions, comments or information about health-related issues on the web.

The National Library of Medicine (NLM) receives health-related questions from consumers from all over the world. Most consumer health questions received are concerned with disease-related information, such as diagnosis, treatment, and prognosis. At NLM, we have been working towards a system that can automatically answer such questions using available resources. Our previous work focused on intermediate tasks such as question frame extraction [2], question decomposition [3], question type recognition [4], anaphora resolution [2], and spelling correction [5].

Much research in biomedical question answering has focused on answering well-formed clinical questions by professionals [6, 7]. However, consumer health questions differ widely in vocabulary and structure from professional questions. In a recent study, Roberts and Demner-Fushman [8] compared various collections of consumer health questions and professional questions and found that:

- Consumer health questions are closer to open-domain language models while professional questions are closer to medical language models
- Consumer health questions are more focused on medical problems than treatments and tests
- Consumer health questions tend to contain more sub-questions than professional questions.

These characteristics along with high rates of misspellings and ungrammatical sentences pose challenges for automatic question understanding, including tasks such as named entity recognition, and frame extraction. Consumer questions

¹http://www.pewinternet.org/2013/01/15/health-online-2013/
²http://www.pewinternet.org/2011/05/12/social-media-in-context/
about medical problems are often centered on specific diseases, symptoms or treatments, which we refer to as the question topics in this paper. Identifying the topic of a question is a critical step in answering it. Consider the following question:

(1) my question is this: I was born w/a esophagus atresia w/dextrocardia. While the heart hasn’t caused problems, the other has. I get food caught all the time. My question is...is there anything that can fix it cause I can’t eat anything lately without getting it caught. I need help or will starve!.

Note that while two diseases are being mentioned in the question (esophagus atresia and dextrocardia), the topic of the question is only esophagus atresia. While the single disease assumption holds true to a large extent, there are questions with multiple topics, especially when the question is about the relationship between diseases. In the example below, both megalocytic interstitial nephritis and malakoplakia are question topics.

(2) I’d like to learn more about megalocytic interstitial nephritis with malakoplakia.

Question topic recognition can be viewed as an extension of named entity recognition, where the goal is to determine only the entities deemed central to answering the question. In this paper, we propose a novel approach to topic extraction that relies on multi-perspective and knowledge-based recognition of named entities. We use open-domain and biomedical knowledge bases to normalize named entities in consumer health questions. More precisely, we combine disambiguation results from DBpedia[9] and UMLS[10] to provide an initial list of candidate named entities. Starting from this set, we represent the problem of topic recognition as a binary classification task and extend the span of detected topic entities with generic rules. Our experiments show that our method improves the state-of-the-art performance and that the combination of knowledge bases outperforms substantially the individual results, demonstrating that open-domain knowledge bases can benefit information extraction from consumer health text.

Related Work

Duan et al. [11] designed a question analysis approach that tackles the recognition of both the question topic, defined as the main context or constraint of a question (e.g., “Berlin” in “What is the population of Berlin?”) and the question focus, which they introduced as a descriptive feature of the question topic (e.g., “population” in the previous question). Their approach for the identification of question topic and focus is based on MDL (minimum description length) tree cut model. They first represent the question as a chain of base noun phrases, considered as topic terms. Each chain is ordered according to the term specificity in a set of questions and a tree of questions is built from the chains of topic terms. Their cut method then separates the tree into two sets of terms: less specific terms considered as focus and more specific terms considered as topic. While their method allows retrieving multiple topics for one question it requires a rich set of similar questions talking about the same topics, and small sets of questions or dissimilar questions won’t lead to relevant specificity values for the topic terms. While such method could work with open domain questions, it is not adaptable to consumer health questions that tend to be highly heterogeneous in terms of topics, making it difficult to find rich sets of similar questions.

Other methods in open domain used search results to recognize the main entities in user questions. For instance, Carroll et al. [12] proposed a method where questions are first classified as entity triggering questions and then submitted to a search engine. The goal of this process is to find entities associated with the retrieved documents and compare them to the entities mentioned in the question. Candidate entities are then scored according to different factors including the proportion of retrieved documents associated with them or the number of their mentions in the snippets generated from these documents. The candidate entity with the best score is then selected as the main entity (topic) of the question and common features associated with the topic in the retrieved documents are presented to the user. The shortcoming of this method is that it is restricted to questions identified as entity-triggering, which are mostly short open-domain questions. Consumer health questions are more elaborate and often contain several named entities that do not represent the question topic (e.g., disease history or diagnostic tests used to identify the main disease), which makes it difficult to find documents that are relevant to the main topic.
Many studies tackled biomedical question answering [13]. Different approaches have been used for question analysis, ranging from keyword-based search [14] to the extraction of structured frames expressing the relations between entities [15]. Demner-Fushman and Lin[16] proposed an approach to recognize the primary medical problems in clinical questions using UMLS concepts belonging to the Disorder semantic group. This is done by ranking the list of concepts belonging to this category according to their occurrence/position in the analyzed text.

Roberts et al. [3] addressed topic recognition in the scope of the decomposition of consumer health questions. In their approach, candidate named entities were first identified with high recall using a lexicon-based method and then ranked using a support vector machine (SVM) classifier. A series of post-processing rules addressed the term boundaries. The method obtained good results (73.6 and 88.1 F1 score with exact and relaxed match, respectively); however, it did not address multi-topic questions, which represent a quarter of the questions in our dataset.

In general, few approaches tackled specifically the recognition of the main topic in biomedical question analysis. This can be explained by the fact that questions submitted by professionals tend to be concise and tend to have a regular structure which makes the task of topic recognition close to simple keyword extraction. This is not the case for non-expert consumer questions that are more complex to process due to the noise added by numerous peripheral entities.

**Methods**

Our approach to detect topics in consumer health questions is twofold. First, we extract candidate named entities with an unsupervised method. More precisely, we detect and normalize textual mentions with different knowledge bases then we perform named entity recognition using the semantic types associated with the knowledge bases concepts. Second, we classify the recognized entities as a question Topic or not. We call the overall normalization, named entity recognition and entity classification approach $K_{map}$.

**A. Knowledge-based normalization**

We use a concept normalization approach inspired by Mrabet et al. [17]. More precisely, we exploit TF-IDF search and optimization techniques to locate and disambiguate the textual mentions that refer to concepts in a knowledge base $k_i$. This modular process does not require learning corpora, which allows our approach to extend naturally with additional knowledge bases when needed. The implemented algorithm follows the steps outlined below:

1. Split the question into sentences and perform part-of-speech tagging\(^3\).
2. For each sentence, select candidate textual mentions corresponding to a sequence of allowed part-of-speech tags (e.g., nouns, adjectives, adverbs).
3. Use each candidate textual mention as a keyword query to look up concepts in knowledge base $k_i$ based on a TF-IDF search.
4. If no exact match is found between the candidate mention and the knowledge base concepts, the subsequence of words with best TF-IDF score is selected instead. The TF-IDF score is computed by the SolR indexer\(^4\). A minimum threshold is fixed to discard weak matches.
5. For ambiguous mentions (i.e., mentions that have more than one corresponding concept with the maximum TF-IDF score) disambiguation is performed according to global coherence: i.e., we select the knowledge base concept that has more relations with the concepts obtained from other textual mentions. This is done using integer linear programming and contextual search as described in Mrabet et al.[17].

---

</tbody>
</table>

As a result of this process, using a different knowledge base will not necessarily lead to the same candidate textual mentions and will provide different perspectives for the same consumer question.

In the course of this study we are interested in the combination of open-domain knowledge bases and biomedical knowledge bases. We use DBpedia as an open-domain knowledge base [9]. DBpedia is built semi-automatically from Wikipedia infoboxes. For a given Wikipedia article, RDF triples in the format '<subject, predicate, object>' are constructed using the article’s title as subject and the infobox columns as a list of predicates and objects. In a final step, manual mappings were performed by the DBpedia community to normalize predicate names to RDF properties defined in a reference ontology [6]. The 2014 version of DBpedia includes more than 4 million concepts and 3 billion triples.

For the biomedical perspective we use UMLS [10] as a reference knowledge base. We leverage UMLS Semantic Network relations for concept-level disambiguation. In contrast with DBpedia, UMLS relations are not established facts but are defined between semantic types, indicating possible factual relations between the concepts belonging to the given semantic types. For example, the Semantic Network relation Disease or Syndrome-TREATS-Pharmacologic Substance licenses a relation between concepts Cold and Paracetamol. By expanding the subject and object using semantic types hierarchy, we obtain 4,895 relations linking 133 semantic types.

We indexed both knowledge bases with SolR [7] and used LpSolve [8] to solve the disambiguation problem by maximizing the number of relations between the selected concepts.

B. Named entity recognition

We consider all textual mentions successfully normalized in the previous step (i.e., mentions linked to only one knowledge base concept) as candidate named entities. The set of candidate concepts associated with a given mention \( m \), according to a knowledge base \( k_i \) is denoted \( C_{k_i}(m) \). In order to associate a category to a given named entity, we perform a mapping between the semantic types of its associated concept \( c \in C_{k_i} \) and target recognition types (e.g., Disorder, Diagnostic Procedure). This mapping is based on simple regular expressions; for example, we look for the presence of the tokens disorder, disease, syndrome, illness, and pathology to recognize entities referring to medical problems in DBpedia. Table 1 presents some examples of exact mappings from DBpedia and UMLS. In the context of this study, we are primarily interested in the identification of entities referring to medical problems and use the corresponding regular expressions for type mapping.

In order to test the impact of the combination of dissimilar domain point-of-views, we merge the named entities obtained by normalizing the text with different knowledge bases. This merge extends simple union by merging candidate mentions \( m_i, m_j \) that have the same mapped semantic type and overlapping or contiguous text spans into a single mention \( m_{ij} \) such that: \( C_B(m_{ij}) = \bigcup_{i=1}^{N} C_{k_i}(m) \). The text span of \( m_{ij} \) is the text segment covered by \( m_i \) and \( m_j \). The main motivation of this procedure is to obtain higher precision, better text spans and to avoid partial matches.

For instance, in the question “Are there any new research studies enrolling people with carbamoyl phosphate synthase synthase [917]
The two candidate mentions “carbamoyl phosphate synthase” and “synthase 1 deficiency” are merged to form a single mention “carbamoyl phosphate synthase 1 deficiency”.

As we do not use learning corpora, the coverage of our approach is limited to the vocabulary defined in the knowledge bases. To overcome this limitation, we apply a rule-based method to obtain better text spans for the extracted entities as in Roberts et al. [3]. More precisely, we use three rules to extend the span of a named entity with (a) preceding adjectives and modifiers, (b) acronyms occurring directly after the entity and (c) generic keywords occurring directly after the entity (e.g., syndrome, disease, condition).

C. Entity Classification

In the last step of our processing, we approach the task of determining whether an entity is a question topic as a supervised classification task. Given an annotated corpus with gold topic mentions, we build automatically a training corpus for this classification task by considering each recognized named entity that overlaps a gold topic mention as a positive example and each entity with no overlap as a negative example. This translation can be applied to any given annotated corpus and does not restrict the scalability of our approach.

We used a support vector machine (SVM) classifier and experimented with various textual, lexical, and knowledge-based features. After empirical tests we kept only the features that have a minimum Pearson’s correlation factor with the class label. The Pearson’s factor indicates how much two variables are linearly correlated, its values range from -1 (total negative correlation) to 1 (total positive correlation) with 0 indicating no correlation. In our experiments we used a minimum absolute threshold value of 0.1. The first 16 features according to the Pearson’s score are presented in Table 2, along with feature values for the classification of question (3). Disease entities recognized with DBpedia are highlighted, disease entities recognized with UMLS are underlined. In Table 2, candidate named entities are taken from the merge of both results.

(3) Is there any evidence that trauma such as a physical injury i.e., neck injury, torn ligament, etc., can worsen McArdle’s disease?

In our experiments we used the LibLinear9 implementation of support vector machines (SVM).

Evaluation and Discussion

A. Data

To evaluate our method we consider two corpora, one from the Genetic and Rare Disease Information Center (GARD) and the other from the U.S. National Library of Medicine (NLM). The GARD dataset consists of 1459 questions taken from a curated online question set10 with answers created by NIH staff. Each question is associated with a genetic or rare disease (e.g., Beckwith-Wiedemann syndrome, SCOT deficiency, cold agglutinin disease), which is typically the topic of the question. This dataset is publicly available as part of the GARD question decomposition dataset11.

The NLM dataset consists of 263 questions collected from questions submitted to NLM websites (e.g., MedlinePlus, PubMed) and manually classified as consumer health questions with at least one disease topic. The question writers are generally concerned with a particular medical problem, though not always a named disease (e.g., pain in right ear, difficulty walking), and are asking for general medical information (such as that available on MedlinePlus), examples (1), (2) and (3) were taken from the NLM dataset. The dataset contains identifying information and is thus not publicly available. A de-identified set of questions largely overlapping with this dataset is in preparation for public release. Table 3 presents more details on each corpus.

On the NLM dataset, our NER process retrieved an average of 10.61 entities per question with DBpedia and 9.68 with UMLS. On the GARD dataset, our NER module retrieved 6.59 entities per question with DBpedia and 6.33 with UMLS.

B. Topic Recognition Results

To test our approach we perform a 10-fold cross validation to associate a class label (topic/none) to each candidate entity (the label is assigned to the entity when the latter is part of the 10% test split). Table 4 presents the results for topic recognition evaluated with 10-fold cross-validation on each corpus.

The merger of both knowledge bases performed substantially better than the individual knowledge bases (cf. Table 4) with an increase of 16.6% in F1 score on the NLM dataset and 2.1% on the GARD dataset for partial matches. For exact matches, the increase is of 3.5% on the GARD dataset and 10.6% on the NLM dataset. Besides the increased recall, this result can also be explained by the fact that our merge method is able to extend the spans of textual mentions from two annotation points-of-view; i.e., the open-domain perspective brought by DBpedia and the medical perspective from UMLS. The number of questions with multiple topics in the GARD dataset is not significant enough to draw reliable conclusions (only 3% of all questions), however we can observe that recall on these questions is above 70%. The NLM dataset contains more multi-topic questions (24.3%) and we can observe that recall on these questions
is more than 10% better than the overall recall with a 12% improvement in precision for exact match, which shows that our approach has higher effectiveness on these questions. This may be explained by the fact that consumers who write multiple-topic questions are looking for a more-precise and fine-grained information requiring a more focused writing to express the link between the different topics, which eases the named entity recognition and classification process.

In Table 5, we compare our results on the GARD dataset with the state-of-the-art approach, denoted \( QD[3] \), which uses a support vector machine over a set of semantic and word-level features to rank an initial set of candidate mentions provided by a lexicon constructed from UMLS. This approach also uses a set of rules (\( R_1 \)) to extend the spans of the detected topic mentions (e.g., appending generic words such as “disease” or “syndrome” if they follow the detected entity in the text). The comparison should be taken with caution as we use a different set of rules to extend entity boundaries. In order to reach more accurate observations, we use both a subset of \( R_1 \) that can be applied to our system, denoted \( R'_1 \) and our full set of rules, denoted \( R_2 \). The \( K_{map} + R_2 \) results correspond to the full-method results presented in Table 4.

</tbody>
</table>

Using a the subset of rules \( R'_1 \) improved performance and the final set of rules \( R_2 \) led to an overall performance increase on both exact matching (+7.4% F1) and partial matching (+2.8% F1) over \( QD + R_1 \). The overall improvement with respect to \( QD \) can be explained by several factors:

- \( QD \) does not tackle multi-topic questions and extracts only one topic for a given question, which reduces recall. More generally, ranking-based methods do not provide a systematic solution to multi-topic questions. Even if a threshold can be fixed to get the \( N \) best entities, relevant extensions are needed in order to determine the number of topics in a question. Binary classification solves this problem as it processes each entity individually from both a local and contextual point of view regardless of the rank/importance of other entities in the question, which provides a natural way of selecting the number of entities to be considered as topic/important in a question.

- Vocabulary coverage: this factor is hard to estimate exactly. While our method used DBpedia as an open-domain knowledge base, it also did not have the same level of coverage on the UMLS part, as it annotates only nouns or noun phrases that correspond to UMLS concepts, while \( QD \) is based on an extended lexicon that is able to detect individual keywords and to annotate verbs and adjectives.
Prior disambiguation: in $K_{map}$ entities are disambiguated using knowledge base relations while $QD$ uses only a lexicon-based method, which helps provide a more reliable set of candidate entities to the binary classifier.

We analyzed two random sets of 20 errors, respectively from the GARD dataset and from the NLM dataset on the basis of exact match evaluation. Table 6 presents the observed error types with percentages and examples.

</tr>
</tbody>
</table>

Classification was the main cause of errors on both datasets, with a more noticeable impact on the NLM dataset, which is clearly harder to process due to the lack of training data (263 questions vs. 1459 in the GARD dataset) and to longer queries (NLM requests are two times longer than GARD requests in average, cf. Table 3). Other errors vary by dataset. In GARD, entity normalization was the second source of errors (15%) as some acronyms and expressions could not be disambiguated with our knowledge-based approach. At a similar rate, the lack of coverage (concepts) in the knowledge bases did not allow detecting some topics. The impact of coverage seemed to be more pronounced on the NLM dataset, where spatial expressions play an important role in problem descriptions (e.g., pain in my shoulder). Errors due to misspellings were also more frequent in the NLM dataset, which may be explained by the fact that these questions are not edited for spelling, as it was done for the GARD dataset.

C. Ablation study

In this section, we study the classification of every instance of recognized entities, as opposed to finding an overall topic of the question as described above. This internal evaluation is important as achieving high classification accuracy is required to assess the scalability of our approach in distinguishing topic entities from other entities. We also tested our classification method with each knowledge base individually, and then with the merger of the knowledge bases results. We report ROC Area and precision, recall and F1 score for the Topic class in Table 7.

Our classifier reached high ROC area on the GARD corpus (93.0%) but obtained a lower performance on the NLM consumer health questions dataset (76.2%). This is partly due to additional noisy entities in the NLM questions which are generally longer than GARD requests, and thus have a lower topic-to-named-entity ratio. NLM questions are also less grammatical and don’t target genetic/rare diseases, which makes the topic term less likely to be a typical

named entity (e.g., “loss of vision” vs. “streiff syndrome”). This makes it more difficult to detect Topic entities with position-based features and TF-IDF scores in the NLM dataset.

The combination of both knowledge bases obtained the best classification performance on both corpora. While higher recall was anticipated, higher precision can be partly explained by the merge heuristic that is performed at entity level which leads to better text spans. The different perspectives of the knowledge bases may also allow the SVM to reach more accurate hyperplanes.

To better understand the behavior of the classifier, we also studied the role of the main corpus features. Table 8 presents the Pearson’s correlation score of the best features for both datasets.

Topic entities often occur at the beginning of consumer health questions which explains the impact of position-related entities on both datasets. Ambiguity was interestingly among the best features. High ambiguity values indicate that an entity is an overly general (open-)domain entity. If such entity is associated with the medical problem type it would be a relevant indicator for positive classification (like generic disease terms such as syndrome), if it is not associated with medical problems it can be a relevant indicator for negative examples. If we compare the features ranking between the two corpora, we note that the semantic type information is substantially more correlated with the class label in the GARD dataset, which suggests a more heterogeneous set of semantic types for topics in the NLM dataset. Ambiguity is also more highly correlated in the GARD dataset, which suggest a more regular use of generic disease terms. More generally, the tokens and lemmas are not among the best features which suggests that our approach may also be ported to other corpora as a baseline for topic recognition in corpora from other domains.

Conclusions

We presented a novel approach to recognition of topics in consumer health questions using both open-domain and biomedical knowledge bases. Our experiments showed that the combination of such knowledge bases leads to substantial improvement. Our binary classification approach was also able to tackle effectively multi-topic questions. Comparison on a standard benchmark also showed that our classification approach outperforms an SVM-based ranking approach. In future work, we plan to include additional knowledge bases to improve the recall of our method by taking into account spatial relations. We will also explore other semantic features such as WordNet synsets to improve the contextual knowledge for entity classification.

Using Drug Similarities for Discovery of Possible Adverse Reactions

Emir Muñoz, MEng\textsuperscript{1,2}, Vít Nováček, PhD\textsuperscript{2}, Pierre-Yves Vandenbussche, PhD\textsuperscript{1}

Abstract

We propose a new computational method for discovery of possible adverse drug reactions. The method consists of two key steps. First we use openly available resources to semi-automatically compile a consolidated data set describing drugs and their features (e.g., chemical structure, related targets, indications or known adverse reaction). The data set is represented as a graph, which allows for definition of graph-based similarity metrics. The metrics can then be used for propagating known adverse reactions between similar drugs, which leads to weighted (i.e., ranked) predictions of previously unknown links between drugs and their possible side effects. We implemented the proposed method in the form of a software prototype and evaluated our approach by discarding known drug-side effect links from our data and checking whether our prototype is able to re-discover them. As this is an evaluation methodology used by several recent state of the art approaches, we could compare our results with them. Our approach scored best in all widely used metrics like precision, recall or the ratio of relevant predictions present among the top ranked results. The improvement was as much as 125.79% over the next best approach. For instance, the F1 score was 0.5606 (66.35% better than the next best method). Most importantly, in 95.32% of cases, the top five results contain at least one, but typically three correctly predicted side effect (36.05% better than the second best approach).

Introduction

Adverse Drug Reactions (ADRs)\textsuperscript{a} can severely limit the intended benefit of drugs and accounts for a large number of hospital admissions, 42% of which could be prevented\textsuperscript{1,2}. ADRs can result in reduction of the patients’ quality of life or even death in extreme cases\textsuperscript{3}. The use of machine learning techniques has now become a common practice to improve drug safety and in particular to detect ADRs. However, many of the state of the art side effect detection systems and procedures depend on patient records or explicit incident reports\textsuperscript{3--5} and therefore assume ADRs already demonstrated within a population. Stakeholders in the drug development and administration lifecycle could greatly benefit from a technique that would help palliating drug’s ADRs before it is released on the market. The presented work addresses the area of computational side effect discovery using information in openly available biomedical databases. In recent years, increasing volume of biomedical data has been openly published online. This includes structured resources like Drugbank\textsuperscript{6} and SIDER\textsuperscript{7} that are represented in a machine-readable and interchangeable standard format in the Bio2RDF project\textsuperscript{8}. The uniform format allows for easy combination of these resources that can help to get different viewpoints on biomedical facts within one interlinked resource --- knowledge graph, an increasingly used umbrella term for loosely structured graph-based knowledge representation\textsuperscript{9}. Knowledge graphs are well suited to discovery of implicit knowledge hidden in the data, which we utilise in our approach to discovery of adverse drug reactions. We infer new links between drugs and side effects using side effect propagation along drug similarity relationships computed using the contents of consolidated Bio2RDF graphs.

The key contributions of our approach can be summarized as follows: (1) Best results in seven metrics traditionally used in the field (e.g., precision, recall or number of correct predictions among the top-ranked results) when compared to recent related works\textsuperscript{10--14}. (2) Best performance in being able to discover actual side effects and rank them so that they appear at the top of the results. In 95.32% of cases, the top 5 results contain at least one correctly predicted side effect (36.05% better than the second best approach). Moreover, the top 5 results typically contain at least 3 correctly predicted side effects. For drug of certain types (like NSAIDs or barbiturates), all the top 5 results are typically correct discoveries\textsuperscript{b}. (3) Superior flexibility - our prototype is able to incorporate many relevant data sets automatically, while all other related approaches would need to either develop additional ad hoc pre-processing tools, or replicate the presented technology.

\textsuperscript{a}Note that we also use several synonyms of ADRs like “adverse drug events” or “drug side effects” interchangeably in the paper.\textsuperscript{b}This is a very important aspect of the presented method, since in many practical applications, it is crucial to provide high-quality results among the top few ones. To give two examples: In clinical applications, physicians have very little time and therefore any automated predictions the use for their decisions have to be concise and highly reliable. In pharmaceutical research, the computational discoveries have to be tested in expensive and long laboratory experiments, and thus a more concise and reliable method like ours can potentially save money and time.
The expected benefits of the presented technology for its target audiences are:

- fully automated prediction of possible side effects;
- flexibility due to support for semi-automated incorporation of new training data sets;
- applicability to decision support in
  - clinical practice -- offering instant, reliable and concise feedback on possible side effects of drugs in daily use, helping to save lives and prevent complications in patients;
  - pharmacological research -- providing comprehensive lists of potential side effects of new compounds based in their similarity to existing drugs, helping to develop drugs faster and save money, while contributing to their safety.

A current limitation of the presented technology is its ability to make predictions about slightly smaller number of drugs than some related approaches. Still, this does not prevent from practical applications bringing the above-mentioned benefits, as explained in detail in the discussion section.

System Overview

The drug-side effect link prediction system consists of two phases: P1) an offline phase where the data processing takes place (integration of the heterogeneous data sources to build a knowledge graph in the RDF format\cite{15}, which is then used for computation of drug similarities), and P2) an on-line phase that provides interfaces for users to query the drug similarities database. Each phase consist of different module interactions to either build the similarities database, or query it. Figure 1 shows the system architecture and components involved in both phases.

![Figure 1. System architecture.](image)

Methods

We gathered all data sets into the pivot RDF format. The formal specification of RDF is convenient, as it allows for the integration of data while preserving their original semantics. We use a graph representation to model the underlying drug-related background knowledge.
**Data sources**

The main data sets we used are DrugBank for drugs, SIDER for drug side-effects, and PubChem for compound IDs which are used to link drugs in DrugBank to the ones in SIDER. Although all the mentioned sources have public access dumps, our method takes advantage of the graph representation using RDF, therefore we use the transformed data made available in the Bio2RDF project\(^8\) (release 4, accessed in December, 2015).

<table>

<td>Drug types, chemical information</td>
</tr>
<tr>
<td>SIDER</td>
<td>Database</td>
<td>Bio2RDF v2015-12-06</td>
<td>Side effects of drugs</td>
</tr>
</tbody>
</table>

The RDF graphs with all data sets are stored in an Apache Jena Fuseki\(^c\) triplestore and accessed using the W3C recommendation SPARQL 1.1\(^d\) query language for RDF.

**Data processing**

The first step in the data processing pipeline is indexing the Bio2RDF data sets to facilitate a uniform access to them. As shown in Figure 1, the data sources considered herein are drug profiles and side effects, which are integrated by the module data integration, to later make them available for querying as an RDF graph using HTTP SPARQL requests. Even when we use different public sources to build the RDF knowledge graph, by design our method is able to work with other sources such as post-market reports. Because of the flexibility of RDF, other structured sources can be used with information about drugs (e.g., chemical, biological, phenotypic), side-effects, drug classification, and diseases.

The number of unique approved small-molecule drugs gathered from the structured data sets was 731, while the number of side-effects gathered was 4,652. Finally, the resulting RDF knowledge graph contains a total number of 10.7 million unique statements.

**Measures**

*Resource Features Vector.* Given a resource (e.g., a drug node in our specific case), we extract a set of features that represent the connections between the resource and other resources in the graph. Formally, we extract the set of incoming and outgoing relationships of a resource \(X\) by using query patterns \(((?,X), (?,?)\) and \((X,?)\), respectively. For example, let \(A\) be the set of features for resource \(a\) in Figure 2. Node \(a\) in the RDF knowledge graph has outgoing relations to the resources \(c\), \(e\), and \(f\) with predicates \(\ell_1\), \(\ell_3\), and \(\ell_4\), respectively; and a unique incoming relation from resource \(d\) with predicate \(\ell_2\). Then \(A\) is defined as follows:

\[
A = \text{Features}_{LD}(a) = \{(\ell_1, c), (\ell_3, e), (\ell_4, f), (\ell_2, d)\}.
\]

Similarly, the set of features for resource \(b\) is given by the set \(B\).

\[
B = \text{Features}_{LD}(b) = \{(\ell_4, e), (\ell_4, f), (\ell_5, g), (\ell_2, d)\}.
\]

In our experiments, we manually remove features with functional properties, properties that can have only one (unique) value for each resource, i.e., there are no two distinct resources with the same property value (e.g., identifiers).

*Similarity Metrics.* In the present experiment we use the 3w-Jaccard binary similarity measure\(^{16}\) between two RDF nodes based on their corresponding feature

---

\(^c\)https://jena.apache.org/
\(^d\)https://www.w3.org/TR/sparql11-query/
sets. Intuitively, the more features two nodes have in common, the more similar they are. Let $x$ be the size of the set of features shared by $a$ and $b$, $y$ the size of the set of features only present in $A$, and $z$ the size of the set of features only present in $B$. The 3w-Jaccard similarity is defined to weight higher common features, and weight lower discriminating features, i.e., those only present in $A$ or $B$.

$$S_{3W-JACCARD}(a, b) = \frac{3x}{3x + y + z}, \text{ with } 0 \leq S_{3W-JACCARD}(a, b) \leq 1.$$ 

Example 1 Consider two drugs, namely, Phenacetin (identified by dbRank:DB03783) and Acetaminophen (identified by dbRank:DB00316), with a subset of their relations including: label, brand name, dosage form, and target proteins. As Figure 3 shows, these two drugs share some relations with the resources "Humans and other mammals"@en, dbBank:capsuleOral, dbBank:liquidOral, dbBank:analgesics, Non-narcotic, and dbBank:target-20.

Based on the relations shown in the graph, the feature vectors for dbRank:DB03783 and dbRank:DB00316 can be generated. Thus, the similarity between these two drugs is given by the 3w-Jaccard similarity of the feature vectors.

$$S_{3W-JACCARD}(\text{dbRank:DB03783}, \text{dbRank:DB00316}) = \frac{3 \times 5}{3 \times 5 + 6 + 5} = 0.5769$$

*We have experimented with other measures such as information content and Jaccard, but 3w-Jaccard performed best with the presently used data. However, combinations of different similarity measures may lead to further improvements and lower sensitivity to similarity thresholding, therefore related studies are an important aspect of our future work.*
**Prediction of Side Effects**

All feature vectors and similarities between every pair of drugs are computed and stored in an in-memory drug similarity database (see Figure 1) optimized to support on-line querying. After this step, the off-line phase of the system is completed. Conceptually, this database represents a vector space model where each drug is represented as a dot in a \( n \)-dimensional space (where \( n \) is the maximum cardinality of the feature vectors). Given a drug \( x_i \), the neighborhood of \( x_i \) is represented by the closest drugs (i.e., the ones with higher similarity). We use \( k \)-NN algorithm\(^{17}\) to extract such neighborhoods. In the presented experiments we consider neighborhoods of size \( k = 50 \), and further filter the neighbors according to different thresholds over the similarity between \([0.0 - 1.0]\) with incremental steps of \(0.1\).

Side effects are propagated from one drug to its closer neighbors. That is, for a given drug \( x_i \), the system collects the already known side effects of the drugs in the neighborhood of \( x_i \). The side effects are combined and ranked according to their co-occurrence (frequency) to determine the link’s weight. Let \( W_{UL} \) be the vector with the distance of \( x_i \) to each neighbor, \( L_{UU} \) be the sum of the distances from \( x_i \) to all its neighbors, \( \sum_{w_i \in W_{UL}} w_i \); and \( f_L \) the vector of the relative frequencies for a given side effect \( s \) in all the neighbor drugs. To compute the weight that the side effect \( s \) will have over \( x_i \), we use the average mean formula:

\[
s_{weight}(x_i) = \frac{1}{L_{UU}} W_{UL} f_L.
\]

During our evaluation, for each drug in our knowledge graph, we produce as many predictions as actual side effects the drug has in SIDER, and check whether we can retrieve the same set of side effects for a given drug. Therefore, to predict the set of side effects for a given drug, we change the vector \( f_L \) accordingly to each side effect in SIDER.

**Results and Discussion**

In this section we first describe the data and the methodology we used for evaluating our results. The results achieved are summarized then, including comparison to related works. We provide examples of selected results, and eventually discuss the benefits and drawbacks of our work in relation to the state of the art.

**Evaluation Data Set and Methodology**

The comparative evaluation of our approach to adverse drug reaction discovery was based on the SIDER data set as available in the Bio2RDF project. Basic statistics about the knowledge graph used in our work, is provided in Table 2.

<table>
<thead>
<tr>
<th>Table 2. Basic statistics about the SIDER dataset used.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of drugs</td>
</tr>
<tr>
<td>Number of side effects (i.e.,) ADR</td>
</tr>
<tr>
<td>Number of drug-side effect relations</td>
</tr>
<tr>
<td>min / max / avg number of side effects per drug</td>
</tr>
<tr>
<td>min / max / avg number of drugs per side effect</td>
</tr>
</tbody>
</table>

We used the SIDER drug-adverse effect relationship instances as a gold standard. We performed leave-one-out cross-validation of our approach, measuring various scores to assess the predictive power of our approach by training it on a subset of the gold standard drugs and testing it on the remainder in an iterative manner. Such an evaluation method is commonly used for assessing the performance of ADR discovery systems\(^{10-14}\) and thus provides convenient means for direct comparison with related state of the art.

For the performance evaluation we use specific evaluation metrics for multi-label learning, which are different from the ones used in traditional supervised learning\(^{18}\). Let \( p \) be the size of the set of drugs, thus, for each drug \( x_i \) with \( 1 \leq i \leq p \) we have a set \( Y(x_i) \) of actual side effects (from SIDER), and a set \( G(x_i) \) of predicted side effects using our method. We compute the following four measures for evaluating the results regardless of the ranking of the predictions:
Figure 4. Plot of the results in relation to the similarity threshold.

\[
\text{accuracy}(A) = \frac{1}{p} \sum_{i=1}^{p} \frac{|Y(x_i) \cap G(x_i)|}{|Y(x_i) \cup G(x_i)|}, \quad \text{precision}(P) = \frac{1}{p} \sum_{i=1}^{p} \frac{|Y(x_i) \cap G(x_i)|}{|G(x_i)|}, \quad \text{recall}(R) = \frac{1}{p} \sum_{i=1}^{p} \frac{|Y(x_i) \cap G(x_i)|}{|Y(x_i)|},
\]

and F1-score, which is known as the harmonic mean of precision and recall. Furthermore, we computed three scores that reflect the prediction ranking and the extent to which the methods produce not only good, but also highly-ranked good results, namely: average precision (AP), as defined in \textsuperscript{19}; TopK score, which is the relative frequency of drugs having at least one known (i.e., gold standard) side-effect which is ranked among the top K high scoring side-effects according to a prediction; P@K score stands for the precision at K, i.e., precision computed only among top K ranking side effects per drug (we used K \in \{3, 5, 10\}). We compute the average values of the particular measures across all drugs with non-empty set of ADR predictions made, which is an approach common to the works we compare ourselves to in the next section.

Among the measures we used, the TopK and P@K are arguably the most accurate scores in terms of evaluating the benefit of ADR discovery for certain types of end users like clinical practitioners. As explained in \textsuperscript{20}, these scores are easily grasped by non-informaticians and are therefore apt for explaining the reliability of the system to them. Moreover, in settings where quick decisions are needed, like in clinical practice, users do not tend to perform comprehensive search among many possible alternatives to find the relevant ones.\textsuperscript{20} The TopK and P@K scores reflect the likelihood that such users will find relevant results very quickly at the top of the list of possibly relevant results. For users who require a comprehensive study of possible ADRs (e.g., pharmaceutical researchers), good evaluation measures across the whole range of predictions are important as well, though.

**Summary of the Results**

Figure 4 shows how the core evaluation metrics depend on the choice of the similarity cut-off threshold.

Although using a non-zero cut-off results in reduced number of drugs for which we are able to predict side effects by propagation, there are significant gains in all measures up until the 0.6 threshold. After that, the slight gain is balanced by a drastic reduction in the number of drugs with predictions, therefore we decided use 0.6 as the preferred cut-off threshold.

Table 3 compares our results achieved for the best similarity threshold (i.e., 0.6) to recent related approaches (i.e., those that used SIDER in a cross-validation experiment). The random baseline assigns |Y(x_i)| ADRs to all drugs x_i in a random manner, where Y(x_i) is the set of actual ADRs for the drug x_i in SIDER. The second line in Table 3 corresponds to our approach. The methods that support ranking of the side effects predicted for particular drugs are prefixed by + in the table.

\textsuperscript{f} Similarly to \textsuperscript{12}, we used K \in \{1, 5\}, but we report a relative instead of absolute frequency as it provides for a better comparison.
The method\(^{11}\) only provides box plots with comparable measures and the value given here is the best mean as observed in the reported plots. The last row of Table 3 presents relative improvement of the presented method achieved over the best previously existing method.

### Examples of Results

Examples of top five results according to the F1 and P@5 measures, respectively, are given in Table 5. There is substantial overlap between the top positions of these lists, therefore we give the top five drugs for the F1 scores, and then the top five drugs out of top 30 of those that performed best at the P@5 score but were not in the top-F1 list. We can see some relatively frequent drug types as best performers, such as barbiturates, anti-histamines or NSAIDs in Table 5. This may indicate that our method can provide very good results for certain drug classes, possibly based on some of their inherent features in the Bio2RDF data. This insight is further supported by analyzing the numbers of drugs that perform well in terms of precision at 3 or 5, as depicted in Figure 5.

The figure shows that although there is relatively large number of drugs that perform rather poorly, there is also disproportional number of drugs that perform very well.

This preliminary analysis may indicate that for some types of drugs, the results of our method can be substantially better than the average values reported above. Also, there may be strong correlations between good results among the top K results and the whole prediction set. After more precisely detecting the types of drugs that exhibit such behavior, our method can be useful in both of the characteristic use cases we have outlined before (i.e., the clinical practice vs. pharmaceutical research).
Discussion

Our results clearly show the superiority of the presented method. We achieve the best performance in all metrics, improve the previous results by up to 125.79%. The main contribution of our method over related state of the art is the combination of the following factors: (1) The presented method achieves better results in the Top1 and Top5 measures than the related approaches (by as much as 36.05%). It also provides the corresponding precision at K scores that help to determine how many of the top results are actually typically relevant (e.g., more than 3 out of top 5). These combined measures allow for better assessment of what can be expected from the system in cases when users may want to process only first few results and still get many relevant predictions. (2) The method does not depend on patient or report data, even though they can be easily integrated (e.g., via the ClinicalTrial.gov data set in Bio2RDF). (3) The method can automatically digest up to 12 data sets related to drugs, their structure, mechanisms of action, etc. (based on Bio2RDF status as of April 2016). This is different from related state of the art methods that would need to write specific pre-processing pipelines for each of the original data sets, or emulate our approach that is capable of using the Linked Open Data versions of biomedical databases in Bio2RDF. (4) There is only one parameter that has substantial influence on the results -- the similarity threshold. And even using the default parameter value determined by our empirical study is robust, as observed in cross-validation experiments.

The most serious limitation of our approach is the comparatively lower number of drugs for which predictions can be made with the presented method due to the drug similarity threshold. At this stage, the limitation can be partly mitigated by relaxing the similarity threshold. For instance, values around 0.2 result in predictions for all drugs we have features for, while the evaluation scores are still relatively competitive (e.g., F1, Top5 and P@5 scores are 0.3804, 0.8413 and 0.4052, respectively). Focusing on the drug classes for which the presented method performs extremely well (such as NSAIDs) can lead to complete mitigation of this limitation in practical applications. For future versions of the presented technology, we have been addressing this issue by more sophisticated propagation methods involving broader neighborhoods in the similarity graph and combinations of multiple complementary similarity measures. This is expected to lead to high quality predictions for all drugs processed by the system.

Conclusions and Future Work

We presented a method for discovery of drug side effects (or, alternatively, adverse drug reactions) based on propagation of known side effects between similar drugs. The drug similarities were computed using features selected from two data sets---DrugBank and SIDER---represented in a common machine-readable format as parts of the Bio2RDF project. The presented method is very flexible in terms of adding new sets of features from other relevant resources represented in Bio2RDF, which is an advantage over many related state of the art approaches. In addition to that, we were able to achieve better results than related systems in seven standard evaluation metrics. Our system produced promising results especially relevant to use cases in which one needs high ratio of relevant results present among top few side effect predictions (e.g., clinical practice where physicians may need to check for possibly dangerous side effects of a drug but do not have time to filter through many possibly relevant options). The results also motivate some interesting areas of future work that could increase practical relevance of the presented method.

Figure 5. Histograms of drug precisions@K.
The most immediate future work stemming from the research presented here addresses the sensitivity of the results to the drug similarity threshold. We aim to investigate the influence of adding additional features (from other data sets available via Bio2RDF) for the similarity computation, which may result in more densely overlapping feature space and thus higher numbers of drugs that make it even over aggressive thresholds. As more features may lead to more noise, we plan to experiment also with various feature extraction techniques to minimize the risk. We also want to experiment with multiple combined similarity measures and incorporate unrestricted propagation of the side effect labels within the computed similarity networks, using the technique first presented in 21. This will effectively mean that a side effect may be propagated not only to direct neighbors in the drug similarity network, but also to nodes further away (if the similarity links are strong enough). Last but not least, we want to perform an in-depth analysis of the performance of our method across specific types of drugs and test its predictive capabilities on drugs not represented in SIDER, following the approach presented in 12.

Acknowledgements

This work has been supported by the TOMOE project funded by Fujitsu Laboratories Limited and Insight Centre for Data Analytics at National University of Ireland Galway. The technology described in this paper is a subject of a European patent pending, No. 15198304.6-1951.

Supplementary Material

We host all experimental data used in this paper at http://bit.ly/AMIA2016KEDI. The materials contain pre-processed versions of DrugBank and SIDER data sets from Bio2RDF v4.0, including fixing of a few syntax errors and a simple documentation.

Abstract

Analysis of user interactions in online communities could improve our understanding of health-related behaviors and inform the design of technological solutions that support behavior change. However, to achieve this we would need methods that provide granular perspective, yet are scalable. In this paper, we present a methodology for high-throughput semantic and network analysis of large social media datasets, combining semi-automated text categorization with social network analytics. We apply this method to derive content-specific network visualizations of 16,492 user interactions in an online community for smoking cessation. Performance of the categorization system was reasonable (average F-measure of 0.74, with system-rater reliability approaching rater-rater reliability). The resulting semantically specific network analysis of user interactions reveals content- and behavior-specific network topologies. Implications for socio-behavioral health and wellness platforms are also discussed.

Introduction and Background

In recent years, the penetration of online communities into everyday lives has been astonishing. Researchers have studied these communities using multidisciplinary methods to better understand human health behaviors [1,2]. Qualitative studies have been conducted to characterize (a) different types of social support embedded in forum communication [3], and (b) quality of information being disseminated in social platforms [4]. A significant limitation of the application of qualitative methods to peer interactions in online social media platforms is that these analyses were conducted on small samples of communication on account of the labor and time intensive nature of manual coding required. Voluminous data accumulating through increasing use of Health 2.0 technologies, such as online communities, require methods that are scalable. To this end, machine learning methods have been used to identify specific features of communication within online communities [5-7]. Classification of conversational and informational questions on Yahoo! Answers has also been attempted using a combination of human coding, statistical analysis, and machine learning [8]. Methods of distributional semantics have also been combined with machine learning algorithms to classify consumer health webpages of based on language use patterns [9]. However, these studies ignore the structure of communication (who communicates with whom), which is important to understand peer influence on behavior. Quantitative network modeling has been the most widely used technique to describe and visualize behavioral diffusion, communication structure, and peer influences in social communities [10,11]. However, most of these studies do not consider communication content.

In this paper, we describe a semi-automated method that involves (a) capturing the semantic nuances of communication in an online community using a variant of Latent Semantic Analysis (LSA) [12], and (b) using content-specific classification to reveal structural variations underlying the communication patterns of users of a health-related community. LSA is a distributional semantics method that provides us with the capability to derive relatedness measures between terms from unannotated text. This is accomplished by representing the terms in a high dimensional vector space. The coordinates of a term vector in semantic space are determined by the distributional statistics for this term, such that similar vector representations are created for terms that occur in similar contexts [13]. Evidence suggests that the semantic relatedness measures derived using distributional semantics techniques agree with human estimates, and can be used to obtain human-like performance in a number of cognitive tasks [12,14]. Studies have used LSA to automate the coding of communication content among group members to assess team cognition [15,16], suggesting the applicability of the method for communication analysis at scale. Other studies have also established the utility of other distributional representations for analysis of social media postings [17,18]. In this paper, we apply LSA to the model content and structural patterns underlying user communication in QuitNet, an online social network designed to promote smoking cessation. The paper proceeds as follows: (a) firstly, we present an overview of the materials used in the study, (b) secondly, we describe automated analyses conducted on the QuitNet dataset, (c) thirdly, we conduct network analysis to characterize content-specific user communication patterns in QuitNet, and (d) finally, we conclude the paper with implications of our findings for design of digital health platform that leverage the power of social connections.
Materials and Overview of Methods

QuitNet is one of the first online social networks aiming to promote health behavior change, and has been in continuous existence for the past 14 years. It is widely used, with over 100,000 new registrants per year [19,20]. Previous studies of QuitNet indicated that participation in the online community was strongly correlated with abstinence [21]. Communication among QuitNet members can occur through private email, one-to-one messages in public threaded forums, and public chat rooms. The data set studied in this paper was drawn from a previously studied quality improvement database [19], and is comprised of de-identified messages in the public threaded forums, in which participants post messages and reply directly to each other. A database of 16,492 de-identified public messages from between March 1, 2007 and April 30, 2007 was used in our study. All messages are stripped of identifiers but recoded for ego id (the individual posting the message) and alter id (the individual whose message is being replied to), date and position within the thread.

The main pre-requisite for the semi-automated method described in this paper was the development of an annotated dataset that provides qualitative characterization of QuitNet user communication. Grounded theory based qualitative analysis [22] was conducted to identify QuitNet communication themes, and literature review was subsequently conducted to identify the theoretical roots underlying these themes. Further description of this analysis is beyond the scope of the paper, but additional details can be found here [23]. Here we present a summary of pertinent methodological details and results of the qualitative analysis. An initial subset of 795 messages was coded manually until thematic saturation, utilizing grounded theory techniques - open coding, axial coding, and constant comparison. Messages were classified into 12 themes: ‘Social support’, ‘Cravings’, ‘Traditions’, ‘Quit Obscure’, ‘Teachable Moments’, ‘Quit Readiness’, ‘Conflict’, ‘Relapse’, ‘Quit Progress’, Family and Friends’, ‘Virtual Rewards’, and ‘Pharmacotherapy’.

In the current work, distributional semantics and machine learning were used to associate unannotated messages with communication themes from this qualitative analysis. The complete dataset was then further analyzed using network description and modeling packages, to understand theme-specific structural patterns of user interactions. In the following sections, we present the methodological details and subsequent results of the automated text analysis (Step One) and network modeling studies (Step Two) in the context of QuitNet.

Step One: Automated Text Analysis of QuitNet Communication

The methods of automated text analysis we have employed infer measures of the relatedness between passages of text from the distributional statistics of terms in a large text corpus. Based on our previous work [24], we concluded that the distributional information in our QuitNet corpus was insufficient for the automated derivation of meaningful measures of semantic relatedness between terms. Therefore, we drew on distributional information from the Touchstone Applied Science Associated (TASA) corpus [25], a collection of 37,657 articles designed to approximate the average reading of an American college freshman. We used LSA [14] to derive vector representations of terms in the TASA corpus, such that terms with similar distributions would have similar vector representations, with similarity between vectors measured using the cosine metric. This corpus has been widely used in distributional semantics research, and when applied to this corpus LSA has been shown to approximate human performance on a number of cognitive tasks [12]. LSA was performed using the open source Semantic Vectors package [26]. The log-entropy weighting metric was used, and terms occurring on the stopword list distributed with the General Text Parser software package [27] were ignored. This stopword list consists of frequently occurring terms that carry little semantic content.

Subsequently, representations of the messages in the QuitNet corpus were generated by adding the vectors for the terms they contain, and normalizing the resulting message vectors (we will refer to these vectors as TASA-based QuitNet message vectors). Representations for terms in the QuitNet corpus were then generated by adding the message vectors for each message they occurred in, and normalizing the resulting vector. Subsequently, a second set of message vectors was generated, which we term QuitNet message vectors. A pictorial depiction of the vector generation is presented in Figure 1. We utilized this approach in order to ensure that terms present in the QuitNet corpus, but not in the TASA corpus, could obtain meaningful vector representations on account of their having similar distributions to terms in this corpus that did occur in the TASA corpus. This approach is similar in nature to the reflective approach that we have utilized previously to infer associations between terms that do not co-occur directly [28], and provides a convenient means to combine distributional information from two disparate corpora (TASA and QuitNet in our case).
Inspection of the nearest neighbors of key terms from the QuitNet corpus revealed that the measurements of semantic relatedness derived using this approach were intuitive and readily interpretable. In order to use these generated vectors to support automated coding of QuitNet messages, we used a k-nearest neighbors (kNN) approach. For each message, the system provided a ranked list of codes based on pre-assigned manual codes to the nearest neighbors. The score for a particular code was obtained by adding the cosine measures of the nearest neighbors corresponding to that code. The cosine measure represents the relatedness of the message to its nearest neighbor. All of the coded messages other than the message in question were considered (leave one out cross-validation). Figure 2 illustrates the scoring procedure for each theme. As shown in the figure, the five nearest neighbors to message 10515456 were retrieved. For each of the themes, a score was calculated by adding up the cosine values of the nearest neighbors to which the theme was attached. For instance, the score for ‘Quit Readiness’ was obtained by adding the cosine scores of the nearest neighbors (10449020 and 10581825). These scores were used in the next stages to fine-tune the system for accuracy and reliability as explained in the next section of the paper.

Experimental Setup

Using the LSA technique described in the methods section, vectors representing all of the messages in our QuitNet dataset were generated. We then conducted three experiments to evaluate the extent to which these vector representations could be used to accomplish the automated analysis as explained below.

**Experiment 1: Evaluation of the system accuracy**

**Methods:** The 790 manually coded messages were again coded by the automated classification system. The system returns a scored list of codes for each message (see Figure 3). However, many messages are coded with a small number of codes. So some cutoff point is required for meaningful evaluation. In the preliminary experiment we used ranking as a cutoff, but subsequently based the cutoff on association strength. In the ranking-based code assignment, we had the system rank the codes at multiple levels (e.g. top 2, top 4) as seen in Figure 3. Threshold-based cutoffs were also tested at various levels of the association strength. For instance, at 30% threshold only the codes with a score greater than 30% of the highest score were retained. As shown in Figure 3, when a 30% threshold was applied, codes with score greater than 0.3*highest score (0.3*4.182=1.255, ‘Social support’, ‘Quit Readiness’) were retained. The recall and precision of the system in assigning thematic codes was calculated at various levels of threshold and ranking. Based on error analysis, messages with low-level codes “miscellaneous” and “game” were excluded from the dataset because the message content is not amenable to content-based analysis. The code “game” was assigned to those posts where QuitNet members play a word association game with each other to engage themselves in an activity to curb the cravings. However, single word postings such as this cannot be dealt with by the system effectively as individual message content does not provide sufficient semantic context to interpret the purpose of these words. Similarly, messages that were coded as “miscellaneous” were also excluded because the content does not relate to any of the smoking cessation related themes. The experiment was then repeated with the dataset excluding the messages that belong to the “miscellaneous”, and “game” categories, leaving 533 messages.
Figure 2. Overview of the scoring and optimization procedures used for automated classification system
All: list of all the codes that the system assigned to the message in question, Top 2: ranking cut-off that retains the codes with the top 2 highest scores, Top 4: ranking cut-off that retains the codes with the top 4 highest scores, Threshold of 30%: cut-off based on association strength that retains the codes with scores greater than 30 percent of the highest score, Threshold of 50%: cut-off based on association strength that retains the codes with scores greater than 50 percent of the highest score.

Results
The graph in Figure 3 provides the optimum F-measure estimating system accuracy. The average recall and precision were calculated to be at 0.77 and 0.71 respectively for the themes when considering 5-nearest neighbors at a threshold of 50%. The F-measure was found to be 0.74 in this case.

Figure 3. Automated classification system accuracy (F-measure) at a Threshold of 50%
Top X (X=2, 3, 4) indicates the ranking-based cutoff, Th(Y), Y=40%-80% indicates association strength based threshold, NN (Z) (Z=1, 3, 5, 10, 20) indicates the number of nearest neighbors retrieved by the system to formulate scores for code assignment.
Experiment 2: Evaluation of the system reliability

Methods: A separate dataset of 100 messages was coded by two researchers using the themes that emerged from the grounded theory analysis. The same data set was fed to the automated classification system that was optimized for better accuracy in the previous experiment. The system assigned themes to these 100 messages which were then used to calculate human-system reliability using Cohen’s Kappa measure.

Results: The inter-rater reliability was calculated be 0.83, and the system-rater reliability was averaged at 0.77. Surprisingly, results indicated that the system agreed better with second coder, who coded just these 100 messages, than with the coder of the initial 790 messages upon which the system was trained.

Conclusion: The reliability measures obtained in this experiment indicate that the average agreement of the system with human raters for QuitNet themes approached the agreement between human coders.

Experiment 3: Incorporation of outside semantic information

Methods: Initially, LSA was performed on QuitNet corpus directly to generate message vector representations without TASA pre-training. Then, the vector generation process outlined in Figure 1 was utilized to generate QuitNet message vectors with TASA pre-training. The reflective nature of the method shown in Figure 1 ensures that terms present in the QuitNet corpus, but not in the TASA corpus, would obtain meaningful vector representations. Then, kNN was applied to both the QuitNet vector representations with and without TASA-pre-training separately. F- measures were used to compare the effect of incorporation of TASA corpus to derive QuitNet message vector representations.

Results: Using kNN (k=5) without and with TASA pre-training, the F-measures were calculated to be is 0.53 and 0.74 respectively. Table 1 shows the effects of incorporating TASA on the nearest neighbors of the term “craving”.

Table 1. Most closely related terms to term “craving”.

<table>
<thead>
<tr>
<th>Without TASA</th>
<th>little; him; update; came; ever; stayed; gone; still</th>
</tr>
</thead>
<tbody>
<tr>
<td>With TASA</td>
<td>cigarette; nicotine; crave; craves; smoker; habit; chantix; cig</td>
</tr>
</tbody>
</table>

Conclusion: The accuracy measures obtained in this experiment emphasize the importance of the incorporation of external world knowledge when analyzing social media interactions to negotiate issues with lack of semantic context on account of terse text and community-specific jargon.

Step Two: Large scale theme-specific network analysis of QuitNet communication

Methods: Our entire database of QuitNet messages, consisting of 16,492 messages, was processed by the automated classification system described in previous sections of the paper. The computer-annotated QuitNet data were then used to create theme-specific networks, amenable to analysis using traditional (structural) network analytics to understand theme-specific patterns of social dynamics. The users of QuitNet were classified into five mutually-exclusive classes based on their self-reported abstinence.

Class 1: users who have remained abstinent throughout the study period
Class 2: users who were active smokers throughout the study period
Class 3: users who have relapsed (ex-smoker → active smoker) during the study period
Class 4: users who have successfully quit smoking (active smoker → ex-smoker) during the study period
Class 5: users who have relapsed multiple times during the study period.

Theme-specific network models of the QuitNet data were created by representing users as nodes, and their communication as edges. For each theme-specific network, only edges representing messages annotated with that theme were included. Gephi, an open-source network analysis and visualization software package [29] was used to visualize and analyze these network models. Differences in network structure across themes for multiple user classes were examined using social network metrics [11] that explain node importance within a network (centrality metrics) and network connectedness (network cohesion metrics). Definitions of the metrics used in this study are provided below [11].

1. Degree (or connectivity): The degree of a node is defined as the number of edges incident with the node. If the graph is directed, the degree of the node has two components: the number of outgoing links (referred to as the out-degree of the node), and the number of ingoing links (referred to as the in-degree of the node).
2. Density: The proportion of direct ties in a network relative to the total number possible.
3. Path length: The minimum number of ties required to connect two particular actors, as popularized by Milgram’s famous ‘six degrees of separation’ small-world experiment [30].
4. Cluster: A group of nodes, each of which is connected to at least one other node in the group.
5. Modularity: It is defined as the number of edges falling within groups minus the expected number in an equivalent network with edges placed at random, and therefore can be considered as a measure of the cohesiveness of communities within the network.
**Results:** Inclusive of all themes, QuitNet user communication network of Class 1 is the largest with network diameter of 10, comprising of 1204 nodes and 6093 edges. It is the most connected network, with average degree of 10.121. Class 2 is the second largest network of QuitNet users, with network diameter of 9, comprising of 732 nodes and 1696 edges. It is also the second-most connected network, with average degree of 4.634. However, the Class 2 network has the lowest density (0.006) of all, meaning that the connections constitute a tiny fraction of all potential connections that could be formed in this network. For illustration purposes, Figure 4 presents four content-specific network topologies for Class 1 (abstinent) QuitNet users (same color nodes implies clustering into a sub community, orange indicates a low modularity sub community, purple indicates a high modularity sub community, and node size indicates degree). As can be seen in the figure, network formations based on ‘Social support’ and ‘Quit Progress’ are populous and have higher average degree (7.42, 5.3) compared to ‘Quit Benefits’ and ‘Cravings’ (2.86, 3.42) respectively. This indicates that this group of ex-smokers mostly focused their communication with peers on content related to exchange of social support and monitoring their quit progress, reflecting on how far each of them have come in their efforts to quit smoking. However, modularity of networks specific to ‘Social support’ (0.54) and ‘Quit Progress’ (0.52) was lower compared to ‘Quit Benefits’ (0.67) and ‘Cravings’ (0.65), which indicated the sub communities of users exchanging information about benefits and cravings were strongly connected among themselves in comparison with the rest of the network. On the other hand, the average path length in ‘Social support’ (3.4) and ‘Quit Progress’ (3.6) networks is lower when compared to average path length in ‘Quit Benefits’ (4.4) and ‘Cravings’-related networks (4.1), which implies faster dissemination of the former content types.

![Figure 4](image-url). Content-specific network representations of communication involving Class 1 QuitNet users.
Similarly, Figure 5 presents the content-specific network formations of Class 2 users (active smokers). Unlike the Class 1 ‘Social support’ network, where the high-degree users cluster within a single sub-community, the majority of Class 2 high-degree users within the social support network formed a separate modularity cluster to the rest of the QuitNet users. Further, the ‘purple’ nodes revealed that the ties among high-degree users in Class 2 ‘Social support’ were stronger amongst themselves when compared with their ties with the rest of the nodes in the network. The average path length across all content types was approximately equal at 4.05, except for in the ‘Cravings’ network which at 5.3 is higher than this path length for Class 1 users indicating lower efficiency in information dissemination. Among all content types indicated in Figure 5, the ‘Quit Benefits’ network of active smokers had highest number of isolates and least number of nodes, making it the sparsest and least effective network.
Figure 6 presents network formations involving QuitNet users who have relapsed (Class 3) and were successful quitters (Class 4) during the study period. Interactions involving Class 3 users resulted in a network with diameter of 6 comprising of 116 nodes and 111 edges. It is the least connected network with average degree of 1.914. In contrast, Class 4 user interactions resulted in a larger network with 456 nodes and 763 edges, with an average degree of 3.346. Content-specific topological analysis of user interactions related to ‘Traditions’ indicated that the Class 4 users formed a single cohesive network with higher modularity (0.68), when compared to Class 3 users exchanging similar content (0.17). This implies that the emergent traditions within QuitNet may play an important role in successful quitting. The same trend of higher modularity among Class 4 QuitNet users was found in the network describing their interactions related to ‘Quit Readiness’ (0.79), however this network had high degree users form the highest modularity sub community (purple color) as compared to the rest of the nodes (orange color).

**Figure 6.** Content-specific network representations of communication involving Class 3 and Class 4 QuitNet users

**Limitations and next steps**

The automated methods and subsequent network analytics described in this paper were based on qualitative analysis of a small data sample of 795 messages that were coded until thematic saturation. However, it may be the case that the remainder of the dataset contains additional themes that were not captured. The rapid growth of digital technologies will further complicate this issue, as it will generate a data deluge of millions of messages transmitted over the Web and mobile media. The QuitNet dataset considered in our analysis was recorded in 2007. For future studies, we will obtain further data drawn from recent and larger datasets. However, we believe that the findings from the reported data on human behavior are still relevant, as the basic tenet of forum-based communication (structure and logistics) remains the same. In addition, use of recently emerged methods of distributional semantics (e.g. Reflective Random Indexing [28], neural word embeddings [31]) will be considered in our future studies. The network analysis conducted in this paper was limited to description and visualization of user interactions using five metrics. A more extensive approach toward network analysis could be adopted to identify network motifs [32], integrate social influence models [33,34], and model topological evolution over time [35].
Conclusions and Discussions

This paper describes two studies which focus on the analysis of online social network communication using automated text analysis methods from distributional semantics and network analysis for describing content-specific topology differences. The key contributions of this paper are as follows - 1) it introduces and validates a method to extend qualitative analysis to large datasets; 2) it provides a proof-of-concept for full-scale content-specific network analysis of user interactions in an online health-related community; and 3) it demonstrates the use of automated text analysis methods as a bridge between the qualitative and network components of online social media analysis.

Given the voluminous nature of online social network data, it is important to develop automated methods that can address the large quantities of free text data that are available online. While the performance of the automated method is reasonable, the accuracy of the system may be further increased by adopting more sophisticated machine learning algorithms. Importantly, the automated method provides a tractable and intuitive mechanism that facilitates code assignment to all the messages in the dataset, thus enabling qualitative analysis of large datasets. The reflective approach adopted in the automated classification system scales in linear proportion with the size of the dataset and therefore the automated system can be applied to analyze millions of messages exchanged on social media platforms. In addition, incorporation of external semantic information enhances the applicability of distributional models to social media text analytics. A significant implication of large-scale qualitative analysis of online social media interactions is that it facilitates the inclusion of semantic content into network models of online communities. Content-specific network analysis of QuitNet revealed attributes that describe nodal importance and network cohesion of communication themes across multiple behavioral states related to smoking cessation. In turn, such understanding will allow us to develop user-information interactions that facilitate efficient information dissemination, robust network formation, and targeted support within technology platforms such as QuitNet [24,34,36].

In summary, methods that facilitate automated extension of granular qualitative analyses, and population-level visualization of the results can extend the research and application frontiers of social media, thereby further enhancing their positive impact on health-related behaviors.

DisVis: Visualizing Discussion Threads in Online Health Communities

Drashko Nakikj, MS, MA, Lena Mamykina, PhD
Department of Biomedical Informatics, Columbia University, New York, NY, USA

Abstract

An increasing number of individuals turn to online health communities (OHC) for information, advice and support about their health condition or disease. As a result of users’ active participation, these forums store overwhelming volumes of information, which can make access to this information challenging and frustrating. To help overcome this problem we designed a discussion visualization tool DisVis. DisVis includes features for overviewing, browsing and finding particular information in a discussion. In a between subjects study, we tested the impact of DisVis on individuals’ ability to provide an overview of a discussion, find topics of interest and summarize opinions. The study showed that after using the tool, the accuracy of participants’ answers increased by 68% (p-value = 0.023) while at the same time exhibiting trends for reducing the time to answer by 38% with no statistical significance (p-value = 0.082). Qualitative interviews showed general enthusiasm regarding tools for improving browsing and searching for information within discussion forums, suggested different usage scenarios, highlighted opportunities for improving the design of DisVis, and outlined new directions for visualizing user-generated content within OHCs.

Introduction

In recent years, online health communities (OHC) have emerged as an important complement to the traditional health care. According to the 2009 Pew Report, close to a 1/3 of all American adults had accessed social media for questions related to health. More than 1/2 of e-patients (patients relying on online medical services) living with chronic disease consume user-generated health information and 1/5 participate in generating that type of information. In response, there emerged a large number of OHCs such as breastcancer.org, TuDiabetes.org, PatientsLikeMe.com, to name a few. Studies showed that these forums serve many purposes, from sharing information and increasing knowledge, to emotional and social support, to connecting with patients with similar health challenges, among others. However, most of these forums continue to rely on text-based discussion boards as their main platform for achieving these goals, thus presenting rich repositories of text-based information.

Because of the amount of information collected within OHCs, satisfying users’ information needs can be a complicated and time consuming process. For example, based on the data collected in 2014, an active forum for diabetes self-management, TuDiabetes.org, has over 36,000 members and includes almost 23,000 discussions on broad range of topics. Many of these discussions include dozens of members and hundreds of posts, and last for several months or years, transforming the initial topic of the discussion in multiple directions. Therefore, finding relevant information and forming an impression of the topics discussed and opinions expressed within a single discussion thread can be challenging. While in many domains this can create inefficiencies and lead to frustration, in the context of health information it can lead to particularly disastrous effects, such as participants arriving at wrong conclusions to the detriment to their health.

To address these issues, the long-term objective of this research is to develop novel discussion visualization tools that will help members of OHCs to navigate discussion threads, quickly form an impression of what is being discussed, and identify the most interesting and relevant parts of the conversation. In this paper we present the prototype of the DisVis discussion visualization tool and discuss the results of its evaluation study with individuals recruited from TuDiabetes. In this between subjects study, the participants in the intervention and the control group were asked to review a single discussion thread and were asked to generate an overview of discussion topics and participants, find topics of interest, and summarize opinions while using DisVis (experimental group) or the original discussion board representation (control group). We compared individuals’ answers to a gold standard, generated by either members of the research team or a healthcare professional; the accuracy of individuals’ answers and time to answer were captured and analyzed. The evaluation session concluded with short qualitative interviews assessing individuals’ subjective impressions from the tool and opportunities for improvement. We will present the detailed results from this study and their implications for the design of new platforms for OHCs in the remainder of the paper.

Related Work

OHCs have become a topic of active investigation within several research communities, with the particular attention on information seeking practices of their members. Previous research within OHCs found that users expressed...
higher levels of satisfaction with their experience when their information needs were matched with appropriate information. Along these lines, previous studies explored common characteristics of health information seeking. These studies suggested that individuals prefer answers by others matched on profile similarity, highlighted the importance of context when posing queries, and suggested that search results should be personalized based on user's medical history. Consequently, recent trends in the research on OHCs increasingly favor new computational solutions for optimizing access to information, expertise and interest matching, mining members' contributions over time to infer their credibility, and using automated ways to extract personal information from members' contributions. In regards to information seeking in OHCs, Nambisan suggested the need to focus on developing tools that make information seeking more effective and efficient.

Beyond health-oriented discussion forums, other domains have explored the question of accessing discussion information through visualization in great depth, including visualization of enterprise flash forums, e-mails, and newsgroups. For example, ConVis is a system that enables the user to quickly form a topic-post-sentiment-author chain connection when inspecting the discussion. ForumReader is a tool developed for exploration and analysis of flash forums based on the thumbnail representation of the discussion. Themail builds a visual display of e-mail based interactions over time, while Newsgroup Crowds graphically represents the population of authors in a particular newsgroup in Usenet and AuthorLines visualizes a particular author's posting activity in the same platform. Other researchers have looked at preserving and visualizing the tree structure in the discussions using the sunburst radial space filling approach, icicle tree layout and adding reply-based sociogram view. Other approaches to visualizing large amounts of information relevant for this research were explored within topic based visual text analysis, large network data visualization with rich user interaction and visualizing social roles. Finally, previous research explored ways to visualize opinions about a product and opinions about ideas.

Despite this ongoing research on visualizing user-generated content collections, addressing information overload in OHC forums with visualization solutions has received limited attention in the past. Within this domain, previous research focused on topic modeling and network visualization to explore patients' experiences and on modeling interpersonal interactions and medication use, as well as health behavior and symptoms polarity. Another direction explored by previous research focused specifically on supporting community moderators. For example, VisOHC is a tool for OHC moderators that integrates visualizing the forum, aggregating diverse dimensions of conversational threads.

Although these systems and tools represent a rich body of knowledge about forum/discussion visualization, few of them focused specifically on helping members of OHCs overview discussion threads within their community, find topics of interest, and synthesize different opinions on these topics. As a result, the goal of this work was to design a simple discussion visualization tool that was tailored to discussions within OHCs, and to evaluate it with members of one such community. In the spirit of technology probes, we intended this prototype as a tool for proving a concept: testing the success of basic design approaches and eliciting user feedback.

**Methods**

**The Prototype: DisVis**

The design of DisVis was informed by our own previous studies of collective sensemaking within TuDiabetes and by review of related literature. Our particular focus was on assisting users in three main directions: 1) forming an overview of the entire discussion thread, 2) finding prevalent topics within a discussion, and 3) summarizing different opinions in regards to the prevalent topics. DisVis interface is logically divided into two main segments: Exploration and Navigation area (Figure 1-B) and Full Content area with a summary (Figure 1-A). These two segments were introduced to allow users to move seamlessly between exploring different aspects of the discussion and reading the text of interest in more detail, respectively. We describe these features in detail below.

**Discussion overview.** The first set of features described here was included to help individuals form a quick impression of the entire discussion thread. The Summary section (2) provides a brief summary of the discussion, including its key descriptors: number of posts, number of participants, duration, and keywords. The Index Panel (4) lists the most prevalent keywords (identified using frequency of keywords within the discussion) and most active contributors (number of posts) in descending order from left to right. The Content-contributor Overview Bar (12) provides the overview of where in the discussion a user talked about a particular keyword. The “k” label provides insight in the distribution of the presence of a given keyword in the discussion, selected from the Keywords in the Index Panel. Analogously, the “u” label does the same for a given user, selected from the Users in the Index Panel. The Timeline (13) gives the overview of when the posts were posted, thus helping to determine the distribution of
activity in the discussion over time. The Posts Length section (9) shows the amount of elaboration in terms of
numbers of words in each of the posts, the line length being proportional to it. The Replies Level section (10) gives
the overview of the users’ depth of engagement – the length of the blue bar represents the depth of the reply.

**Finding topics of interest:** the key feature for enabling this capability is the Keywords in the Index Panel (4). By
selecting a keyword from Keywords, only posts that contain that keyword are displayed in the Discussion section
(3), keeping their sequential order. A second level of filtering topics of interest is introduced in the Posts Keywords
(identified by tf-idf metric where a post is considered to be the document and the discussion the corpus) section (8),
where the user can see which are most important keywords for that particular post.

**Summary of opinions:** the key feature in this category is the Index Panel (4) again. By selecting a keyword from
Keywords and a discussion participant from Participants, the user can filter the posts that mention that keyword and
come from that participant.

![Figure 1](image_url)

A snapshot of the DisVis user interface in use with functionality markers: (1) Category and Heading; (2)
Summary; (3) Discussion; (4) Index Panel; (5) Interaction; (6) Context; (7) Authors; (8) Posts Keywords; (9) Posts
Length; (10) Replies Level; (11) Slider; (12) Content-contributor Overview Bar; (13) Timeline; (14) Time and Date.

In addition to these three main groups of features, the remaining features of DisVis allow for integration between
the two main segments (A and B). The most important of these is the Slider (11). Its cursor can be moved to point to a
given post in its graphical presentation. Here, each post is represented by a vertical line segment, preserving the
sequential order in the standard discussion representation (3); the different characteristics of these segments indicate
their length (line height - 9), keywords (8), author (7), chronological position (13), time and date (14), and depth of
engagement (rectangle height -10). To provide the social and informational context of the selected post, the
Interaction feature (5) shows the set of people the author of that post had interacted the most in the discussion and
through Context (6) it shows the posts that replied to it and the post it replied to.

**Usage scenario.** Elizabeth was recently diagnosed with Type 1 diabetes and was recommended an insulin pump as a
treatment. She has heard about TuDiabetes and decides to visit the forum to learn more about it. She finds a
discussion thread (displayed in the traditional way) that appears to be focused on insulin pumps, but finds that it has
5 pages of posts (a minimum of 41 posts). Elizabeth is not sure whether this is the right thread to focus on and
decides to use DisVis to learn more about who participated and what was discussed. From the Summary section (2),
Elizabeth can immediately see that 19 members of TuDiabetes participated in the discussion contributing 46 posts
over only 2 weeks, and that the main topics included insulin pump, infusion sets, insulin, MDI, basal rates and
She notices that one of the keywords included in the Index Panel (4) refers to the topic she is interested in, “pumps”, and decides to investigate further. Elizabeth also notices that many of the posts have multiple replies by looking at the Replies Level section (10), which suggests to her that participants engaged in a discussion over the topics of mutual interest. This high-level overview gives Elizabeth a good sense of the complexity, richness and duration of the discussion, as well as participants’ engagement. The initial post of the discussion is an appeal from Jennifer for troubleshooting unsuccessful insulin pump treatment and finding alternatives. After reading that, Elizabeth wants to explore Jennifer’s opinions about pumps and whether they changed during the discussion. In the Index Panel (4), she selects “Jenifer” as the user, and selects the keyword “pump” from the Index Panel (4) as her topic of interest. In the Discussion section (3), she sees filtered posts that contain “pump” as a keyword and Jennifer as the author. She then reads those posts and formulates the opinion that Jennifer had on pumps. She does that for 2hoobit1 and other participants. However, she also notices that participants are mentioning MDI as an alternative treatment. Elizabeth goes through an analogous process to find out what they think about MDIs. As a result of these explorations, Elizabeth forms a pretty good idea of the different perspectives on pumps that were expressed in this discussion, and how members’ perspectives changed over time. She also identifies an alternative treatment – MDI, that she can read more about in the future. She makes a mental note of the names of active participants and decides to pay attention to their posts in the future. And she is able to accomplish all of that in a matter of minutes, without reading every single post in this discussion thread.

**Study Design**

**Sample and setting.** The participants of the study were recruited among members of the TuDiabetes OHC using announcements on its home page and with the help of the community leadership. Being a member of this OHC was the only eligibility criterion for the study. The study was conducted on-line, using the Join.me shared screen platform for interacting with a discussion using the tool or within its original environment in TuDiabetes.

**Assessment measures.** There were three types (subsets) of questions used to evaluate the tool: S1, S2 and S3, with a total of 15 questions: a) general overview of the discussion (S1), related to providing a summary of the discussion - finding the key concepts discussed and most active participants, activity of the discussion, etc. (e.g. What were some key concepts discussed here?); b) finding topics of interest (S2), related to the ability to filter posts about a given topic (e.g. Who contributed the most posts that talked about infusion sets?); c) opinion synthesis (S3), related to finding what different opinions are on a given topic (e.g. How would you summarize the general opinion about MDI, do you think most participants think it’s a good idea, bad idea, or is there a split in opinions?). To assess participants’ accuracy, we developed a gold standard answers (GS) for each of the 15 questions. For purely objective questions (e.g.: How many individuals participated in the discussion?) the answers were generated by the members of the research team. For questions that required domain knowledge and synthesis of opinions (e.g.: What were the key concepts discussed in this post?), the gold standard answers were generated by a clinician (a doctoral student in nursing with experience in diabetes self-management). We took the following approach to measure the accuracy based on the developed gold standard. For answers that had a single discrete value, the score could be either 0 or 1 (accurate=1, inaccurate=0) and for those that had several discrete values, we calculated the Jaccard* similarity coefficient between the values provided in the answer and the GS answer. For those that were qualitative and more descriptive, we assessed the similarity by Jaccard to the GS based on the key points covered in the answer compared to the GS (each key point being a discrete value, hence the user’s answer and the GS answer being two sets of discrete values). To assess participants’ time to answer questions, the researchers reviewed audio records of the sessions and measured time (in seconds) from the end of the question to the end of the final answer provided by the participant. The participants were given a maximum of 5 min. to start answering a question. If in that time frame an answer was not provided, their accuracy score would get set to 0 and time to answer would get set to 300 sec (this never happened however).

**Study procedures.** Upon enrollment, the participants were randomized into the experimental condition or the control condition (N=5 for each group). The participants in the control group were presented with a discussion thread within its original environment, TuDiabetes, and were asked a set of questions about the information contained in the discussion. After they answered all the questions, they were presented with DisVis, received a short tutorial, and asked for their initial feedback about the tool. The participants in the intervention group were presented with the same discussion thread within the DisVis interface. After receiving the same tutorial for the tool, they were asked the same questions as the control group. Then, they were asked for their feedback on the design of the tool and their

* Jaccard similarity is a metric for measuring the overlap between two sets of discrete elements which can take a value between 0 and 1. A higher value means a bigger overlap.
experience using it. All evaluation sessions were done through the Join.me platform and audio recorded and transcribed verbatim for analysis.

**Analysis.** To find out whether DisVis had an effect, we performed a two-tailed two sample t-test for each of the two outcomes: time and accuracy. Additionally, we wanted to see the tool’s effect for each type of questions separately: S1, S2 and S3. Due to the small number of questions in each of the question categories, we used non-parametric Mann-Whitney U Test (Wilcoxon Rank Sum Test) to determine the statistical significance of our findings. For the ranking, we used the average performance of each participant for the given set of questions. For the qualitative data collected in the study (participants reflections on the tool and their experience with it) we used inductive thematic analysis. The recorded evaluation sessions were transcribed and open coding approach was taken to help us identify and categorize the prevalent themes from the user feedback. The first author (DN) coded all transcripts independently. The emerging categories were then discussed during meetings between the authors and iteratively refined in a collaborative process.

**Results**

Ten participants were recruited to participate in the study (N=5 in each group), 6 male and 4 female. More than half of the participants were above 60 years of age; diabetes diagnoses included both Type 1 and Type 2 diabetes having experience living with the disease ranging from 3 to 45 years (half of them for more than 20 years). The experience with the TuDiabetes.org ranged from only several months to being present in the community since its inception – almost 8 years. However, the vast majority of the participants were regular visitors of the forum, both for reading and contributing purposes; only one participant self-described as a sporadic user of TuDiabetes.

Noticeable differences were observed in the advantage the tool brings over the control group. The tool was shown to highly improve the accuracy of and time to answering questions. Also, participants in the intervention group outperformed those in the control group for some, but not all of the question sets tested. From Table 1 (All) we can see that the average time to answer a question for the control group was 65.52 sec (sd=46.77 and median of 63.8 sec) as compared to 40.51 sec (sd=26.38 and median of 37.6 sec) for the intervention group. The average accuracy score for the control group was 0.38 (sd=0.28 with median of 0.35), and 0.64 for the intervention group (sd=0.31 with median of 0.8). The t-test showed that there is an effect for the accuracy of answering when using the tool: the accuracy when using the tool being 68% higher than without the tool (p-value = 0.023). However, the positive trends in reducing the time to answer questions by 38% was shown to be statistically insignificant (p-value = 0.082). The tool was shown to perform better than or at least as good as the control in all cases, except for time to answer questions from S3. However, statistical significance was observed in only two of the cases in respect to question types: improving the accuracy of questions of type 1 (S1) and type 3 (S3), both with p-value = 0.016.

**Qualitative**

The focus of the qualitative interviews was on the participants’ subjective impressions of the tool and their experience using it. The analysis of the transcripts suggested that the participants’ experiences with the tool, and
with the forum at large, differed depending on their overall goal. In some cases, the participants came to the forum without any specific questions, but rather to look around for what’s new, which included browsing of recent additions to the discussion threads, and skimming of the new content. However, in other cases, the participants came to the forum with a particular question in mind and their interaction focused on identifying relevant information through reading relevant posts and threads, and comparing different opinions on the topic. Notably, these two scenarios were interchangeably utilized across most of the participants. Also, and not surprisingly, these two usage scenarios were associated with very different expectations for how to optimize individuals’ experiences and the desired set of functions within the forum. Below, we describe the participants overall assessment of the DisVis tool in terms of usefulness and usability, as well as the more specific comments from the perspective of browsing and searching for specific information.

**Overall assessment of the DisVis tool.** Overall, the majority of participants agreed with the general premise of the tool, and found its goal of increasing readability of discussion threads and promoting individuals’ ability to explore threads to be promising and potentially useful. P1: “Well, I think it’s a great idea because I’ve had some struggles reading discussions, to be honest...” P8: “Well, for sure the tool is good to have since it gives you a clear idea about what’s going on.” However, together with these positive general perceptions, the participants had many critical comments regarding the tools’ current design. Many thought it was too complicated and overthought and provided too much information, at times, without a clear purpose. P5: “And I back up a little bit more, from my way that I use the site, this stuff would be more noise than signal.” Notably, those who could not find personal use of the tool proposed that it might be most useful for those who started the thread, as well as for moderators, analysts, and researchers. P9: “I mean, if you are a scientist analyzing it [the discussion] and you are trying like to pinpoint things like you’ve been asking me, than I can understand it [the reason for using the tool], but just for an average reader – I don’t think I would use it.”

Finally, the participants were split in their opinions about the tool’s intuitiveness. Most users were able to successfully navigate the tool after the brief tutorial. However, several noted that they would require more experience using the tool to become proficient, which indicated limitations in its intuitiveness. P1: “…there are also I think some struggles at the beginning, but now I think with a bit like getting used to it, it’s not that difficult to use.” P2: “Well, you know I understood the instructions when you gave them, but putting them into practice, I think after I practice with it a couple or three times, I would have a down path, but just based on one run through, I don’t -- I would need more time to learn it and practice with it.” To address this problem specifically, given the number of different features available to users, several participants suggested the use of tool tips to remind them of the purpose of different features.

**Exploratory browsing.** While talking about their experience using the tool, many participants contextualized them within their overall experiences with TuDiabetes and its particular platform. As we mentioned above, these experiences fell within two distinct categories: exploratory browsing and focused information search. We found that many of the specific comments in regards to DisVis’s usefulness were also made in reference to its ability to support either browsing, or focused search.

Most participants made positive comments in regards to the tool’s ability to support browsing. For example, the participants found the overview of the discussion, Summary statistics of the discussion and the Timeline, to be particularly helpful. P2: “I like the dates, I like the date of the -- I really like knowing the timeframe of the thread and the number of participants. All of that summary information is very good.” On the other hand, the Slider did not live up to the expectations. For example, the interactive graphical part of the visualization that involved the Slider, developed for navigational purposes for quick browsing, caused the most negative reactions. This was primarily due to the density of information, small font size used in that area and poor adjustability for different screen sizes, especially for small screens. The participants had split opinions about the list of participants and their number. Some of the participants found those useful for formulating opinion summaries or knowing what positions to expect in the discussion; others found them somewhat irrelevant.

More generally, however, some participants questioned the tool’s attention on a single discussion thread as the only focus in the visualization. When describing their browsing experiences, these participants often talked about the need to see a discussion within the context of the forum, rather than as an isolated instance. P3: “I’m more inclined to look at all the discussions, all the responses.” These participants were likely to perceive individual threads as existing in a symbiotic relationship with other discussions that are on the same topic or have a certain amount of

---

* At the time of the study, TuDiabetes used Ning as its platform; since then the forum switched to Discourse
overlap in the topics they cover, alluding for a broader relevant context when reading a particular discussion. This colored their perceptions of the tool’s focus on a single discussion thread: P7: “...so if you clicked on pump you would see a list here of all of the discussions’ summaries of whatever, of, of whatever is related in, in another discussion, that, that would be good.” These participants wished to see the overlap between different discussions on the same topic, and to compare the topics between discussion threads. P10: “Perhaps instead of, instead of this, maybe, on keywords, if you clicked on insulin or mdi or pump instead of showing where it shows up, here, what other discussions are mentioning pump, insulin and mdi...” Participants were also interested to see forum wide statistics, a more quantitative description of what was going on in the forum: P3: “I might want to compare this to discussions and see what the keywords are for both and see if I could cross reference some keywords. I might also want to know what the community’s trending keywords are.” Finally, the participants proposed the following new features for more efficient skimming of discussions: highlighting keywords of interest in the text, finding the latest posts in the discussion, and labeling the read posts.

Focused information search. According to the participants, the tool was helpful in finding specific information of interest. The most-liked feature for this task was the Index Panel with its Keywords section. P2: “I would love to sort of sort out especially with long threads the ones that really went back to the key points of the initial discussion, like in this case pump and insulin I would probably because I’m an insulin user. I would probably pick on insulin and pump. So it does help me...” However, some participants thought they could not find much use of the Index Panel in real life, although it helped them answer the questions in the study. The participants also proposed specific enhancements to existing features. These included: more prominent highlighting of the selections in the Index Panel, and selection of multiple keywords for the purpose of building more complex Boolean queries.

Further, the participants made many comments regarding desired new features that could improve searching for specific information. These included features for identifying posts of relevance within a particular discussion (as was the case in DisVis) as well as for finding information of interest within the forum at large, or as some participants referred to it “starting from scratch”. P10: “So let’s say I go in, onto the home page, and I have a question about the pump... you know... how do I find it from scratch?! Instead of being right here on this open page that’s already started and everything, how would I get to that page from scratch?? – Do I see five different discussions going on, 20 different discussions and then, what would I do??” For the first case, the participants proposed keywords (terms) that distinguish a discussion from other similar discussions, as well as a keyword cloud. P4: “…I’m in the insulin pump users’ forum so I would already expect there to be discussions about the pump and oftentimes, a lot of the discussions are going to include comments about the infusion set, about the insulin, about the basal rates and multiple daily injections. So I guess the question for me is how could we better define keywords that actually provide more relevance... […] Yeah, I think more about differentiating the discussions [in terms of keywords] because I think a lot of people will come out in these forums and will search for somebody having the same issue or same challenge that they have today.” For the second case, the participants strongly wished for a better search engine, claiming that the current one is simply not delivering the most relevant and recent discussions, and it seems to be more oriented towards individual posts within a discussion, rather than a discussion as a whole. P1: “If you search for a key word it doesn't really show you what you are looking for, like searches for specific answers and I want the overall discussions, so that's not much of help...” In addition, an ability to identify clusters of discussions was highly desired as a feature that can improve the searching process. Finally, the participants liked the idea of exploring different opinions about a topic of interest. However, there was no clear agreement regarding the best way to achieve this. Some wished for a condensed, potentially computer-generated summary; others felt that only reading multiple posts from the same person on a topic of interest could help to synthesize their perspective, an ability which comes through long time presence in the community and reading of the forum.

Discussion

Previously proposed tools for visualizing participant-generated content explored several different perspectives. Many tools focused on providing an overview of the entire volume of the content collected (e-mails or news group postings), rather than focusing on a specific conversation. These included visualizations of interpersonal interactions and topics covered in those interactions; engagement of participants in discussions and individuals’ activity and volume of contributions over time. Other tools took an approach more consistent with the one explored in this work and focused on providing overviews of individual discussions as well as more detailed information about them. Some of these tools placed greater emphasis on finding relevant posts based on topics of interest and participants, while also incorporating information regarding the sentiment of the topic. Others were concerned with providing visual, often scatterplot-based depictions of clustered discussion content. These tools distinguished discussions and threads of conversation within the discussion, highlighted different topics and participants, and
importance of individual posts. The evaluation studies of these tools focused on users’ ability to find topics of interest, summarize, compare and contrast opinions, understand the sentiment about a topic, activity of the participants, their expertise and their interpersonal interactions and relationships. The authors’ activity oriented studies showed that knowing authors behavioral patterns in terms of activity and types of contributions was highly valued for understanding their roles and domain knowledge in the community. On the other hand, the discussion visualization studies found that users particularly liked the ability to find posts that match their topic of interest, which was found useful in answering questions related to summarizing opinions. Here, however, the findings about the importance of authors’ details were dependent on the task study participants were asked to complete.

Consistently with these previous studies, the participants in our study were positive about the general premise of an interactive tool for visualizing salient features of a discussion thread and exploring its different characteristics and attributes. We found that the participants viewed the tool in the context of two typical scenarios of use, corresponding to the two general types of engagement they experienced with the forum, a distinction not considered in the previous research. On one hand, they looked for features that could help to summarize the thread in a bird’s eye view, highlighting such characteristics as most prevalent keywords and most active participants. On the other hand, they particularly liked the possibility to find posts of interest using the Index Panel, which helped in finding specific pieces of information and formulating opinions about a topic. This is consistent with other studies which found that users particularly liked the ability to find posts that match their topic of interest. In addition, the participants valued an ability to view a temporal visualization of the discussion in the interactive timeline, an ability that has not received much attention in prior research, but was considered particularly useful in our study. These positive impressions were also supported by the results of the quantitative assessment: participants in the intervention group who used DisVis interface were able to answer questions related to the discussion thread with higher accuracy and in less time than the baseline. However, together with these positive impressions, the participants made a number of critical comments, particularly in regards to the tools’ intuitiveness and clarity. Most importantly, they found the information display to be too dense and hard to read, and some of the interactive features, for example the Slider, too difficult to operate. This can be related to a finding from another study, where participants underperformed when exposed to both visualization of the discussion and text analytics compared to a standard discussion representation. However, it contradicts our case in which, based on the quantitative findings, the complexity of the tool actually improved performance as compared to the baseline. From the perspective of general browsing, the participants questioned the tool’s focus on a single discussion thread, and desired an overview of topics of interest throughout all discussion threads in the forum. In contrast to our work, this kind of an approach was predominant in VisOHC which focused on OHC moderators. From the perspective of focused search for information, participants found one keyword selection to be limiting and wished for an ability to construct more complex queries. In addition, they wished for an ability to see keywords selected within the Index Panel highlighted in the discussion’s text.

The study helped us to formulate a number of design implications for the next generation of tools for visualizing discussions in OHCs. First of all, the study once again stressed the importance of designing tools that could be used by a variety of individuals regardless of their background, age, specifics of their disease, and computer literacy. Since these tools are likely to be used in an unsupervised fashion and without any possibility for training or instruction, they need to be intuitive and easy to learn. The study also generated a number of specific recommendations for features that could promote the two complementary ways of engaging with information. First, regarding the browsing experience, the desired features included: 1) discussion summary (statistics); 2) larger context, including immediate access to relevant discussions; 3) capabilities to estimate and locate the overlap between the relevant discussions; and 4) keeping track of what was read and what is new. Second, regarding the focused information searching, the desired features included: 1) description of the discussion that distinguishes it from the others; 2) building more complex queries to search a particular discussion and 3) computationally assisted ways to summarize different opinions within the discussion.

In addition, the study generated new design directions for helping individuals engage with user-generated content within OHCs. These include: a) identifying and highlighting relationships between different discussion threads, for example those that include similar topics and b) developing customizable mechanisms to summarize varying opinions on topics of interest. However, in regards to summarizing opinions, the participants lacked clear consensus on whether they were comfortable relying on computer-generated summaries or whether they preferred tools that helped humans to synthesize opinions in a more efficient way. This division is reminiscent of the long-standing argument about the comparative benefits of computational agents and information visualization displays with direct manipulation. Just as this debate came to the conclusion that an ultimate solution requires a combination of both
approaches, we suspect that future tools for supporting online discussion forums should incorporate both computational methods and information visualization techniques.

Study limitations. This study has a number of limitations. First, because the study relied on a real discussion thread captured within TuDiabetes, and because we did not screen participants on their previous exposure to this particular thread, it is possible that some of them saw it before the study. In fact, one of the participants mentioned that the thread looked familiar, but could not recall any specific details. In addition, because the study used only a single discussion thread, it is possible that the findings of the study are specific to this thread and may not generalize to other threads within the same forum or to other forums. In addition, the questions used for assessing the tool’s efficacy may not be relevant to all individuals who frequent OHCs. In fact, few of these questions were found less than relevant by some of the study participants. Additionally, sharing the screen occasionally caused some difficulties with interaction on the participants’ side for both study groups, which was more pronounced for those that needed to interact with the tool.

Conclusion
In this paper, we introduced DisVis – a tool for visualizing discussion threads in an OHC and discussed the results of a study examining DisVis’s impact on individuals’ ability to find information of interest and better understand discussion threads. The study showed that DisVis had a positive overall effect on individuals’ ability to provide overview of the discussion, find topics of interest and summarize opinions. The tool increased the accuracy of the answers by 68% and reduced the time to answer questions by 38% (the latter being statistically not significant). The study also showed that the community members are open to these types of solutions and suggested a set of enhancements and new features for the tool that we plan to address in our future work.

Abstract

In blood transfusion studies, plasma transfusion (PPT) and bleeding are known to be associated with risk of prolonged ICU length of stay (ICU-LOS). However, as patients can show significant heterogeneity in response to a treatment, there might exist subgroups with differential effects. The existence and characteristics of these subpopulations in blood transfusion has not been well-studied. Further, the impact of bleeding in patients offered PPT on prolonged ICU-LOS is not known. This study presents a causal and predictive framework to examine these problems. The two-step approach first estimates the effect of bleeding in PPT patients on prolonged ICU-LOS and then estimates risks of bleeding and prolonged ICU-LOS. The framework integrates a classification model for risks prediction and a regression model to predict actual LOS. Results showed that the effect of bleeding in PPT patients significantly increases risk of prolonged ICU-LOS (55%, p=0.00) while no bleeding significantly reduces ICU-LOS (4%, p=0.046).

Keywords: Blood transfusion, perioperative, bleeding, machine learning, classification.

Introduction

Great progress has been made in improving patient outcomes associated with major surgical operations in recent years. This has been manifested by the reduction in intraoperative and postoperative mortality and the overall reduction in transfusion requirements 1. Despite these advances, bleeding is still the most frequent serious complication during or early after major surgical procedures. For example, bleeding in the immediate postoperative period occurs in approximately 20% of patients undergoing liver transplant and about 12% in patients exposed to cardiopulmonary bypass 2. Bleeding in the perioperative period has been found in many studies to be significantly associated with increased health care resource utilization as reflected by increased intensive care unit (ICU) length of stay (LOS) 3;4, morbidity and mortality 5.

After major surgical operations patients are typically managed in the ICU, thus the duration of stay is an important indicator of the quality of care a patient receives as well as resource utilization. Patients with prolonged ICU-LOS generally comprise a very small proportion of all ICU patients, yet studies have repeatedly shown that they consume a significant share of ICU resources 6;7. Early identification of patients who might stay longer in the ICU can help improve resource utilization and efficiency of ICU care.

Many studies have reported risk factors for prolonged ICU-LOS and bleeding and a few have reported accurate models for early identification of patients who might experience these outcomes 6–8. The majority of these studies have considered the outcomes independently. Little attention has been given to the identification of patients groups with prolonged ICU-LOS or increased risk of bleeding attributable to other important clinical outcomes or interventions. A number of studies have investigated the attributable mortality and ICU-LOS of major bleeding using matched cohort analysis or Cox regression models 3,4,7. In the analysis, variables observed in the intraoperative and early postoperative periods are typically incorporated in the models for improved performance. For example, in Kramer and Zimmerman 7 predictive models for prolonged ICU-LOS that incorporate patient data observed as late as day 5 of ICU admission produced more accurate results than day 1 data. However, as such studies assume the availability of intraoperative and/or post-operative data they are inapplicable when only preoperative data is available. The authors of this study are unaware of any study that has investigated the causal relationship between prolonged ICU-LOS in patients intervened on with a treatment as plasma transfusion, and methods to early identify patients who might experienced these outcomes using only predictor variables observed at the preoperative period.

1Unless otherwise mentioned, any reference to bleeding will be understood as perioperative bleeding.
A key step to identify patients who might stay long in the ICU attributable to bleeding is to assess preoperatively, patients who might bleed during or early after surgery. Across many centers in the US, substantial emphasis is often placed on preoperative screening tests, such as the international normalized ratio (INR): a major driver of decisions about preoperative plasma transfusion. Fresh frozen plasma (FFP) infusions are commonly used to improve coagulation or clotting and are the main therapy option for patients with elevated INR. A large proportion of plasma components are transfused in the perioperative environment, however, they are frequently administered prophylactically in the absence of significant active bleeding. This practice persists despite a growing body of literature questioning its efficacy. Through the use of machine learning methods, a recent study conducted by the authors confirmed previous findings that population-wise, preoperative plasma transfusion (PPT) significantly increases the risk of bleeding, ICU-LOS, re-operation due to bleeding, and other important outcomes for patients undergoing non-surgical procedures.

The goal of this study is to present a causal and predictive framework where in a first step, the causal effect (attributable risk) of bleeding in patients offered PPT on prolonged ICU-LOS is estimated. Then in a second step, a predictive model estimates the risk of (1) bleeding and prolonged ICU-LOS attributable to bleeding in patients offered PPT, and (2) all causes of prolonged ICU-LOS. The predictive risk modeling step is designed as a two level structure where in the first level, a classification model estimates the probability of bleeding given that a patient was offered PPT. In the second level, a regression model is constructed specifically for patients identified by the first level model to be at high risk of bleeding to predict the actual ICU-LOS. Given that bleeding patients tend to have longer ICU-LOS as determined by the causal framework, the regression model therefore targets a more homogeneous group of patients at risk of prolonged ICU-LOS compared to the overall heterogeneous ICU population.

Prediction results for patients undergoing non-surgical procedures from the Mayo Clinic perioperative datamart showed that the classification model can effectively identify patients at risk of all courses of prolonged ICU-LOS and bleeding in patients offered PPT with AUC as high as 0.84, sensitivity of 0.79 and G-mean of 0.75. The regression model on the other hand can identify patients at risk of prolonged ICU-LOS attributable to bleeding in patients offered PPT with acceptable accuracy (MAE=0.86, median predictions within 2 day of true median ICU-LOS). Through a simple transformation of the bleeding and PPT variables, the causal inference showed that the effect of bleeding in PPT patients significantly increases the risk of prolonged ICU-LOS (55%, p=0.00) and “no” bleeding in patients offered PPT significantly reduces ICU-LOS (4%, p=0.046).

Study Setting and Datasets

Over the past few years, there has been a significant increased in the application of machine learning methods to solve medical and health care problems. Often the problem reduces to applying standard classification or regression models. However, there are some problems that challenges standard application of machine learning methods. Two of such problems are considered in this study: to find a meaningful association between longer ICU-LOS and bleeding due to PPT before surgery, and to identify patients who are at elevated risk of bleeding due to PPT and those at risk of all causes of extended ICU-LOS. This section presents a causal and predictive framework in attempt to address these problems.

Outcome-Treatment Variable Transformation

To facilitate the estimation of the effect of bleeding in patients offered PPT on prolonged ICU-LOS and prediction of the risk of bleeding, the training data is grouped into 4 mutually exclusive classes as shown in Table 1. Class A represents patients who bled and were given PPT while class B are patients who did not bleed but were also given PPT. A similar interpretation can be made for the other classes. Using baseline covariates measured before PPT, causal and predictive models can be constructed to to make inference on the four classes. Specifically, the causal inference considers each of the classes in Table 1 as a treatment or exposure variable and then computes its effect on prolonged ICU-LOS. Thus estimates of the treatment effect in class A can be interpreted as the causal effect of bleeding as a “complication” of PPT on prolonged ICU-LOS. The predictive inference on the other hand simply constructs binary classification models for each of the four classes. A multiclass classification model can equally be constructed for the 4 classes.

Effect of Bleeding as complication of PPT on prolonged ICU-LOS

The standard approach to investigate the causal relationship between a treatment or exposure (e.g. PPT or bleeding) and an outcome (e.g. ICU-LOS) is to construct statistical regression models in which the outcome is regressed against baseline covariates and the treatment variable. The attributable effect of the treatment is then read off as the corresponding regression coefficient. This study takes a different approach and estimates the treatment effect through application of machine learning methods. The theory of causal inference or technical details of the considered estimation procedure are beyond the scope of this study. The interested reader is referred to 13-15 for more details. However, for the purposes of this study, a brief discussion of the data structure required to compute these estimators is presented next.

Data structure and likelihood. The observations for each patient in the data set can be written as $O = (X, Y, Z)$ where $Z \in \{0, 1\}$ is the treatment indicator (e.g. class A, B, C or D in Table 1) with $Z = 1$ if patient was treated and $Z = 0$ if patient was not treated. $X$ is a vector of baseline covariates that records information specific to each patient prior to treatment. $Y$ is the outcome such as prolonged ICU-LOS (e.g. $Y = 1$ if ICU-LOS ≥ 7 days and $Y = 0$ if ICU-LOS < 7 days). The relationship between the observed variables in $O$ can be written in a factorize data likelihood as

$$Pr(X, Y, Z) = \frac{Q}{Pr(Z|X)Pr(Y|X, Z)Pr(X)}.$$  \hspace{1cm} (1)

$Pr(X)$ and $Pr(Y|X, Z)$ are referred to as the $Q$ component of the likelihood while $Pr(Z|X)$ is the $g$ component. $g(Z|X)$ represents the propensity or the causal disposition of the treatment to produce some outcome. $Q(Z, X) = E[Y|Z, X]$ is the expected potential outcomes conditional on the observed characteristics. Estimates of $g$ and $Q$ can be obtained by standard regression or machine learning methods.

For a binary outcomes and in the presence of no confounding variables, a straightforward approach to obtain the treatment effect is to compute the expectations $\psi_1 = E[Y|Z=1]$ and $\psi_0 = E[Y|Z=0]$, where $E[Y|Z=1]$ is the mean of $Y$ assuming every patient in the population was exposed at level $Z = 1$. These two statistics can then be combined in useful ways to assess the effect of different levels of the treatment. Three commonly reported summary statistics include: (1) Additive Treatment Effect : $ATE = \psi_1 - \psi_0$, (2) Risk Ratio : $RR = \psi_1/\psi_0$, and (3) Odds Ratio : $RO = RR \times (1 - \psi_0)/(1 - \psi_1)$.

The $ATE$ quantifies the additive effect of every patient being exposed to the event versus not being exposed. Thus if the event is class A i.e. bleeding as a complication of PPT, a meaningful interpretation of $ATE = 0.05$ could read: “being exposed to the event of bleeding as a complication of PPT versus not increases the risk of prolonged ICU-LOS by 5%”. The $RR$ quantifies the multiplicative effect of being exposed versus not. A $RR$ of 5 can be interpreted as: “being exposed to the event of bleeding as a complication of PPT versus not would lead to a 5 times increase in the risk of prolonged ICU-LOS”. Since the $OR$ is a function of $RR$, a similar interpretation can be given for $OR$.

Targeted maximum likelihood estimation. In observational studies, estimators of treatment effect need to account for possible confounding, i.e the (apparent) effect of the treatment is actually the effect of another characteristic which
is associated with the treatment and with the outcome. Several methods have been proposed for the estimation of ATE, RR and OR that can mitigate the effects of confounding (and model misspecification), e.g. G-computation formula, propensity score matching, inverse probability of treatment weighting (IPTW), and doubly-robust estimation. See 13,14 for more in-depth discussion of these estimators. In this study, the Targeted maximum likelihood estimation (TMLE) 15,16 method is considered because of its double robustness and bias reduction properties. TMLE is a two stage doubly robust semi-parametric estimation methodology designed to minimize the bias of the parameters of interest. The first stage of the method estimates the density of the data generating distribution (specifically $Q$) while the second stage solves an efficient influence curve estimating equation. The influence curve describes the behavior of the target parameter under slight changes of the initial density estimates. In TMLE, if either $g$ or $Q$ are consistently estimated, then the TMLE estimator is guaranteed to be asymptotically unbiased. However, TMLE will not return consistent estimates of the parameter of interest when both $g$ and $Q$ are misspecified. Thus it is important to avoid overfitting these measures.

As discussed above, estimating the two statistics $\psi_1$ and $\psi_0$ allows for calculating any of the causal effects ATE, RR and OR. The TMLE estimate of $\psi_z (z \in \{0, 1\})$ is given by

$$\hat{\psi}_z = \frac{1}{n} \sum_{i=1}^{n} Q^*(z, x_i)$$

where $Q^*(z, x_i)$ is an update of $Q(z, x_i)^2$. The targeting step for updating $Q(z, x_i)$ is done by fluctuating $Q(z, x_i)$ through a parametric sub-model of the form: $logit(Q^*(z, x)) = logit(Q(z, x)) + \varepsilon H_z(z, x)$, where $\varepsilon$ is the fluctuation parameter, $H(z, x) = I(Z = z)/\hat{g}(z, x)$ is the efficient influence curve equations, and $I$ is the indicator function. The MLE of $\varepsilon$ is obtained by a logistic regression of $Y$ on $H_z(z, x)$ with offset $logit(Q(z, x))$. Confidence intervals and p-value for TMLE can be obtained through the variance of the influence curve.

TMLE can use initial estimates of $Q$ and $g$ from any fixed parametric model such as generalized linear models (GLM) (e.g logistic regression). However, parametric models require assumptions regarding the functional form, distribution of variables and variable selection which are often not realistic such that model misspecification is difficult to avoid. It is therefore recommended to used machine learning methods that makes little or no assumptions and are able to estimate complex relationships between the outcome and observed variables.

**Two Level Predictive Model**

![Figure 1: Two Level Predictive Model](image)

In the proposed two level predictive model, classification models are constructed to predict each of the classes in Table 1. Specifically, a classifier is trained on a modified training set defined by $\{X, Y\}$, where $X$ is a matrix containing the patients baseline covariates and $Y$ is a binary variable representing one of the classes in Table 1 such that $Y = 1$ for all

---

2the hat (‘’) notation represents estimates of a parameter from the data
patients in the corresponding class and 0 otherwise. During training, the classifier is trained on the complete training set to predict $Y$ and a regression model is trained to predict ICU-LOS using a subset of the training set for which $Y = 1$. In the case where class A is the outcome of interest, the second level regression model is trained to specifically target patient at high risk of longer ICU-LOS. This is as a consequence of the known relationship between PPT, bleeding, and prolonged ICU-LOS from the literature $^{3,4,12}$, and specifically from causal relationship between these variables derived in this study.

Model validation proceeds as follows; given a new patient, the classification model is first applied to predict the outcome $\hat{Y}$ for the patient. If $\hat{Y} = 1$, then the regression model is applied to predict the corresponding ICU-LOS. Figure 1 illustrates the training and testing steps of the two level predictive model.

**Predicting prolonged ICU-LOS attributable to Bleeding as a complication of PPT.** Given that class A in Table 1 represents patients who bled and were administered PPT and the fact that bleeding has been found to be significantly associated with prolonged ICU-LOS $^{3,4,12}$, a regression model to predict ICU-LOS is constructed only for patients in this sub-population. The rationale behind this strategy is that since this sub-population is relatively homogeneous, the approach allows for optimal targeting of patients at risk of longer ICU-LOS attributable to bleeding as a complication of PPT compared to a model constructed on the general ICU population. Similar regression models can also be constructed for patients identified in each of the other classes in Table 1 to predict the actual ICU-LOS. Class B is of particular interest as these patients did not bleed but were administered PPT. The study of these sub-groups with respect to prolonged ICU-LOS could potentially shed lights on the characteristics of patients who stand to benefit from plasma transfusions.

**Predicting all causes of prolonged ICU-LOS.** Without taking into account any particular cause, prolonged ICU-LOS was defined as ICU-LOS $\geq 7$ days and classification models were constructed to predict this binary outcome. The 7 days threshold was chosen because it represented a reasonable number of days where physicians might be concern about a prolonged stay. This variable was also used in TMLE estimation to estimate the effects of the four exposures in Table 1 on ICU stays of 7 days or more.

**Experiments**

This section describes the study population and presents empirical evaluation results.

**Study Population**

The data used in this study are derived from the Mayo Clinic transfusion datamart$^{17}$ that captures demographics, disease conditions, laboratory test results, medications, operative and postoperative measurements and outcomes for all patients admitted to acute care environments. To be considered for study participation, patients must meet the following criteria: age $\geq 18$ years, noncardiac surgery and an INR $\geq 1.5$ in the 30 days preceding surgery. Between 2008 and 2011, a total of 1,233 patients were identified and comprised the study population.

**Baseline Variables.** Baseline patient demographics include age, height, weight, gender and the ASA status I-V classifications. Disease conditions included myocardial infarction, congestive heart failure, cerebrovascular disease, dementia, chronic pulmonary disease, diabetes mellitus, etc. Preoperative laboratory values included INR, hemoglobin, platelet counts, creatinine, albumin, and APTT. A total of 51 predictors were considered for inclusion in the analyses. Table 2 presents the characteristics segmented according to the four classes in Table 1. The table show that the four groups are significantly different across demographics (except gender), laboratory, medications, and planned procedure types. The groups are however similar across majority of disease conditions. Further, patients who bled and were offered PPT had significantly longer ICU-LOS compared to those who did not.

**Outcomes and Treatment.** Bleeding was taken as the World Health Organization (WHO) grade 3 bleeding events, defined as the need for early perioperative RBC transfusion$^{18}$. The term perioperative RBC transfusion was defined as the administration of allogeneic RBC components during the interval beginning with entry into the operating room and ending 24 hours after exit from the operating room. ICU-LOS is the number of days spent in the ICU after surgery. The treatment indicator PPT indicates if a patient was offered plasma transfusion after INR test and before surgery. ICU-LOS

ICU-LOS: A: 5.1, B: > 6.0, C: > 7.1, D: > 8.0, p < 0.001

Results

To demonstrate the effectiveness of the two level approach in identifying patients at risk of longer ICU-LOS attributable to bleeding as a complication of PPT, the second level regression model is compared with a regression model trained on the complete training data. The median predicted ICU-LOS and the true median ICU-LOS are also reported for the complete test set and for the top 75% percentile of the true distribution of ICU-LOS.

Figure 2 shows the distribution of observed ICU-LOS for the entire population truncated at 250 patients with no ICU admission and 30 days length of stay. It can be seen that the distribution of ICU stays is highly skewed to the right. Learning to identify extreme values at the tail of the distribution can be a very challenging task for a regression model constructed using the entire data. However, this task can be made easier if one focuses only on the extreme values.
The random forest (RF) and the gradient boosting machine (GBM) algorithms were considered for classification and regression. The algorithms were trained and evaluated using 100 bootstraps. On each bootstrap iterate, the algorithms are trained on approximately 63% of the data and the left out samples was used for testing. Model selection, i.e. hyperparameter tuning (by grid search) was done using a 5-fold cross-validation procedure. Random forest was trained with 1000 trees.

In calculating estimates of TMLE, RF and GBM along with 6 other algorithms: logistic regression, k-nearest neighbors, support vector machines, neural networks, decision trees, and lasso and elastic net were combined in a Super Learner algorithm. Super Learning is a strategy for combining several data-adaptive estimators into one improved estimator. Specifically, the functions $g$ and $Q_z$ in equation (2) are each estimated by these algorithms and combined by the Super Learner to produce better estimates. For comparison, estimates of TMLE are also computed using standard logistic regression (GLM).

**Effect of Bleeding as a complication of PPT on prolonged ICU-LOS.** Table 3 presents the TMLE estimates of ATE, RR, and OR quantifying the effect of each of the exposures in Table 1, all causes of bleeding, and PPT on prolonged ICU-LOS. Results for TMLE using the Super Learner and a simple main effect GLM are shown for comparison. However, it should be noted that diagnostic tests to ensure that the GLM model fit the data were not performed, thus subsequent discussions will be based on the Super Learner. To save on space, the discussions will also be restricted to
the ATE summary statistics; interpretations for RR and OR can be similarly made.

Results in Table 3 show that bleeding as a complication of PPT (exposure A in Table 1), all causes of bleeding, and PPT significantly increases the risk of prolonged ICU-LOS by 57%, 17% and 4% respectively (95% confidence intervals are shown in brackets). The event of no bleeding in patients offered PPT (exposure B) was found to reduce the risk of prolonged ICU by 4% (p-value = 0.05) while the event of bleeding when no PPT was administered (exposure C) increases the risk of prolonged ICU-LOS by 9%. These results illustrates that by a simple transformation of the treatment variable, one can identify groups of patients with differential effects of the treatment. Patients identified in group B might show beneficial effects of PPT and thus can be targeted for treatment to mitigate bleeding and reduce ICU-LOS.

Performance of Classification Models. Table 4 presents performance results for predicting the four classes in Table 1. Overall, the models performed very well. Best results for all classes was obtained for RF with AUC as high as 0.84 (class A) and 0.67 (class B). However, no significant difference was observed in the performances. For completeness, Table 4 also show the average per-class performance of a multiclass RF model trained using all four classes in Table 1. The the sensitivity of the multiclass model is however inferior to that of the least performing binary RF model.

Performance of Regression Models. Results for the two level predictive model (TwoLevel) as previously described is compared with regression models trained on the complete training set (OneLevel). Table 5 shows that the TwoLevel training approach makes smaller errors for classes A and D while OneLevel training makes smaller errors for classes B and C. These differences were however not significant. A close look at the actual predicted median ICU-LOS in days (see Table 6) for the top 75% percentile of the true distribution of ICU-LOS (i.e. longer ICU-LOS) show that TwoLevel regression models tend to make smaller errors for all classes. Overall, the predicted median ICU length of stay from the TwoLevel model were off from the observed median value by less than 2 days while OneLevel was at least 4 days.

D 0.33 (0.02,1.94) 0.48 (0.03,2.72) 0.00 (0.00,12.96)

These results show that using only pretreatment variables, with the TwoLevel model one can predict with high accuracy the risk of a patient bleeding as a complication of PPT and then use this information to determine if the patient is likely going to stay longer in the ICU with sufficient accuracy.

Important Characteristics of Patients at Risk of Prolonged ICU-LOS. Table 7 presents the top 10 important variables for the RF regression model (averaged over 100 bootstrap). The TwoLevel model identified the INR for patients who bled and PLT (platelet count) for patients who did not bleed in the case where these patients were offered PPT as the most predictive variables. Hemoglobin level was the most predictive characteristics for all patients. Though appearing in different order, six top variables are common to all models.

Conclusion

This study establishes a previously unknown causal relationship between prolonged ICU-LOS, bleeding, and PPT. Through a simple transformation of the bleeding and PPT variables, it was shown that the effect of bleeding in patients offered PPT more than doubled the risk of prolonged ICU-LOS, and that the event of no bleeding in patients also offered PPT significantly reduces the risk of prolonged ICU-LOS. Motivated by these results, this study developed a predictive framework for early identification of patients with (1) increased risk of all causes of prolonged ICU-LOS, and prolonged ICU-LOS attributable to bleeding as a complication of PPT, and (2) increased risk of bleeding as a complication of PPT. Given that the performance of models for ICU-LOS often deteriorate for patients with extended ICU-LOS, a two level predictive modeling approach was proposed to improve performance at the tail of the ICU-LOS distribution. The two level model was shown through a series of experiments using data for patients undergoing non-surgical procedures to be capable of identifying patient at risk or bleeding and longer ICU-LOS with acceptable accuracy. Based on the characteristics and predicted risk scores generated by the framework, patients at risk of extended ICU stays can be targeted and special intervention procedures implemented to reduce ICU-LOS and
improve perioperative care.

A possible weakness of this study is the use of the treatment effects \textit{ATE, RR} and \textit{OR}. As these are population averages, their use entails that the effect is uniform across sub-populations or individuals and therefore not very useful for characterizing the effect of the treatment for each patient. Thus, an interesting potential future study of this work is to investigate methods of combining the four probabilities in Table 1 to derive individualized treatment effects.

Abstract

The paper assesses the utility of Medtex on automating Cancer Registry notifications from narrative histology and cytology reports from the Queensland state-wide pathology information system. A corpus of 45.3 million pathology HL7 messages (including 119,581 histology and cytology reports) from a Queensland pathology repository for the year of 2009 was analysed by Medtex for cancer notification. Reports analysed by Medtex were consolidated at a patient level and compared against patients with notifiable cancers from the Queensland Oncology Repository (QOR). A stratified random sample of 1,000 patients was manually reviewed by a cancer clinical coder to analyse agreements and discrepancies. Sensitivity of 96.5% (95% confidence interval: 94.5-97.8%), specificity of 96.5% (95.3-97.4%) and positive predictive value of 83.7% (79.6-86.8%) were achieved for identifying cancer notifiable patients. Medtex achieved high sensitivity and specificity across the breadth of cancers, report types, pathology laboratories and pathologists throughout the State of Queensland. The high sensitivity also resulted in the identification of cancer patients that were not found in the QOR. High sensitivity was at the expense of positive predictive value; however, these cases may be considered as lower priority to Cancer Registries as they can be quickly reviewed. Error analysis revealed that system errors tended to be tumour stream dependent. Medtex is proving to be a promising medical text analytic system. High value cancer information can be generated through intelligent data classification and extraction on large volumes of unstructured pathology reports.

Introduction

The Queensland Cancer Registry (QCR) is a population based cancer registry that monitors and records the incidence and mortality of cancer in the State of Queensland, Australia over time by collecting cancer notifications from a variety of sources. The QCR collection, therefore, has a number of intrinsic values, which it derives from its population base, and provides the capacity to support longitudinal analysis. The QCR also supports key activities in Queensland and nationally such as health service planning and cancer research.

Pathology laboratories throughout Queensland are legally required to notify the Cancer Registry of pathology tests that contain a result of cancer. In Queensland, notifiable cancers to the registry include:

1. All invasive cancers excluding basal cell carcinoma (BCC) and squamous cell carcinomas (SCC) of the skin;
2. Any cancer with uncertain behaviour;
3. All in-situ conditions; and

All of the pathology cancer notifications are currently paper based and the incidence of cancers is increasing with the number of new cancer cases in Queensland increasing by more than 177% between 1982 and 2012; the growth in new cancer cases is largely due to population growth and ageing¹. A growing backlog is delaying the delivery of more timely cancer information due to the extent of manual processing and an out-dated information collection system. This highlights the need for introducing new technologies to assist with automating cancer registry processes.

With some updated technology changes, pathology laboratories can now send pathology electronically via HL7 feeds to the Queensland Oncology Repository (QOR). However, this is still not without its challenges. There is no mechanism to determine whether an electronic pathology message is cancer notifiable or not, apart from reading and interpreting the contents of the HL7 pathology report. As such, a computer-assisted approach is required to automatically identify pathology reports that are cancer notifiable.
Background

A number of systems have been proposed to address the automatic detection of cancer notifiable (or reportable) pathology reports. These systems rely solely on the use of custom made list of cancer and non-cancer related terms, phrases, and disease codes that may be institution specific, or the development of reportable cancer or tumour specific machine learning classification models\(^1\)\(^-\)\(^5\). The proposed method however aims to be generic supporting the full range of tumour streams (or types of cancers) from a breadth of pathology laboratories, report types and pathologists.

Commercial cancer finding and reporting systems that selects reports that contain reportable cancer findings based on dictionary and linguistic analysis are also available\(^6\)\(^-\)\(^7\). Although, conceptually similar to the proposed approach, it is unclear as to how much modification is required to achieve high levels of accuracy within the context of an Australian Cancer Registry.

The proposed approach is based on Medtex\(^8\). Medtex is an emerging medical text analytic capability that conducts intelligent data classification and extraction on large volumes of unstructured pathology reports, which can result in the generation of high value cancer information. Medtex has been developed to automate Cancer Registry notification using QCR business rules, natural language processing, and symbolic reasoning using SNOMED CT subsumption querying\(^9\)\(^-\)\(^13\). Medtex can assist in supporting the continuous improvement of cancer notification and enables improved decision support for Registry clinical coders.

Related work on automating cancer notifications using Medtex has shown that the system classified cancer notifiable reports with a sensitivity, specificity, and positive predictive value (PPV) of 0.98, 0.96, and 0.96, respectively, for an evaluation set of 479 histology and cytology reports\(^9\). Although very promising results were achieved, outperforming many of the systems in the literature, the dataset was very limited in size. The reports were selectively sampled such that an approximately balanced dataset resulted with half of the dataset covering a range of cancers, while the other half containing non-cancers. In spite of this, Medtex aims to be generic and was developed using Cancer Registry business rules and the normalisation and reasoning of reports using standard clinical terminologies; it does not rely on custom phrases, explicitly mentioned disease codes, or the development of machine-learning classification models\(^2\)\(^-\)\(^5\).

This research extends previous work and evaluates the utility of Medtex to identify notifiable cancer pathology reports on a larger and representative cancer population based dataset. Results show that high sensitivity and specificity can be achieved for a representative dataset containing a breadth of tumour streams, report types, pathology laboratories and pathologists. Analysis of discrepancies revealed that Medtex was able to 1) identify cancer patients not found in the QOR potentially underestimating the incidence of cancer and 2) actual system errors tended to be tumour stream dependent. These insights were not possible with the previous study that used a smaller and unrepresentative dataset. These insights also allow for specific system limitations to be addressed in future developments.

Method

System description

A high-level architecture of the Medtex medical text analytic system for cancer notifications classification and data extraction is shown in Figure 1.

In this paper, the cancer notification classification component of the system will be evaluated. A two-pass approach is adopted to classify whether pathology reports were cancer notifiable or not\(^9\). The first pass queries and filters pathology HL7 messages from the pathology data repository to identify report types that are required by the Cancer Registry, while the second pass analyses the free text reports and classifies them as either “Cancer Notifiable” (i.e., positive histology or cytology reports, excluding urine, sputum and pap smears), “Not Cancer Notifiable” or “Supporting Notifiable Reports” (i.e., those with further excisions resulting in no residual cancer, re-excisions and/or suspected notifiable cancers).

More specifically, Medtex is developed using the General Architecture for Text Engineering (GATE) platform\(^14\). It unifies the language in pathology reports by mapping spans in the text (e.g., clinical terms, abbreviations and acronyms, short-hand terms and relevant legacy codes) into SNOMED CT concepts\(^4\). Cancer notification identification is then based on finding the most likely primary site and histological type of the cancer based on SNOMED CT subsumption querying, and analyzing the report substructure and contextual information surrounding the concept to ensure that the concept’s mention was not modified by negative or uncertain assertions. Following QCR business rules, histological types that were either squamous or basal cell carcinoma (SCC or BCC) and was associated with the skin were classified as “Not Cancer Notifiable”\(^10\). Here, if SCC or BCC concepts were associated with a “skin” concept (i.e., concepts co-occurred within the same sentence), then such a classification would be made. The
QCR business rules are consistent and align with those nationally for the notification of cancers. More details on the cancer notification classification component of the system can be found in previous work.\(^9\)

The architecture supporting Medtex is characterised by a messaging framework built on the concept of message queues, producers and consumers\(^11,15\). Because multiple message consumers can be set up in parallel to receive messages from the same queue, Medtex provides high throughput, making it an ideal framework for analysing large streams of electronic pathology feeds.

Figure 1. High-level architecture of cancer notification classification and data extraction modules in Medtex.

The producer queries for pathology report types, which are potentially notifiable to the Cancer Registry (i.e., histology and cytology), and adds them to the input queue for Medtex processing. Medtex can then be set up either as a single instance or in parallel as consumers acting on the input queue, where each consumer will take a message from the input queue in turn for processing and analysis. The results from the Medtex analysis are then published to an output queue where another consumer can subscribe to the output queue to store the results in a SQL database. Figure 2 shows the database output schema portraying the range of cancer notification information extracted from pathology reports such as primary site of cancer, histology, grade, laterality, metastatic sites, as well as synoptic data including stage\(^9,13\).
Data collection and processing

With research ethics approval from the Queensland Health Research Ethics Committee, a corpus of 45.3 million HL7 pathology messages from the Queensland Oncology Repository (QOR), for the year of 2009 was used. QOR compiles and collates data from a range of Queensland cancer data source systems including the Queensland Cancer Registry (QCR), hospital admissions data, death data, treatment systems, public and private pathology and various hospital clinical data systems. The QOR is a resource managed by the Queensland Cancer Control Analysis Team (QCCAT) within the Department of Health, Queensland.

The corpus comprises of pathology laboratory results in the State of Queensland from the public health sector; these include bloods, tumour markers, etc. A total of 100 out of 114 possible unique report codes (or report types) were identified in the corpus. Upon filtering of the HL7 pathology feeds for histology and cytology report types (16 report types in total; e.g., histology frozen, histology biopsy, cytology (fluids), flow cytology, haematology) that are potentially relevant for Cancer Registry notifications, 119,581 histology and cytology reports remained for Medtex processing.

The histology and cytology reports were reported from 34 pathology laboratories in Queensland and therefore cover a breadth of report types, tumour streams (including non-cancer cases), laboratories and pathologists.

Performance evaluation

The 119,581 histology and cytology reports were analysed as a batch process by Medtex for reports requiring notification to the Cancer Registry.

These reports were consolidated at a patient level based on the exact matching of their first and last names, sex and date of birth (DOB). Patients with invalid or potentially multiple first/last name, sex and DOB combinations were removed from the analysis; for example, patients with punctuations in names (e.g., commas, quotes, hyphens), unknown sex and DOB. Patients with a combination of the above, for example, patients having same first name, sex and DOB but a different last name due to a hyphen (e.g., “FirstName LastName” and “FirstName MaidenName-LastName” with same DOB and Sex, and patients having the same first and last name and DOB as those with an unknown sex), were also removed from the analysis. The removal of such patients was to ensure that that the full set of reports processed by Medtex for a patient most likely corresponded to the set of reports for patients used by the Cancer Registry for cancer notifications coding.

A patient was classified as “Cancer Notifiable” if Medtex classified at least one of its reports as “Cancer Notifiable”, and vice versa, if Medtex classified all reports for a patient as “Not Cancer Notifiable”, then the patient was classified as “Not Cancer Notifiable”. For the purposes of the evaluations conducted in this paper, “Supporting Notifiable Report” classifications by Medtex were assumed “Cancer Notifiable” for the patient-level consolidation process. This assumption is likely to over estimate the number of patient-level cancer cases resulting from Medtex.
The QOR was used as the ground truth to identify actual patients diagnosed with cancer. A patient was considered to be “Cancer Notifiable” if the patient existed in the QOR database, and vice versa, the patient was assumed “Not Cancer Notifiable” if the patient could not be found in the QOR. A cancer clinical coder reviewed a stratified sample of 1,000 patients (each with potentially multiple reports) to analyse the agreements and discrepancies between Medtex and the QOR. A larger number of patients were selected from the stratum where Medtex and the QOR were in disagreement. This was purposely done to study the potential limitations of the system. The cancer clinical coder manually reviewed all the reports pertaining to the patients independently and classified their findings as “Cancer Notifiable”, “Not Cancer Notifiable” and “Supporting Notifiable Reports” in a similar way that Medtex classifies them. Again, results from a report-level were consolidated at a patient-level for analysis. Discrepancies between the coder’s judgements and that from Medtex and the QOR were analysed to uncover the cause of the discrepancy.

An adjusted contingency table (or confusion matrix) of True Positive (TP), True Negative (TN), False Positive (FP) and False Negative (FN) was generated (in light of the review of discrepancies) to compute the sensitivity (or recall), specificity, positive predictive value (or precision) and F1 score of Medtex in classifying cancer notifications.

**Results**

Medtex filtered the 45.3 million HL7 pathology messages and processed and analysed the 119,581 histology and cytology reports in just under 5 days using 3 Medtex instances running in parallel (average processing rate of 3.6 seconds per report). A range of cancer characteristics were extracted, however, the current evaluation is only concerned with the cancer notification classification output by Medtex. Upon patient consolidation and the removal of 1,359 patients whose reports could not be reliably aggregated at a patient-level based on the exact match of first and last name, sex and DOB, 85,502 unique patients remained for the evaluation against cancer patients from the QOR.

The contingency table showing the distribution of matches and mismatches between Medtex and the QOR at a patient-level is shown in Table 1.

**Table 1.** Contingency table of patient matches and mismatches between Medtex and the Queensland Oncology Repository (QOR).

As there were a high number of discrepancies between the information contained in the QOR and the classification output by Medtex, a stratified sample of 1,000 patients was randomly selected from the quadrants of the contingency table for manual review by an experienced cancer clinical coder. The breakdown of the patients and their reports are summarised in Table 2.

A summary of the results and analyses are reported in the following section. The aim of the analyses is two-fold: 1) to generate an adjusted contingency table to determine the indicative performance of the system, and 2) identify insights and system limitations for ongoing research and development. The classification results from the cancer clinical coder and Medtex and associated detailed error analyses can be made available upon request.
1. Analysis of Medtex patient notifiable classification and patient exists in the QOR

The manual review of 150 patients that exist in the QOR and were also classified as “Cancer Notifiable” by Medtex revealed that there were 8 patients whose reports did not suggest the need for a cancer notification; these patients existed in the QOR but for cancers diagnosed in other years (not in 2009). An error analysis on these Medtex misclassified cases were observed to fall into two categories, namely, 1) Medtex misclassifying SCC/BCC of the skin, which are to be excluded from Cancer Registry notifications, and 2) other algorithm related issues from Medtex such as the missed detection of negative assertion phrases. Due to the 8 false positive cases, there is an error rate of 8/150 = 0.0533 (95% Confidence Interval (CI): 0.025-0.1059). Extrapolating these false positive findings within the respective patient stratum revealed that 682 patients (i.e. error rate x 12,799; 95% CI: 320-1,356) were Medtex notifiable but indeed did not have cancer; thus requiring adjustment.

2. Analysis of Medtex patient not notifiable classification and patient not exist in the QOR

The manual review of 150 patients that did not exist in the QOR and were also classified as “Not Cancer Notifiable” by Medtex revealed that there was 1 patient whose reports did suggest a cancer notification. Upon consultation with the QCR, it was confirmed that the patient case would indeed be not notifiable. As a result, no adjustments were required for patients within this stratum where the patient did not exist in the QOR and Medtex patient is not notifiable.

3. Analysis of Medtex patient not notifiable classification and patient exists in the QOR

The manual review of 350 patients that exist in the QOR but were classified as “Not Cancer Notifiable” by Medtex revealed that there were:

- 9 patients whose reports did suggest the need for a cancer notification,
- 6 patients whose reports contained supplementary-only material for cancer notifications, and
- 335 patients whose reports did not suggest the need for a cancer notification.

An analysis on the 335 patients in the QOR with non-notifiable reports revealed that 30 patients were diagnosed in 2009 but had non-notifiable 2009 reports due to patients being either 1) from the private sector or from another Australian state, 2) having cancer notifications from other sources beyond histology and cytology reports, for example, hospital notifications, and 3) having incomplete records due to the inaccessibility of reports occurring in early 2009 due to pathology feeds only being fully operational from mid-March 2009. The remaining 305 patients in the QOR with non-notifiable 2009 reports were cancers diagnosed in other years. Due to the 335 true negative cases, there is an adjustment rate of 335/350 = 0.9571 (95% CI: 0.9287-0.9749). Extrapolating these true negative findings within the respective patient stratum revealed that 10,549 patients (i.e., adjustment rate x 11,021; 95% CI: 10,235-10,744) were correctly classified as Medtex not notifiable; thus requiring adjustment.

With regards to the 9 patients where Medtex did misclassify reports as “Not Cancer Notifiable”, these errors were observed to broadly fall into 3 categories, namely, 1) Free text to SNOMED CT mapping errors, 2) Incorrect implementation of Cancer Registry business rules, and 3) other algorithm related issues from Medtex such as the incorrect application of negative assertion phrases to SNOMED CT concepts. These algorithmic issues can be the target of future refinements and therefore may be possible to rectify and resolve through the updating of business rules and improvements to the Medtex free text to SNOMED CT mapping engines and negation detection algorithms. Due to the 9 false negative cases, there is an error rate of 9/350 = 0.0257 (95% CI: 0.0126-0.05). Extrapolating these false negative findings within the respective patient stratum revealed that 283 patients (i.e., error rate x 11,021; 95% CI: 139 to 551) were Medtex not notifiable but do contain cancer. As these cases are within the correct patient stratum where Medtex classified a patient incorrectly as “Not Cancer Notifiable”, no further adjustments were required for these errors. These cases may be considered as high importance as these represent missed cancer cases. But as mentioned above, these errors can be potentially rectified or resolved through further system improvements.

4. Analysis of Medtex patient notifiable classification and patient not exist in the QOR

The manual review of 350 patients that do not exist in the QOR but were classified as “Cancer Notifiable” by Medtex revealed that there were:

---

1 95% confidence interval calculated using Wilson’s procedure (including continuity correction; http://www.vassarstats.net/prop1.html)
• 82 patients whose reports did suggest the need for a cancer notification,
• 23 patients whose reports only contained supplementary-only material for cancer notifications (as well as another 68 classifications where both Medtex and the cancer clinical coder assigned patients as “Supporting Notifiable Report”), and
• 125 patients whose reports did not suggest the need for a cancer notification.

An error analysis on the 125 patients that Medtex misclassified as “Cancer Notifiable” revealed that the majority of cases were misclassified into particular tumour streams such as skin (misclassifying melanoma and SCC/BCC of skin; Medtex was unable to ascertain whether the SCC/BCC was associated with “skin”), brain and blood cancers. Due to the 125 false positive cases, there is an error rate of 125/350 = 0.3571 (95% CI: 0.3073-0.4101). Extrapolating these false positive findings within the respective patient stratum revealed that 1,135 patients (i.e., error rate x 3,178; 95% CI: 977 to 1303) were Medtex notifiable but do not contain cancer. As these cases are within the correct patient stratum where Medtex classified a patient incorrectly as “Cancer Notifiable”, no further adjustments are required for these errors.

Regarding the 82 patients who were not in the QOR but were indeed cancer notifiable patients, 9 of the patients were recorded in the QOR with different names and therefore could not be computationally matched. Of the remaining 73 patients who could not be found in the QOR, 52 cases related to leukemia, prostate and cervix cancers. Others were distributed with low frequency counts across other tumour streams. In terms of histological type, 57 out of the 73 patients had cancers in the following four morphologies: SCC, CIN 3, adenocarcinoma and chronic lymphocytic leukaemia, B-cell type. Others were distributed with low frequency counts across other morphologies. Due to the 82 true positive cases, there is an adjustment rate of 82/350 = 0.2343 (95% CI: 0.1916-0.2829). Extrapolating these true positive findings within the respective patient stratum revealed that 745 patients (i.e., adjustment rate x 3,178; 95% CI: 609 to 899) were Medtex notifiable and patients were in fact “Cancer Notifiable”. Note that 663 (i.e., 73/350 x 3,178; 95% CI: 534 to 813) out of the 745 (95% CI: 609 to 899) “Cancer Notifiable” patients were not found in the QOR. These cases may be considered as high importance as these cases result in unreported cancers.

**Adjusted contingency table and overall system performance**

In light of the analysis of the comparisons between the QOR, Medtex, and an expert clinical coder, adjustments to Table 1 were required in order to reflect the true performance of Medtex. In particular, the following adjustments were required:

• 682 (95% CI: 320 to 1356) “Cancer Notifiable” patients identified by Medtex but were “Not Cancer Notifiable”
• 10,549 (95% CI: 10,235-10,744) “Not Cancer Notifiable” patients identified by Medtex who are in the QOR but did not have cancer notifiable 2009 pathology reports, and
• 745 (95% CI: 609 to 899) “Cancer Notifiable” patients identified by Medtex who were not in the QOR but indeed had cancers.

Furthermore, to take into account of “Supporting Notifiable Report” classifications, which may over estimate the number of “Cancer Notifiable” cases during the patient-level consolidation process by Medtex, this effect was accounted for by further adjusting the contingency table, especially in the patient stratum where Medtex classified a patient as “Cancer Notifiable” but the patient did not exist in the QOR; here there were 68 out of the 350 cases where both Medtex and the cancer clinical coder assigned patients as “Supporting Notifiable Report” within the respective patient stratum. As a result, there is an adjustment rate of 68/350 = 0.1943 (95% CI: 0.155-0.2405). Extrapolating this result within the respective patient stratum reveals that 617 patients (i.e., adjustment rate x 3,178; 95% CI: 493 to 764) were Medtex “Cancer Notifiable” but were technically “Supporting Notifiable Reports”. A further adjustment is therefore applied to the contingency table:

• 617 (95% CI: 493 to 764) Medtex “Cancer Notifiable” patients who were not in the QOR but are technically “Not Cancer Notifiable” due to “Supporting Notifiable Report” classifications, indicating either suspected or re-excisions with no residual cancers.

Table 3 presents the adjusted contingency table and Table 4 presents a summary of Medtex’ performance in terms of sensitivity, specificity, positive predicted value and F1 score.

Discussion

Medtex achieves high sensitivity and specificity in identifying cancer notifiable patients from histology and cytology HL7 reports in line with the results from previous work using a smaller and unrepresentative dataset. As a consequence of Medtex’ high sensitivity, the system was able to identify cancer patients who were not found in the QOR. The high sensitivity, however, was at the expense of PPV. Although the effect of “Supporting Notifiable Report” classifications on false positives was partially taken into account, the lower PPV is considered to be of lower priority (or importance) as these cases can be quickly reviewed manually. The observed lower PPV finding was only possible through this larger scale study with a larger range of report types, tumour streams, pathology laboratories and pathologists; previous work on a smaller dataset did not reveal this. Error analysis reveals that system errors (both false negative and false positives) were mainly tumour stream dependent and therefore could be targeted as part of future work. Future work would also include the evaluation of cancer notifications at a cancer case level to ensure that “Cancer Notifiable” patients were correctly matched to their specific cancers.

Unlike other approaches to cancer notifiable classification that rely on custom phrases, explicitly mentioned disease codes, or the development of tumour specific classification models, Medtex aims to be generic and relies on Cancer Registry business rules and the normalisation and reasoning of records using standard clinical terminologies, specifically SNOMED CT. Although, the symbolic rule-based approach used in Medtex was developed from a small development data set, the current study shows how the utility of such a system can be assessed when applied on larger datasets. The findings from this larger dataset study can be used to bootstrap the development of the symbolic rule-based system. Machine-learning approaches to classification require larger training datasets to generalise but labelled data can be difficult to obtain especially from busy and highly skilled health personnel.

The Medtex processing of reports can also be applied at pathology laboratories to assist with fulfilling mandatory cancer notification requirements. Medtex could be used by pathology laboratories to accurately and automatically flag cancer reports for notification to cancer registries. Not only would this benefit cancer registries, but also individual pathology laboratories; thus improving cancer notification management.

Medtex also has the added advantage of producing uniform data, reducing manual processing and assisting in preventing inaccuracies in the data. This can allow cancer registries and pathology laboratories to devote staffing resources to other high value adding areas such as quality assurance, data integrity and manage the registry in a cost effective manner.
Conclusion

The utility of a medical text analytic system, Medtex, on automating Cancer Registry notifications from narrative histology and cytology HL7 reports from an Australian state-wide pathology repository was assessed. The system was developed using Cancer Registry business rules, natural language processing and symbolic reasoning using the SNOMED CT ontology. Cancer report notifications were consolidated at a patient level and compared against patients with notifiable cancers from the Queensland Oncology Repository (QOR).

A stratified random sample of 1,000 patients was manually reviewed by an expert clinical coder to analyse agreements and discrepancies. Upon extrapolation of the results to the full dataset, sensitivity of 96.5% (95% CI: 94.5-97.8%), specificity of 96.5% (95.3-97.4%), positive predictive value of 83.7% (79.6-86.8%), and an F1 score of 89.6% (86.4-91.9%) were achieved for identifying cancer notifiable patients. Medtex was also able to identify cancer patients that were not found in the QOR; resulting in unreported cancers. Error analysis revealed that system errors tended to be tumour stream dependent with specific cancer sites and histological types causing a large portion of the errors. The evaluation of Medtex on large-scale medical records enabled insights for assessing the utility of the medical text analytic system as well as highlighting avenues for future system developments.

The system is currently being piloted within the Department of Health, Queensland Government, to process the historical and new incoming electronic HL7 pathology reports, not only for identifying cancer notifiable cases, but also the automatic extraction of cancer notifications data including cancer stage.

The Medtex processing of other sources of cancer notification including feeds from private pathology laboratories, radiology reports and death certificates is also currently being investigated. Medtex can also be applied to other medical domains beyond cancer.

Acknowledgements

This research was done in partnership between the Australian e-Health Research Centre (AEHRC) within CSIRO and the Queensland Cancer Control Analysis Team (QCCAT) within the Department of Health, Queensland Government. The authors acknowledge Stephen Armstrong and Nilesh Mendis from QCCAT for data access as well as help in getting Medtex deployed on the Department of Health’s infrastructure.

Tracking the Remodeling of SNOMED CT’s Bacterial Infectious Diseases

Christopher Ochs, PhD¹, James T. Case, DVM, PhD², Yehoshua Perl, PhD¹
¹New Jersey Institute of Technology, Newark, NJ; ²NLM/NIH, Bethesda, MD

Abstract
SNOMED CT’s content undergoes many changes from one release to the next. Over the last year SNOMED CT’s Bacterial infectious disease subhierarchy has undergone significant editing to bring consistent modeling to its concepts. In this paper we analyze the stated and inferred structural modifications that affected the Bacterial infectious disease subhierarchy between the Jan 2015 and Jan 2016 SNOMED CT releases using a two-phased approach. First, we introduce a methodology for creating a human readable list of changes. Next, we utilize partial-area taxonomies, which are compact summaries of SNOMED CT’s content and structure, to identify the “big picture” changes that occurred in the subhierarchy. We illustrate how partial-area taxonomies can be used to help identify groups of concepts that were affected by these editing operations and the nature of these changes. Modeling issues identified using our two-phase methodology are discussed.

Introduction
SNOMED CT [1] is a large and complex medical terminology that is maintained by the International Health Terminology Standards Development Organization (IHTSDO) [2]. Extensive editorial work goes into each SNOMED CT release. Additional content, in the form of new concepts and new relationships, is added and existing content is revised to address errors and inconsistencies, while content that is no longer valid is retired.

The IHTSDO sometimes focuses editorial resources on a specific portion of SNOMED CT’s content. The Bacterial infectious disease subhierarchy, with over 2000 concepts, underwent significant remodeling in the July 2015 and Jan 2016 releases. The editorial staff at the IHTSDO determined that the concepts in this subhierarchy were modeled inconsistently. The goal of the remodeling is to make stated changes that enable SNOMED CT’s classifier to better infer correct hierarchical relationships. The still ongoing revision has affected hundreds of the Bacterial infectious disease concepts, requiring thousands of individual editing operations. SNOMED CT’s editors and end users need to be aware of the overall impact of these modifications on the content of the terminology. Editors need to ensure that all of their modifications were correct and end users need to know that their systems will still work correctly.

In this paper we analyze how the current, but incomplete modifications to the concepts in the Bacterial infectious disease affected the subhierarchy. However, the task of analyzing changes across multiple SNOMED CT releases is not straightforward. The IHTSDO does not provide a “user friendly” change log. A list of individual changes (a “delta”) is provided with each release, but one editing operation may result in multiple entries. The delta provides no additional information about the change (e.g., is the new target of a relationship more specific, less specific, or unrelated to the old target?), or what motivated it. Additionally, a list of changes, as provided by the delta, does not provide the “big picture” of what changed. When hundreds of concepts are modified it is difficult to review each individual change. As a result, an editor or end user may decide to avoid an in-depth review of the changes. However, such a review is critical, not just to ensure the correctness of each change, but also because some changes result in unintended consequences, causing new errors and inconsistencies, as demonstrated in Wang et al. [3].

To support the identification and analysis of structural changes between SNOMED CT releases we introduce a two-phase summarization-based approach. First, we introduce a method to create a human-readable SNOMED CT change log (based on the delta files provided with each release) that captures and summarizes the individual structural changes that occurred in the stated and inferred versions of SNOMED CT. Second, we utilize partial-area taxonomies[4], which summarize structurally and semantically similar concepts, to capture a summary of the major changes that occurred to groups of these similar concepts. We use this two-phase approach to identify significant structural changes in the Bacterial infectious disease subhierarchy. Between the July 2015 and Jan 2016 releases we identified thousands of editing operations applied to hundreds of concepts. We illustrate how the remodeling significantly affected, and continues to affect, the content of the subhierarchy.

Background

SNOMED CT
The Jan 2016 release of SNOMED CT consists of over 300,000 active concepts and over 1.5 million relationships among these concepts. SNOMED CT is released as a series of tab-delimited files that represent the concepts,
relationships, and descriptions of the terminology. SNOMED CT is based on Description Logics and it is distributed with both the stated relationships, which were explicitly defined by SNOMED CT editors, and inferred relationships, which were obtained by applying a reasoner to the stated relationships. Each SNOMED CT release comes with a “snapshot” of the terminology, which contains all the content for a given release, and with a “delta,” which identifies the individual changes that occurred between the last two releases. A full history of changes for every concept is also provided.

Various studies have looked at SNOMED CT’s content. Ceuster’s [5] analyzed changes in 18 releases of SNOMED CT and identified the need for better documentation of changes. Specifically, documentation on what motivated SNOMED CT authors to introduce changes of a certain type was identified as important. Rector et al. [6] and Mortensen et al. [7] looked at quality issues in SNOMED CT content.

**Partial-area Taxonomies**

We define an Abstraction Network [8] as a hierarchy of nodes, where each node represents a set of structurally similar concepts. It serves as a compact summary of a terminology’s content and structure. In previous work [4, 9-11], we have developed different Abstraction Networks to summarize biomedical terminologies and ontologies, such as the National Cancer Institute thesaurus (NCIt) [12], the Gene Ontology (GO) [13], and SNOMED CT. We have shown that Abstraction Networks support various SNOMED CT use cases, such as quality assurance (QA) [4], characterizing the modeling complexity of SNOMED CT [14], and observing changes to content due to QA [15].

One Abstraction Network we developed to support SNOMED CT QA is the partial-area taxonomy [4, 11], which summarizes groups of structurally and semantically similar concepts. We define a subject subtaxonomy as a partial-area taxonomy rooted at concept that represents a subject area (e.g., Bacterial infectious disease). In Ochs et al. [4] we looked at the properties of subject subtaxonomies for ten important Clinical finding subhierarchies (e.g., Cancer and Heart disease). We will now illustrate the derivation of a subject subtaxonomy using an excerpt from the Jan 2016 release of SNOMED CT using Bacterial infectious disease as the selected subject concept.
Given a SNOMED CT subhierarchy rooted at a concept $c$, we define an area as the set of all concepts in the subhierarchy with the same set of attribute relationship types. Only the types of the relationships are considered; target concepts are disregarded. Areas are named after their set of attribute relationship types (e.g., \{Causative agent, Pathological process\}). We say that the set of concepts summarized by an area are structurally similar, as the concepts are modeled using the same set of attribute relationship types. All areas are disjoint in terms of the concepts they summarize. We define an area taxonomy as an Abstraction Network composed of areas that are connected by hierarchy child-of links based on the underlying IS-A relationships. We define a root concept of an area as a concept that has no parent concepts in its area. An area $A$ is child-of another area $B$ if a root concept in $A$ has a parent concept in $B$. Figure 1 (b) shows the area taxonomy derived from the concepts in Figure 1 (a).

A partial-area consists of a root concept and all of its descendant concepts in its area. Partial-areas are named after their root and labeled with the total number of concepts summarized (this will be written using parenthesis, e.g., Bacterial sepsis (2)). Partial-areas summarize subhierarchies of semantically similar concepts within each area, since all of the concepts in the partial-area are descendants of the root. Multiple partial-areas may summarize the same concept. A partial-area taxonomy is an Abstraction Network, consisting of partial-area nodes, that refines an area taxonomy by explicitly identifying these subhierarchies of semantically similar concepts. Figure 1 (c) shows the partial-area taxonomy (subject subtaxonomy, since it is rooted at a chosen subject concept) for the concepts in Figure 1 (a). We note that partial-area taxonomies can be derived using inferred or stated relationships. To derive partial-area taxonomies we developed a software tool called BLUSNO [16], which provides a user interface for exploring partial-area taxonomies across multiple SNOMED CT releases.

**Terminology Diffs**

We note that there has been extensive work in the area of detecting changes between terminology releases (“diffs,” e.g., [17, 18]). As noted earlier, SNOMED CT provides pre-computed diff information with each release in the form of delta files. In [19] we observe that terminology diff tools often output an overwhelming amount of information (i.e., tens of thousands of identified changes) when many concepts are modified. The two-phase approach described in this paper visually identifies changes to sets of similar concepts, reducing the amount of information one has to view, and provides a more descriptive list of changes than is provided by many diff tool.

**Methods**

To determine how SNOMED CT’s content changed it is necessary to have a list of the editing operations that were applied to the concepts. SNOMED CT’s editors do not maintain such a list and there is no record of justifications for changes. We look at the stated changes SNOMED CT’s editors applied and their effect on the inferred version of the terminology. The delta files provided with each release are not “human readable” and one editing operation may be represented by multiple entries. For example, in the stated version of the July 2015 release, the concept Bacillus infection due to Bacillus had a parent Disease due to Gram-positive bacteria that was replaced by a more general parent, Disease. In the delta file this is expressed as two changes: the removal of the IS-A relationship to Disease due to Gram-positive bacteria and the addition of the IS-A relationship to Disease. There are thousands of entries in the delta file due to the changes in the Bacterial infectious disease subhierarchy. While a list of changes will provide a glimpse at the structural editing operations that were applied, such a list does not give the “big picture” of the overall impact of the changes. Thus, a methodology for detecting and visualizing the overall impact of the changes in the inferred version of SNOMED CT is also necessary.

**Editing Operation Detection and Summarization**

A relationship $r_i$ we abbreviate this as $(s_i, t_i, d_i, g_i)$. In the following we refer to a relationship that no longer exists in a release as an inactive relationship and we refer to a new relationship in a release as an activated relationship. Given the set of activated and inactive relationships, as expressed in one release’s delta files, we can infer the editing operations that were applied and create a “human readable” log of changes that also reduces the overall complexity of the change information. Table 1 identifies five kinds of editing operations that can be detected in the delta file.

We distinguish between hierarchical changes and changes to attribute relationships. We separate editing operations 1–4 in Table 1 into operations applied to IS-A relationships and operations applied to attribute relationships (e.g., added parent and added attribute relationship). These editing operations can be computed using the delta for the stated relationships (i.e., editing operations applied by a SNOMED CT editor) or from the delta for the inferred relationships (i.e., the implicit changes that were inferred by the classifier).
We note that it is possible to identify other kinds of editing operations using the approach described in Table 1. For example, Tuberculous dactylitis has a removed Finding site relationship to Finger structure and an added Finding site relationship to Entire digit. This could be considered a “changed attribute relationship target” operation. In this study we found relatively few removed relationship editing operations. Thus, for this study, we do not explicitly identify this kind of operation. From the delta files we can also infer why some changes occurred. For example, if a destination concept in a relationship is deactivated then it would necessitate that the target change, if the kind of relationship is still needed to model the source concept.

**Table 1.** Five kinds of editing operations which can be identified from SNOMED CT’s relationship delta file

Tuberculoma => Disease

To enable our editing operation analysis we created a module for the BLUSNO system that is able to process the delta files and output the editing operations. Output is provided as tab delimited text.

**Reflecting on Change Using Subject Subtaxonomies**

Subject subtaxonomies summarize groups of structurally and semantically similar concepts, all of which are related to a chosen subject concept (e.g., Bacterial infectious diseases). By comparing the areas and partial-areas in the partial-area subtaxonomies derived for multiple SNOMED CT releases, one obtains a summary of the major changes that occurred. Consider the examples in Figure 2, which capture how many of the 372 concepts in the Jan 2015 Bacterial infection by site (372) partial-area, in the \{Causative agent, Finding site, Pathological process\} area, changed in July 2015 and Jan 2016. We identify several significant changes based on the subject subtaxonomies in Figure 2. These changes result in modifications to the areas and partial-areas in the subject subtaxonomy.

**Resulting introduced partial-areas.** One major change in July 2015 was the introduction of 110 partial-areas to the \{Causative agent, Finding site, Pathological process\} area (19 are shown in Figure 2(b)). The concepts in these 110 partial-areas were summarized by Bacterial infection by site (372) in Jan 2015. These concepts (e.g., the root of the Tuberculosis of gastrointestinal tract (9) partial-area in Figure 2(b)) did not change structurally (i.e., they have same set of attribute relationships in both releases) but they did change semantically (i.e., the hierarchy changed and they are no longer descendants of Bacterial infection by site).
Figure 2. An example of how the changes to the concepts in the Bacterial infection by site (372) partial-area are captured in subject subtaxonomies derived for three SNOMED CT versions. (a) The Jan 2015 ‘Causative agent, Finding site, Pathological process’ area with its single partial-area. (b) The July 2015 version of the area from (a). The partial-area Bacterial infection by site lost 196 concepts and a total of 110 new partial-areas (19 shown) appeared due to changes in the underlying concept hierarchy. (c) Jan 2016 version of the area from (a). The blue partial-areas in (b) were merged back into the Bacterial infection by site partial-area. New partial-areas (e.g., Tetanus (9)) also appeared, indicating a change in their concept’s semantics. Several partial-areas (e.g., Lepromatous leprosy (2)) still exist in the area. Other partial-areas moved to areas with more relationships (e.g., Tuberculosis of genitourinary system (6) moved to the area ‘Associated morphology, Causative agent, Finding site, Pathological process’) and grew to 19 concepts). The concepts in Tuberculosis of urinary organs (4) moved to this partial-area.

There were no stated editing operations applied to Tuberculosis of gastrointestinal tract. Thus, one needs to look at the inferred changes. Three such changes occurred: the classifier inferred a less refined parent (Disorder of gastrointestinal tract), a new Causative agent attribute relationship to Genus Mycobacterium, and a Pathological process attribute relationship was moved to a relationship group with the inherited Causative agent relationship. The stated editing operations that lead to this change were applied to Mycobacteriosis, the parent of Tuberculosis.

By investigating the root concepts of the other new partial-areas in Figure 2(b) we observe a similar phenomenon. All of the (former) descendant concepts of Bacterial infection by site that did not have the same relationship group organization (i.e., the Finding site attribute was not assigned to a relationship group with Causative agent and Pathological process attribute relationships), were no longer classified under Bacterial infection by site after July 2015, and thus, appeared as new partial-areas. Looking at the Jan 2016 version of this area in Figure 2(c), one observes that some of these partial-areas are still in the area (e.g., Lepromatous leprosy (2)). One can also see that several partial-areas were added (e.g., Tetanus (9)), again indicating that sets of concepts are no longer being inferred as descendants of Bacterial infection by site.

**Resulting removed partial-areas.** Some of the partial-areas introduced in the July 2015 ‘Causative agent, Finding site, Pathological process’ area no longer exist in the area in Jan 2016. The concepts in certain partial-areas (colored blue in Figure 2(b)) returned to Bacterial infection by site in Jan 2016 due to some combination of editing operations. Other partial-areas, however, moved to entirely different areas, indicating a change in structure.

**Resulting changes to areas.** When a concept moves from one area to another it indicates a change in the structure of the concept. Specifically, it means additional (or fewer) types of attribute relationships are used to define the concept. For example, the partial-area Tuberculosis of bones and/or joints (20), in ‘Causative agent, Finding site, Pathological process’ in July 2015, moved to ‘Associated morphology, Causative agent, Finding site, Pathological process’ in Jan 2016. Additionally, eight concepts (e.g., Tuberculosis of hip and Tuberculosis synovitis) were inferred as belonging to this partial-area’s subhierarchy. In July 2015, four of the eight concepts were summarized by only Bacterial arthritis (33) in ‘Associated morphology, Causative agent, Finding site, Pathological process’ (not shown in Figure 2(b)). In Jan 2016 the concepts are summarized by both the Tuberculosis of bones and/or joints (28) and Bacterial arthritis (37) partial-areas. Others concepts (e.g., Tuberculous necrosis of bone) were summarized by a singleton partial-area (i.e., it has only one concept) in ‘Associated morphology, Causative agent, Finding site, Pathological process’ in July 2015 but were absorbed into Tuberculosis of bones and/or joints (28) in
Jan 2016. Additional, the concepts from Tuberculosis of gastrointestinal tract (9) in July 2015 are in Bacterial gastroenteritis (24) in Jan 2016, indicating a change in both structure and semantics.

From these examples one can see that the differences between subject subtaxonomies can be used to identify major changes to the hierarchy (via the addition and removal of partial-areas, indicating significant modifications and disruptions) and structure of the concepts (via sets of concepts moving between One does not need to review individual concepts. There are typically significantly fewer partial-areas than concepts, thus, one can review significantly less information, saving editorial resources and enabling a better orientation to the impact of the remodeling. When a significant change is identified via the subject taxonomy, only then would an editor need to review the individual changes which occurred. With a better orientation into the global impact of the changes one will have a greater chance of discovering unwanted side effects of the remodeling and focus future editorial work on correcting the incorrect inferences.

Principles Guiding the Remodeling of Bacterial Infectious Diseases

The above methodologies, implemented in the BLUSNO software tool, allow a user to identify what changed in a summarized manner. However, to understand why the content changed, one needs to look at and understand some of the modeling principles followed by IHTSDO’s editors. The end goal of the remodeling effort was to enable SNOMED CT’s classifier to infer most of the hierarchical connections between concepts in the subhierarchy. This will save SNOMED CT’s editors significant time and effort. Furthermore, the prior modeling of the Bacterial infectious disease concepts led to incorrect inferences that affected the quality of the content.

No proximal primitive parent: One common design pattern in SNOMED CT is the use of a closest proximal primitive parent in the stated modeling of a concept. A proximal primitive parent is the closest parent in the hierarchy to a concept being modeled that is not fully defined [20]. For example, in the Jan 2016 stated version of SNOMED CT, the closest proximal primitive parent of the concept Furuncle of face is Disease. By modeling concepts using the closest proximal primitive parent design pattern, the SNOMED CT classifier can more accurately infer parents and subtypes. In Jan 2015 few of the concepts in the Bacterial infectious disease hierarchy followed this pattern. The major focus of the hierarchy redesign has been to consistently apply this pattern to the content.

Many of the concepts in the Bacterial infectious disease subhierarchy (1404, 68.9% in Jan 2015) that did not follow the proximal primitive parent pattern had one or more stated parents that were fully defined. These parents are unnecessary and often cause incorrect inferences. When these concepts are modeled with a Pathological process relationship with a target of Infectious process and a Causative agent with a target of some kind of bacteria, the classifier auto-classifies the concepts into the Bacterial infectious disease subhierarchy.

Inconsistent relationship grouping: A concept may have multiple relationships of the same type (e.g., multiple Finding site relationships, like Boil of lower limb in Figure 3(b)). To correctly associate sets of related relationships SNOMED CT includes a mechanism to organize relationships into sets called relationship groups [21]. In the Bacterial infectious disease subhierarchy the attribute relationships for many of the concepts were not consistently organized into relationship groups.

A large portion of the subhierarchy’s concepts (1857, 91.2% of the hierarchy) had at least one of the above issues and were considered to be inconsistent. The remodeling process was carried out by one editor, (JTC). The remodeling process was done manually, requiring the editor to modify each concept to fit the model. Several editing operations may be required to remodel a concept. Figure 3 (a) and (b) illustrate the stated remodeling of Boil of lower limb. This concept required a closest proximal primitive parent (Disease) and several stated attribute relationships. Figure 3 (e) and (f) illustrate the remodeling of Staphylococcal infection of skin. The kind of stated remodeling shown in Figure 3 was applied to nearly 1000 concepts between the Jan 2015 and Jan 2016 releases.

Consider again Tuberculosis of gastrointestinal tract. The parent that was removed in July 2015, Bacterial gastrointestinal infectious disease, underwent remodeling to fit the closest proximal primitive parent concept model and all of its attribute relationships were assigned the same relationship group. However, in July 2015 Tuberculosis of gastrointestinal tract was not yet remodeled to fit the closest proximal primitive parent model.

Thus, its Finding site attribute relationship was not in the same relationship group as its Causative agent and Pathological process attribute relationships. Due to this difference, SNOMED CT’s classifier could not infer Bacterial gastrointestinal infectious disease as a parent of Tuberculosis of gastrointestinal tract in July 2015.
Figure 3. Examples of stated modeling for concepts remodeled between Jan 2015 and Jan 2016. (a-d) Show the modeling of Boil of lower limb and (e-h) show the modeling of Staphylococcal infection of skin. (a) Stated, Jan 2015. (b) Stated, Jan 2016. (c) Inferred, Jan 2015. (d) Inferred, Jan 2016. (e) Stated, Jan 2015. (f) Stated, Jan 2016. (g) Inferred, Jan 2015. (h) Inferred, Jan 2016.

In Jan 2016 Tuberculosis of gastrointestinal tract was remodeled to fit the closest proximal parent model. The classifier inferred a more refined parent Bacterial gastroenteritis, a child of Bacterial gastrointestinal infectious disease. Thus, in Jan 2016, Tuberculosis of gastrointestinal tract was inferred with a more specific classification.

By reviewing the partial-areas that appeared in \{Causative agent, Finding site, Pathological process\} in July 2015 and then “merged back” into the Bacterial infection by site partial-area in Jan 2016, we observe that their root concepts all underwent remodeling to fit the closest proximal primitive parent model. Once this remodeling was complete the concepts summarized by these partial-areas were correctly inferred as being descendants of Bacterial infection by site. As a larger proportion of the hierarchy is remodeled in future releases, we expect that the concepts in the remaining partial-areas (e.g., Lepromatous leprosy) will eventually “merge” back into the Bacterial infection by site partial-area or move to another area, indicating that their remodeling has been completed.

Results

We obtained the Jan 2015, July 2015, and Jan 2016 international releases of SNOMED CT in RF2 format [22]. For each release we used our BLUSNO tool to create a subject subtaxonomy rooted at Bacterial infectious disease using each concept’s inferred relationships. For each subject subtaxonomy we determined the area and partial-area(s) that summarized each concept. For the July 2015 and Jan 2016 releases we identified the stated editing operations and inferred changes that affected the subhierarchy’s active concepts. Table 2 provides metrics for the subhierarchy and subject subtaxonomies for each release and illustrates the desired improvements that were expected from the remodeling effort (e.g., a decrease in primitive concepts and a decrease in the use of stated fully defined parents).
Table 2. *Bacterial infectious disease* subhierarchy and subject subtaxonomy metrics across the three releases

In the July 2015 release we identified 2218 editing operations that affected 541 (/2006 = 27.0%) active concepts in the subhierarchy. In the Jan 2016 release there were 2215 editing operations that affected 560 (/2066 = 27.1%) concepts. There were 17 concepts that had editing operations applied in both releases. In the inferred version of the subhierarchy the stated editing operations led to many inferred changes. In the July 2015 release there were 7209 implicit changes that affected 1791 (/2066 = 86.7%) concepts. In the Jan 2016 release there were 4543 implicit changes that affected 1016 (/2066 = 49.2%) concepts. A total of 742 concepts were affected in both releases. Table 3 lists the various editing operations that were applied to the subhierarchy, and their frequency for each release.

</table>

Several editing operations were typically applied to each remodeled concept, with several instances of a given type of editing operation typically applied. For example, *Salmonella infection* had one instance of a “less refined stated parent” editing operation and two instances of an “added attribute relationship” editing operation. Most concepts (346 in July 2015, 365 in Jan 2016) had two kinds of editing operations applied. The most common pair of editing operations was making a stated parent less refined and adding one or more attribute relationships (e.g., the examples in Figure 3). The most common less refined parent was *Disease*, with 494 instances in July 2015 and 533 in Jan 2016. Many concepts had several stated fully defined parents replaced by a single stated *Disease* parent. The second most common stated parent was *Sexually transmitted infectious disease* (a primitive concept).

From Table 2 we observe two important aspects of the changes to the subhierarchy. First, the percentage of primitive concepts decreases significantly between the releases. A higher proportion of fully defined concepts are desirable because it indicates that more concepts are sufficiently defined and are distinguished from their parent concepts. Fully defined concepts can also be used by SNOMED CT’s classifier to infer additional relationships.

Second, we observed that the size of the *Bacterial infectious disease* hierarchy changed between each release. In the July 2015 release 136 concepts were removed from the subhierarchy and 105 concepts were added. Some of this change was the result of deactivating concepts. However, many of the removed concepts (97 total) were still active in July 2015 but were no longer inferred as belonging to the subhierarchy (e.g., *Bacterial tonsillitis*, *Brodie's abscess*, and *Traveler's diarrhea*). The continued remodeling for the Jan 2016 release saw only 34 concepts removed from the subhierarchy and the addition of 94 concepts. Out of the 94 added concepts, 63 were removed in the July 2015 release and are now correctly inferred as belonging to the subhierarchy (e.g., *Traveler's diarrhea*). A total of 71 concepts that were in the subhierarchy in Jan 2015, and are still active in Jan 2016, have not returned to the *Bacterial infectious disease* subhierarchy (e.g., *Brodie's abscess* and *Tuberculosis of abdomen*).
Discussion

The Bacterial infectious disease subhierarchy has undergone significant remodeling over the last year. The same effort is planned for the entire Infectious disease subhierarchy, with 6,239 concepts in Jan 2016. A similar effort is ongoing for the Congenital disease subhierarchy. The benefit of the remodeling effort is that the concepts will follow a consistent model, enabling the classifier to infer most of the hierarchical connections between concepts. The remodeling of the Bacterial infectious disease subhierarchy will reduce the amount of future work needed to maintain the subhierarchy in later releases.

The significant amount of change from this remodeling effort is reflected in the Bacterial infectious disease subject subtaxonomies. From Table 2, we observe that the number of partial-areas increased greatly between the Jan 2015 and July 2015 releases, while the number of areas largely stayed the same and the number of concepts slightly decreased. The number of concepts in each area also did not change significantly. This indicates a significant change in semantics. In the July 2015 subtaxonomy we observed the addition of 214 partial-areas (110 of which were in the {Causative agent, Finding site, Pathological process} area) and the removal of 72 partial-areas. A total of 287 concepts were summarized by new partial-areas while still being in the same area and only 17 concepts were summarized by a new partial-area in a different area, indicating that the amount of structural change was minimal.

Jan 2016 saw fewer added partial-areas (76). A total of 74 concepts were in the same area but in new partial-areas (e.g., Tetanus in Figure 2(c)). In Jan 2016 there were significantly more concepts summarized by new partial-areas in different areas (60, e.g., Tuberculosis of bones and/or joints). In comparison to the July 2015 subject subtaxonomy, there were relatively many removed partial-areas (135 total), summarizing 159 concepts. A total of 106 of these concepts returned to their original Jan 2015 partial-areas (e.g., the blue partial-areas in Figure 2(b)). A total of 93 of the partial-areas removed in Jan 2016 only existed in July 2015. The Jan 2016 release thus saw a greater change in attribute relationship structure. For example, 130 concepts moved to the {Associated morphology, Causative agent, Finding site, Pathological process} area, either as part of their partial-area (e.g., Tuberculosis of bones and/or joints) or to a new partial-area (e.g., Tuberculosis of gastrointestinal tract). These concepts were thus modeled with one or more additional kinds of attribute relationships versus their Jan 2015 modeling.

One aspect of the remodeling that is surprising is how disruptive the process has been. As highlighted by the addition and removal of hundreds of partial-areas over the two releases, there has been significant change to these concepts. The concepts in the 110 partial-areas that “emerged” from the Bacterial infection by site partial-area in the July 2015 release were no longer classified as bacterial infections by site. As additional concepts undergo remodeling they will be reclassified into the Bacterial infection by site subhierarchy, however this process is incomplete and it is expected that this hierarchy will be inconsistent for several more SNOMED CT releases.

The editing tool that was used to remodel the content, the IHTSDO Workbench [23] does not support certain collaborative terminology development functionality, such as branching. Typically, when undertaking a significant development project, a terminology will be “branched” and all modifications are made to a separate copy of the terminology. Only after the entire task has been completed will the changes be integrated into the release version of the terminology. In contrast, for the Bacterial infectious disease remodeling project, incomplete remodeling was released in the July 2015 and Jan 2016 releases.

Conclusions

In this paper we described a two-phase methodology to track important changes in a SNOMED CT subhierarchy. We introduced a method of summarizing the editing operations that were applied to a subhierarchy based on the delta files provided in each SNOMED CT release. We also illustrated how partial-area taxonomies highlight the major changes that occurred in the Bacterial infectious disease subhierarchy. We utilized this methodology to analyze the impact of remodeling the Bacterial infectious disease subhierarchy, whose concepts are being modified to fit a standardized concept model. This methodology can help track remodeling changes in other subhierarchies.

Using Natural Language Processing and Network Analysis to Develop a Conceptual Framework for Medication Therapy Management Research

William Ogallo, RPh., MA, MPhil1, Andrew S. Kanter, MD, MPH, FACMI1

1Department of Biomedical Informatics, Columbia University, New York

Abstract

This paper describes a theory derivation process used to develop a conceptual framework for medication therapy management (MTM) research. The MTM service model and chronic care model were selected as parent theories. Review article abstracts targeting medication therapy management in chronic disease care were retrieved from Ovid Medline (2000-2016). Unique concepts in each abstract were extracted using MetaMap and their pairwise co-occurrence determined. The information was used to construct a network graph of concept co-occurrence that was analyzed to identify content for the new conceptual model. 142 abstracts were analyzed. Medication adherence is the most studied drug therapy problem and co-occurred with concepts related to patient-centered interventions targeting self-management. The enhanced model consists of 65 concepts clustered into 14 constructs. The framework requires additional refinement and evaluation to determine its relevance and applicability across a broad audience including underserved settings.

Introduction

Drug therapy problems are undesirable events or circumstances that involve drugs and interfere with the achievement of desired goals of therapy. They can be categorized according to medication indication (e.g., unnecessary treatment, need for additional treatment), effectiveness (e.g., ineffective drug, dosage too low), safety (e.g., adverse drug reactions, dosage too high), and adherence (non-adherence). Drug therapy problems are often deleterious and costly. In the United States, it is estimated that adverse drug events are responsible for an estimated 3.5 million physician office visits, 1 million emergency department visits and 125,000 hospital admissions per year.

Medication therapy management (MTM) is a standard practice for assessing patient drug-related needs, and identifying and resolving drug therapy problems. MTM services are pharmacist-provided, non-dispensing services that aim to optimize drug therapy and improve clinical outcomes of patients. MTM services are the embodiment of the philosophy of pharmaceutical care. This philosophy asserts that it is the responsibility of the pharmacist to meet all drug-related needs of the patient, to be held accountable for those needs and to assist the patient in achieving his or her therapeutic goals through collaboration with other health professionals. MTM promotes medication adherence, safety, and effectiveness and is useful in improving the patient’s medication experience especially in chronic disease.

A conceptual framework is a meaningfully integrated collection of concepts, concept relationships, and assumptions that broadly explains phenomena of interest, expresses assumptions and reflects a philosophical stance. Conceptual frameworks are constructed to predict or explain the relationships, events or behaviors of phenomena. They are essential for strengthening theory-driven research whose aim is to investigate phenomena and support generalizability of findings. There are few examples of substantiated conceptual frameworks for guiding theoretical research in MTM. Consequently, studies within the MTM domain lack shared definitions and are highly heterogeneous with respect to the methods, predictors, and outcomes of interest. Furthermore, currently available conceptual frameworks such as the MTM Service Model in pharmacy practice describe specific dimensions of care delivery rather than specify relationships among concepts that could be scientifically investigated in hypothesis-driven studies. Therefore, it is important to develop new explanatory conceptual frameworks that could be used to strengthen correlational research within the MTM domain.

A common conceptual framework development strategy is theory derivation. In this process, a parent theory is selected and used to guide the development of a new model supported by evidence from current literature. Theory derivation is useful when related concepts could benefit from a structural representation of their inter-relationships, and when
this insight can inform future research. Conventional theory derivation requires the application of thematic analysis where semantic themes are manually derived by coding literature excerpts and collating the codes into themes. While this is arguably the most logical approach for synthesizing information from text, it is often labor- and time-intensive and is subject to investigator bias. Natural language processing is essential for automating knowledge discovery from literature corpora for decision support, guideline development, and medical literature indexing. Text mining using natural language processing has the advantage of enabling fast and efficient analysis of large corpora of documents and may be less prone to investigator bias. Combining this approach with network analysis may provide a systematic way quantitatively analyzing and visualizing salient aspects in biomedical literature.

This article describes the first iteration of a theory derivation process for the development of a conceptual framework to guide medication therapy management research. The model, entitled Enhanced Medication Therapy Management Evaluation Framework, is based on the MTM Service Model in pharmacy practice and the Chronic Care Model that were selected as parent theories. Concepts incorporated into the enhanced model were extracted from abstracts of systematic review and meta-analysis articles using natural language processing and characterized using network theory. This study reports our current findings.

**Methods**

The theory derivation process applied in this study is a four-step process: a) selection of parent theory, b) literature search and review, c) semantic concept analysis, and d) content development. These are described further below.

**Selection of Parent Theory**

We focused on delineating concepts and relationships at the intersection of medication therapy management and chronic disease care. As such, the MTM Service Model in pharmacy practice and the Chronic Care Model were selected as parent frameworks. The MTM service model includes five core elements: medication therapy review, personal medication record, medication-related action plan, intervention and/or referral for drug therapy problems, and documentation and follow-up. These core elements were established through consensus by a group of seven national pharmacy organizations in the United States in 2008. They form a framework for the delivery of MTM services in pharmacy practice. The MTM service model was used to provide an understanding of the goals, core features, process and outcomes associated with the delivery of MTM services. The chronic care model is an organizing framework for improving the management of chronic diseases. It asserts that comprehensive care improvement requires an approach that incorporates six interdependent components: community resources, health system support, self-management support, delivery system design, decision support and clinical information systems. Researchers have revised this model to demonstrate how eHealth tools can assist patients in managing their own chronic illnesses. The chronic care model was used in this study to provide insight into the role of self-management support, community involvement, healthcare delivery system design, decision support and clinical information systems in chronic disease management.

**Literature search and Review**

One author (WO) conducted a literature search to identify systematic review and meta-analysis articles that covered the topics related to medication therapy management in chronic care. For inclusion, articles must have reported results about antecedent factors associated with drug therapy problems or intervention strategies for drug therapy problems in chronic disease care. Studies were identified by electronically searching the Ovid Medline® database. The search strategy involved using medical subject headings (MeSH) and search strings associated with constructs of the MTM service model and the chronic care model frameworks (Table 1). The search was limited to abstracts of original or review articles published in English between 2000 and 2016. A total of 285 abstracts were identified out of which 12 duplicates were removed. An additional 131 articles were rejected through title and abstract review leaving 142 articles that were included in the analysis corpus.

**Semantic Concept Analysis**

The goal of the semantic concept analysis step was to identify and select the key concepts that could be incorporated into the enhanced conceptual framework. This step involved using natural language processing to extract the concepts reported in the abstracts selected for analysis, computing the frequencies of the identified concepts and concept-concept pairs, and using graph analysis to describe and visualize the resulting information. This analysis was based on the assumption that each biomedical literature abstract consists of a set of concepts that reflect the core contents of
Table 1. Terms and strategy for literature search in Ovid Medline.

what was studied and reported. Consequently, the frequencies of concepts and co-occurrent concept pairs in a corpus of abstracts about a given topic provide a reasonable quantitative description of the relevant themes related to that topic. Concepts in the abstracts selected for the study were extracted using MetaMap and analyzed using graph theory. MetaMap is a natural language processing program that maps biomedical text to the UMLS Metathesaurus 16. Graph theory is the study of graphs – data structures that represent pairwise relationships between discrete objects 17.

Each of the 142 abstracts selected for the study was preprocessing by removing all non-ASCII characters to enable processing via MetaMap. Next, the MetaMap 2016 Web API was used to process the abstracts. The MetaMap output files were further analyzed in R Statistical Programming Language 18. All identified concepts were reviewed to eliminate those that were not relevant based on their UMLS semantic types. Relevant concepts that had similar or related meanings such as therapy adherence, adherence to medication regime, and medication compliance were identified and merged after looking up concept-concept relationships in a local installation of the UMLS 2015AB Metathesaurus 16. All unique concept-concept pairs in each abstract were identified and their frequencies across the entire corpus computed. The results of this process were a list of all relevant concepts (nodes/vertices), and a list of all unique pairs of co-occurrent concepts (edges) as well as their frequencies (edge weights). These data were used to construct and visualize a weighted graph of concepts and their relationships in Gephi 0.9.1 19. Key concepts were identified by computing the weighted degree centrality and decomposing the graphs at various pairwise co-occurrence frequency cutoffs.

Content development

The final step of the conceptual framework creation was the manual refinement and organization of the concepts identified in the previous steps. This involved the process of concept reduction where abstract constructs were refined to concepts which can be reduced to measurable variables. The Donabedian’s Quality Framework was used to organize the entities of the new conceptual framework meaningfully. The Donabedian model is a model for assessing the quality of health. It is based on the assertion that structures of care influence processes of care, and that the latter influence Health outcomes. Structures of care describe the physical and organizational aspects such as infrastructure, equipment, financing, and personnel. Processes of care are the resources and mechanisms for carrying out healthcare activities. Health outcomes are the goals and effects of healthcare on patients such as recovery, survival, and patient satisfaction.

Results

Semantic Concept Analysis Results

Table 2 provides the summary statistics of the concepts, concept pairs and graph analyzed of the 142 abstracts included in the study. A total of 27,094 text tokens in the corpus were mapped to 4,090 unique UMLS concepts. Of these, only 50 concepts (1.2%) were considered relevant and included. A majority of the excluded concepts resulted from the

Figure 1. Network graph of concepts identified from literature abstracts on drug therapy problems. The graph has a total of 50 nodes and 102 edges. Nodes represent UMLS concepts. Larger nodes have higher weighted degree centrality. Edges represent the frequency of co-occurrence of UMLS concept pairs across the document corpus. Thicker edges correspond to co-occurrence frequency. The top 10 nodes and edges, based on weighted degree centrality, are highlighted in blue.
Figure 2. The Enhanced Medication Therapy Management Evaluation Framework. Structure entities are shown in blue, process entities in orange and outcomes in green. Arrows indicate fluidity between structure, process and outcome constructs.
one-to-many mapping of text tokens including stop words to multiple concepts. Medication adherence was the most prevalent concept in the corpus, occurring in 93% of the abstracts. Other high-frequency concepts include self-management, tailored intervention and patient engagement (Table 3). These highly frequent concepts also formed the most frequent concept-concept pairs in the corpus (Table 4).

The network graph identified and analyzed in the study had 50 nodes and 102 edges (Figure 1). It is a sparse undirected graph with a density of 8.3%. The most dominant nodes and edges in the graph are highlighted in blue and further described in Tables 3 and 4 respectively. Medication adherence, connected to 47 nodes, is the most central node in the network. 19 nodes (38% of the full graph) are one-degree vertices connected to the medication adherence node. Its removal from the network results in a much smaller graph with 32 nodes and 55 edges. The other dominant nodes are closely related to the medication adherence as contributors or interventions to medication non-adherence. Interestingly, no other drug-related categories were identified in the network. The adverse drug event concept identified in the network analysis was discussed in the reviewed abstracts as an antecedent contributor to medication non-adherence rather than a drug therapy problem per se.

Conceptual Model Development

The enhanced model developed in this study meaningfully organizes the synthesized information in a manner that clearly shows the relationships and fluidity of the constructs and concepts about the application of medication therapy management for addressing drug therapy problems as illustrated in figure 2. The model consists of 65 concepts clustered into 14 constructs that are further organized into structural, process and outcome constructs. Structural constructs are shown in blue, process constructs in orange and outcome constructs in green. The constructs are derived from the parent theories and represent clusters of concepts that may contribute to drug therapy problems that were identified by network analysis and abstract review. The process constructs represent actors, activities, drug therapy problems and critical measurements associated with MTM service provision. The outcome constructs represent the key process, intermediate and clinical outcomes related to MTM service delivery. Because the concepts in this domain are highly heterogeneous, specific concept to concept relationships are not shown, and concepts have not been reduced to measurable variables.

Discussion

This paper describes the first iteration of a process used to develop a conceptual framework to guide a program of research in medication therapy management (MTM). We selected the MTM Service Model in pharmacy practice 3 and the Chronic Care Model 14 as parent theories and enhanced these through theory derivation 8. Content included in the enhanced model were extracted from abstracts of review articles using natural language processing and analyzed using network theory. The derived model was organized according to the structure, process and outcome constructs of the Donabedian Model 20. The framework requires additional elaboration as specific concept-concept relationships are currently not described.

Medication adherence was the most studied drug therapy problem. This may be attributed to the fact that medication adherence is often considered the single most significant predictor of treatment success for chronic diseases 21. Indeed, an estimated 70% of hospital admissions due to drug therapy problems are related to medication adherence 22. Our findings confirm the fact that adherence is a complex phenomenon influenced by a variety of heterogeneous factors, and that there appears to be no consensus on the most practical approaches for measuring and promoting adherence in chronic diseases 23-25. However, providing patient-centered care and enhancing patient self-management through patient engagement, education, and psychosocial support are accepted strategies for improving adherence.

Our review and model development highlights several knowledge gaps in the literature. First, clearer definitions of factors associated with drug therapy problems are needed. This would help researchers to formulate research questions and evaluate relationships in this domain more effectively. Second, there are knowledge gaps about factors associated with medication indication, effectiveness, and safety. More research on these drug therapy problems is needed to demonstrate their importance and the role of MTM in addressing them. Third, researchers have not adequately examined the process of task redistribution in the provision of MTM services. Task redistribution is the appropriate delegation of health service responsibilities to less specialized but more readily available health professionals, and in some cases non-professionals 26-29. Studies have shown that task-redistribution enhances patient engagement and self-efficacy through education and psychosocial support across different populations and intervention modalities 30-32. However, its role in MTM service provision remains unstudied. In high-resource settings where MTM services are primarily provided by pharmacists, the role of task-redistribution in MTM services is not adequately described.
Conversely, in resource-poor settings where task redistribution is popular, little is known of the standard practice of MTM. The application of mobile health (mHealth) technology to complement this approach by improving recording keeping and decision support has been shown to increase the quality and efficiency of this strategy.\textsuperscript{33,34} Lastly, while acknowledging the importance of complementing drug therapy problem intervention strategies with reminder tools and decision to support adherence,\textsuperscript{35,36} further informatics research is needed on the role these technology solutions in operationalizing of MTM service activities such as care coordination and eligibility determination.

Two key challenges should be expected when using natural language processing and network analysis to extract automatically and characterize concepts during conceptual framework development. First, the effectiveness of this approach is limited by currently available natural language processing technologies. For example, while natural language processing tools such as MetaMap can effectively automate the extraction of concepts from biomedical texts, technologies that could effectively extract semantic relationships between concepts are currently available. It is, therefore, necessary to rely on surrogate approaches such as pairwise concept co-occurrence analysis to identifying and quantify the strength of plausible relationships between concepts reported in biomedical texts. Second, natural language processing tools such as MetaMap often map idiosyncratic texts including stop words, acronyms, and abbreviations to concepts.\textsuperscript{12} Therefore, it may be necessary to review the extracted concepts to eliminate those that are not relevant. Because this review is manual, it may not be useful to scale the approach to larger numbers of biomedical texts.

There are several limitations in this study. First, due to pragmatic constraints associated with using MetaMap, we restricted our concept extraction to published abstracts of systematic reviews and meta-analyses indexed in Ovid Medline. This was done with the assumption that theoretical saturation would be achieved as long as a critical mass of literature texts were analyzed. Using full texts, including other types of published articles or incorporating articles from other bibliographic databases could have resulted in richer content, but would imply additional computation and manual review. Second, we relied on pairwise concept co-occurrence analysis as a surrogate measure of the relationships between concepts occurring in the analyzed abstracts. However, doing so does not give an accurate interpretation of the true strength of the relationship between co-occurring concepts in the analyzed abstracts. For example, a pair of concepts that occur in the same abstract may not be related. Conversely, just because two concepts do not co-occur together does not imply that they are not related directly or indirectly. We lost information about the directionality of plausible concept-concept relationships. Nonetheless, our goal at this stage was not to establish the true relationships between concepts, but to quantify what biomedical researchers have been interested in studying within the MTM domain. Our next steps are to refine the framework further by characterizing the interrelationships among the individual concepts and describing the measurable variables associated with these concepts. This will be followed by the use of domain experts to evaluate the framework extensively to determine its relevance across a variety of settings including in underserved settings.

Conclusions

This paper describes the use of natural language processing and network analysis for the development of a conceptual framework to guide a program of research in medication therapy management. The developed model consists of 65 concepts clustered into 14 constructs derived from the MTM service model and the chronic care model. It requires further refinement and evaluation to determine its applicability across a broad audience including underserved settings. Our analysis confirms that medication adherence is the most studied drug therapy problem. Patient-centered care approaches and enhancing patient self-management through engagement, education, regimen simplification and psychosocial support are important strategies for promoting adherence. Drug therapy problems associated with medication indication, safety and effectiveness require more studies. Further research is also needed to understand the roles of task redistribution and medical informatics interventions in operationalizing MTM activities. We recommend that researchers evaluating tools to address drug therapy problems should consider the fact that the efficacy of such tools could be influenced by a multitude of complex factors. In situations where controlled experiments cannot be carried out, these factors should be investigated as potential confounders and effect measure modifiers.

Abstract
Health reminders are integral to self-managing chronic illness. However, to act on these health reminders, patients face many challenges, such as lack of motivation and ability to perform health tasks. As a result, patients experience negative consequences for their health. To investigate the design of health reminders that persuade patients to take action, we conducted six participatory design sessions with two cohorts: mothers of children with asthma, and older adults with type 2 diabetes. Participants used collages, storyboards, and photos to express design ideas for future health reminder systems. From their design artifacts, we identified four types of persuasive reminders for health self-management: introspective, socially supportive, adaptive, and symbolic. We contribute insights into desired features for persuasive reminder systems from the perspectives of patients and informal caregivers, including features that support users to understand why and how to complete health tasks ahead of time, and affordances for intra-familial and patient-provider collaboration.

Introduction
Reminders for health tasks, such as obtaining recommended lab tests and taking medications, are important for supporting patients who are living with chronic health conditions to manage their health. For these individuals and their families, reminders are a part of everyday life, helping patients to manage their health in the home rather than in the clinic or the hospital. Moreover, unlike acute care reminders for short-term health concerns, reminders for chronic illness care are often associated with making and maintaining significant changes in health behaviors, such as eating, exercising, and tracking health indicators over time. For these patients, simply alerting them to health tasks could be insufficient for supporting them to adopt and maintain medical and lifestyle changes. Rather, these individuals might benefit from reminders that are designed to be motivational, or even persuasive.

Strategies for supporting patients to change health behaviors and complete health tasks are well documented. In particular, increasing patients’ self-efficacy to solve problems through informational, emotional, and social support are key for catalyzing sustainable behavior change for health. However, the use of these strategies to design reminder systems for preventive and chronic health tasks is underexplored. Health reminders are typically designed to trigger health behaviors at the right time, but are not usually designed to employ persuasive strategies that can influence patients to adopt those behaviors. As a result, institutionalized reminders such as those coming from healthcare organizations likely do not live up to their full potential to support and encourage optimal self-care. Improving these reminder systems could enhance patient care, reduce disease burden, and potentially save health care costs for both patients and health insurers.

To inform the design of persuasive health care reminders, we explored desired persuasive strategies from the perspectives of individuals who are responsible for managing a chronic illness. Our goal was to understand how reminders could help patients to build self-management skills and engage in self-management tasks. We conducted six participatory design workshops with older adults who have type 2 diabetes and with mothers caring for children with asthma. Participants reflected on current reminder systems and designed future reminder systems that made it easier and more attractive to complete health self-management tasks. We found that the participants envisioned four types of persuasive health reminders: introspective, socially supportive, adaptive, and symbolic.

In this paper, we contribute empirical findings to inform the design of persuasive reminder systems based on the perspectives and expertise of patients managing chronic illnesses. We describe how persuasive health reminders are deeply personal, reflecting patients’ health values, relationships, and goals.

Related Work
In this section, we discuss the background of persuasive technology design, including persuasive design frameworks, strategies, and ethics. We focus on the application of persuasive systems in the health domain, but acknowledge that persuasive technologies have been applied in other domains such as sustainability and safety.
Persuasive technology design

Persuasive technology design emerged in the 1990s, and the health domain was identified early on as a key domain for such persuasive systems. Several models for designing persuasive technologies have informed the design of systems that influence health behavior change. One of the best known models is Fogg’s Behavior Model. Fogg’s model emphasizes three factors that must be present at the same time to influence behavior change: (1) motivation, (2) ability, and (3) triggers (e.g., alarms). When people have both the motivation and ability to perform a behavior, reminders that trigger the behavior at the right time are more likely to be effective. Typical health reminders aim to trigger tasks at the right moment. However, when lacking ability and/or motivation, people can benefit from triggers that facilitate and motivate them to perform a task. Fogg calls these triggers “facilitators” and “sparks,” and differentiates them from “signals” that remind rather than persuade. We used Fogg’s model to understand the significance of elements in participants’ designs that increased both their motivation and ability to perform health tasks and achieve health goals.

Building on these behavior change models, persuasive systems designers often employ specific, empirically grounded persuasive strategies, including: feedback about performance, rewards, authority, progress monitoring, and social influence. These persuasive strategies have been implemented in the design of systems that motivate health behavior change, including increasing physical activity, water intake, and engagement in diabetes self-care. These strategies have also been employed to design persuasive health reminder systems. For example, Walji et al. used iterative design to explore the acceptability of persuasive appointment reminders using the strategies of commitment, liking, authority, and scarcity. Another example is Langrial et al.’s email reminder system that used feedback and social support to increase logging of fizzy drink consumption. Finally, Oliveira et al. created a socially competitive game to engage elders in medication adherence, and found that it improved the timing and accuracy of taking medications. These examples highlight approaches to persuading people to perform recommended health tasks. Our research adds insights into the persuasive ways in which individuals link health tasks to their broader health goals for self-care.

Health behavior change researchers have also explored the design of personalized persuasive systems for health. For example, Kaptein et al. designed a reminder system to reduce snacking that sent reminders tailored to each user’s susceptibility to four social influence strategies: scarcity, authority, consensus, and commitment. They found that tailored persuasive reminders were more effective than random reminders. In another study, Kaptein et al. showed that persuasive reminders designed to increase physical activity and fruit intake were more effective when adapted to individuals’ persuasion profiles. In contrast to personalized persuasive systems that targeted a prescribed behavior (e.g., physical activity), Baumer et al. supported the agency of users to define healthy behaviors. Their system, VERA, enabled users to post photos of their health behaviors to encourage persuasive open-ended social awareness. Our findings show that there may be a middle ground between prescriptive and open-ended persuasive systems wherein users can contextualize prescribed health tasks within personally significant health goals.

Ethics of persuasive system design

Finally, the user’s agency in defining the strategies and goals of persuasive systems is an important ethical consideration. Davis described how design methods can influence the ethics of persuasive systems. She advocated for the use of Participatory Design (PD), a method that emphasizes equal participation and mutual learning between designers and users. PD is a human-centered design tradition that emphasizes the expertise of users, especially when designers have little first-hand knowledge of users’ experiences. For example, PD has been used to design with and for cancer patients, adults with amnesia, and children. Ethical dilemmas in persuasive systems can arise from the asymmetrical power relations between the persuader (i.e. the designer) and the user. PD is well-suited to balancing power relations, and increasing the user’s voice in the ways in which they are persuaded.

Our work contributes to this tradition of using PD to inform the design of ethical persuasive systems for health. In particular, we contribute insights into designing health reminders that align with patient’s personal health values and attitudes and that increase their confidence as self-managers. We identified four types of health reminders designed by patients to increase their motivation and ability to adopt health behaviors: retrospective, socially supportive, adaptive, and symbolic. These persuasive reminder types can inform new approaches to designing patient-centered systems that support health self-management.
**Participatory Design Method**

The participatory design approach enabled us to engage patients and caregivers in designing future reminder systems that could support them to manage chronic illnesses. Participants used creative, hands-on design activities to embody their perspectives in design artifacts, including collages, storyboards, and cultural probes. These artifacts enabled us to capture participants’ visions of future states of health and reminders.

**Participants**

We sampled 23 participants from two populations of people who managed complex chronic illnesses: older adults with type 2 diabetes, and mothers of children with asthma. This sampling strategy enabled us to include the perspectives of both patients and caregivers involved in chronic illness management and a wide spectrum of ages (31 to 89, µ=57). Within these two distinct populations, we oversampled individuals from underrepresented minorities and low socioeconomic backgrounds to ensure a diversity of patient and caregiver experiences on the design teams [see Table 1]. Participants were recruited from Group Health Cooperative, an integrated care and delivery system in Washington State.

We grouped participants into three design teams, each with 8 participants: (1) mothers of children with asthma (A1-A8); (2) older adults with diabetes (D1-D8); and (3) a mixed team of mothers and older adults (A9-A11; D9-D12). Each team participated in two 90-minute workshops, one week apart. Two researchers (the first and second authors) facilitated each workshop. Participants did three types of activities: collages, storyboards, and cultural probes.

**Collages**

Collages are an ideal tool for helping people to “articulate experiences” using stimuli like images and words. We provided participants with a set of images relevant to chronic illness management, such as health care providers, patients, medical equipment (e.g. glucose monitors and asthma inhalers), hospital and home spaces (e.g., clinic office, bedroom, kitchen), wellness activities (e.g., walking, aerobics), and reminder tools (e.g., mobile phones, sticky notes, email). We also provided materials for free-form expression, including pens, colored paper, scissors, glue, and health-related magazines. The research team pilot tested this collage toolkit to ensure that it provided a balance of structure and ambiguity to encourage creativity.

Participants created two collages. In Design Workshop 1, participants worked independently to create a collage representing a magical system that would help them to achieve a health goal, such as healthy blood glucose levels, weight loss, or asthma control. In Design Workshop 2, we handed participants their collages and toolkit from the first workshop, and invited them to build off of these to imagine explicitly how reminders for health tasks fit into the picture of health self-management. Participants worked in pairs for the second workshop.

**Cultural probes**

Cultural probes are take-home materials that provoke participants to reflect on and capture aspects of their everyday environments—a common technique for stimulating design ideation. In between the first and second workshops, participants completed short activities at home about reminders that had persuaded them, and that they had authored to persuade someone else. We also provided each participant with a Polaroid camera to take photos of personally significant health reminders. The cameras were loaded with 5 mini films for instantly printing color photos.

**Storyboards**

In the second design workshop, after the paired collage activity, we asked participants to fill-in-the-blanks in a storyboard template. Storyboards and scenarios are common techniques for engaging users in the design process. We provided participants with a 3-panel storyboard depicting a patient “before” and “after” the intervention of a magical genie. In the first panel, participants wrote their thoughts and feelings when they experience a challenging health task. In the middle, they wrote what the genie would say or do to help them overcome this challenge. Then, in
the final panel they wrote their thoughts and feelings after the genie’s intervention. The focus on thoughts and feelings gave us insight into the psychological and informational barriers people faced when completing health tasks, and the type and tone of support they desired for successful task completion.

Analysis
Each workshop was video recorded and transcribed by an attending court recorder. The researchers analyzed the transcriptions, collages, storyboards, and cultural probe photos using a general inductive approach. The general inductive approach is a systematic way to develop a framework of underlying themes that connect clearly to research objectives. Our analysis was guided by the research goal of understanding the ways in which reminders helped people to achieve their health tasks and goals. The first two authors iterated on a codebook, first establishing themes such as, “rewards of health,” and then clustering these into broader categories such as “symbolic reminder.”

Findings
Participants designed persuasive health reminder systems aimed at provoking reflection on health priorities, increasing confidence in completing health tasks, tailoring the reminder mode and message, and symbolizing the rewards of good health. Below, we describe four types of persuasive health reminders envisioned by participants: introspective, socially supportive, adaptive, and symbolic.

Introspective reminders
Introspective reminders triggered reflection on health goals. These reminders helped patients plan and prioritize their daily health tasks. A6 created a collage that centered on taking time to reflect (Figure 1a). She described that, “I know in order for me to be successful, sometimes I have to sit back and reflect on those [health] goals. You know, what I can do to keep me going towards my health. So that's why I had the word reflect.” Her magical reminder was a kiosk at her front door where she could reflect on her goals and tasks: “I call it a self-check in. […] I would have to do a check in [to get] daily reminders or affirmations to get you going, or remind yourself what you need to work on today.”

Figure 1. Introspective reminders. (a) self-check in reminder; (b) health road map; (c) weight loss visualization.

A4 also described a reminder system that helped her to reflect throughout the day on healthful behaviors. “So my magical system, is just kind of about balance and time […] It's hard to maintain balance with other elements in my life. Like the exercise element. The healthy diet element. Relaxation and sleep element. […] It would be great to have some type of a system to help interface with all those different elements.” She phrased her reminders as questions that helped her to introspect on healthy behaviors: “Have I done enough stuff throughout the day? Have I eaten what I need to eat? Have I maintained enough sleep?” She explained why these types of reminders would be valuable, “When I get caught up in my work schedule, and go, go, go, do, do, do, sometimes those other elements in my life fall by the wayside and those are important for health too.”

Similar to A4’s daily, short-term introspective reminders, D7 and D8 designed a reminder system that supported self-monitoring over the short and long term. D7 and D8 worked together on their collage in the second workshop (Figure 1b). D8 described the introspective reminder system they created: “We liked the idea of having a health goals kind of road map, where there's short and long term goals, and that somehow you have access to that information. And incorporated in it are like little daily, hourly, encouragements, and humor, and things like that.”
D5 also created a reminder system that supported awareness of past, present, and future states of health (Figure 1c). She explained the nested colors depicting her losing weight over time, "So this [orange] is as I see myself now. This [green] is as I continue to work on these things. The smaller circles [yellow] are where I'm going to be—is where I'm going to." She pointed to the "1lb" water drops around her image, “And these are the pounds just dripping off me as I do exercise; and these are some of the things that I do to help, you know, make that happen.” This creative depiction of her health goal of “losing weight” shows the power of reminders that encourage reflection on desired future states of health. Participants described how these introspective reminders, featuring self-check ins, health elements, and road maps, would support them to connect their concrete health tasks to broader health goals.

**Socially supportive reminders**

In contrast to introspective reminders designed primarily for individual contemplation, **socially supportive reminders** involved motivational and mentoring relationships. Participants described persuasive health reminders that leveraged social support to not only remember tasks, but to increase confidence in performing them. These reminders were targeted at concrete health tasks like medication and exercise, rather than broader health goals.

One mother, A2, photographed a socially supportive reminder system that she was currently using to motivate her five children to take on more responsibility for their health. She described her system of collecting tally marks on the fridge to indicate a completed task, such as ‘Don’t forget to take your medicine’: “And for every time you do something you get a tally mark. And the goal is on the day that we score the highest score as a family we get to do something fun as a family. So everyone is working to try to get more tallies.” This system helped the mother to shift accountability for health self-management to her children, which benefited the entire family. This approach highlights the importance of designing health reminders for family units to change their health behaviors together. The mother added, “It’s a good way because then they’re reminding me. ‘We need to take our medicine because we want our points.’”

Many of the socially supportive reminders were exemplified in the storyboard activity. Participants were asked to depict how a magical genie would help them to overcome a health challenge. In her storyboard, D3 described the kind of social support that would help her to overcome obstacles to taking her blood sugar,

> “I was frustrated because I didn't want to take my blood sugars. I was upset because I wasted the needles, I poked my finger and the blood didn't come out and the machine said it wouldn't work. I didn't want to do it in the first place anyway, and so I was discouraged and upset. The magic person came in, showed me why it was helpful and how to be able to do it correctly. She infused in me confidence. She had an interest in knowing what the outcome was going to be and why it was important for me to be able to do that, and she infused in me the fact that it would be a great activity. After she did that, I felt much lighter. I also felt more energetic, positive, ready to get started.”

Being reminded of the rationale for the task, the outcome expectations, and her capacity to complete it, were central to this participant’s vision of a system that would increase her confidence to perform a self-administered blood glucose test. Some participant’s socially supportive genies were less comforting, yet still instructive. For example, D6 envisioned a genie who would help her to set up a reminder system that would prevent her from forgetting to take evening medications,

> “So genie said, ‘Well, you like little reminders. Put a reminder in an obvious place.’ And she said, ‘The solutions are put one in the bathroom, put one in the bedroom, put one wherever you're going to be before going to bed.’ So I put a sign on the mirror in the bathroom because I brush my teeth. And I usually have a cup of tea or something in the kitchen, so on the television I put a little small sign in red saying ‘Meds.’ So if I picked the cup up and looked at the screen, I would see the sign. And I said, ‘Thank you, genie,’ and genie said, ‘Think on your own.’”

This reminder was not a just-in-time alert to the task, rather it was well ahead of time and targeted at how to remember the task. Moreover, the “tough love” tone of social support was designed to encourage independence from the system. D2 also emphasized the importance of being reminded of how to refill medications so that he could ultimately take care of it himself,

> “I don’t have a car, so to get my medications at the clinic is kind of a chore. I have to go on the bus. So a genie came along and offered to fly me there. He also told me that they do have a system [at Group Health] for medication, but
you can't wait to the last minute anymore. Just got to plan ahead and order ahead of time. So at the end I was thankful for the genie, but also I realized I could take care of this problem myself.”

This reminder helped D2 to understand the time horizon for medication refills using the online system, which was essential to his a success with the task. These examples of socially supportive reminders demonstrate the importance of receiving certain reminders well ahead of time that explain why and how to complete health tasks.

Adaptive reminders
Participants designed adaptive health reminders that persuaded them by adapting to their personal health information. Some participants distinguished these personalized health reminders from standardized reminder letters provided by the health cooperative. For example, A2 and A3 worked together on a collage that emphasized this distinction. A2 explained, “We all get that form letter every year that says, ‘Hey, come in, your child is due.’ And it’s that generic form letter that’s been the same for the last twenty years or whatever and you don’t even read it anymore, do you? Like, ‘Yep, whoosh.’” The health tasks included in these standardized reminder letters are based on health conditions, gender, and age. Participants described how personalized letters would compel them to retain the information and act on it, as A4 said, “It makes me focus on the reminder. I will remember it a lot more and be willing to follow through. [...] I’m not just a number.” A1 suggested that, “maybe it would motivate us to get our health assessments done if we knew that we were going to get more personalized tips.”

Participants highlighted the importance of using tailored reminders to catch their attention and help them to prioritize health tasks. For example, A3 designed a system that anticipated health needs and made suggestions based on her and her children’s personal health information. She explained, “This one would be a super app, so it would have your medical goals and specifications. Like my daughter’s asthma would be on there. And then I thought it would be cool if it helped you maintain an active lifestyle. If you’re going to exercise, it asks you: ‘How much time do you have to exercise today?’” She continued, “It might give you guidelines for how much sleep your kids need for their age group.” This example suggests that persuasive systems will use personal health information to tailor reminders that help people to choose highly relevant healthy behaviors. Moreover, designing for the family unit is an important feature of reminder systems envisioned by caregivers.

We also found that the personalization of health reminders applied to both the medium (i.e., the technology) and the message (i.e., the content) of the reminder. For example, in contrast to A3’s design of a mobile phone application, D3 and D4 designed a reminder system for diabetes self-management that was embedded in a refrigerator—a device that was very central in their chronic illness. The system was designed to adapt health reminders and notifications based on data that it collects from the user. D3 explained, “The refrigerator would see what his [glucose] numbers are, be concerned about the fact that his number is low or high, and would be able to tell him that his number is low, [and] he should probably not eat certain type of things.” The system also used the personal data to help the patient prepare for appointments. D3 continued, “It reminds you, ‘This is your appointment; this is your appointment day; this is the time; and these are the things that you need to discuss with the doctor,’ based on the things that you’ve already inputted into the thing.” This example highlights the persuasiveness of embodying reminders in a medium that is relevant to the task, in this case, the refrigerator is directly relevant to healthy eating.

D1 and D2 created another example of a centrally located technology designed to gather personal health information. Similar to D3 and D4, their system highlighted the importance of enabling patients to coordinate care with their providers. They designed an information “hub” that automatically generated appointments and reminders in response to data inputted by patients and their providers. This system would enable patients to shift accountability for certain health tasks to their providers. For example, rather than patients initiating health appointments and reminders, this system helped providers to monitor health data so that they could create appointments and reminders as needed. D1 explained that after the provider inputs lab test results,

“It goes back to the patient; and the patient, when we do all of our testing at home, you can put that in your computer, too [...] So all of that [personal data] will be in there; and it can help the doctor tell you when the next appointment is, when the next test is. And all of that goes into this one computer program which collects it all and generates it [reminder].”
Adaptive reminders revealed patients’ desire for shared accountability among provider, system, and patient. To simplify and engage with complex self-management tasks, patients designed reminder systems that reduced the burden of personalization while facilitating active patient-provider collaboration.

**Symbolic reminders**

The final type of reminder we identified was **symbolic reminders**. Symbolic reminders motivated participants to do health tasks by reminding them of personally significant reasons for healthy behaviors. These reminders were exemplified in the cultural probes data, wherein participants were instructed to take photos of helpful reminders using a Polaroid camera. Their photos were often deeply personal, reflecting the relationships and values that helped them to put health in perspective. For example, A4 featured her son as her reminder (Fig. 2a), “I took a picture of my son and I outside of the YMCA here, so it’s just a reminder to me to keep fit and healthy and active.” Similarly, D1 photographed her dog (Fig. 2b) who reminded her to walk every day, “My puppy gets very annoyed if we don’t go walking every day, at least once, so that’s why I took a picture of her [...] She follows me around and I say, ‘Do you want to go for a walk?’ And she runs to the door. So, anyway, she’s a reminder.”

**Figure 2. Symbolic reminders.** (a) Child; (b) Dog; (c) Flowers; (d) Medications.

Some participants photographed symbols of the rewards of good health. For example, D7 described a reminder that symbolized enjoyment of the outdoors. He used his Polaroid camera to take “a picture of being able to look outside and enjoy the day. [...] Just a reminder to myself, I’ll get a chance to see another day.” D9 also took a picture of the outdoors; hers focused on flowers (Fig. 2c). She explained how she was temporarily barred from sewing because of pain in her hand, “I’m off limits now with this hand. It’s driving me crazy, so I got to remember ‘I’ll get back to it, just relax.’ [...] If I can’t sew, I’ll go out and smell the flowers and take it easy.” In contrast to these positive symbols of good health, D6 reminded himself of the costs of poor health (Fig. 2d): “I took a picture of all of my medications because whenever I look at them I’m reminded of how much poor health can cost you. They all add up, and so they remind me to try to watch my weight and watch what I eat so hopefully keep my problems under control—hypertension and diabetes and also my chemotherapy drugs.” These symbolic reminders were part of patients’ everyday lives, motivating them to seek the rewards of healthy behaviors.

**Discussion**

Our participatory design approach to understanding persuasive reminders for health self-management revealed several implications for future systems. First, participants challenged the traditional conception of delivering reminders at the right time. Rather, participants emphasized the persuasive value of reminders that sparked behaviors well ahead of time. For example, introspective reminders were oriented toward helping patients to plan ahead and prioritize health tasks. Participants emphasized that being triggered well ahead of tasks was important for helping them to build awareness of their health trajectory and contextualize their health tasks within it. Introspection on the relationship between health tasks and goals enabled patients to reflect on cause-and-effect relationships between health behaviors and outcomes over long time spans. This reflection aided contemplation on the rationales—the why—for performing health tasks. Similarly, symbolic reminders that were embedded in everyday activities and relationships were not conceptualized as just-in-time triggers. Rather, the image of a child, a favorite
hobby, or an outdoor scene were omnipresent reminders that heightened awareness of personally significant rationales for being healthy. Thus, reminders that spark health behaviors well ahead of time enable persuasive messaging that increases self-awareness and motivation to perform health tasks.

We found that, in addition to systems that increased motivation, participants designed systems that increased their ability to perform them. While introspective and symbolic reminders helped patients to understand why they were doing health tasks, socially supportive and adaptive reminders emphasized how to perform tasks. Such systems provided them with information about resources, services, and instructions relevant to tasks that helped them to develop expertise. For example, some participants designed “divine interventions” by genies who reminded them of the skills and resources needed for tasks. The focus on skills mastery that characterized socially supportive reminders was designed to facilitate shifting accountability for health tasks from parents to children, and from patients alone to patient-provider collaboration. Similarly, the emphasis of adaptive reminders on anticipating needs and making recommendations created new opportunities for sharing accountability between patients and providers. Participants valued socially supportive and adaptive reminders for enabling them to reduce the burden and frustration of chronic illness management. They described how these reminder systems would help them have more confidence in their ability to be effective self-managers and to work together to remember and achieve health goals.

We also found that participants considered personalization to be crucial to persuasive reminders for health self-management. Participants linked personalization to feeling more engaged in health care and more willing to follow through on health tasks. They designed systems that were personalized in terms of both the message being delivered, and the mode of its delivery. For example, a mother designed a mobile-phone based application that delivered tailored messages about asthma care based on her child’s personal health information. The application would detect weather conditions and other information relevant to asthma to create reminders as the context changed. An older adult designed a refrigerator-based system that gathered information and delivered reminders relevant to nutritional management for patients with diabetes. These examples demonstrate that the technological embodiment of reminders for asthma require different affordances than those for diabetes care due to the unique contexts of certain health behaviors. Studies have demonstrated that persuasive health reminders personalized to individuals’ susceptibility to different persuasive strategies exceed the impact of generic reminders. Our findings confirm and expand this finding by suggesting that patients are most likely to be persuaded by health reminders that are personalized to their health goals and values, in addition to their preferences for different persuasive strategies.

Finally, the four types of persuasive reminders that we identified—introspective, socially supportive, adaptive, and symbolic—had different affordances for individual, intra-familial, and patient-provider interactions. These different patterns of interaction influenced both the scope of persuasive strategies, and the roles of patients, caregivers, and providers in health self-management. For example, introspective reminders were primarily designed for individual contemplation, whereas socially supportive reminders aided families, and adaptive reminders featured collaboration between providers and patients. Designing for these different units of analysis offers new ways to innovate health reminders that promote shared accountability and social learning for health. Our findings point to the importance of designing persuasive health reminder systems that individuals, families, and patient-provider pairs can interact with.

**Conclusion**

We used a participatory design approach to understanding patients’ and caregivers’ desires for health reminder systems that persuade them to manage the myriad and complex tasks of preventive and chronic illness management. Participants embodied their perspectives of desired futures in design artefacts that revealed four types of persuasive reminders for health self-management: introspective, socially supportive, adaptive, and symbolic. We contribute insights into implications for the design of persuasive health reminders including designing for the how and why of performing health tasks, triggering tasks well ahead of time, and personalizing both the message and the medium of reminders. Our contributions to persuasive system design are grounded in an ethical approach to engaging patients as authors of their own persuasive strategies that reflect their attitudes toward health self-management. This approach is significant for informing the design of patient-centered systems that empower people to adopt health behaviors in ways that are sensitive to their cultural, personal, and interpersonal values.

Assessments of the Veteran Medication Allergy Knowledge Gap and Potential Safety Improvements with the Veteran Health Information Exchange (VHIE)

Abstract

The U.S. Department of Veterans Affairs (VA) Veteran Health Information Exchange (VHIE, formerly Virtual Lifetime Electronic Record, or VLER) had been deployed at all VA sites and used to exchange clinical information with private sector healthcare partners nationally. This paper examined VHIE’s effect on allergy documentation. Review of all inbound VHIE transactions in FY14 showed that VHIE use was associated with a nearly eight-fold increase in allergy documentation rate. Preliminary manual document review further showed that VA and partners had shared knowledge of only 38% of patient allergies, while VA had exclusive knowledge of another 58% of patient allergies, and partners had exclusive knowledge of the last 5% of patient allergies. To our knowledge, this is the first study that examined the effect of HIE on allergy documentation.

Background

Allergies rank sixth as a cause of chronic illness in the United States, affecting more than 50 million Americans each year with an annual cost of more than $18 billion. Drug allergies worldwide are estimated to occur in 1% to 2% of all hospital admissions and 3% to 5% of hospitalized patients. Because allergic reactions may cause death or severe morbidity, documentation and exchange of allergy information is necessary for appropriate patient care. Missing information such as the knowledge that a patient has a life-threatening allergy to a medication—can result in catastrophic adverse events. In addition, maintaining medication allergy lists is a functionality included in the Centers for Medicare and Medicaid meaningful use program.

Interoperability across electronic health record (EHR) systems is important so that providers can share allergy information. Using a health information exchange (HIE) enables the storage of information about active allergies and medications so that providers can view medication lists and improve patient safety by avoiding drug/allergy interactions. Having drug information can improve efficiency by reducing the amount of time spent reviewing medication lists. Electronic medication administration records, ePrescribing, and provider order entry depend upon accurate medication and allergy lists. A U.S. Government Accountability Office study found that patient allergy information was among the most critical types of information needed by providers through health information exchange. That study reported that existing standards for exchange of allergy information are not adequate; one EHR system may label an allergic reaction as a side effect, while another system may classify the same reaction as an allergy.

Goss et al. indicated that the correct terminology for encoding allergies is complicated and that there are gaps in existing standards. They described the differences between the terms allergy, intolerance, hypersensitivity, and adverse sensitivity and pointed out that allergies are often poorly documented in EHRs. They conducted a comparative analysis of different standard terminologies for encoding information about allergies and recommended criteria for assessing standard terminologies. The Veterans Administration (VA) and the U.S. Department of Defense conducted early work in this area and constructed a framework to exchange standardized codified drug allergy information.

In a survey of emergency department physicians’ views of HIE, 21% of respondents chose allergy information as one of the top five data elements they would like to see included in an HIE. A survey of primary care physicians found that allergy information was described, among only three items, as highly important. Another survey found that most respondents indicated that verifying a medication and allergy list obtained through an HIE was faster than creating one.

Objective

The VA is pursuing interoperability between its EHR and private sector EHR systems through its Veteran Health Information Exchange program (VHIE, formerly known as the Virtual Lifetime Electronic Record, or VLER program.) Potential outcomes of VHIE include support for decision making, improved quality, safety and
coordination of care, reduced redundant testing and cost savings, and more and better access to information. The VHIE program has the potential to increase availability of allergy information to VA clinicians and partner clinicians in the private sector. The objective of this article is to assess whether VHIE helps improve allergy documentation in the EHRs of veterans seeking care by examining several different aspects of allergy documentation in different subgroups or contexts:

1. How often do VHIE-supported VA visits (i.e., a VA clinical encounter where the VA provider retrieved a VHIE document from an external partner organization) coincide with new allergy entries or updates to existing allergy entries? How does this rate compare with that of a non-VHIE Veteran?
2. How often are VHIE partner organizations aware of allergies in Veterans whom VA believed to have No Known Drug Allergies (NKDA)?
3. In Veterans who have documented allergies at VA, how do VA and partner allergy documentations compare? How complete are VA records? How complete are partner records?

Methods

We defined the intervention group as all Veterans who had an inbound VHIE transaction in fiscal year 2014 (FY14, October 2013 through September 2014) as reported by the Veteran Authorization and Preference (VAP) system, with all test users and test transactions removed. The VAP server was also used to identify all VHIE-participating Veterans so they can be excluded from the control group.

The Veteran demographic information reported by the VAP server was then linked to Veteran visit history and VA allergy documentation stored in VA's clinical data warehouse (CDW). SAS software was used to retrieve data via SQL queries and calculate the following variables:

1. What percentage of FY14 VHIE inbound transactions occur on the same day as a VA visit and either a) a new allergy record, or b) an update to an existing allergy record?
2. What percentage of 10,000 randomly selected FY14 VA visits in non-VHIE participating Veterans occur on the same day as either a) a new allergy record, or b) an update to an existing allergy record?

The authors then conducted preliminary manual record reviews using two separate samples of 10 charts:

1. Review of all inbound VHIE documents of 10 randomly selected Veterans in the intervention group who has no VA allergy records. The Veterans were then classified into three categories: a) Confirmed NKDA from partner organizations; b) No allergy documentation from partner organizations; or c) Documented allergies from partner organizations.
2. Review of all VA allergy records and all inbound VHIE documents of 10 randomly selected Veterans in the intervention group who had one or more VA allergy records. One of the physician authors (Dr. Pan) then manually reconciled and de-duplicated all documented allergies for each Veteran to determine a) total number of allergies documented for each Veteran; b) the number of allergies known only to VA; c) the number of allergies known only to partner organizations; and d) the number of allergies known to both VA and partners organizations.

The data analysis for this paper was generated using SAS software, Version 9.3 of the SAS System for Microsoft Windows and Microsoft Excel 2010.

Results

During FY14, over 6,000 Veterans benefitted from VA providers retrieving their non-VA medical records via VHIE. After de-duplicating multiple retrievals on the same day, there were 6,331 unique VHIE inbound transactions (i.e. unique Veteran-date pairs) in FY14. When cross-referenced against VA’s CDW allergy documentation database, there were 476 allergy creation or modification entries for these Veterans that occurred on the same day as their respective inbound VHIE transactions, or approximately 7.5% of the VHIE-supported VA visits (See Table 1: Frequency of Allergy Updates in VHIE and non-VHIE Visits below). In comparison, in a sample of 10,000 randomly selected visits from non-VHIE Veterans, only 84 visits were associated with a corresponding change in allergy documentation. Based on these comparisons, the use of VHIE is associated with a nearly 8 fold increase in allergy documentation rate (7.5% vs. 0.84%).

</table>

In addition to the analysis of allergy documentation rates discussed above, the authors manually reviewed the VHIE transactions and allergy records of 10 Veterans with no known drug allergy and 10 Veterans with known allergies. For the 10 Veterans in which VA is unaware of any drug allergies, 3 of them were explicitly documented as NKDA by VHIE partners. In addition, 6 of the Veterans simply had blank or empty allergy sections in their VHIE documents, passively confirming that the VHIE partners are also unaware of any drug allergies. However, VHIE partners reported a previously unknown drug allergy on one of the Veterans, an important patient safety contribution to VA sites caring for this Veteran (Figure 1, below).

Figure 1. Partner knowledge when VA has no documented allergies

The authors also reviewed 63 VA allergy records and 25 VHIE partner allergy records on 10 Veterans with known drug allergies (Figure 2. Number of allergies documented by VA and Partners, below.) After manual reconciliation and de-duplication, there were 53 unique Veteran allergies documented. VA allergy documentations included 49 out of these 53 unique Veteran allergies. As such, VA is aware of 95% of the Veteran’s allergies (Figure 3. Percentage of allergies known to VA vs. Partners, below.) Based on the VHIE documentations reviewed, VHIE partners are only reporting 25 unique Veteran allergies, or merely 43% of all known allergies. In addition, 38% of the 53 unique Veteran allergies are known to both VA and VHIE partners. So, only 5% of all allergies are known exclusively to VHIE partners.
Discussion

This paper presented a preliminary study of HIE’s impact on allergy documentation through analysis of the correlation between VA providers’ retrieval of external clinical documentation through VHIE and their updates to the Veteran’s allergy documentation. We further examined the contents of the shared VHIE allergy documentation to support the potential for VHIE information sharing to improve both VA and external clinician’s knowledge of Veteran allergies.

At baseline, our random sample of 10,000 VA visits showed an allergy documentation update rate of 86/10,000, or 0.86%. Considering that Veterans in our sample ranged from 1 visit per year to more than 100 visits during FY14, the update rate could be as high as 1 allergy entry update per Veteran per year, which is not insignificant or unreasonable. However, it paled in comparison to the allergy documentation update rate of 7.5% among VHIE-supported visits to VA providers. This was a 772% increase, or nearly an 8-fold difference. There’s several possible explanations for this dramatic difference. First, the VA allergy documentation database captured both new allergy entries and updates to existing allergy entries. So these transactions included both when VA providers learned of a new Veteran allergy from non-VA records, and when an existing allergy documented by VA is confirmed by external records. Second, we may be observing a transient increase in allergy documentations due to the initial
reconciliation between two or more data sources of Veteran allergies. This would imply that the allergy documentation rate would decrease, or decay, as more documents are exchanged on the same patient. Finally, some providers may simply be copying external allergy documentations into VA records en masse without deduplication for medicolegal purposes, leading to a superficial increase in allergy documentation rates. Therefore, future studies should follow allergy documentation rates in the same population over time to monitor whether this increase is sustainable. In addition, in-depth content analysis of existing VA allergy documentation, VA allergy documentation updates, and allergy documentation shared by VHIE partners would help to confirm whether the information shared and updated had clinical significance.

In the small group of ten Veterans with known drug allergies to VA examined in this study, less than 40% of allergies were known to both VA and external providers. This is a dangerous situation for patient safety. While we did not conduct further chart reviews to determine how much patient harm occurred due to this lack of information, some avoidable events undoubtedly occurred. This preliminary and rudimentary analysis highlighted the current knowledge gaps and illustrated the potential patient safety impacts of HIE efforts such as VHIE.

Although these results are preliminary and limited in scope and sample size, the three analyses demonstrated reasonable internal consistency. When comparing indicators of VHIE partner contribution of allergy documentation and knowledge, the VA provider documentation update rate of 7.5%, the partner report of allergy in 10% of Veterans with no known drug allergies to VA, and the 5% allergies known exclusively to partners, all help to constrain VHIE partner contribution to VA allergy knowledge between 5 to 10%. In comparison, VA’s ability to contribute 58% of unique knowledge about Veteran allergies cannot be understated, and should continue to motivate VA to promote sharing of VA records with non-VA providers.

**Conclusion**

To our knowledge, this is the first study to examine the relationship between HIE use and allergy documentation. In this sample of 6,183 Veterans with 6,331 inbound documents in FY14, the use of VHIE was associated with an eight-fold increase in the allergy documentation rate (7.5% vs. 0.84%). In addition, selected manual review of both Veterans with no known allergies and known allergies had shown that VHIE partners can contribute previously unknown (to VA) allergy information at least 5–10% of the times. It was informative to learn that VHIE partners are only aware of less than half of Veteran’s allergies. As such, continued efforts to promote partner use of VHIE to retrieve VA documentations would greatly enhance partner’s knowledge of Veteran allergies and improve patient safety.

ABSTRACT

Terminology services serve an important role supporting clinical and research applications, and underpin a diverse set of processes and use cases. Through standardization efforts, terminology service-to-system interactions can leverage well-defined interfaces and predictable integration patterns. Often, however, users interact more directly with terminologies, and no such blueprints are available for describing terminology service-to-user interactions. In this work, we explore the main architecture principles necessary to build a user-centered terminology system, using an Extract-Transform-Load process as our primary usage scenario. To analyze our architecture, we present a prototype implementation based on the Common Terminology Services 2 (CTS2) standard using the Patient-Centered Network of Learning Health Systems (LHSNet) project as a concrete use case. We perform a preliminary evaluation of our prototype architecture using three architectural quality attributes: interoperability, adaptability and usability. We find that a design-time focus on user needs, cognitive models, and existing patterns is essential to maximize system utility.

INTRODUCTION

Controlled terminologies are an important part of the medical record. The semantics they provide to heath care data is critical not only for interoperability between systems and institutions, but for analytics and secondary use[1]. Demand for these terminology resources at an enterprise level has driven the creation of functional requirements[2], formalizing the role of a terminology service in the enterprise. Because of their broad importance, terminology services are generally thought of as infrastructural components, existing to support other applications[3, 4] such as clinical decision support[5] and data processing pipelines[1].

There are, however, many instances where users may interact more directly with terminologies. One such example is the Extract-Transform-Load (ETL) use case. ETL scenarios, usually involved in data warehousing, not only must transform data structure, but data semantics as well[6]. Metadata describing the data semantics is not always readily available[7], which frequently places the responsibility of capturing, managing, and mapping these semantics on the ETL developers. This presents two problems. First, semantic transformation logic may become intermixed with the structural transformation process, and any captured terminology becomes a black box rather than an explicit, shareable knowledge artifact[8]. Second, clinical terminology is complex, and ETL developers often need subject matter experts’ and clinicians’ engagement to properly capture semantics[9].

In this work we present a design approach to the application of terminology services, centered around the ETL use case, that is deliberately focused on the needs and goals of the user, or user-centered[10]. We propose this not because existing terminology services are insufficient, but because domain mastery of terminology modeling and services is not universal, and should not be a prerequisite for utilizing these services – a notion we borrow from a recent study of bioimaging software[11]. Lowering the barrier to entry to these services while keeping users’ processes and cognitive models in mind increases usability[10] and ultimately, utility. Our focus is less around a terminology service in isolation, and more centered on a terminology system – or, the service along with other components in the context of a use case. With this in mind, we present a set of architectural principles necessary to satisfy both our functional and usability goals of a terminology system. Finally, through a concrete case-study, we analyze a prototype system against these principles.
MATERIALS AND METHODS

Use Case: The Patient-Centered Network of Learning Health Systems

The National Patient-Centered Outcomes Research Institute (PCORI), authorized by Congress in 2010, is an independent nonprofit, nongovernmental organization centered around Clinical Effectiveness Research (CER)[12] with the goal of advancing clinical care by utilizing an evidence-based comparison of methods[13]. The National Patient-Centered Clinical Research Network (PCORnet), a PCORI initiative, focuses on the development of networks to share health care related data[14]. The Patient-Centered Network of Learning Health Systems (LHSNet), a collaboration of ten institutions, is our specific segment of the PCORnet network[15]. The goals of LHSNet build on the objectives of PCORI and PCORnet, and focus on the ability to distribute queries throughout the network. Although the sites are not exchanging patient data – only summary-level query results – a precondition for the network is that each site maintain a common data model-based data mart.

PCORnet Common Data Model. It is necessary for any distributed data set to agree on common data structures and semantics[16]. For PCORI, this agreement is in the form of the PCORnet Common Data Model (CDM)[17]. The PCORnet CDM provides database agnostic information on the data structure (such as data types and referential integrity), as well as data semantics (in terms of allowable values for codified data).

Creating the Data Mart. Construction of a PCORnet CDM compliant data mart introduces our ETL use case. Integrating multiple diverse data sources into a common representation presents significant challenges. First, the data must be structurally aligned at a schema level. Given multiple data sources, this problem compounds[18] – naming of objects and attributes may differ, and differences in granularity will need to be reconciled. Structural differences are only one aspect, however. Semantic alignment needs to be considered as well, and is of particular interest to this study because it often requires a dedicated terminology service[19, 20, 7]. Semantic alignment, or the reconciliation of analogous codifications, is an important aspect to maximizing data utility, especially across institutions[21].

Related Use Cases. LHSNet draws many similarities to other multi-institutional research network initiatives – mainly, the Informatics for Integrating Biology and the Bedside (i2b2)[22] and Observational Health Data Sciences and Informatics (OHDSI)[23] projects. We explore below in brief the data model and terminology integration of the two.

The i2b2 data model is centered around observations on a patient, or “facts”[24]. Each of these facts is associated with a single concept – either a locally defined term or a concept from an external standard. The concepts themselves are arranged into a collection, or i2b2 ontology, which can then be used to build dynamic queries into the data.

OHDSI uses the Observational Medical Outcomes Partnership (OMOP) Common Data Model as a data specification. WhiteRabbit,1 an OHDSI developed tool, supports the ETL process by allowing examination of the source and target database structure and content. OMOP provides extensive guidance around both terminology and its structure via the OMOP Common Data Model Standard Vocabulary Specification Version 4.5[25]. Both of these use cases require the use of a defined CDM, and thus, require some sort of ETL process to import data. As with LHSNet, this data import requires the management of the data semantics. Huser and Cimino, while analyzing both OMOP and i2b2, suggest that “[a] terminology driven ETL process” would be a useful, especially when mapping local codes to external standards[20]. This observation aligns with our examination of the LHSNet use case, and suggests some degree of a shared need.

Terminology Models and Services

Value Sets. For our purposes, we define a value set as a set of codes used to define a semantic domain of interest. They must have some notion of a unique identifier and also may carry various metadata, such as names and descriptions. The PCORnet CDM defines 70 value sets to constrain attributes in the data model. These value sets are identified by a unique name and contain concepts specified by a code, name, and optional description. For example, the PCORnet CDM Race value set is shown in Table 1.

Mappings. Mapping is a process of asserting relationships between concepts from different value sets[26]. These relationships can signify equivalence (or degrees thereof), hierarchical association (such as broader/narrower), or that no match exists for a concept. This is often done for interoperability purposes, where diverse data sets need to be aligned into a common semantic model[27]. It is also prevalent in ETL and data warehousing operations, where the target data model may specify value sets to which the incoming data must conform. To align these semantics, an institution will need to map their internal value sets to the target data sets. This is certainly the situation with our LHSNet use case, as multiple internal value sets need to be aligned to the PCORnet CDM semantics. Table 2 shows a sample view of a mapping of institution-specific codes to the PCORnet Race value set.

General System Functionality

Our goal is not to enumerate the functional requirements of our specific use case. We aim to reason about a broader architecture – one capable of supporting functionality outside of our current needs. There are, however, some general functional statements we can assume for our system that should broadly apply. Although not exhaustive, the following functional areas of concentration serve to scope our discussion.

**Terminology Content and Services.** Access to terminology resources depends on two factors: (1) the robustness of the structures used to model them, and (2) the completeness of the services in place to access these structures. At a minimum, the system shall provide a model for value sets and mappings, as well as services providing Create, Read, Update, and Delete operations. Content, both institution-specific and externally defined standardized terminologies, is generally necessary but use case dependent.

**Graphical User Interface.** User interfaces are often highly contextual, and effective ones focus on the specific concerns of the intended user base[28]. Because of this, we will not attempt to enumerate all user interface requirements here. At a minimum, manipulation of both value sets and mappings should be supported. Also, discussion and collaboration tooling is known to be important to the overall process of terminology refinement and validation[29], and should be supported natively to promote broader user engagement.

Architectural Quality Attributes

Evaluating the quality of a proposed architecture is a non-trivial task[30]. Quality goals often become represented as non-functional requirements, such as *the system shall be easy for users to use*. This not only presents implementers with a requirement that is untestable[31], it often pushes high-level goals down to individual components or modules, where the overall context can be lost. To avoid this, Architectural Quality Attributes[32] may be used to state system-level goals. They also serve to both influence and measure the system architecture. Below are three important quality attributes for our proposed system. This is by no means an exhaustive list, but was considered the minimal set to meet our stated system characteristics. Implementers are expected to add to this list as appropriate.

**Quality Attribute 1: Interoperability.** With this quality attribute, we aim to measure how well the components of our system share data with each other and external systems[33]. In previous work, the Strategic Health IT Advanced Research Projects (SHARP) demonstrated the need for standardization of data semantics using terminology services when normalizing Electronic Health Record (EHR) data[1]. While clinical data interoperability is the overarching goal, interoperability of the terminology services themselves can be a catalyst to achieving this. The standardization of terminology services can not only provide predictable integration patterns – and thus, greater uptake – but also promote sharing of terminology resources across the enterprise and beyond.

**Quality Attribute 2: Adaptability.** The use cases for terminology systems are continually changing and evolving. Meaningful Use, a large incentive program for leveraging value from the EHR, phases in new functionality over several years[34]. The standards landscape is also changing. Specifically, the increasing use of Fast Healthcare Interoperability Resources (FHIR)[35] will place new demands on terminology systems. Responding to stakeholder needs is critical, and we expect these needs to evolve over time[36]. We use this quality attribute to examine how easily and quickly the system may be changed to meet these evolving needs[32].

**Quality Attribute 3: Usability.** This quality attribute measures the “quality of a user’s experience”[32], with a particular focus on user goals, motivations, and background. Software tooling for terminologies cannot be usable by terminologists alone – it takes a varied mix of subject matter experts to extract the maximum knowledge from the data[37]. Our target user base is highly skilled and often specialized, so impeding these users with usability issues is an expensive proposition. Historically, however, many health care systems are difficult for the intended users to use because they lacked a user-centered design[38]. This leads to poor adoption and can have a direct impact on system success[39]. As usability is of particular interest to our system, we utilize the TURF Framework as a design-time guide – or as the framework states, guidelines for “built-in usability”[40]. This framework, originally designed for analyzing EHR usability, focuses analysis into four components: Task, User, Representation, and Function. Respectively, these components examine the steps or tasks that the user must complete, who uses the system, how the tasks are represented...
to the user, and the basic function the system is to perform. Using this framework will scope our current qualitative design-time discussion and provide a platform for future quantitative usability tests.

**IMPLEMENTATION**

With a concrete use case providing functional requirements and enumerated quality attributes, we now have a mechanism for analyzing an implemented system. Our prototype system implementation is based on three main pillars: (1) a Common Terminology Services 2 (CTS2)[41] compliant network of terminology services, (2) a user-centered graphical user interface to expose functionality to end users, and (3) a loosely-coupled, componentized architectural style. These three implementation focuses are described further in the sections below.

**Terminology Service: CTS2**

CTS2 is an Object Management Group® (OMG) terminology services standard, and includes both a structural model and service specification. It is based on Representational State Transfer (REST)[42] principles, and is comprised of a Platform Independent Model (PIM) and two Platform Specific Models (PSM)s.

**PIM.** CTS2 is specified using Unified Modeling Language® (UML)[43]. Using a platform-independent modeling representation allows for (1) an implementation-independent yet unambiguous specification, and (2) the ability to derive platform-specific models tailored to a specific implementation or computational platform.

**PSM.** The OMG specification provides two platform-specific models, Hypertext Transfer Protocol (HTTP)[44] REST and Simple Object Access Protocol (SOAP)[45]. For our implementation, we will focus primarily on the REST PSM.

**Implementing the Specification.** To speed development, the CTS2 Development Framework was used as a base for implementation. This open-source project is a toolkit for building CTS2 compliant applications, providing compliant HTTP REST bindings, parameter validation, error handling, and a variety of other features. This leaves implementers responsible for more use case specific tasks, such efficient storage and retrieval of terminology data.

To align with the REST architectural style, the CTS2 specification is divided into the structural representation of resource types (Structural Profiles) and a common interface to interact with them (Functional Profiles). As stated above, our system at a minimum must support value set and mapping resources. This requires, at a minimum, a CTS2 service which supports the VALUE_SET_DEFINITION and MAP_VERSION structural profiles. Functionally, to allow full read/write access to these resources, the READ, QUERY, and MAINTENANCE functional profiles should be implemented. See the full OMG specification (http://www.omg.org/spec/CTS2/) for more information on these profiles.

**Graphical User Interface: The CTS2 Workbench**

User experience is of critical importance to our system, and nothing factors into user experience more than the user interface. It is important, however, that although the system is standards-based, it is user-centered. This means that to maximize usability, user interfaces must be in alignment with the cognitive models of the intended users, not simply expose the standardized functionality. For our prototype system, we propose the CTS2 Workbench, a web-based platform for interacting with terminology resources. Although functionally based on CTS2, the Workbench aims to abstract as much detail as possible away from the end user, favoring user task accomplishment over 100% CTS2 functionality exposure. Selected functional capabilities are further described below.

**Value Set Import.** In keeping with our user-centered approach, it is important to understand how value sets (or data dictionaries) are currently being managed. Spreadsheets are ubiquitous in the enterprise, readily available to end users, and for better or worse, serving important roles in business function[46]. For our purposes, they are also a simple storage mechanism for tabular data – a schema in which value sets and mappings may be readily fit. Rather than force an alternative workflow onto the user, we prefer to leverage the existing spreadsheets by viewing them as part

---

2 Source code available at https://github.com/cts2/cts2-framework
of the workflow[47]. Figure 1 shows how the CTS2 Workbench, via a graphical value set import wizard, can accept copy/pasted spreadsheet data and consume it as a CTS2 value set. We assume no a priori knowledge of the imported data structure, so the user is required to apply the appropriate metadata to the parsed columns via a drag-and-drop interface.

![Figure 1: Importing a CTS2 value set using data from a spreadsheet with user-applied drag-and-drop metadata.](image)

**Mapping Creation.** At a high level, terminology mapping is an exercise in linkage. This is important to note, because through past experiences and daily environmental interactions, users may have pre-conceived cognitive models of how linkages are represented. We can capture these notions as image schemas, or representations of these existing models[48]. Constructing a CTS2 MAPENTRY resource is the functional goal of mapping concepts, but approaching this activity with the linkage image schemas in mind will improve usability. Intuitively, a line connecting two objects is a strong way to convey linkage[49]. Figure 2 contrasts an approach based heavily on the CTS2 structure (Detailed View) with one aligned to a linkage image schema (Simple View). The CTS2 Workbench is implemented to allow both views to be used, giving users the option of either a simplified interface or a more powerful, detailed one. This layered approach to interface complexity is used throughout the CTS2 workbench and can be an effective way of engaging users with different levels of experience or domain knowledge[50].

**Architectural Style: Microservices**

Microservices is an architectural style where targeted, task-specific software modules are implemented, deployed, and maintained independently, while together functioning to fulfill a larger task[51, 52]. Using this style can allow for rapid, incremental expansion of the system as needs arise. For example, in our prototype, functionality was added to the system to automatically map two value sets based on lexical similarity. This presented two challenges: (1) it was outside of the scope of the CTS2 specification, and (2) computing lexical similarity is a complex task. By deploying this functionality as a microservice, we are able to wrap CTS2 services without modifying the larger CTS2 infrastructure. Also, because this service has a separate development/deployment lifecycle, we are free to redeploy rapidly as our lexical mapping implementation improves.
Figure 2: Using established cognitive models to abstract CTS2-specific details when creating terminology mappings.

**DISCUSSION**

**Quality Attributes.** Seventy value sets specified by the PCORnet CDM were imported into the system, as well as an increasing number of internal value sets and mappings from various sources. The CTS2 specification demonstrates the ability to model these constructs without degradation of semantics. More importantly, via microservices, our architecture is positioned to respond to evolving user demands. This demonstrates a degree of **Adaptability**.

Leveraging existing terminology sources reduces the system implementation burden. By utilizing the CTS2 specification, we are able to consume data from the National Cancer Institute (NCI) CTS2 implementation. This rich source of data provides numerous standard vocabularies, eliminating the need for us to manage them ourselves. Because the data and service interactions have been standardized, the CTS2 Workbench is able to consume both data points seamlessly. Without the **Interoperability** enabled by CTS2, system cost would have been much higher.

Centering the design on the user drove much of the implementation. At the beginning of the LHSNet effort, all value sets and mappings were managed on spreadsheets. Rather than disregard this process as inefficient, it was leveraged as insight into the cognitive models of end users. Placing a focus on importing data from spreadsheets also allows us to lower the barrier to entry of the system. Focusing on the user, their existing processes, and their cognitive models allows the system to have high potential **Usability**.

**TURF Framework.** The four components of the TURF Framework played a large role in the usability design. First, the **User Analysis** focused mainly on ETL developers engaged in creating the PCORnet CDM compliant data mart for the LHSNet project. This analysis, conducted using semi-weekly meetings, provided an overview of their experience with terminology services as well as their motivations for applying these services to an ETL process.

Next, LHSNet and two related use cases (i2b2 and OHDSI) were examined for overall functional requirements. This allowed us to derive some generalized functionality statements necessary to support creation of the PCORnet CDM compliant data mart, our primary use case. Aligning the design to concrete use cases was part of the **Functional Analysis** of the system.

After analyzing functionality, **Task Analysis** was used to determine the steps currently taken by users to facilitate the ETL process. By examining the users’ current workflow and tools, we were able to align the architecture to incorporate

---

3https://wiki.nci.nih.gov/display/LexEVS/LexEVS+6.2+CTS2
existing spreadsheet-based methods by providing import functionality. Furthermore, through task analysis, we can isolate steps in the user processes that can be streamlined with additional tooling support. Using microservices, we can quickly respond to this need, as demonstrated by the automated mapping example.

Finally, Representation Analysis was used to ensure user interface components expressed these tasks in straightforward ways. Through interviews of LHSNet ETL developers and an analysis of their current tools, alignment of the design to their existing cognitive models could be measured. Through this process, mapping visualization was identified by the users as a deficiency of the spreadsheet-based approach. An image schema was developed for this feature in collaboration with the users and served as the basis for implementation, shown in Figure 2. Iterative development with user feedback was used to validate and refine the implementation.

**Summary.** We find that these quality attributes along with the TURF Framework are effective architectural tools for designing a user-centered terminology system. Through our prototype implementation, we demonstrate that the design-time emphasis on usability, interoperability, and adaptability can be successfully applied to the development of a terminology system, maximizing system utility.

**Limitations and Future Work.** For the LHSNet project, semantic concept to concept alignment was not necessarily sufficient. Smoking Status was one such example. As Figure 3 shows, the alignment of semantics sometimes depends on business logic. In this example, we attempt to align the internal semantics of tobacco use with the PCORnet CDM. To be classified as a PCORnet smoker, we must assert that tobacco is currently in *use* and that the tobacco is being smoked. As shown by the PCORnet CDM value set, further classification of *light/heavy/etc.* is possible, introducing the need for further business rules. Although the CTS2 specification supports a rule-based mapping, it is unspecified as to how those rules should be encoded or executed. Furthermore, user interaction with business rules (such as authoring and testing) is often difficult for non-technical users[53], and would introduce new usability challenges.

Although the TURF Framework served our need as a design-time guide for building-in usability, a quantitative usability study using this framework was beyond the scope of this work. As the prototype implementation matures, the TURF Framework can be used to gather usability metrics (such as task completion time), which in turn can be used to provide evidence-based recommendations for future development iterations.

![Figure 3: Intermixing business logic and semantic mapping: A flowchart for aligning Smoking value sets.](image)

Abstract

We present a pre/post intervention study, where HARVEST, a general-purpose patient record summarization tool, was introduced to ten data abstraction specialists. The specialists are responsible for reviewing hundreds of patient charts each month and reporting disease-specific quality metrics to a variety of online registries and databases. We qualitatively and quantitatively investigated whether HARVEST improved the process of quality metric abstraction. Study instruments included pre/post questionnaires and log analyses of the specialists’ actions in the electronic health record (EHR). The specialists reported favorable impressions of HARVEST and suggested that it was most useful when abstracting metrics from patients with long hospitalizations and for metrics that were not consistently captured in a structured manner in the EHR. A statistically significant reduction in time spent per chart before and after use of HARVEST was observed for 50% of the specialists and 90% of the specialists continue to use HARVEST after the study period.

Introduction

In 1999, the Institute of Medicine released To Err is Human,1 which elucidated shortcomings in healthcare and ignited the movement to improve quality and patient safety. Many initiatives aimed at improving healthcare quality were developed, several of which involved the creation of large-scale data registries that are populated using both claims data and manual data abstraction.2

Indicators used to assess quality of care are often buried within patient records. To accurately abstract these quality indicators, specially trained nurses manually comb through patient records to locate relevant information. Our 2,600-bed institution employs 35 full-time data abstraction specialists dedicated to reporting quality metrics for 30 databases covering 13 disease states and processes of care. Measures include CMS and Joint Commission databases for Core Measures, as well as disease-specific registries such as transplant, sepsis and stroke. The goals of the databases vary, from national benchmarking, to inclusion in value-based purchasing, to peer-comparisons for facilitating quality improvement. Participation in some databases is voluntary, such as the Society for Thoracic Surgery data registry, while participation in others is a regulatory requirement, such as the UNOS transplant database.

Each data abstracter is responsible for extracting a particular set of data using a combination of structured and unstructured clinical data including laboratory test information, comorbidities and complications through review of clinical documentation, and changes in clinical status throughout a patient’s hospital stay. The complexity of each database and ease of access to information is highly variable. Some registries populate data through electronic feeds of structured documentation while others require complete manual abstraction for everything from demographics to time of symptom onset. Although every data abstracter is responsible for reporting information from patients’ heterogeneous and voluminous records, the information they seek is very different, and the tools they use are different as well.

While there are many benefits in participating in quality improvement registries and databases, the burden of manual abstraction can be excessive. In fact, it is estimated that for physician practices, physicians and staff spend on average 15.1 hours per week and approximately 15.4 billion dollars annually dealing with the reporting of quality measures.7 Despite the large time burden, it is likely that the number of reported quality metrics will continue to grow.8

There has been some recent success in developing natural language processing (NLP) approaches for quality metric abstraction. However, these approaches are evaluated in a retrospective fashion, outside the workflow of clinical data abstraction experts, and have largely been disease- or metric-specific. Some tools have been developed mainly for internal comparison purposes3 and others optimized to report quality metrics to specific databases: Yetisgen et al. developed a system for automated extraction of comorbidities, operation type, and operation indication for surgical care reporting4 and Raju et al. developed an automated method for the specific extraction of adenomas mentions5.
Beyond the barriers of moving from retrospective studies to interventions, and deploying NLP-based systems in a hospital setting, there exist barriers specific to the DA work: the metrics, diseases, and types of information needed vary drastically from one database to another. Furthermore, most of the DA work consists of abstracting (rather than extracting specific facts from the record) based on unstructured guidelines (although there has been work on automatically structuring quality metrics\(^6\)). The disease-specific work has yielded promising results and shown that some disease-specific metrics can be extracted in a fully automated fashion. Still, to date there are few available disease-specific quality metric abstraction tools as they are difficult to create and optimize, especially as the gathering of quality metrics is very heterogeneous. We hypothesize that a more holistic and broad approach could provide much needed support to a variety of DAs at once.

There has been some research demonstrating the potential benefit of holistic clinical summarization tools for physicians at the point of care\(^9,10\), however, there has been much less work examining the information needs and utility of a holistic summarization tool for the purpose of quality abstraction. Our institution already provides EHR users access to HARVEST\(^11\), a real-time, patient-level, summarization and visualization system. HARVEST was originally developed to aggregate relevant patient information for busy clinicians who often do not have the time to read or even skim through all available previous clinical notes. In this study, we explore the value of HARVEST in a different scenario—as a support tool for DAs in their abstraction work. HARVEST’s interface consists of three sections: a Timeline, a Problem Cloud, and a Note Panel (Figure 1). The Timeline is interactive and provides a high-level display of a patient’s inpatient, outpatient, and ED visits. The Problem Cloud displays all of the patient’s documented problems (as extracted from parsing of all the patient’s notes) with the most salient problems for this patient during the selected time range appearing larger and on top. HARVEST is a general-purpose summarization system: it extracts all problems relevant to a patient and operates on all patients in the institution. As such, it differs from the dedicated NLP approaches to quality abstraction described above in that it does not aim to do the work of the DAs, but rather support them in their search for information in the vast amount of documentation available for a given patient.

![Figure 1](https://example.com/harvest-screenshot.jpg)

**Figure 1.** Screenshot of HARVEST for a de-identified patient record. The Timeline focuses on a single admission, and the user has selected "vomiting" in the Problem Cloud. The Note Panel shows the notes for that visit which mention the problem. The user has selected specific note (on the right) and all the mentions of that problem are highlighted.
Our overall research question for this study is whether a patient record summarization tool, such as HARVEST, supports the needs of DAs during their abstraction work. Towards that goal we designed a pre/post intervention study aimed at DAs with a heterogeneous range of metrics and abstraction workflows. We investigated the DAs’ subjective satisfaction of the tool as well as the impact on workflow based on their usage logs of the EHR.

Methods

Data Collection

After obtaining appropriate institutional review approval, we presented HARVEST in November 2015 to Data Abstraction specialists at NYP as part of one of their “Lunch and Learn” meetings. The presentation included a 10-minute demonstration of HARVEST and where to access it on the EHR. DAs were recruited to participate in our study and consented one by one.

DA study participation consisted of four parts: (1) subjects were asked to answer a pre-study questionnaire; (2) for 4 weeks, the subjects were asked to use HARVEST during their normal course of abstraction, whenever they felt it might be useful to their abstraction and for any given patient; and (3) after the study period, the subjects were asked to respond to a post-study questionnaire. Finally, for all subjects, (4) their EHR usage logs were collected for three months before the beginning of the study and two months after the end of the study period (i.e., three months after beginning of study).

The pre-study questionnaire consisted of 20 questions and captured basic information about the DAs, including how long they had done abstraction work, which database they abstract for, how many data elements they need to abstract for a given patient chart, and a description of their typical workflow when abstracting a chart (i.e., which part of the EHR they visit and in which order). The pre-study questionnaire also asked for expectations of where HARVEST might be most useful, and where it may fit into the DA’s specific workflow.

During the 4-week study period, we sent weekly reminders to the subjects that they could use HARVEST whenever they felt it would be useful to them.

The post-study questionnaire consisted of 33 questions. The questions were inspired by the Technology Acceptance Model (TAM) and the System Usability Scale (SUS). Many of the SUS questions were included in the questionnaire to measure ease of use and intention to use. Other questions were included to capture the DA’s overall perception of HARVEST, for what purposes they used HARVEST, its perceived usefulness for their abstraction work, whether they had identified any unintended consequences of using HARVEST, and whether the subjects planned to continue using HARVEST in their daily work.

The questionnaires were distributed and results were collected using Qualtrics. The EHR usage logs were obtained for all systems in the NYP EHR ecosystem (which include HARVEST usage logs). The logs contained information about which function within the EHR was accessed and at what time. Examples of action types include document review, laboratory test results overview, and visit summary review. Usage log analysis enabled the computation of metrics such as time spent abstracting a given patient chart and how many patients were reviewed with or without access to HARVEST. Basic workflow information can also be derived from the usage logs as frequent sequences of actions of the different users.

Metrics

We assessed the impact of HARVEST on DA workflow in three different ways: user perception, workflow changes, and user retention. All data processing and statistical analyses were done using a combination of python and R.

User perception about HARVEST was measured through the pre and post-questionnaire questions. We compare how the DAs predicted they would use HARVEST and how they actually used HARVEST during the study period.

For the workflow analysis, we present DA self-reported workflows and measure workflow changes using the EHR log data. Workflow changes were measured in two different ways: how long DAs spend and how many EHR action types DAs take on individual patient abstractions before and after the introduction of HARVEST. The pre-HARVEST period was defined as 3 months before the DA was introduced to HARVEST, and the post-HARVEST period was defined as 3 months after the DA was introduced to HARVEST. A t-test with Bonferroni correction was used to measure whether there was a change in time spent per patient or a change in number of EHR actions for each DA before and after the introduction of HARVEST. Of note, all patients abstracted in the post-HARVEST period (whether seen with HARVEST or not) were included in the EHR log analyses.
To measure the most common workflows within HARVEST, we ran the SPADE algorithm\textsuperscript{1} for sequence event mining (using the cSPADE package in R) for all HARVEST accesses during the study period.

Retention was measured using EHR logs to see how many DAs returned to HARVEST after the study was completed and how often they used HARVEST after the study was completed. The log-based retention was compared to how the DA predicted they would use HARVEST in the future.

**Results**

**Subjects and DA abstraction tasks**

10 DAs out of the 35 DAs enrolled in the study. Subjects were nurses, and most have worked as DAs for less than 5 years (minimum experience was 1 year, maximum was 13 years). Each completed both the pre-questionnaire and the post-questionnaire 4 weeks after. The median time to completion for the pre and post-study questionnaire was 25 and 13 minutes, respectively.

Together, the enrolled subjects abstract quality metrics for 7 different databases, corresponding to 6 diseases of interest (cardiac metrics are reported to multiple databases). Databases to abstract patient information varied in the number of data elements to abstract, as well as the number of forms to fill out per patient: some have 6-10 different forms per patient while others only 1. In addition, DAs may return to the same patient over time; for example, transplant DAs fill out one form for a patient pre-transplant and another for the same patient at 6 months post-transplant.

Table 1 summarizes the self-reported DAs experiences and workflows, as captured by the pre-study questionnaire. A majority of the DAs abstract over 75 individual data elements for each patient. The data elements are found in at least 7 different EHR data types (e.g., physician and nurse notes, laboratory tests, flowsheets, medication orders, etc.). To find each of the 75+ data elements the DAs routinely visit multiple clinical systems during their workflow, likely a consequence of the fragmented and legacy systems that house patient data in our large academic medical center. One commonality across all DAs is they reported that most of their time is spent reading and abstracting from clinical notes.

Table 1. Participant-reported data from the pre-study questionnaires on what is abstracted, from where, and what is the DA’s general workflow.

When asked further about their abstraction workflow, 9 out of 10 subjects reported that finding relevant information from clinical documentation was tedious, and only 30% of DAs agreed that patient chart review was efficient. There
was in fact a very wide range of perceived time spent per patient chart review across DAs and in particular across databases. Stroke DAs reported spending on average between 20 and 45 minutes per patient; bariatric reported 35-50 minutes per patient; surgery reported 45 minutes per patient; transplant DAs reported between 20 and 90 minutes per patient; cardiac DAs reported 20-45 minutes per patient for one database and 30-120 minutes for another; and sepsis DAs reported 120-180 minutes per patient on average.

**DAs Satisfaction with HARVEST**

In the post-study questionnaire, all subjects agreed that HARVEST was accurate, all elements in the HARVEST interface were necessary and not redundant. All subjects felt confident using HARVEST and did not perceive any negative impact when using it for patient chart review. In addition, most subjects (80%) found the system easy to learn, easy to use, and not unnecessarily complex.

The majority of subjects thought that HARVEST positively impacted their abstraction process (60%), while the rest saw no impact on their abstraction process (40%). None saw a negative impact. Similarly, 60% of the subjects thought they would continue using HARVEST. When asked when HARVEST was useful and when it was not, subjects provided feedback as summarized in Table 2. Subjects found HARVEST most useful when patients had longer charts and they liked the problem-oriented approach to navigating the record. Subjects who did not find HARVEST helpful to their abstraction process reported that the data they abstract is typically easy to find in the patient chart already.

| HARVEST is most useful in when patients have longer charts | “It was helpful in all the cases I abstracted, but definitely helped me save time with longer charts, as we have many elements to abstract. It helped me narrow down timing of events such as onset of sepsis or comorbidities/complications during the patient’s stay” |
| No added value to HARVEST when the information needed is easy to access in the chart. | “Most of the patients I’m abstracting have very short visits so it's easy to read the chart through. Most of the data points are related to the current visit so it's easy to get all the information directly from the short charts. The only data points that Possibly helpful was the history. If this wasn’t included in the H&P (which is rare) then I would try to use HARVEST for it.” |
| HARVEST’s problem-oriented navigation of the chart is helpful. | “It’s easier to find the notes with correlating information” |

Table 2. Common perceptions of HARVEST from subjects and quotes from the post-study questionnaire.
Some DAs found that HARVEST played a positive role in data verification (2 found it to be very helpful, and 2 sometimes used it for verification). 6 DAs found that HARVEST was able to help identify things that they would have missed while others thought they would have found the information, but perhaps it would have taken longer.

**Workflow**

While the DAs were able to explain their workflow (i.e., series of actions in the EHR to carry out the abstraction for a given patient) in a detailed fashion in the pre-study questionnaire, the workflows were not as easily discernable when analyzing the EHR usage logs. Nevertheless, there were some clear patterns identified when comparing EHR usage logs 3-months pre-study, and 3-months after introduction to HARVEST.

**Time spent on patient abstraction.** When looking at the distribution of time spent per patient before and after HARVEST, and binning the distributions into quartiles, we found statistically significant reduction in time spent on patient abstraction for 50% of the subjects: one subject had a reduction in overall time spent over all quartiles resulting in an average 20 minutes time gained per patient, two subjects saw a reduction in time spent on short abstractions (first quartile of the distribution), and two subjects saw a reduction in time spent on long abstractions (last quartile of the distribution). For illustrative purposes, Figure 2 displays examples of distributions time before and after the introduction of HARVEST. Additionally, 1 DA saw a statistically significant increase in time spent post-HARVEST.

These findings from the EHR usage logs were confirmed by the subjects’ perceived impact of HARVEST on their workflow: 4 of the 5 DAs who had statistically significant shorter times reported also reported that their workflow was shortened by HARVEST. The DA who had an increase in time spent on abstraction post study did not report a perceived increase.

![Figure 2](image-url) Density plots of the time spent per patient pre- and post-HARVEST introduction. A t-test demonstrated that the sepsis abstractor had a significant reduction (p < 0.001) in total time spent. On average, the sepsis abstractor saved 20 minutes per patient. The bariatric DA had no statistically significant reduction in time spent on chart review.

**EHR actions.** There was a significant decrease in EHR actions related to accessing the list of visits and information related to the visits. In fact, the only EHR action that increased pre- and post-HARVEST introduction was access to the HARVEST tab in the EHR. Table 3 displays some of the statistically significant differences in EHR actions and their usage pre- and post-HARVEST introduction. We hypothesize that the decrease indicates that subjects used the Timeline view of HARVEST, which visualizes all of the patients’ visits from all settings, as an alternative to the traditional EHR visit list. EHR access to notes was also decreased for 3 DAs. This finding was also confirmed by the
perceived impact of HARVEST as reported in the post-study questionnaire, where access to documentation through the problem-oriented view was seen as helpful to the abstraction process.

Table 3. All EHR actions with a statistically significant pre- and post-HARVEST difference for at least two DAs. Each of the rows displayed has a Bonferroni corrected p-value < 0.001. Documentation review had a significant decrease for 3 DAs.

**HARVEST workflow for patient chart abstraction.** A deeper dive into the workflows within HARVEST found that aside from the basic action of loading HARVEST and setting a time period to view, the most frequent parts of HARVEST used are the selection of a problem in the Problem Cloud and opening of a note. Across the entire study period and 10 DAs, there were 222 sequences where HARVEST was used. Table 4 shows the 11 possible actions as part of the HARVEST interface, and the usage frequency of each by the subjects during the 3-month post-HARVEST introduction period.

</tbody>
</table>

Table 4: The usage frequency of each of the 11 actions across all DAs in the study.

As complement to these findings from the log analysis, the pre- and post-study questionnaire showed the following trends: 80% of the subjects expected the Timeline to be useful pre-study, but only 60% found it useful after the 1-month study period. 70% of the subjects reported finding the note access functionality in HARVEST useful, which is
also reflected in the 72% usage of the “Open Note” functionality based on the EHR logs. And similarly, 60% of the subjects found the Problem Cloud useful for their abstraction workflow in the post-study questionnaire; also reflected by the 68% usage of the “Expand Problem Cloud” function in HARVEST (Table 4).

Figure 3 shows the most common sequences of HARVEST actions, as derived from all subjects in the 3-months post-HARVEST introduction. Most commonly DAs just went straight to note without clicking term. Many times they would select and re-select the timeline, move the timeline (Figure 3). Multiple “Load HARVEST for Patient” within one sequence occur if the DA accesses another tab and returns to HARVEST or refreshes the HARVEST page.

**Figure 3**: Most frequent workflows in the HARVEST application during one session identified using the SPADE algorithm. The width of the arrow represents frequency with which this event sequence occurs.

**HARVEST Usage and Post-Study Retention**

Overall, 70% of the study participants used HARVEST for at least 10% of their abstractions. The 2 Sepsis DAs used HARVEST on over 80% of their patient abstractions.

When the DAs were asked if they would continue to use HARVEST, 60% predicted that they would. Most commonly these DAs found that HARVEST would continue to be a part of their work because it helps filter and search through notes in a fast and accurate way, it has the ability to enable search for conditions and events that would be hard especially during extended admission, and it saves time. For the 40% who predicted they would not use HARVEST in the future, the problem-oriented view of the record presented by HARVEST did not align with the type of information they abstract in their tasks (for instance, one DA said “None of the problem cloud words are ones I would use.”), or that the data they needed was already easily accessible in the chart (see quotes in Table 2).

Interestingly, even though only 60% of subjects said they would continue using HARVEST, 90% of the study participants continued to use it in the post-study period of two months (see Figure 4). Even for some of the subjects for whom there was no significant time gained in patient chart abstraction, they continued using the tool for a significant portion of their charts (e.g., bariatric DA). The main exception to post-study retention were the cardiac DAs: 2 of the 3 abstractors predicted that they would continue to use HARVEST; however, according to the EHR logs their usage of the tool dropped after study completion. It is not clear exactly why the cardiac abstractors used HARVEST less than expected, but it seems that the tool did not become well integrated into their workflow. Alternatively, the sepsis team, which has one of the longest and most complex abstraction workflow (up to 180 minutes pre-HARVEST), saw such a change in workflow that they adopted the use of HARVEST as part of their protocol for chart abstraction.
Figure 4. The retention rates of the DAs use of HARVEST. HARVEST usage stayed fairly steady after the study period for all metric types except cardiac where the use was much reduced, and stroke where the use more than doubled.

Discussion

The pre-study questionnaire reflected the complex and widely diverse activities involved in the process of chart abstraction across diseases of interest and quality databases.

Questionnaires and EHR usage log analyses provided complementary views of the impact of HARVEST on abstraction tasks across diseases. Our findings suggest that a problem-oriented patient summarizer coupled with a patient timeline can support the nurses and their information needs. HARVEST is most useful for DAs who are asked to locate data elements for patients with lengthy hospitalizations (and thus with large amounts of clinical documentation in their charts) as well as to locate data elements that are distributed in many parts of the record. However, the extent to which a summarizer such as HARVEST can be useful is variable and depends on the specific abstraction task, as well as to which extent the patient chart already documents the desired data elements in one place.

In general, DAs had a mostly positive response to HARVEST and found it useful for data verification, searching within clinical notes, and identifying the timing of events. We also found that HARVEST was able to provide statistically significant time savings for some groups of DAs. Although not all of the DAs had a statistically significant reduction in the time spent abstracting and some reported that HARVEST did not have specific terms that were necessary for their specific abstraction, 90% continued to use HARVEST after the study completion of the study.

In addition to the 10 staff who participated in the HARVEST study, the use of HARVEST continues to spread across the Division of Quality and Patient Safety at NYP. Sepsis abstractors have recently trained Trauma abstractors on how Sepsis uses HARVEST and where it fits best into their workflow. 3 DAs abstracting for trauma, cardiac, and core measures who were not enrolled in the study have been found to consistently using HARVEST. Finally, 1 DA who was recently reassigned to a new database has switched from never using HARVEST to visiting the HARVEST for 56% of their patient abstractions.

Regarding our initial question on the usefulness of a general-purpose summarizer for abstraction, our results indicate that HARVEST supports the needs of abstraction for up to 10 out of the 30 quality databases at NYP.

Limitations

Even though the DAs workflows are well-defined and are without any colleague or patient interruptions like for clinicians at the point of care\textsuperscript{15}, the workflows of the DAs are still complex and unique to each. As such, the EHR usage log analysis was not successful at generalizing workflows similar to the DA self-described ones. Finally, this study is limited to one academic medical center, where HARVEST is deployed. However, it is clear that the quality abstraction burden is ubiquitous across the nation\textsuperscript{7}.

Future Work

Following the most common suggestion from the DAs, we are working to incorporate more data types into HARVEST, presenting salient problems in clinical notes alongside laboratory test results, medications, and billing codes. This is
a non-trivial task, as we want to present all these data types in an accurate and coherent fashion, all the while keeping the problem-oriented view of the record.

It has been suggested that HARVEST could support not only researchers conducting chart reviews, primary care clinicians at the point of care, and emergency department physicians working to obtain a brief overview of a patient they had never seen before, but also EHR users involved in other initiatives across the hospital. We hope to investigate whether HARVEST can be a useful tool when conducting root cause analyses for investigation of serious adverse events in the hospital, coding for patient billing, or chart reviews conducted by the legal department.

**Conclusion**

Patient chart abstraction for the sake of identifying quality metrics is a complex and time-consuming activity, yet a critical one for hospitals. Because the reporting of quality metrics requires interpretation of patient data, it is not clear that simple extraction of facts form the patient record (in particular extraction using natural language processing) is the most helpful and robust way to support data abstraction specialists. A general-purpose summarization system, such as HARVEST, which supports a broad array of data abstractors in their abstraction tasks by helping them access salient part of the record, is a promising alternative solution.

Abstract

Participatory design, a method by which system users and stakeholders meaningfully contribute to the development of a new process or technology, has great potential to revolutionize healthcare technology, yet has seen limited adoption. We conducted a design session with eleven physicians working to create a novel clinical information tool utilizing participatory design methods. During the two-hour session, the physicians quickly engaged in the process and generated a large quantity of information, informing the design of a future tool. By utilizing facilitators experienced in design methodology, with detailed domain expertise, and well integrated into the healthcare organization, the participatory design session engaged a group of users who are often disenfranchised with existing processes as well as health information technology in general. We provide insight into why participatory design works with clinicians and provide guiding principles for how to implement these methods in healthcare organizations interested in advancing health information technology.

Introduction

Over the past 20 years, and accelerated by the introduction of the Health Information Technology for Economic and Clinical Health (HITECH) Act1 in 2009, healthcare organizations in the United States have been rapidly adopting health information technology to improve the delivery of health care and reduce medical spending. However, implementing and deploying successful informatics solutions in clinical settings has proved challenging.2 Managers and other C-suite hospital executives often have an incomplete knowledge of the detailed operational workflows the system must support. Thus the primary decision makers often make design choices that are inefficient for end users. Researchers in the field of Human-Computer Interaction have long advocated participatory approaches to system design, in which end users play an active role in the design process, and user-centered design occurs from the beginning of the design cycle. Traditionally, user input or usability testing happens at the end of system development, or at least after major requirements and feature decisions have been set. Health information technology has tended to follow a similar process.3 But within the human-computer interaction community, methods that involve users at earlier stages of the design process are increasingly popular: the earlier users are involved, the more likely it is that the end product will meet their needs. In one such method, Participatory Design (PD), the eventual users of a system contribute to its design in even the most formative stages.4 PD was first developed in Scandinavia in the 1970s as a reaction to the disruptive introduction of computers into the workplace. Those people most affected by information technology—the workers whose jobs were being transformed or even eliminated—had little input into how their information systems were designed, and little power to enact change.5 Participatory design emerged from this context as a set of methods and practices that allow groups of non-designers to engage in discussions around information technology, to develop and refine prototypes, and to express their values with respect to the technology that affects their lives.

Can such approaches work within an existing clinical context? Further: can a hospital involve its own clinicians in designing health related technology? PD has been successfully employed in a wide variety of populations and topics, from marginalized teens6,7 to civic engagement8, even the delivery of healthcare itself9, and is a commonly used technique in Human-Computer Interaction research. PD has also shown promise in the design of healthcare technology, where it has been most frequently employed in the design of patient-facing technology.10 However, given PD’s origins in workplace systems, surprisingly few researchers have used PD to inform the design of clinician-focused systems. Gennari and Reddy introduced the technique to the American Medical Informatics Association community in 2000 in a paper describing the design of a clinical trial protocol management system; however, their paper focused more on interviews and contextual inquiry than on PD workshops as a technique.11 More recently, Kusunoki and Sarcevic, functioning in the role of outside consultants, used PD to inform the design of emergency room awareness systems, including the PICTIVE technique we discuss in this paper.12 Despite the success of these studies, PD work with clinicians has yet to take hold within the Medical Informatics community and little is known about how PD translates into measurable success for health information technology.
In this study, we asked physicians to participate in the design of a novel clinical prioritization tool utilizing PD methods. Our goal was to explore how physicians engage in the PD process and demonstrate their effectiveness in the design of clinical information tools. In previous work, we identified and modified an existing framework, knowledge crystallization, to frame and understand how physicians collect, process, and utilize data during the clinical prioritization process (i.e., identifying individual patients that need attention first). The framework demonstrated that clinicians collect data to categorize and prioritize patients according to an expected clinical course. However, when data does not support their expectations, or when categorization indicates potential for morbidity, physicians increase efforts to act or re-categorize patients. Unexpected clinical changes have a significant impact on the decision-making and prioritization by clinicians. With this foundation, we asked physicians to design a tool to help them with this specific task. In this paper, we identify the factors leading to a successful PD session with physician participants, describe challenges that we experienced, and ultimately provide a series of guiding principles for future physician-focused PD work.

Methods

We conducted an IRB-approved, two-hour participatory design workshop at Seattle Children’s Hospital, located in Seattle, Washington in early 2015. Participants worked individually and in groups to answer the motivating question “Which patient should I see next?”

Recruitment
To be included in this study, we required that physicians be credentialed at either the attending (supervising physician) or fellow (sub-specialty trainee) level, and that they provided acute clinical services to hospitalized patients. The primary author (AP) sent individual emails to 23 different providers at the study site, inviting their participation. We targeted a diverse audience with regards to gender, medical specialty, academic rank, and clinical experience. Given the professional relationships between AP and the medical staff, we identified individuals who we felt would make a positive and significant contribution to our PD session.

Our roles
Three researchers attended the workshop. The first author contacted participants, gave the opening presentation, guided the brainstorming session, and supervised the design activities, asking questions and offering guidance as needed. The other two researchers took notes and photos, documenting groups’ progress and social dynamics. The entire research team provided input on the format and organization of the session.

Session design
We utilized the PICTIVE participatory design technique to provide an environment that supports equal opportunities for a diverse set of participants to engage in the design process. First developed in 1991, the PICTIVE technique was intended to allow those with limited design experience and expertise to have “equal opportunity to contribute their ideas.” Sessions begin with brainstorming activities, designed to stimulate thought and create a dialog between participants, then followed by activities that allow the ideas to be physically expressed through the use of low-tech objects to support the creative process. This process ensures that all are able to contribute their ideas in a meaningful way. While PICTIVE explores the needs of users at a more detailed level, it doesn’t focus on workflow or other system level processes that may support the specific task at hand. Other PD methods, such as CARD, were developed to fill this gap, with the intent to help analyze and design workflows used in software systems. Given our previous work detailed the workflows of physicians for our specific task we asked physicians to focus on, PICTIVE was selected over other participatory design techniques such as CARD given the former’s emphasis on participant generated designs and less on collaborative analysis and workflow.

Materials
We provided a set of craft supplies to aid participants in creating their designs. Participants were able to make use of colored paper, stickers, pom-poms, pipe cleaners, glitter glue, scissors, glue guns, markers, and colored pencils in their designs. Each group was also provided with a foam core board on which they could mount their final design for presentation.

Design workshop overview
We conducted the session in the early evening to maximize participant availability, and provided a boxed dinner for each participant. Before the workshop, we divided participants into three groups: two groups of four, and one group of three. In selecting the groups, we looked for a diversity of experiences and seniority levels. For example, we tried to avoid creating groups where one person was in a group with his or her supervisor. We used participants’ boxed
dinners as place cards; as participants arrived each one sat at their group’s table and socialized before we began the main design activity.

The workshop began with a PowerPoint presentation. The lead author introduced the study, gave an overview of our previous work, and presented participants with the motivating question: “What patient should I see next?” Participants then began the individual brainstorming portion. We asked participants to write down, on notecards, what information they would need, when they would want it, why they would want it, and where they would want it. Participants worked individually for approximately 10 minutes, and then participated in a group brainstorming discussion for the next 20 minutes. We recorded participants’ suggestions on a whiteboard so they could refer to their ideas during the hands on design portion of the workshop.

We then introduced the design challenge and constraints (Table 1). We encouraged participants to use the craft materials and allowed them to divide their time as they wished. Periodically during the design phase, the first author discussed groups’ thoughts and progress with them. In this design review, we sought not to shape participants’ designs but to elucidate their thought processes and stimulate intra-group discussion. In the last 20 minutes of the workshop, participating groups presented their designs to each other.

Data
We collected various types of data in this exercise. We audio-recorded the entire workshop, using smartphones running voice recorder apps at each group table. We also video-recorded the final presentations. One researcher took detailed ethnographic field notes of the entire session, while another researcher alternated between taking notes and taking photographs of groups’ progress. We collected and scanned individual brainstorm cards, and photographed the whiteboard with the brainstorm ideas on it. We collected the artifacts used in the presentations. Finally, the first author had a number of informal conversations with participants in the days following the workshop.

Analysis
Immediately following the workshop, the researchers held a debrief session amongst themselves. We discussed our perceptions of the workshop and proposed initial themes and observations to each other. We listened to the audio recordings and produced a more fine-grained analysis of each group’s work process. We looked particularly for power dynamics within the groups and key ideation points where groups made decisions or shifted phases. We also combined our field notes, notes from the audio-recordings, and photographs of the design sessions to generate a narrative about each group’s progress. Several days after the workshop, we met to share these analyses and refine themes. Finally, we explored each design through a standardized coding tool that had six prompts: (1) What does the design look like, (2) What info is included, prioritized, seen in other designs?, (3) What does the tool do?, (4) What information is missing?, (5) Any new ideas?, (6) How does the design tie back to the original framework?

Results

Participants
We recruited 11 physicians (five females) representing six different medical specialties (Table 2). Five of the subjects had participated in our previous study and therefore had some previous exposure to the topic. We divided the subjects into three groups, two groups of four and one group of three and they sat with their respective groups during all segments of the design session.

Overall Session Output
During the individual brainstorming session (approximately 20 minutes), ten subjects (one subject arrived late and did not participate in this phase of the session) generated 47 ideas representing approximately 20 different topics or concepts. Individual subjects generated on average 4.7 ideas each (range 3 – 7). Some subjects needed additional clarification and an example to begin the exercise while others had no trouble with the original instructions. When asked to share their individual ideas the most senior physicians spoke up first with the younger physicians contributing later during the discussion, though eventually all subjects participated and spoke up during the group brainstorming session (approximately 20 minutes). This subsequent discussion covered 20 topics or concepts of which 10 were new and not documented during the individual process, suggesting that the group discussion supported the generation of new, more complex ideas (Figure 1).

The sketching and prototyping session lasted for approximately 50 minutes. During this time, groups one and two immediately began working collaboratively generating ideas, while group three started working individually and eventually worked as a group. Despite the productivity and diversity of ideas generated in the brainstorming segment, the prototyping and sketching segment generated far fewer concepts with groups one and two only coming up with one design concept and group three generating four different ideas which could be subdivided into two main concepts. The disparity between groups correlates with each group’s initial process of individual or group brainstorming with the former leading to more design concepts. However, overall each group generated a unique design concept, with each one differing from the others (Figure 2).

Prototyping Process
Two groups (Groups 1 & 2) began the prototyping session brainstorming together as a group and the third group began working independently and then eventually came together as a group to discuss their individual ideas. Interestingly each group had a slightly different process (Figure 3) that led to the generation of their final design concept. Despite this variation all three groups settled on their final design concept relatively early in the prototyping session and spent the rest of the time iterating and flushing out the design. All three groups had articulated their design concept prior to formally discussing the various requirements and data elements of the tool itself. Once the design had been articulated, the teams explored the data it could potentially present, how users could interact with it, and the goals it would accomplish. The teams spent much of their time discussing these various
requirements in no specific order, cycling between the topics and requirements looping back to their design, and repeating for the duration of the prototyping session. With each iterative conversation clarifying their concept as well as the problem the design addressed, and ultimately moving the group closer towards their final design.

A significant portion of the group design time was spent discussing various visual encoding strategies and how best to represent different data elements. The most common strategies discussed were color, size, position, and iconography. Similar to the primary design concept, once an encoding strategy was presented there was limited debate within the group if other strategies had better visual potential. Most of the discussion instead surrounded what data could be presented by the specific encoding method chosen that supported the overall design concept and framework.

All three groups explored familiar technological tools and applications, including both medical and non-medical references, which led to a significant influence on their final design. The largest influence, modern multi-touch devices, provided some of the most fundamental functional requirements for each team. In fact, we observed on multiple occasions the participants attempting to interact with their design as if it were a functional multi-touch tablet device, touching or swiping with their fingers. In addition to the interaction, design inspiration came from various smart phone applications including those focused on weather, social media, and other productivity tools. Finally, groups also turned to more familiar medical application tools, such as the current electronic medical record used at the study site and even flow cytometry. Groups had no trouble finding inspiration to help guide their overall design process.

In the second half of the prototyping session, once each group had a strong idea of their final design concept, the primary author (AP) went to each group asking them to discuss their design. Through open-ended as well specific questions, this interaction often uncovered an incomplete design or even idea. For example, in response to the question: “How does the tool highlight this important piece of information?” it wasn’t uncommon to hear the response: “Oh, I hadn’t thought about that yet” or “That’s a great question, we still need to figure that out!”

In addition, AP discussed with each group the potential advantages and disadvantages of the different encoding strategies utilized in the various designs. Teams were asked if they had (1) recognized the advantages and disadvantages of different encoding strategies and once recognized (2) if they had any concerns with their choices. Despite the groups employing encoding strategies with less precision than other techniques (e.g. area vs. length), we uncovered the motivation behind the encoding, and more importantly why they needed the data or information for their specific task.

**Individual Participation**

All individuals participated in the design session, contributing in all phases of the study. However, the senior physicians dominated the discussions in two of three groups as well as the group interaction. This influence was apparent in both the overall discussion as well as the design decisions individual groups made during the process. At no time did any of the researchers overhear or observe any behavior or actions exhibited by any of the physicians that could have been interpreted as creating a power hierarchy within a group. However, Group 1, which had the least variability in terms of participant seniority, had the highest level of equality regarding the degree of individual participation. As the discussion behind the design concept came to a conclusion and the groups transitioned to actually producing their final design drawings, participation within all the groups became more equally distributed.

Finally, two of the physicians had clinical responsibilities during the design session, which led to repeated interruptions, at times leaving for more than 5 minutes at a time. After returning, these two participants had potentially missed critical discussions and decisions, and had to spend time getting themselves caught up with the rest of the group.
The physician participants in our study not only identified valuable information to help design a future information tool used within the hospital setting, they also provided great insight into utilizing participatory design methods with a group of domain experts. Under the appropriate conditions, our physician designers demonstrated the effectiveness of PD as a design method, showing its potential to improve the technology utilized in healthcare organizations. In our discussion, we describe why PD works with physicians, some of the challenges we experienced and finally go on to identify a set of guiding principles for physician focused participatory design sessions.

Showing Knowledge-in-Action
Initially the brainstorming session might have been too vague for some participants, with a few needing additional instruction and direction. However, once started, the group maintained significant momentum carrying it forward allowing seamless transitions between activities. In addition, the warm up activity allowed the participants to become comfortable with each other as well as the design challenge itself. Given the number of unique and overlapping ideas as well as the speed at which they were generated, participants indirectly expressed their clear motivation to improve and advance the current state of health information technology.

During the brainstorming activity, participants generated many inter-related ideas quickly. Participants’ facility with the idea generation aspect of PD also demonstrates the high level of domain knowledge of our expert end users. The physician designers quickly and easily articulated their needs responding and building off each other’s ideas. Schon refers to this as “knowing-in-action,” which he defines as “the sorts of know-how we reveal in our intelligent action, publicly observable…like riding a bicycle and private operations like instant analysis of a balance sheet. In both cases, the knowing is in the action. We reveal it by our spontaneous, skillful execution of the performance, and we are characteristically unable to make it verbally explicit.” The physician designers’ ability to generate design concepts without first needing to develop functional requirements or explicitly stating a use case clearly supports the theory. Our designers used their implicit knowledge of their practice patterns and information needs to generate their initial design concepts. Through the PD process they had to explain and further expand on their original idea, unpacking their expertise and making it explicit. Not only did PD uncover and expose the underlying process of clinical prioritization, it also forced the participants to step back and reflect on their current practice ultimately defining their true needs. The activity required them to ask questions of their workflow and clinical processes that under regular circumstances do not require a significant amount of cognitive processing to execute as expert practitioners.

Throughout the session, participants engaged in progressive iteration, building off of their initial design concept as they worked. In some ways, participants’ approach resembles the practice of agile software development. Agile software development is a process “in which requirements and solutions evolve through collaboration…It promotes adaptive planning, evolutionary development, early delivery, continuous improvement, and encourages rapid and flexible response to change.” Each of our groups followed a similar process where they generated an idea, iterated and brainstormed on that idea, ultimately incorporating it into their design, and then repeating this process for the duration of the design period. It is interesting to note that no groups followed a more traditional waterfall approach where specific requirements are identified and settled upon before moving onto the next phase of the design process. It is unclear if this relates back to their expert status, the participatory design process, or just their excitement to create and engage in the process, but the results clearly suggest agile methods as a successful tool for generating ideas with this population of experts.

Becoming PD-atriicians
The authors of this paper have collectively conducted and observed dozens of participatory design workshops over the years. One of us has considerable experience working with patients as designers, and another has conducted workshops with youth and teens. But the physicians in this study were a different breed. In some areas, they outperformed our expectations. For example, given relatively little guidance, participants in our study were able to generate sophisticated ideas during the individual brainstorming phase, and synthesize those into broad concepts during the whiteboard discussion. We were particularly struck by how little time and effort each group devoted to picking a design concept. In our experience with non-physician participants, participatory design groups will often spend significant time in this phase, trying out different design concepts and playing with the craft materials as a way to express competing ideas. With our physician designers, the opposite happened. Groups settled on an idea relatively quickly, and then used the materials as a way to realize their vision and express it for presentation. While selecting a single idea early certainly allowed participants to create more in-depth designs, we missed the
opportunity to hear additional concepts and ideas from participants as most groups did not discuss and debate different design ideas.

In their professional lives, our participants are frequently called on to synthesize data and quickly reach intuitive conclusions. They are often asked to improvise a solution based on limited data, but rarely called upon to design something or engage in blue-sky thinking. They are practitioners, and are used to working on deadline. Indeed, some of the effects we described above may simply arise from participants’ awareness of the tight schedule of the design session, and their desire to ensure they had something to present. Finally, the physicians were articulate presenters and offered collegial and supportive critique.

Nevertheless, our study shows that participatory design with physicians can work well, provided the workshops themselves are designed with physicians in mind. Brainstorming and ideation can be accomplished successfully with relatively little guidance, provided the intended design is one that meets physicians’ current needs and experiences. Designs may not shift dramatically from early concepts, but a participatory design exercise can still capture value through surfacing physicians’ priorities. The participants were clearly engaged by the exercise and very motivated to solve real information challenges they experience while providing clinical care to their patients.

Recognizing Challenges and Constraints
Despite the overall success of the design session, we also experienced several challenges. We had no trouble finding interested participants; instead, we had difficulty finding a time to conduct our two-hour design session that fit into the busy schedule of our physician designers. Initial efforts to conduct a session during regular office hours failed to find a time that worked for multiple participants. Therefore, we elected to hold an evening dinner session, scheduled one month in advance, which made it much easier for our physician designers to participate. In addition, because we conducted the session after hours, participants seemed to have fewer distractions (checking their email) and less time constraints. In the end, the timing of our session allowed the participants to free themselves of their usual routines and fully immerse themselves in the design process.

Organizing the design sessions, within the two-hour time constraint, had its own challenges. We needed to ensure adequate time for brainstorming, designing, sharing, and ultimately feedback. Even though the design exercise took up over half of the entire session, having more time might have benefited both the physician designers as well as the research team. We asked that the physician designers produce one final design concept for each group, but did not put any methodological constraints on how to reach that final design. As we described, the teams settled on their design relatively early and refined the concept for the majority of the session. Rapid serial iteration has been shown to increase the diversity of design concepts leading to more successful products. In addition, producing multiple alternative ideas in parallel encourages designers to uncover previously unnoticed constraints and identify new opportunities. Unfortunately, given the time constraint of the session, we did not require or even encourage the physician designers to develop multiple ideas in parallel. Even Group Three, which spent time individually brainstorming ideas, only focused their efforts on a single design. In addition, people are more likely to provide more honest and critical feedback when they present and are presented with multiple designs versus single ideas.

When our physician designers shared their final concepts, the other teams for the most part provided positive feedback. We clearly saw the influence of social dynamics and professional hierarchy play out during other parts of the session. Senior physicians typically spoke first, for longer periods of time, and often led the conversation in each of the groups. When assembling the groups, we attempted to minimize this phenomenon, though we had limited success. In addition, the groups that exhibited more obvious participation discrepancies tended to delegate the less cognitive tasks to the more junior physicians. With idea generation one of the primary goals of participatory design, it is important to understand and recognize the role social dynamics might play in influencing productivity within a group of physician designers.

The final issue we encountered concerned the actual designs themselves. Because the physician designers had no or limited design experience, some of their designs incorporated visual encoding strategies that went against well-defined best design practices. Designs attempting to communicate large volumes of numerical information should leverage the innate ability of our visual system to recognize certain information without any higher-level cognitive input. Pre-attentive processing allows for rapid interpretation of visual information with the proper

Figure 4: Leveraging pre-attentive processing. Utilizing the innate ability of our visual system allows individuals to identify differences in length more accurately than those of area. In both examples the shape on the right is 5% smaller than the shape on the left.
framing and organization of the information. Size has the potential to communicate information rapidly, leveraging pre-attentive processing, though only when done correctly. For example, it is much easier to recognize size discrepancies along a single dimension, such as length versus a difference found in two or more dimensions, such as area (Figure 4). Some of the final designs produced during the prototyping session utilized differences in size along two dimensions (i.e. area) to communicate differences in scale. As designers we immediately recognized the potential limitation of this encoding strategy, though when pressed the physician designers seemed less concerned. However, while the physical designs created during the PD sessions have their place in the final design, more important are the ideas, values, and needs expressed by the non-expert designers. The output of participatory design is not a final design specification, but rather information for an expert designer to use when designing the final product, taking into consideration the physical design as well as the needs and requirements identified during the design session by the domain experts.

Engaging PD-atricians
When we step back and evaluate our own process, the PD session, as well as the actual content generated, we identified an underlying theme that led to the overall success of our work. Having a facilitator with a detailed understanding of the organization, domain expertise in the clinical context as well as human centered design methods allowed us to tailor and adapt the sessions to ensure they achieved the desired outcomes. With this knowledge, we identified a motivating challenge and recruited participants with the potential to make a meaningful contribution to the PD process. In addition, since the lead author was a peer of the session participants, it allowed them to trust this new, unfamiliar process and engage in a way that would not have been possible without the professional connection. Therefore, organizations investing in HIT and a desire to employ PD methods need to ensure they have informatics professionals with these diverse skill sets and established interpersonal relationships.

Guiding Principles for Future PD-atricians
Given the high costs associated with health information technology system failures, organizations need to take the time required to ensure the technology leads to the desired benefit and not introduce any harm. Although some researchers have described the economic benefits of iterative design and others have clearly demonstrated its rigor, many organizations simply undervalue its potential. For less than $500 (costs associated with this PD session), we now have a solid foundation to begin the design process. In addition, by engaging physicians in this process, not only do we gain their valuable insight, but also their interest in seeing the successful deployment of the tool as they are now partial owners of its ultimate success. In order to support others as they pursue participatory design methods to help advance health information technology, we offer a series of guiding principles developed from our presented experiences (Table 3).

In addition to the principles and ideas previously discussed, it is important to ensure that appropriate subjects are selected to participate in the PD session. Ideally, the organizers want to find those who are interested and acknowledge the existence of the challenge or problem. Participants need to have good communication skills, be open to feedback, and be willing to engage in the design process, as well as domain expertise. While it is important to have a diverse group of participants, session organizers need to consider the potential for these differences to negatively influence the group’s performance. Therefore, playing close attention to how the groups are structured should help to minimize any negative group dynamics.

Besides needing a diverse group of participants, it is just as important to have a diverse team facilitating the PD session. In the medical setting, the team needs to have knowledge and expertise not only in PD and design principles, but also the domain itself. Having these backgrounds allows the facilitators to ask directed and focused questions with the intent of pushing the participants to expand their thinking and ultimately their designs. The diversity of our backgrounds allowed us to form questions based on both the domain content as well as design aesthetics. Our team also had the benefit of our primary author being a physician and peer of the session participants, with a proven track record of improving the clinical information tools at the study location. The personal connection with each of the participants improved our recruiting capabilities as well as lead to increased engagement.

Limitations

Despite the diversity of medical providers within our sample, all of the participants were pediatricians at a single organization. In addition, Seattle Children’s Hospital supports the active engagement of its medical providers and encourages their participation in continuous process improvement activities. Therefore, they are very familiar with identifying system challenges and working collaboratively and iteratively towards consensus driven solutions. These factors might limit the generalizability of our study since physicians at other organizations may be less familiar with these organizational processes. However, given PD methods support non-experienced designers in the creation process, it should minimize these concerns.

In addition, we need to recognize the fact that only 11 individual physicians participated in a single PD session. While this also raises questions about generalizability, we feel our findings still provide insight into a process with genuine potential. Strauss and Corbin, describe the value of recognizing both the messages or theories derived from qualitative work, as well as the situation and conditions from which the theory was derived. Therefore, with the provided descriptions of our methods and institutional culture, others can use our work as a starting point and adapt it to fit their own organization.

Conclusion

Participatory design, a method well known to the Human-Computer Interaction community, has the potential to significantly enhance and improve the development of health information technology. Shifting design activities that involve end users to earlier in the development process should lead to applications that better meet the needs of stakeholders. Though it has seen limited adoption in the healthcare community, we have demonstrated its potential to make significant contributions. Utilizing well-described methods, we provide a series of guiding principles to engage physicians in designing new clinical information tools through participatory design. Organizations need to invest in human centered design methods such as PD by training their existing informatics professionals. Utilizing practicing clinicians with experience in Human-Computer Interaction, informatics, and deep domain expertise, project teams can build trust with typically skeptical end users leading to active participant engagement, translating into more successful projects.

Abstract

We present an approach for manually and automatically classifying the resource type of medical questions. Three types of resources are considered: patient-specific, general knowledge, and research. Using this approach, an automatic question answering system could select the best type of resource from which to consider answers. We first describe our methodology for manually annotating resource type on four different question corpora totaling over 5,000 questions. We then describe our approach for automatically identifying the appropriate type of resource. A supervised machine learning approach is used with lexical, syntactic, semantic, and topic-based feature types. This approach is able to achieve accuracies in the range of 80.9\% to 92.8\% across four datasets. Finally, we discuss the difficulties encountered in both manual and automatic classification of this challenging task.

Introduction

The answers to medical questions can be found in a wide variety of resources. These resources include general medical knowledge (such as that found in textbooks or encyclopedias), highly specialized research knowledge (such as the biomedical literature), and even source specific to the given patient (such as the patient’s electronic health record (EHR) information). For automatic question answering (QA) systems that intend to answer a wide variety of medical questions, having the ability to properly target a specific resource (such as a corpus, sub-corpus, or database) would be very useful. Consider the following three questions from the datasets used in this study:

(1) \textit{What kind of allergy does he have?}

(2) \textit{Is it necessary to wait until age 7 before doing an allergy evaluation?}

(3) \textit{Is there anything in the literature about allergy testing or desensitization to acyclovir?}

While all these questions are topically concerned with allergies, they require different resources for answers. The first question is patient-specific, and the answer must come from the patient’s allergy list or notes in the health record. If the information is missing there, the patient himself must be questioned, as any attempt to look in a non-patient-specific source will yield useless results. The second question requires general medical knowledge, either in a textbook, practice guidelines, or manuals. The final question specifically asks for scientific literature, and would not be appropriately answered by a background knowledge data source. All three types of questions are commonly asked by clinicians at the point of care (indeed, all three of the above questions were asked by physicians and collected by Ely\textsuperscript{1} and Patrick and Li\textsuperscript{2}). A QA system designed to aid clinicians at the point of care, therefore, should be able to determine which resource contains the most appropriate answer to the question.

In this work we develop both manually annotated datasets and automatic methods for classifying questions by their intended resource. We focus on the three types of resources discussed above: patient-specific, general or background medical knowledge, and scientific research. To the best of our knowledge, this is the first work to address this particular facet of QA despite it being a critical task in developing general-purpose QA systems for clinicians. We have manually annotated over 5,000 questions from four existing question collections. A supervised machine learning method is then employed to classify questions using lexical, syntactic, semantic, and topic-based features. Finally, we discuss the difficulties in both manual and automatic resource classification for questions.
Background

The need for medical QA systems to handle a wide variety of questions has resulted in questions being classified along many dimensions: answer type, topic, relation, user, answerability, and now resource. These will be discussed in more detail below, but the type that impacts the most on resource choice (besides what we discuss in this paper) is the user. Specifically, the assessment of the user’s medical expertise. Users are often organized into one of two groups: consumers and professionals\cite{3,4} (though it has been shown that this distinction is oversimplified\cite{5}). Importantly, resource choice is based on the user profile\cite{6}; while a physician might be directed to a resource such as UpToDate, a consumer might be best suited by MedlinePlus. This is largely orthogonal to the study of resource type presented here, however, we acknowledge that certain general knowledge sources are better suited to consumers, while others are better suited to professionals. The same might be said about patient-specific and research resources, where patient portals and consumer-focused research news sites such as HealthDay\footnote{http://consumer.healthday.com/} might be considered more appropriate for consumers. Thus, resource selection requires both understanding the user and type of knowledge source. For the purpose of this study, we focus entirely on the resource type.

As noted above, there are many other ways of classifying questions. It is important to understand the breadth of medical question classification schemes, as many have an impact on resource classification. The most common classification in the open domain is answer type, sometimes referred to as the expected answer type or even simply question type. The answer type is the semantic type of the answer, and is useful in candidate answer extraction. Answer types are more studied in non-medical questions\cite{6,7,8}, where factoid-style questions with entity answers are common. Answer type methods for medical questions have been proposed by Cruchet et al.\cite{9}, who studied a small number of English and French questions, and by McRoy et al.\cite{10}, who focus on cancer-related questions. In analyzing answer types, both Cruchet et al.\cite{9} and Roberts and Demner-Fushman\cite{4} have found that boolean (i.e., true/false, yes/no) questions are the most common surface type. However, as observed by those researchers, often a higher-level type is more appropriate. For example, the question “Can Group B streptococcus cause urinary tract infections in adults?” is a boolean question on the surface, but is really asking for cause/etiology. This higher level answer type has been called many names: medical type, topic, and commonly just question type. This is the most common type of question classification studied by researchers, and has a critical impact on resource as some types are more likely to be discussed in some resources than others (e.g., definition questions are appropriate for general knowledge resources, while comparative effectiveness of treatments is more likely to be discussed in research studies). Among the proposed methods for this general question type are Cruchet et al.’s bilingual system, Roberts et al.’s\cite{11} consumer QA system, and several systems utilizing Ely’s\cite{12} general topics\cite{13,14,15}, which includes types such as diagnosis, history, prognosis, and treatment/prevention. Many medical QA approaches have focused on identifying question templates, common question types with slots for specific items with the question. Cimino et al.\cite{16} maps questions to templates such as “PHARMACOLOGIC\_SUBSTANCE treats DISEASE\_OR\_SYNDROME” using a rule-based approach. Patrick and Li\cite{2} developed EHR question templates such as “Did the patient have X, Y?” and utilized a multi-layered supervised machine learning approach to classify templates and slot components. A very common template approach for research questions is PICO (problem/population, intervention, comparison, and outcome). The PICO approach has been utilized by Demner-Fushman and Lin\cite{17} and Schardt et al.\cite{18}, amongst others. Beyond these types of question classification, other approaches have studied (a) relation extraction\cite{19} using SemRep\cite{20}, (b) disease classification\cite{21}, (c) anatomy classification\cite{13}, and (d) question answerability\cite{22,23}.

As mentioned, all these types of question classification have a relation to the best resource (patient-specific, general, research) in which to find the question’s answer. The previous work that is the most overtly overlapping with our own are the answer type approach by McRoy et al. and the answerability approaches by Yu and colleagues. McRoy et al.’s\cite{10} answer types form a taxonomy that contains three top-level nodes: factual, patient-specific, and non-clinician. Patient-specific questions correspond to those considered here, while factual questions may include both general knowledge and research. Non-clinician questions deal with non-medical issues such as insurance and legal advice. We found such questions in our dataset as well, but exclude them from our study as we are focused on clinical questions. Similarly, the answerability classification performed by Yu and Sable\cite{22} and Yu et al.\cite{23} isolates patient-specific questions as “unanswerable” based on Ely’s taxonomy\cite{12}. In all these cases, no distinction is made between research questions
and general/background medical knowledge. Admittedly, this distinction is often unclear, so in the next section we attempt to develop an initial specification for when questions belong to different resource categories.

Data and Annotations

We utilize four different question sets:

1. **ELY** ($n = 1,500$): These questions come from the Clinical Questions collection$^2$ which was collected by Ely et al.$^{[1,24,25]}$ and D’Alessandro et al.$^{[26]}$ and is maintained by the National Library of Medicine (NLM). The questions were collected from physicians, either during direct observation or during a phone interview. They are largely designed to represent the stream-of-conscious questions that physicians have on a day-to-day basis, the vast majority of which go unanswered. There are 4,654 questions in the collection, from which we randomly sampled 1,500.

2. **MEDPix** ($n = 1,666$): These questions came from MedPix$^3$, which is an image database with over 53,000 images from over 13,000 patients. Originally built by James Smirniotopoulos at the Uniformed Services University, it is now maintained by NLM. MedPix contains hundreds of cases that are associated with quiz-style multiple choice questions, allowing radiologists to receive CME credits. The question set contains patient-specific questions forcing users to review the patient’s image and note, as well as medical knowledge questions inspired by the patient but not requiring any patient-specific answer. These knowledge questions may involve general radiology knowledge, or require being familiar with recent research.

3. **GARD** ($n = 1,476$): These questions were submitted by consumers to the Genetic and Rare Diseases Information Center (GARD)$^4$. The questions are then curated, answered by NIH experts, and maintained on the GARD website in an FAQ format. Despite being consumer questions, the nature of the subject matter makes them more similar to clinician questions than other types of consumer questions$^5$. The questions were originally in a paragraph style, but manually decomposed into individual questions$^6$. When isolated from the original request, the questions appear as either patient-specific (as they are about details provided in the full request) or for medical knowledge. Since they are topically concerned with genetic and rare diseases, the users mostly understand the scientific literature might be the only source of answers for the particular disease.

4. **Li** ($n = 486$): These questions were collected by Patrick and Li$^7$ and are included in Li’s dissertation$^8$. They are organized by the taxonomy discussed in Patrick and Li. The focus of the questions are patients in the intensive care unit, and thus almost all are patient-specific. We use only the sub-set of questions, defined by the taxonomy, of clinical relevance (ignoring, e.g., questions about the hospital organization). As such, they need not be manually annotated in the manner of the above corpora. Instead, the existing taxonomy classification is utilized, where only a small number (7) of general information questions are included.

A selection of questions from these corpora can be seen in Table 2.

To annotate each question, we used the following guidelines to distinguish between patient-specific, general, research, and other questions.

a. **PatientSpecific**: In these questions, the answer is either contained directly in the patient’s chart or information needs to be retrieved from the chart to answer the question.

- What is her latest A1c value?
- Is this rash shingles or staphylococal impetigo?

---

$^2$http://clinques.nlm.nih.gov/

$^4$https://rarediseases.info.nih.gov/gard

1042
Table 1: Annotation data for the four corpora. The LI corpus was annotated using data from Li[28].

b. GENERAL: In these questions, the answer should be contained in a general medical knowledge source, exemplified by a medical textbook. This could include textbooks for specialties and sub-specialties.

- What causes scleromyxedema?
- How do you do a paracentesis?
- What are the immunizations for an 18-year-old?
- What urological symptoms are associated with Beckwith Weidemann Syndrome?

c. RESEARCH: In these questions, the answer should be best found in a research-type source. This includes both original scientific articles (bench and clinical) and articles summarizing the state-of-the-art in some area, including reviews and practice guidelines. While guidelines could arguably be considered general knowledge, we include them as research because they are typically updated more frequently than textbooks and they are closely associated with review articles that are published in the scientific literature.

- What research is being done at present regarding CDPX1?
- What percent of patients with Congenital Adrenal Hyperplasia (CAH) will have upper genitourinary tract abnormalities (e.g., vesicoureteral reflux and hydronephrosis)?
- How are the newer medications for attention-deficit hyperactivity disorder being used?
- Is glimepiride better than other sulfonylureas for diabetes?

d. OTHER: These are non-clinical questions. Sometimes they are financial in nature, other times they are marked as OTHER because it is too difficult to understand the question and they should not be considered part of the dataset.

- Mother paid $101 for 50-dose desmopressin spray. Can that be the correct cost?
- Can you help me?
- Which of the following is True?

All of the questions except the LI set were double-annotated by an MD/PhD (LR) and a medical librarian (SS). Table 1 contains the reconciled statistics for all four corpora: numbers (and percents) of PATIENTSPECIFIC, GENERAL, RESEARCH, and OTHER questions. As can be seen, the three manually annotated corpora are heavily imbalanced toward general questions (one of the main reasons we chose to also include the almost entirely patient-specific LI corpus). Table 1 additionally contains the κ agreement for the three manually annotated corpora, ranging from 0.62 to 0.78. These inter-annotator agreement numbers are decent, but by no means great. This should serve to emphasize that resource choice is still difficult for humans. Half of the disagreements were GENERAL versus RESEARCH (ELY: 50%, MEDPIX: 51%, GARD: 41%). Many of the disagreements involved confusion of what to consider OTHER (ELY: 34%, MEDPIX: 26%, GARD: 50%), so we had to carefully re-evaluate what to consider part of the scope of this work. Most of these OTHER disagreements were due to peculiarities in the datasets themselves and so should not be a concern for a clinical QA system. For instance, the GARD questions were automatically extracted from longer questions, resulting in some elliptical questions such as “How?” and “Can you help me?”. In MEDPIX, some of the questions made little sense without knowing the multiple-choice answers. These are not the type of question to be asked without context to a clinical QA system, so these inter-annotator disagreements can safely be ignored.

Methods

Here we present an initial approach for automatically classifying the resource type for medical questions. Our goal is to characterize the linguistic criteria necessary to distinguish between questions requiring different resource types. As such, we forgo exhaustive experimentation and instead experiment with a variety of features at different linguistic levels: lexical, syntactic, semantic, and topic.

1. **Lexical**: We consider two bag-of-words features and length-based lexical features. The bag-of-words features include a simple unigram feature and a subset of unigrams that do not belong to a medical concept. To recognize concepts, we utilize the latest version of MetaMap$^{[29]}$ and restricted concepts to a specific set of UMLS$^{[30]}$ semantic types: `diap`, `cgab`, `acab`, `inpo`, `patf`, `dsyn`, `anab`, `neop`, `mobd`, `sosy`, `drdd`, `clnd`, `antb`, `phsu`, `nsba`, `strd`, `vita`. Thus, this feature could be considered lexico-semantic as it incorporates a semantic resource. The purpose of the non-concept unigram feature is to ignore medical terms that may be used in any resource (such as diseases) and instead focus on words that help delineate resource type. Additionally, we experiment with word- and character-length features. Upon observation, RESEARCH questions tend to be longer (in words) and contain words that are longer (in characters) than GENERAL questions.

2. **Syntactic**: We consider a syntax feature based on the syntactic dependency parse. Syntax can help disambiguate different uses of the same word. For example, the word `patient` in “What is the diagnosis for the patient” (PATIENTSPECIFIC) and “My patient has Hepatitis A and I’m wondering if there are any recent treatments?” (RESEARCH). We use the Stanford CoreNLP dependency parser$^{[31]}$. As features, we consider subgraphs of the full dependency parse. Figure 1 shows a sample of dependency subgraphs for the question “What kind of allergy does he have?” Since these are even sparser than n-grams, we pre-calculate the most frequent subgraphs in each question corpus using the ParSeMiS implementation$^5$ of the Gaston frequent subgraph mining algorithm$^{[32]}$ similar to the method employed in Luo et al.$^{[33]}$. This still results in a large number of subgraphs, so we further filter based on the statistical association of a subgraph and an output class using Fisher’s exact test, taking all subgraphs above a threshold. All Fisher scores are calculated on the training set.

3. **Semantic**: We consider a concept feature based on MetaMap as well as distributional semantic features that represent each question in a semantic vector space. The concept feature indicates the semantic types present in the question, as different semantic types are more prevalent with different resource types. The distributional semantic features utilize paragraph2vec$^{[34]}$, a word sequence extension to the popular word2vec word

The gensim implementation of paragraph2vec (known there as doc2vec) is used with default options. The vectors are pre-built using all questions as well as the 450,000-sentence health reference corpus used in Kilicoglu et al.[37]. We experiment with two versions of this feature: the first uses the embedding vector directly, while the second counts the output classes of the k-nearest neighbors (e.g., 5-NN) using cosine distance between the embedding vectors on the questions from the training set. Table 2 shows question similarity examples using embeddings based on PARAGRAPH2VEC.

4. **Topics**: We consider topic model features that represent questions as distributions over topics. We utilize the gensim version of Latent Dirichlet Allocation[38]. The unlabeled data and features are otherwise identical to the embedding features described above. Table 2 also shows question similarity examples using topics based on LDA.

Using the above features, we utilize a single 3-class support vector machine (SVM) with a linear kernel[39]. Four datasets are used for evaluation: (1) ELY, (2) MEDPIX, (3) GARD, and (4) ALL = {ELY, MEDPIX, GARD, LI}. The LI dataset alone is too imbalanced for consideration. The feature set for each dataset is chosen from the features described above using a greedy search algorithm[40] on a development split of the data. The evaluation results reported in the next section are computed using a 5-fold cross validation of each corpus.

**Results**

The selected features for each dataset are as follows:
As can be seen, different features were automatically selected for each dataset. A unigram feature (either the basic unigram or the non-concept unigram feature) was chosen as a base feature, while lexical, syntactic, semantic, and topic features were chosen to augment the bag-of-words feature. No dataset utilized the distributional semantic features, despite these being a good method for assessing similarity. It is thus likely that the distinguishing factor between resource type questions is quite localized (a single word or short phrase), while the similarity based on paragraph2vec is based on the entire question. In our experiments, the paragraph2vec-based vectors tended to better represent overall question similarity than the LDA-based vectors; however, the latter were chosen in three datasets (ELY, GARD, and ALL). Since LDA uses a bag-of-words assumption instead of the language model type assumption used by paragraph2vec, it tends to group words that are used in the same context but have very different semantic functions (this is why it is referred to as a topic model). This topical grouping effect might be more robust for this task than the full-question semantic similarity used by paragraph2vec.

Table 3 contains the results for each dataset. The baseline unigram feature alone greatly outperforms the weak baseline of choosing the most frequent resource type (ELY: +2.7%, MEDPix: +14.28%, GARD: +4.55%, ALL: +6.95%). The selected features, however, only slightly outperform this stronger baseline feature (ELY: +1.88%, MEDPix: +1.42%, GARD: +0.44%, ALL: +0.45%). This suggests that not only are simple lexical features the most important for classifying resource type, but the higher-level linguistic features are not easily representable with the features studied here (despite the fact that these are state-of-the-art features in many text classification tasks). In the Discussion below, we perform some error analysis to uncover the links between human disagreements and errors in the automatic system.

**Discussion**

Providing relevant answers ultimately depends on finding the most appropriate source of information for a given question. As discussed in the Background, this involves not only the semantics of the question itself, but also the user’s background knowledge. In this work, however, we seek to isolate the resource choice from other considerations, grouping resources in a cross-sectional way (e.g., all general medical knowledge resources, regardless of whether the user is a high school student or highly-trained cardiologist). This reduces the need to jointly understand all the possible resource choice factors at once, which is especially useful if a system is designed to be used by a specific sub-group (e.g., clinicians).

At the highest level of granularity, the resources can be split into **PATIENTSPECIFIC** (e.g., EHR or personal health record), **GENERAL** (e.g., textbooks and other background knowledge literature), and **RESEARCH** (e.g., journal articles, systematic reviews). Our results show that separating the literature (GENERAL and RESEARCH) into distinct buckets might not be feasible. Instead, one could consider a continuum ranging from the most basic background knowledge
(e.g., *Harrison’s Principles of Internal Medicine*) to the most late-breaking research (e.g., the latest updates on the Zika virus in PubMed). While some questions are unambiguously background knowledge (e.g., “Is Williams syndrome inherited?”), and others unambiguously require research answers (e.g., Question (3)), many questions fall into a zone of ambiguity. In terms of manual annotation, the GENERAL vs. RESEARCH ambiguity resulted in many disagreements. If one only considers questions both annotators agree are either GENERAL or RESEARCH (i.e., ignore questions either annotator marked as PATIENTSPECIFIC or OTHER), then inter-annotator agreement would be lower on two of the three datasets (ELY: 0.47, MEDPix: 0.28, GARD: 0.67). In terms of automatic annotation, this was a large source of classifier error, such as the following mis-classifications:

(4) Should a gestational diabetic have any antenatal fetal well-being testing done?

(5) What are the best exercises for rotator cuff?

(6) What is the success rate of various methods of endometrial biopsy? (that is, getting in)?

(7) Is Keflex the drug of choice for a patient with positive streptococcal screen (allergic to penicillin, sulfa)?

Here, Questions (4) and (5) are GENERAL questions mis-classified as RESEARCH, while (6) and (7) are RESEARCH questions mis-classified as GENERAL. The choice of resource type is largely based on the granularity of information needed. The annotators felt that the first two questions concerned large populations and did not ask for detailed specifics, while the second two questions asks for details that often don’t make it into textbook-style knowledge resources (i.e., the exact success rate for (6) and the review of efficacy of various streptococcal drugs for (7)).

On the other hand, PATIENTSPECIFIC questions are distinct and less ambiguous since they do not belong on such a continuum. However, there were difficulties when a question requires both patient-specific information and possibly external knowledge as well. For example:

(8) What should I do about this bullous lesion found on sinus films?

Here, more knowledge from the patient chart is needed regarding the lesion, after which other knowledge sources might be required as well. We chose to consider such questions as PATIENTSPECIFIC, but another option would involve a multi-label approach that might also label the question as GENERAL. In fact, this question was indeed mis-classified as GENERAL. Optimistically, however, one might claim that with an automatic QA system, users would not ask questions that required multiple information sources, so these questions should be less of a concern.

Perhaps, instead of using a 3-class resource type representation, the most ideal solution would be a large corpus of question-answer pairs. That is, instead of pre-deciding where a given answer is most likely to be found for a question, search a range of knowledge resources and identify the ones that actually contain an answer. The corpus created here was annotated in isolation from any possible answers (i.e., annotators did not look for an answer it multiple sources to see where one happened to be available). Rather, the annotators used their best judgement about where certain types of medical information would likely be found. With a large corpus of question-answer pairs, however, there is no need for such assumptions. The trade-off is obviously the additional cost of annotating answers over simply a 3-class determination in isolation. Our experience has indicated that annotating answers is incredibly time consuming[41], requiring approximately two orders of magnitude more time to find an answer than to simply classify a question in isolation. Further, rather than a 3-class classification problem, this would result in a far more granular representation which would either require far more annotations to achieve the same result, or an approach entirely different from the one presented here. Alternatively, a compromise solution could involve a more fine-grained hierarchical ontology of medical knowledge sources, encompassing many of the different types of publications (e.g., original research, systematic reviews, web articles). This could extend, for example, the MeSH article types to include other types of medical knowledge sources. Ambiguities could then be represented by selecting multiple nodes in the ontology.

**Conclusion**

We have presented our approach for classifying resource types of medical questions to aid QA systems in selecting the most appropriate data source. Three resource types were considered: patient-specific, general knowledge, and research
knowledge. To develop the approach, four different corpora totaling over 5,000 questions were annotated with the three resource types, with moderate inter-annotator agreement. An initial automatic method was proposed utilizing state-of-the-art features, including dependency subgraph, distributional semantic, and topic modeling features. Nonetheless, basic lexical features provided the vast majority of the gain, suggesting that many existing state-of-the-art features cannot easily distinguish between these questions. Further advances, therefore, are needed not only in the automatic classification, but also in the representational methods used to identify the most appropriate medical resource.

**Data Availability**  The annotated question corpora are available by request (kirk.roberts@uth.tmc.edu).

Acceptability of Fitbit for physical activity tracking within clinical care among men with prostate cancer

Dori Rosenberg, PHD, MPH1, Elyse A Kadokura, BS2, Erin D Bouldin, MPH, PHD2,3, Christina E Miyawaki, MSW, PHD4, Celestia S. Higano, MD5, Andrea L. Hartzler, PhD1

1Group Health Research Institute, Seattle, WA; 2University of Washington, Seattle, WA; 3VA Puget Sound Health Services Research & Development, Seattle, WA; 4University of Houston, Houston, TX; 5Fred Hutchinson Cancer Research Center

Abstract
Prior research has not examined the acceptability of commercially available fitness tracking devices in men with prostate cancer, many of whom are at risk for conditions that physical activity could alleviate. We conducted an exploratory 3-week field study to examine acceptability of the Fitbit Zip and attitudes towards integrating fitness tracking into clinical care among men with prostate cancer. Twenty-six men used the Fitbit Zip for a one-week baseline phase followed by a 2-week optional use phase and then completed in-depth interviews. Interview data was analyzed using inductive thematic analysis. Participants found the device comfortable and easy to wear. Barriers to use included health and technology difficulties. Participants expressed value in sharing Fitbit data with their health care team. Findings support the use of easy to use and simple fitness trackers among men with prostate cancer and there could be opportunities to integrate fitness tracker data into clinical care.

Introduction
Men with prostate cancer, particularly those taking androgen deprivation therapy (ADT), are at high risk for side effects of treatments such as loss of muscle mass and strength, increased fat mass and cholesterol, glucose intolerance, and decreased bone mineral density1,2. The negative impacts of these side effects can be mitigated by regular light or moderate-to-vigorous physical activity. There is evidence suggesting that men with prostate cancer who are provided with supervised and/or home-based aerobic and resistance exercise programs have improvements in quality of life, fitness, body composition, lower body strength, and glucose intolerance5,6. Exercise has also been associated with reduced risk of recurrence and mortality in men with prostate cancer5,6. In spite of these benefits, men with prostate cancer have objectively lower physical activity than the general population of men over age 607.

Patients with chronic disease have reported benefits from tracking health indicators such as weight, physical activity, and diet.8 Commercially available wearable activity trackers such as the Fitbit® are promising tools that could be used as a mechanism to encourage daily physical activity among populations that are highly inactive and could be employed to improve healthy aging in the general population9,10. They also have the potential to be used by health care providers as a way to monitor patient prognosis and recovery through tracking activity levels and mobility11. In a qualitative study, health care providers who were asked questions about the use of self-monitoring tools among older adults reported that data taken from wellness monitoring tools could be used as an education, tracking, and problem solving tool as well as an indicator on how to prioritize care12. The same study interviewed community-dwelling older adults and found positive reactions to the idea of sharing information from wellness trackers with their doctors. Both health care providers and older adults believed that sharing wellness information would improve patient-doctor communication; however, researchers found that older adults in the study were not likely to adopt self-monitoring tools for everyday use due to low perceived personal usefulness and control over data privacy12. Even when this technology is found acceptable, patients’ and providers’ expectations for use of the data in healthcare do not necessarily align13.

Wearable activity trackers can track step count, distance walked, and calories burned. They also have the capability of setting goals, posting to social media sites, creating networks with friends and family, and displaying visual presentations of data if the user syncs their device with a smartphone or computer. For these devices to be effective in motivating health behavior change, they need to be affordable, accurate, and comfortable to wear. The data collected needs to be displayed in a way that is easy to access and interpret by the user14. If these needs are not met, despite good intention, these devices may pose substantial barriers to adoption and use among older adults who, on average, are not as comfortable with technological devices as younger adults15.
Studies that have assessed wearable activity tracker usability in older adult populations and in populations with chronic conditions have yielded mixed results. In a study of older adults with chronic disease, researchers found that participants thought wearable fitness trackers were comfortable and increased awareness of their physical activity, but lack of instructions and limited outside assistance on how to use the tracker were barriers to adoption. Another study assessing the usability and validity of the Fitbit among patients with chronic obstructive pulmonary disease (COPD) found that participants gave the Fitbit high usability scores and reported that the device was pleasant and easy to wear. In a small study of older adults who wore three different wearable activity trackers, participants were initially excited about wearing activity trackers, but 5 out of 8 participants stated that they would not continue using the devices because they felt the devices were uncomfortable, inaccurate or a waste of time. Surprisingly, none of the participants stated technological issues as a reason for discontinuation of use. All of these studies concluded that wearable activity trackers could be useful for self-management of chronic disease, but leave open many questions about their acceptability and use in healthcare integration.

Given the enormous potential for wearable fitness trackers to improve the physical health and well-being of patients with chronic diseases, it is important to further characterize and address any barriers to use and assess the feasibility of adoption of these technologies among older populations. We conducted an exploratory investigation using a 3-week field study with qualitative feedback to capture acceptability of using wearable activity trackers and attitudes towards integrating the use of these devices into clinical care among men with prostate cancer.

Methods

We undertook the Physical Activity and Sedentary Time (PAST) project to better understand device-measured physical activity and sedentary time patterns in men with prostate cancer including those with a history of ADT use. One piece of the project we report on here is a 3-week field study using mixed methods to better understand prostate cancer patients’ acceptability of fitness tracking and its potential to be used within health care. We divided the field study in two phases: an initial one-week baseline phase with required use of one commercially available fitness tracker (Fitbit Zip) followed by a 2-week phase of optional use. We conducted qualitative in-depth interviews at the end of the 3-week study.

Study Population and Recruitment

Men with prostate cancer (N=31) were recruited from a medium sized health care system in Washington State from October 2014 to May 2015. Human subjects approval was obtained from the Group Health Research Institute. Potentially eligible participants were identified using electronic health record data. Men with Surveillance, Epidemiology, and End Results (SEER) codes indicating prostate cancer without distant or metastasized disease were included (summary stages 0-5). We excluded men with encounter codes for palliative care, or diagnosis codes indicating a serious mental health disorder or substance use disorder. Letters were mailed to eligible men inviting them to phone a study staff member if they were interested in participating. On the phone, a study staff member completed oral informed consent and asked additional screening questions. Exclusion criteria were not having prostate cancer, unable to stand, unable to walk one block, and not speaking and reading English.

Procedures

Participants attended in-person visit to receive a Fitbit Zip device to wear for one required baseline week and completed a brief baseline survey. The baseline week allowed us to characterize participants’ on step count levels to ensure there was a diverse range of physical activity levels. During the visit we helped participants set up and sync the device to their Fitbit account. Participants were also provided with written instructions on how to wear and sync the Fitbit device. After the baseline phase, participants were given the Fitbit to keep and use for two optional use weeks, along with instructions for how to use and sync the device to a personal computer or smartphone. At the end of this 2-week phase, we conducted an in-depth exit interview by phone. Using an app we built to access data from Fitbit server through Fitbit’s Web Application Programming Interface (API), we downloaded participants’ Fitbit data for analysis of steps. Participants kept their Fitbit and were paid $10 for completing the study.

Data collection and analysis

Collected data included the baseline survey, Fitbit steps, and interviews. The baseline survey collected participant demographics, health characteristics and level of technology use and ownership from items used in the National Health and Aging Trends Survey. We analyzed surveys with descriptive statistics to characterize participants and compare participant groups by those who had received ADT and those who had not.
To describe physical activity levels, average daily step counts were computed for each participant during the baseline phase and for those who used the Fitbit in the optional use phase. We noted whether or not participants had synced their Fitbit on their own during the optional use phase using the API (indicated by having step count data on at least one day during the optional use phase and coded as yes/no). We also asked the participant whether they used their Fitbit (yes/no) in the optional use phase during the exit interview. We classified prior use of a wearable physical activity tracker (e.g. pedometer, Fitbit, Jawbone) before participating in the PAST study (yes/no) from answers to the baseline survey or during the exit interview.

Qualitative data was collected through semi-structured in-depth interviews to capture attitudes on acceptability of the Fitbit for personal use and interest in sharing Fitbit data with health care providers through the electronic health record. Interview questions were open ended with follow-up prompts. Example questions included:

- What did you think of the Fitbit? What did you like about wearing the Fitbit? What didn’t you like about wearing the Fitbit?
- How have you used your Fitbit during the past 2 weeks? What would have helped you use the Fitbit more?
- Would you want a healthcare team member to see your Fitbit data? If so, who?
- Would you be open to having your Fitbit data go into your electronic medical record? What concerns would you have about this?

The interviews were audio-recorded and transcribed. A coding team of 4 members reviewed transcripts, developed codes and definitions (i.e., codebook), and refined the codebook in an iterative process using inductive thematic analysis. Transcripts were coded using Atlas.ti software to assist with summarizing quotes for each code and identifying themes.

**Results**

**Participants**

Out of 205 people contacted for participation, 31 (15%) completed the in-person visit. One participant dropped out of the study, and two participants were unable to complete exit-interviews. Two participants did not wear their Fitbit Zip properly during the baseline phase and were not included in the analysis. Of the 26 participants who completed the study, 14 (54%) had ADT treatment. Men with a history of taking ADT were older, were more likely to be retired, had lower body mass index (BMI) and had a lower daily step count (over 2000 fewer steps on average) than men without a history of ADT use (Table 1). Men in both groups had many chronic conditions and were relatively similar in their use of technology and ownership of various types of devices. Only about half of the men used email and texting regularly, but all owned a cell phone. Only six participants reported owning fitness trackers and these were primarily men with no history of ADT treatment.

**Physical Activity**

Table 2 shows participants’ Fitbit use by group. During the baseline week, participants wore the Fitbit for a minimum of 5 days. Daily steps ranged from 2041 to 11205. Fourteen participants (54%) reported using the Fitbit during the optional use two-week phase. Of these, six (43%) had received ADT and seven (50%) had never used a pedometer or wearable activity tracker before participating in this study. The data in Table 2 indicate that many men taking ADT, and several with very low step counts (< 4,000 steps/day) were able and willing to use a new technology for fitness tracking during the optional use phase. Of the 8 men without a history of using ADT who used the Fitbit during the optional use phase, all but two men had prior experience using a fitness tracker and baseline phase step counts were a mixture of relatively low (~5,000 steps/day) to high (~10,000 steps/day).

**Attitudes Toward Use**

Themes that emerged from exit interviews regarding attitudes towards Fitbit use include wearability, ease of using technology, value in use, barriers to use, helpful features, and integration with healthcare. Next we describe each theme and provide illustrative quotes.
Wearability

Most participants (93%) found the Fitbit Zip easy to wear and comfortable. Participants noted that the device was easy to put on and said they forgot that they had it on and that wearing the device did not inconvenience them in any way:

*Once I put it on in the morning I was totally unaware of its presence on my body or in my pocket.* P17

Very few problems wearing the Fitbit were reported. A few participants expressed that they sometimes forgot to put on the device in the morning or to reattach the Fitbit when they changed clothes:

*Sometimes I forgot to take it off, because I was sick and I wasn’t moving around that much. Sometimes I forgot to put it on. I wore it when I remembered.* P14

One participant reported the device fell out of its case and another did not like that they had to remove the Fitbit when they used their hot tub.

**Wearability**

Most participants (93%) found the Fitbit Zip easy to wear and comfortable. Participants noted that the device was easy to put on and said they forgot that they had it on and that wearing the device did not inconvenience them in any way:

*Once I put it on in the morning I was totally unaware of its presence on my body or in my pocket.* P17

Very few problems wearing the Fitbit were reported. A few participants expressed that they sometimes forgot to put on the device in the morning or to reattach the Fitbit when they changed clothes:

*Sometimes I forgot to take it off, because I was sick and I wasn’t moving around that much. Sometimes I forgot to put it on. I wore it when I remembered.* P14

One participant reported the device fell out of its case and another did not like that they had to remove the Fitbit when they used their hot tub.
Ease of using technology

Six participants successfully used a smartphone or computer to sync their Fitbit during the optional use phase, although the syncing process was challenging for some of these participants. A few men reported needing help from a family member to successfully sync their devices:

*My wife is whiz kid on the computer and so she would call me in at the end of each day just before we went to bed and say, “Okay, stand here so the computer can read what’s on your Fitbit ... sometimes I had to stand a little – there a few minutes before the information was transferred from my Fitbit to the computer, but then it all lit up in color and it was, not a bar graph, but whatever you call that, a graph. And that was very interesting. It was easy to read, easy to understand.* P17

However, four participants found it easy to sync their devices and considered the process user friendly and presented data they found interesting, for example one participant reported:

*Every day or two I sync it. I download it to Fitbit application for my iPhone and so every day or two I sync it. And then I just sort of look at the information there ... It’s very easy. The Fitbit application is very – I think the term is user friendly.* P5

The remaining three participants had difficulty syncing their Fitbits by themselves:

*I guess that’s one of the things about this particular FitBit that was somewhat more difficult because I had to go online to the FitBit webpage to find out why I couldn’t get it to sync; it did not sync in the beginning. So I had to do a number of things to make it work.* P24

For some participants, the frustration led to giving up on using the device:

*a Could not sync device due to technical difficulties so did not use the Fitbit
*b Reported using the Fitbit during the 2-week period of optional use during the interview
*c Based on accessing the Fitbit API to determine whether or not they synced their Fitbit during the optional use phase

---

1054
Largely, I’m not wearing it because it doesn’t interact with my computer very easily...why bother? I just go use my manual step counter. P11

Participants who did not sync their Fitbit said they did not try because they were either too busy or did not care about connecting to their account because they could use the display on the device without using their computer or smartphone. In other cases, participants attempted to sync their device but encountered technical difficulties they could not overcome. Indeed, difficulties using technology were a common reason participants gave for not using the Fitbit during the optional use phase.

Value in using

Participants were divided in their opinions on the usefulness of the Fitbit for increasing their activity levels. For some, the Fitbit improved their awareness of their own physical activity level and motivated them to increase it by setting daily step count goals or helped them maintain their activity level:

I think I like to make sure I’m doing some minimal amount of activity. And it’s kind of fun to see what you’ve been doing, how many steps you’ve done, how many miles you’ve gone. P23

Well, I think it was fascinating to find out how many steps I had done for one thing or another and it was helpful on the walk that my wife and I try to take but fail to take every day. P10

Being able to check their step count throughout the day made them more conscious of how active they had been and enabled them to identify opportunities to increase activity to meet their goal. In other cases, participants reported the device would not be useful because they felt they were active enough and did not need to change their activity levels with or without the Fitbit.

Well, I’m not sure that I need to wear it, because I’m pretty active, like I go golfing, and I go walking, as much as possible, and I go up and down stairs all day long, so I don’t feel like I – I do sit for a long periods of time, also, but I lift weights, and I’m pretty active. P2

Because I’m very active usually and I’m up going and running here and there so I don’t think I need to keep track of it. P3

Participants also liked having the ability to track their own data. Family members were also cited as contributing to the usefulness and motivation aspects of the Fitbit if they had similar devices and could serve as challengers in activity competitions. Participants also felt the Fitbit motivated them by providing a reward:

So I think it builds in a positive feedback loop that it can provide, and that little instrument, the FitBit, is a really powerful way of doing that, so I think it – I have mostly all positive things to say. I don’t think there’s any negative, maybe you just have to remember to log in on some point, sync your FitBit to your computer; that’s about the only thing that you have to do. P24

People like to get...rewards, and by being able to look at it easily online and on my phone. I know both my wife and I have sometimes been at 10:00 p.m. occasionally dressed for bed and see that we only need, oh, 600 more steps to get to that 10,000 and go put your coat on and walk around the block. P22

Many participants endorsed value in continuing to use the Fitbit and expected they would continue to use the device indefinitely.

Barriers to Fitbit use

Conversely, some participants reported that the Fitbit was not helpful because they felt unable to alter their level of physical activity due to physical health challenges like pain and injuries. Fatigue and poor stamina limited participants’ ability to walk for long periods or to engage in other activities.

My situation is if I did not have pain, I would be active enough that I wouldn’t need the Fitbit because I would know I’m getting – I’m not very sedentary – well, I’m retired, so I guess I am sedentary. But when I don’t have pain and I’m not limited by the energy that I have from my treatment, I’m quite active. P1
Another barrier included several participants’ concern that the step count is inaccurate or did not capture important activities of daily living in which other forms of physical activity are used (e.g., muscle-strengthening, stretching):

So I'll give you a case. I filled my laundry, and it's logged I walked 2,000 steps. I did not walk 2,000 steps. P20

I guess the only surprise was that it seemed to register less activity than I felt I actually did because it was only measuring steps, and I was doing more than steps. I was lifting. I was bending. I was twisting. I was doing all that other sort of stuff. P11

Priority Fitbit features

Step count and distance walked were the two features used most by participants. Some participants used social features with family members. Very few participants reported using other Fitbit features (e.g., calories, active minutes, challenges):

I’d only use it [Fitbit] for a pedometer. I mean that’s all. I don’t give a [darn] about the calories and all that stuff.” P4

I think I like to make sure I’m doing some minimal amount of activity. And it’s kind of fun to see what you’ve been doing, how many steps you’ve done, how many miles you’ve gone. P23

Two participants who had continued to wear the Fitbit during the optional use phase and had also previously owned Fitbits reported using the social features:

I like it. I mean, it gives me weekly updates. Every now and then we’ll challenge our daughters because the whole family has one now. We bought them for them, too. So we’ll do a challenge every now and then, and I'll try to kick butt. P21

I've got some family members that are "Fitbit friends," so we kinda see each week how many steps everybody walked. P20

Attitudes toward integrating Fitbit with care

When asked about whether they were open to having their Fitbit data go into their electronic health record, participants felt comfortable sharing their Fitbit data for this purpose though some endorsed the need for limitations:

Yeah. I think it keeps people honest in that case. But at the same time, I don’t wanna start getting ads for granola bars every day in my inbox. P18

That would be fine with me. I think if it would help a physician or someone understands how you’re doing, there would be no problem with that. P23

Other participants describe additional information that would be needed to contextualize data shared with providers:

That’s a good question because, I think I most generally would. I think there might need to be some notes along with it, like I said, if there was a decrease in activity it might be because of illness, or something like that. So I think it tells part of a story, but not all of a story. If you did that, you would need to have...something like, a mechanism usually about the person’s physical ability to walk or whatever. P24

Many felt it would be helpful information for their provider to have to ensure their health is supported and that interventions are provided at appropriate times:

Again, somebody I had a relationship with, no matter who it was as long as it was where you had already established something and could be looking at that and either saying, “Well, that was just great. It was just 10,011 steps yesterday.” Or, “I saw you were only doing 1,000 steps. Are you feeling okay? Is there something getting in the way of your walking?” That kind of stuff. P10

Clearly, the primary care physician, the one that’s supposed to be your first point of contact, and so the ongoing collaborator in your wellbeing would be essential. And then depending on each person’s situation, and the teams wrapped around, and whatever team would seem appropriate to be looking at that data that would help them design a better intervention or better and better treatment that all makes sense to me. P18
Other participants were not sure how it would be helpful to their health care team and worried it might burden physicians, in particular:

*The thing for me would be, this would be all right for them, but if it’s just one little piece of information going into my record, I don’t see it making much difference one way or the other. And it’s the kind of thing that I don’t, and I may be wrong, I don’t see doctors or even nurses spending a whole lot of time looking at my Fitbit data.* P19

Many participants suggested that someone other than the physician such as a physical therapist or personal trainer should be the person to go over their data with them for feedback.

**Discussion**

Findings from our 3-week exploratory field study suggest that some men with prostate cancer find wearable fitness trackers like Fitbits highly acceptable—participants generally found the device comfortable and easy to wear, averaging over 6,000 steps per day when used. When given the choice, over half of participants continued using the Fitbit during the optional use two-week phase. While participants found step count and social features most useful, they experienced several barriers to use, including health-related limitations, problems syncing devices, and data inaccuracies and omissions. Despite these issues, many participants expressed value in sharing Fitbit data with their health care team. These insights expand on prior work by further characterizing feasibility of wearable fitness tracker adoption among an older population, men with prostate cancer.

Our qualitative themes align well within existing technology acceptance frameworks (e.g. the Technology Acceptance Model) and prior work. The TAM emphasizes the importance of perceived usefulness and perceived ease of use in shaping actual system use. We demonstrated actual use by having men use a Fitbit during a baseline week and two optional use weeks. While men were very willing to wear the device for the required baseline week, only half of the men used the Fitbit during the optional use phase that followed. Men with a history of ADT treatment were less likely to use the device than men without an ADT treatment history during the optional use phase. One factor that likely contributed to this disparity is the difference in average age between these two groups: the average age of ADT users in this sample was 10 years higher than those who had not received ADT. Also, men with a history of ADT use had less prior experience using fitness trackers. However, it is promising that many ADT users with very low step counts and who did not have prior experience using such fitness tracking technologies continued using their Fitbit during the optional use phase.

Regarding perceived ease of use, participants generally found the Fitbit to be easy to use and comfortable. However, many experienced technological barriers when trying to sync their Fitbit, which discouraged them from using the device. Some gave up trying to use their Fitbit while others sought help from family members that were more experienced with using technology. We selected the Fitbit Zip because it does not require smart phone ownership (which was low in our sample; 56%) and participants could sync it to a computer (96% owned a computer) or view the step count and distance walked for the current day on the device display. Therefore, simple tracking devices appear preferred by the older men in this study.

One design recommendation that could help improve ease of use includes continuing to offer fitness trackers that have a display that do not require syncing. Furthermore, having a medical team member request that patients use a fitness tracker and work with them over time to understand the data and learn to use more technologically advanced features of devices (e.g. syncing) could help promote a positive feedback loop that many participants were excited about. Giving patients clear and simple instructions for using wearable tracker devices, syncing them, and using their features could also facilitate adoption. This recommendation dovetails well with prior work indicating that health care providers could work together with older adults to help them understand their wellness monitoring data.

Regarding perceived usefulness, many participants endorsed value in using the Fitbit to ensure they engaged in a “minimal amount of activity” (P23) and to motivate them to squeeze in more steps. Barriers to usefulness included health limitations and feeling very active already. The latter is somewhat concerning considering that the average step count was well below recommendations for older adults or those with chronic conditions (8,000 steps/day). Particularly among men with a history of ADT use, step counts were very low (~5,000 steps/day). This further underscores the importance of helping men with prostate cancer receive feedback and education on their level of physical activity and its importance in supporting them as they age. Many men were quite active to start with, although wearable trackers like Fitbit could help these men continue to stay active as levels of physical activity decline with age.
All of the men were willing to wear the Fitbit if asked by someone from their health care system. This suggests that if used in clinical practice to get a sense of habitual activity, a health care provider might be able to discuss the importance of being even more active or continue to remain active. Indeed, all men reported willingness to share their Fitbit data with their health care provider and few had concerns about the information becoming part of the electronic health record. This willingness could, in part, be due to their involvement in a study that took place within their own health care system. There were some limitations on willingness to share the data including not wanting to be bombarded with messages about their health and being able to amend the data in order to explain or contextualize it.

Much prior work that has examined physical activity trackers in older adults has been limited to perspectives on use or required use over a week or less. Our 3-week field study enabled us to capture their use for longer. When offered the opportunity, many participants opted to continue using the Fitbit during the optional two-week phase but faced several technical barriers. While this method offered further insights into adoption, our small sample of men with prostate cancer and other chronic conditions could limit the generalizability of findings to other groups or devices. Additional support for using and syncing Fitbit devices could have impacted participants’ overall experience or improved optional use. There is merit in future work to further characterize and address the physical activity tracking needs of older adults and connection with healthcare providers. In particular, studies are needed to examine longer-term use of devices in larger and more diverse samples of older adults. Our findings suggest such devices should be designed to be simple for older adults to use, incorporate social features, and capture additional physical activities beyond walking, such as muscle strengthening and stretching. More targeted and easy to technology could improve adoption by older adults. Future work is also needed to explore how to integrate physical activity data into clinical care, including information and workflow needs of health care providers, in ways that minimize burden and promote utility. It may not be feasible to fully review and contextualize a detailed data stream within short provider visits. Future work should examine the right places for this data to enter into clinical workflow and the right health care team members to receive, review, and provide patient feedback on the data.

Conclusion

Our exploratory field study found that there are many opportunities to link fitness tracking to clinical care and to help the broader population of men with prostate cancer, and possibly other chronic health conditions, become more active and prevent further health declines. Our findings are congruent with those of Huh’s work in people with various chronic conditions and Vooijs’s work with COPD. This accumulation of evidence suggests that small-scale feasibility studies integrating fitness trackers with clinical care for high risk populations (e.g. COPD, prostate cancer) are warranted. These future interventions will need to make the technology as straightforward as possible, most likely through in-person demonstration sessions in conjunction with simple written materials and interactions with the health care team.

GT2RDF: Semantic Representation of Genetic Testing Data

Anamika Paul Rupa, MS, Sweta Singh, Qian Zhu, PhD
Department of Information Systems, University of Maryland Baltimore County, Baltimore, MD, US

Abstract

Accelerated by the Human Genome Project, genetic testing has become an increasingly integral component in diagnosis, treatment, management, and prevention of numerous diseases and conditions. More than 480 laboratories perform genetic tests for more than 4,600 rare and common medical conditions. These tests can effectively help health professionals to determine or predict the genetic conditions of their patients. However, physicians have not actively incorporated such innovative genetic technology into their clinical practices according to two national wide surveys commissioned by UnitedHealth Group. To fill the gap of insufficient use of a large number of genetic tests, we generated a single Resource Description Framework (RDF) resource, called GT2RDF (Genetic Testing data to RDF) by integrating information about disease, gene, phenotype, genetic test, and drug from multiple sources including Genetic Testing Registry (GTR), Online Mendelian Inheritance in Man (OMIM), MedGen, Human Phenotype Ontology (HPO), ClinVar, National Drug File Reference Terminology (NDF-RT).

Meanwhile, we manually annotated and extracted information from 200 randomly selected GeneReviews chapters, and integrated into the GT2RDF. We performed two case studies to demonstrate the usability of the GT2RDF. GT2RDF will serve as a data foundation to support the design of a genetic testing recommendation system, called iGenetics, which will ultimately facilitate the pace of precision medicine by means of actively and effectively incorporating innovative genetic technology in clinical settings.

Introduction

30 million people in the United States are living with rare diseases, and 80% of rare diseases are genetic. According to a recent survey of patients, family members, physicians and allied health care professionals regarding physician training in rare disease, these patients visit an average of 7.3 physicians before receiving an accurate diagnosis. Survey results indicated that both primary care physicians and specialists were equally likely to consult someone they considered a “disease expert” to help them make the diagnosis, which can potentially lead to the treatment delay. Consistently, forty-four percent of patients agreed with the statement, “Because of a slow diagnosis, treatment was delayed and the impact on my condition has been negative.”

This survey concludes that there is an urgent need to bridge the knowledge gap by educating and connecting patients, families, physicians and specialists, and urges families to educate themselves and their doctors about genetic testing technologies that may expedite an accurate diagnosis and lead to effective timely and appropriate treatment.

With the advance in genetic technology, more than 680 laboratories perform genetic tests for more than 4,600 rare and common medical conditions. No wonder so much hope is riding on the promise of “precision medicine”, in which genetic screening and other tests give doctors more evidence for tailoring treatments to patients, potentially improving health care and saving money. However, physicians have not actively incorporated such innovative technology into their clinical practices according to two national wide surveys commissioned by UnitedHealth Group in conjunction with Harris Interactive (n=2,760). About half of the physicians surveyed stated that the lack of familiarity with genetic tests is the main barrier to apply them in their regular practice, and over three-quarters of physicians are either somewhat or very concerned about the lack of evidence supporting the use of genetic testing. Meanwhile, these physicians identified four possible solutions that would possibly encourage them actively use of these genetic tests, a) enhanced medical and continuing education, b) provision of clinical decision support guidance, c) better access to clinical evidence, and d) affordable tests. To meet physicians’ needs, in this study, we designed and generated a centralized data resource about genetic testing in RDF, in order to provide a comprehensive view of integrative genetic testing information and recommend appropriate genetic tests and relevant information to support clinical decision-making.
A large volume of genetic disease related information has been accumulated, as a result of efforts and collaborations made by the NIH and other stakeholders. These include the primary resources, GTR(6), ClinVar(7), MedGen(8), OMIM(9), HPO(10), NDF-RT(11). In addition, genetic guidelines are continuously published for public use. For instance, GeneReviews(12), pharmacogenomics guidelines published by the Clinical Pharmacogenetics Implementation Consortium (CPIC)(13), Evaluation of Genomic Applications in Practice and Prevention (EGAPP)(14), a systematic, evidence-based process for assessing genetic tests and other applications of genomic technology. Although these resources provide invaluable information about genetic tests, distributed storage and diverse data representation lack interoperability and capability for its better integration and adoption at an institutional level. The effort required for adopting, ensuring appropriate protections, integrating, and maintaining such information within clinical infrastructures remains significant. Semantic web technology (SWT) is used to construct a common framework that accelerates data sharing and reuse across different applications, institutions, and community boundaries. SWT proposes to apply RDF as a flexible data model, which “effectively capture data semantics and enable semantic query and matching, as well as efficient data integration.”(15) A variety of RDF-based Semantic Web resources have been generated for biomedical data. For instance, Bio2RDF(16) offers a strategy to generate and query RDF based biological data with around 4 billion RDF triples across over 30 biological resources. Chem2Bio2RDF(17) aggregates data from multiple chemogenomics repositories in RDF. However, to our knowledge, no effort has been made for generating RDF based genetic testing data to support future clinical decision-making. In this present work, we generated an RDF resource, GT2RDF by integrating genetic testing relevant information from multiple well-known data resources, including GTR, OMIM and GeneReviews and incorporating a meta-ontology defined in OWL (Web Ontology Language) to formally capture the semantics of GT2RDF. We present use cases of how GT2RDF can be applied in seeking pertinent information regarding genetic tests and genetic diseases via SPARQL Protocol and RDF Query Language (SPARQL).

In the rest of paper, we briefly introduce the materials used in this study in the Materials section. We describe details about the generation of GT2RDF in the Methods section. Then we present the result and case study in the Result section. Finally, we discuss the benefit we obtained, the lesson we learnt from this study and our future direction in the Discussion section.

Materials

GT2RDF integrates diverse types of information extracted from seven different resources, which are briefly described below.

GTR(6) provides a central location for voluntary submission of genetic test information by providers. We downloaded GTR by November 1, 2015. We primarily accessed ‘test_condition_gene’ and ‘test_version’ files from GTR to retrieve information about test, disease and genes.

ClinVar(7) is a public archive of reports of the relationships among human variations and phenotypes, with supporting evidence. We extracted disease, gene and allele information by accessing ‘gene_condition_source_id’ and ‘variant_summary’ files by November 1, 2015.

MedGen(8) organizes information related to human medical genetics, such as attributes of conditions with a genetic contribution. We accessed ‘MedGen_HPO_OMIM_Mapping’ file by November 1, 2015, that contains mappings among MedGen, HPO and OMIM. We extracted disease and phenotype related information and association between disease and phenotype from MedGen.

OMIM(9) is a comprehensive, authoritative compendium of human genes and genetic phenotypes with the primary focus on the relationship between phenotype and genotype. We extracted Disease and Gene information and the association between them by accessing ‘morbidmap’ file from OMIM by November 1, 2015.

HPO(10) provides a standardized vocabulary of phenotypic abnormalities encountered in human disease. We extracted Gene and Phenotype information from ‘diseases_to_genes_to_phenotypes’ file by November 1, 2015.

GeneReviews(12) is expert-authored, peer-reviewed disease descriptions “chapters” presented in free text and focused on clinically relevant and medically actionable information on the diagnosis, management, and genetic counseling of patients and families with specific inherited conditions. We accessed GeneReviews by September 10, 2015, and extracted gene, phenotypes, genetic tests and family risk information associated with particular genetic diseases.
**NDF-RT** is a collection of drug relevant information and it provides RESTful web services to access those data. We collected drug and disease information by specifying particular parameters, ‘may_treat’, ‘has_contradiction’ from NDF-RT via its REST API by February 24, 2016.

**Methods**

In this study, we generated an integrative and standardized data resource for genetic test via multiple steps, 1) we semi-automatically collected genetic testing relevant data from multiple resources; 2) we normalized the collected data in standard form for further data integration; 3) we designed a meta-ontology using Protégé in order to capture the semantic meaning and semantic relations presenting in the collected data; 4) we generated and published GT2RDF by incorporating the meta-ontology with the implementation of D2RQ. The workflow performed in this study is shown in Figure 1.

![General workflow of GT2RDF](image)

**Figure 1. General workflow of GT2RDF**

1. **Data Collection.**

The seven data resources mentioned in the Materials section vary in their data representation forms. Thus, we applied different strategies to collect them accordingly.

**Structured data collection.** OMIM, GTR, HPO, MedGen, ClinVar are in structured form. Once we downloaded the data from their websites, we uploaded them into a MySQL database directly. We extracted drug and disease information from NDF-RT by invoking its REST API via two steps, 1) retrieving all disease and drug information by passing ‘DISEASE_KIND’ and ‘DRUG_KIND’ as an input parameter respectively to invoke one API resource named “allconcepts” which returns concept information for specified kinds; 2) disambiguating relations between drug and disease, i.e., indication and contraindication. We extracted indications and contraindications for each drug by filtering “rolenames” by “may_treat” and “CI_with” respectively from the
returned drug information by invoking the API resource named “allInfo” which returns concept information for a specified concept.

**Unstructured data collection.** GeneReviews provides tremendous information about significant patient characteristics relevant to individual genetic diseases, which are critical for further genetic test prediction. In this study, we (SS) manually annotated information presenting in the sections of Diagnosis, Clinical Characteristics, Management and Genetic Counseling for 200 GeneReviews Chapters. In the section of Genetic Counseling, it contains detailed information regarding genetic risk assessment, carrier detection, prenatal testing, and related genetic counseling issues for family members. In this study, we primarily focused on “risk to family members”, which includes information about the parents, sibs, and offspring risk of being affected, being a carrier or being unaffected. Given the complex structure of the section of Genetic Counseling that is out of the scope of this study, we only included ones with explicit content information including the risks of family members. In addition, we did not incorporate information presenting in the sections of Treatment and Prevention although we extracted them, as more information extraction process is needed to retrieve more refined annotation to be integrated into the GT2RDF, which will be proposed as the future work. AR and QZ have manually evaluated the annotation results and corrected the errors and problems. The corrected annotations have been integrated into the database.

2. **Data Normalization.**

To facilitate data manipulation and integration, data normalization is a key. In this study, while we mapped the collected concepts to Unified Medical Language System (UMLS) (21) by using MetaMap (22), we also maintained the existing identifiers as standard representation, such as Test ID from the GTR as an identifier for genetic test; HPO ID as an identifier for Phenotypes; OMIM number as an identifier for genetic diseases; rsID as an identifier for SNP; gene symbol for genes; NUI as NDF-RT unique identifier for drugs. More specifically, we automatically mapped a unique list of the diseases, phenotypes, genetic tests, and drugs to UMLS via the batch process function available at MetaMap. The mapping results generated by the MetaMap, include the UMLS preferred terms along with mapping scores. In order to exclude false positive annotations and labor insensitively manual evaluation, in this study, we only included the annotations with mapping score equaling to “1000”, which refers to an exact mapping between original concept and the preferred terms from UMLS. As only 200 GeneReviews chapters have been manually processed, the number of extractions is manageable, so we manually selected annotation results generated by the MetaMap, in order to maintain the high mapping accuracy. Due to some non-standard terms are used among the aforementioned resources, missing mappings were observed even the “1000” score has been applied. We manually evaluated a random set of annotation results to ensure the accuracy of mapping prior to the GT2RDF generation, in addition, we analyzed the causes of missing mappings for further extension.

3. **Meta-ontology Design.**

In order to capture the semantic meaning and semantic relationships among the collected concepts, e.g., diseases, gene, allele, genetic tests, phenotypes, risks of family members, drugs, we designed a meta-ontology using Protégé (16).

**OWL Object Property Definition.** Object properties are defined in a way to represent the relationships among classes. The list of Object properties is shown in table 1.

**OWL Data Property Definition.** Data properties link individuals to data values. The defined data properties for each class, along with some explanation are shown in Table 2. It is worthy to note that we included information from NDF-RT, which contains non-genetic diseases, thus we defined an additional data property, ‘IsGenetic’ for “Disease” to distinguish genetic diseases from non-genetic diseases.

**4. GT2RDF Generation.**

In this study, we included seven types of information, such as genetic test, disease, genes, genetic variations, phenotypes, medication and family risk according to the definition of the meta-ontology. For the GT2RDF generation, we applied D2RQ, which offers RDF-based access to the content of relational databases without having to replicate it into an RDF store, to transform data in the relational database to RDF. The mapping tool of D2RQ creates a default mapping file by analyzing the schema of an existing database. To map our data with the defined meta-ontology, we manually customized the mapping file accordingly. The data is then published in RDF through the D2RQ server, and can be queried via a D2RQ SPARQL endpoint. We also took an RDF dump from D2RQ into Virtuoso(23) to run federated queries. GT2RDF can be accessed via the URL http://biomedinformatics.is.umbc.edu:2020/.

**Result**

**1. Data collection.**

We collected data from seven data resources to generate the GT2RDF. Table 3 shows the detailed information for the data collection.
2. UMLS Mapping.

To represent GT2RDF in a normal form for further data integration, we mapped the individual terms belonging to the four classes, Disease, Drug, Phenotype and Test to UMLS. It is shown in Table 3 that diseases are extracted from several sources, but only GTR and MedGen provide UMLS mappings. Thus, we mapped the rest of the 15,078 disease terms to UMLS using MetaMap. NDF-RT provides 25,800 UMLS mappings among 26154 drugs and rest of the 354 drug terms have no mappings to UMLS. We tried to map the missing terms in MetaMap and found UMLS CUI for 17 drug names and included them in our database. We mapped all the phenotype terms and test terms using MetaMap because none of the resources provide UMLS mappings for them.

</table>

In order to ensure the accuracy of the mapping results, although we only selected UMLS preferred terms with mapping score equaling to 1000, we randomly selected one hundred mapping results for each type of terms and manually reviewed the mapping results. According to our evaluations, there are no incorrect mapping for one hundred Disease and one hundred Drug terms, but there are two incorrect mappings among one hundred Phenotype terms and four incorrect mappings among one hundred Test terms caused due to substring matching. The reasons causing the missing mappings are discussed with examples in the Discussion section. The overall accuracy of UMLS mapping is 98.5% which illustrates the high performance of mapping process using MetaMap. To clarify, “Total Number of Concepts Mapped to UMLS” is part of “Total Number of Concepts” because the concepts with mapping score less than 1000 have not been counted to the mapped concepts. The UMLS mapping result is shown in Table 4.

3. GT2RDF generation.

There are total 2,309,014 triples contained in the GT2RDF. Among them 32,815 triples are related to Gene, 34,695 triples are related to Disease, 8,787 triples are related to Test, 26,154 triples are related to Drug, 134,010 triples are related to Allele.

4. Case Study.

In order to demonstrate the usability of the GT2RDF, we performed two case studies accordingly.
Case study 1. Hemophilia A, (24) is a genetic disease caused by missing or defective factor VIII, a clotting protein. Information about diagnosis or management of Hemophilia A is available at OMIM and GTR. However, it is inefficient during the clinical practice to manually review and identify the most significant points. In this case study, we searched against the GT2RDF to retrieve pertinent information about Hemophilia A by composing and executing a SPARQL query shown in the section of “SPARQL query” in Table 5. Specifically, we are searching for related genes, appropriate genetic tests, available drugs, possible clinical features and risk for family members, shown in the section of “Results” in the Table 5. The retrieved risk information shown in Table 5 can be interpreted as “if the proband’s mother is a carrier each male sib is at a 50% risk of having hemophilia A” and “if the proband’s mother is a carrier each female sib is at a 50% risk of being a carrier”.

</table>
In this study, we introduced a novel RDF data resource by integrating heterogeneous information about genetic test from multiple data sources. The GT2RDF serves a data foundation, which will ultimately support the development of clinical decision support (CDS) system, iGenetics. Multiple advantages of the GT2RDF have been observed in the case studies, for instance, it provides comprehensive information regarding genetic disease and genetic test by searching the GT2RDF and other relevant Linked Open Data (LOD) (23). Besides the advantages, we also learnt lesson as well, since we are still in the early stage of this project and much future work is under planning.

Currently, more and more genetic relevant data has been accumulated to support more complex scientific and clinical questions. However, they are represented in their own forms and templates, which hinders its wide use and sharing. In this study, we dedicated our efforts on data normalization with UMLS and other vocabularies, such as OMIM, GTR, and etc., to facilitate further data integration. Showing in Table 4, a majority of selected GT2RDF terms have been mapped to the UMLS via MetaMap, but there is still a small portion of terms have not been mapped to UMLS. The main reason for failed mapping, especially for tests, is because preferred terms with mapping score equaling to 1000 have been selected and we excluded one to many mappings. For instance, one genetic test concept, “ACADM Sequence Analysis”, MetaMap results in two terms, “ACADM” with a score 660 and “Sequence Analysis” with a score 901 for. Similar to drug, “ALIROCUMAB 150MG/ML INJ, SYR, 1ML”, a drug concept with drug signature information like strength, form etc., are mapped to three UMLS terms, “ALIROCUMAB” with a mapping score 645, “ML” with a mapping score 645 and “INJ” with a mapping score 812. In this study, we excluded all of these mappings. But in order to increase the number of UMLS mappings in the future, we will include the mappings with a score less than 1000 and one-to-many mappings (one concept is mapped to multiple UMLS preferred terms). In addition to ensure the mapping accuracy, we will perform manual evaluation afterward. In addition, the primary terminology, UMLS has been applied in the data normalization step, in the future study, we will also utilize other domain vocabularies, such as SNOMED-CT(26) for genetic diseases and LOINC(27) for genetic tests.

Given the demonstrated advantage of SWT in biomedical domain with an increasing number of successful applications, we applied SWT to generate the GT2RDF. Web Ontology Language (OWL) as a web standard language for formally describing the semantics of a set of concepts within a domain, and semantic relationships between those concepts within Semantic Web. In this study, we defined a meta-ontology in OWL to capture the semantics of the GT2RDF. By incorporating with the defined meta-ontology, we formally represented our data in RDF. The meta-ontology and associated annotation not only improves the semantic utility of the GT2RDF, but also decreases the complexity of the SPARQL query (e.g., no need to understand the RDF schema of each data source during the SPARQL construction). Currently, we defined seven primary classes and associated properties in the meta-ontology, which meets our requirement for the current version of the GT2RDF. More complex structure of the meta-ontology will be defined while more data will be integrated into the GT2RDF. In addition, in the experimental phase, we are manually customizing the mapping file for translating original data to RDF based on the meta-ontology, which may not be realistically once we have quite complex data and ontology structures. In the next step, we will move the transformation process in an automated fashion.

By representing data as labeled graphs, RDF provides a powerful framework for expressing and integrating any types of data, and searching across different online resources, which is the outstanding advantage comparing to the relational databases. As of April 2014, under the auspices of an initiative called the Linked Open Data (LOD), more

```

Case Study 2. In this case study, we aimed to obtained more information about the drugs, like dosage level, drug-drug interaction and drug category for Wilson Disease (25) from GT2RDF and DrugBank from Bio2RDF via executing a federated query, which shows the ability to take a query and provide solutions based on information from many different sources. Wilson Disease is an autosomal recessive genetic disorder in which copper accumulates in tissues and it is a treatable disease by using appropriate medications. Thus, more information about drugs used for Wilson disease will be critical for appropriate drug selection. The composed federated SPARQL query and the retrieved results are shown in Table 6.

Discussion and conclusion.

In this study, we introduced a novel RDF data resource by integrating heterogeneous information about genetic test from multiple data sources. The GT2RDF serves a data foundation, which will ultimately support the development of clinical decision support (CDS) system, iGenetics. Multiple advantages of the GT2RDF have been observed in the case studies, for instance, it provides comprehensive information regarding genetic disease and genetic test by searching the GT2RDF and other relevant Linked Open Data (LOD) (23). Besides the advantages, we also learnt lesson as well, since we are still in the early stage of this project and much future work is under planning.

Currently, more and more genetic relevant data has been accumulated to support more complex scientific and clinical questions. However, they are represented in their own forms and templates, which hinders its wide use and sharing. In this study, we dedicated our efforts on data normalization with UMLS and other vocabularies, such as OMIM, GTR, and etc., to facilitate further data integration. Showing in Table 4, a majority of selected GT2RDF terms have been mapped to the UMLS via MetaMap, but there is still a small portion of terms have not been mapped to UMLS. The main reason for failed mapping, especially for tests, is because preferred terms with mapping score equaling to 1000 have been selected and we excluded one to many mappings. For instance, one genetic test concept, “ACADM Sequence Analysis”, MetaMap results in two terms, “ACADM” with a score 660 and “Sequence Analysis” with a score 901 for. Similar to drug, “ALIROCUMAB 150MG/ML INJ, SYR, 1ML”, a drug concept with drug signature information like strength, form etc., are mapped to three UMLS terms, “ALIROCUMAB” with a mapping score 645, “ML” with a mapping score 645 and “INJ” with a mapping score 812. In this study, we excluded all of these mappings. But in order to increase the number of UMLS mappings in the future, we will include the mappings with a score less than 1000 and one-to-many mappings (one concept is mapped to multiple UMLS preferred terms). In addition to ensure the mapping accuracy, we will perform manual evaluation afterward. In addition, the primary terminology, UMLS has been applied in the data normalization step, in the future study, we will also utilize other domain vocabularies, such as SNOMED-CT(26) for genetic diseases and LOINC(27) for genetic tests.

Given the demonstrated advantage of SWT in biomedical domain with an increasing number of successful applications, we applied SWT to generate the GT2RDF. Web Ontology Language (OWL) as a web standard language for formally describing the semantics of a set of concepts within a domain, and semantic relationships between those concepts within Semantic Web. In this study, we defined a meta-ontology in OWL to capture the semantics of the GT2RDF. By incorporating with the defined meta-ontology, we formally represented our data in RDF. The meta-ontology and associated annotation not only improves the semantic utility of the GT2RDF, but also decreases the complexity of the SPARQL query (e.g., no need to understand the RDF schema of each data source during the SPARQL construction). Currently, we defined seven primary classes and associated properties in the meta-ontology, which meets our requirement for the current version of the GT2RDF. More complex structure of the meta-ontology will be defined while more data will be integrated into the GT2RDF. In addition, in the experimental phase, we are manually customizing the mapping file for translating original data to RDF based on the meta-ontology, which may not be realistically once we have quite complex data and ontology structures. In the next step, we will move the transformation process in an automated fashion.

By representing data as labeled graphs, RDF provides a powerful framework for expressing and integrating any types of data, and searching across different online resources, which is the outstanding advantage comparing to the relational databases. As of April 2014, under the auspices of an initiative called the Linked Open Data (LOD), more
than 1000 public datasets from multiple domains (i.e., everything from geographical locations, to mortality data, to species, genes, drugs, and diseases) are available in RDF, and have been integrated by specifying approximately 60 billion RDF triples. LOD has been successfully applied in medical and clinical studies. Federated query allows retrieving more diverse types of information from multiple datasets. In the second case study, we demonstrated the usage of federated query to obtain information related to genetic disease and genetic test, and more information about drugs, such as drug-drug interaction and dosage from the GT2RDF and Linked Open Data (LOD), such as DrugBank. In our future work, we will explore more datasets available from LOD combining with the GT2RDF, in order to provide a more comprehensive view of the interested genetic disease or other queries. Additionally, the communication over the network can quickly become a performance bottleneck, leading to high query latencies, especially for federated query, is running across multiple RDF graphs, which requires transiting data across the network at the time of query in order to match complex SPARQL patterns navigating the RDF graphs. Recently, various solutions for federated query processing of heterogeneous RDF data sources have been discussed in the literature. But none of them were attempting to leverage Big Data techniques, such as MapReduce and NoSQL database to overcome the aforementioned barriers. In our future work, we will explore Big Data techniques to improve the performance of federated query.

In this study, we have integrated multiple resources. However, in order to provide more comprehensive information to support clinical decision-making, we will integrate more data into the GT2RDF. We will primarily focus on several data extensions, 1) GeneReviews has been widely used in the clinical settings, physicians are most likely to seek solutions from GeneReviews by manually reviewing the entire chapter, which is time consuming. In the early stage of this project, we manually annotated 200 chapters of the GeneReviews, from where we successfully retrieved information about genes, diseases, phenotypes, treatments, and family risk from multiple sections. In the next step, we will semi-automatically process the entire 649 GeneReviews chapters (at the time of writing) with the existing NLP tools, including MetaMap and NCBO annotator to achieve better annotation results. Meanwhile, we will invite domain experts to review and prove the annotations prior to integrate it into GT2RDF. 2) In order to enhance the scientific strength of the associations presenting in the GT2RDF, we will integrate scientific evidence extracted from scientific literature for each association. To be specific, we will explore Semantic MEDLINE to identify and map relevant literature information, i.e., PubMed ID to each association. 3) Although GeneReviews provides information about clinical characteristics for individual patients, such information is insufficient to support individualized genetic test recommendation. Conversely, Electronic Health Records (EHR) contains a wide spectrum of patient medical information, including billing data, laboratory test results, medication records, clinical documentation and imaging results. In the next step, we will statistically identify significantly clinical characteristics associated with each genetic disease via retrospective study over EHR data and deposit into the GT2RDF for further prediction.

Scientific Reproducibility in Biomedical Research: Provenance Metadata Ontology for Semantic Annotation of Study Description

Satya S. Sahoo, PhD1, Joshua Valdez, BS1, Michael Rueschman, MPH2
1Division of Medical Informatics, School of Medicine, Case Western Reserve University, Cleveland, OH; 2Department of Medicine, Brigham and Women’s Hospital and Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Abstract
Scientific reproducibility is key to scientific progress as it allows the research community to build on validated results, protect patients from potentially harmful trial drugs derived from incorrect results, and reduce wastage of valuable resources. The National Institutes of Health (NIH) recently published a systematic guideline titled “Rigor and Reproducibility” for supporting reproducible research studies, which has also been accepted by several scientific journals. These journals will require published articles to conform to these new guidelines. Provenance metadata describes the history or origin of data and it has been long used in computer science to capture metadata information for ensuring data quality and supporting scientific reproducibility. In this paper, we describe the development of Provenance for Clinical and healthcare Research (ProvCaRe) framework together with a provenance ontology to support scientific reproducibility by formally modeling a core set of data elements representing details of research study. We extend the PROV Ontology (PROV-O), which has been recommended as the provenance representation model by World Wide Web Consortium (W3C), to represent both: (a) data provenance, and (b) process provenance. We use 124 study variables from 6 clinical research studies from the National Sleep Research Resource (NSRR) to evaluate the coverage of the provenance ontology. NSRR is the largest repository of NIH-funded sleep datasets with 50,000 studies from 36,000 participants. The provenance ontology reuses ontology concepts from existing biomedical ontologies, for example the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), to model the provenance information of research studies. The ProvCaRe framework is being developed as part of the Big Data to Knowledge (BD2K) data provenance project.

Introduction
Scientific results from basic and clinical experiments represent the core building blocks of progress in biomedical research, which include future preclinical experiments and clinical trials. Therefore, the reproducibility of results from these studies is critical for driving scientific progress (1, 2). Scientific reproducibility is rapidly gaining critical importance in biomedical research, which is highlighted by the recent National Institutes of Health (NIH) guidelines called “Rigor and Reproducibility” that aim to improve poor reporting standards and address significant challenges impeding study replicability (2). The lack of appropriate reporting standards and metadata information, such as statistical technique used to estimate sample size and inclusion or exclusion criteria, leads to low reproducibility in biomedical research. A recent analysis of past biomedical research studies estimated that about $28 billion per year is spent on non-reproducible research in the United States (3). Similarly, an analysis of studies carried out as part of the National Institute of Neurological Disorders and Stroke (NINDS)-funded “Facilities of Research Excellence – Spinal Cord Injury” (FORE-SCI) program found that many of these studies cannot be replicated (4). In cancer research, a review of 100 articles identified that only 28% of the papers have correctly reported the experiment techniques, for example randomization of allocation to treatment groups (5). Therefore, there is a clear and urgent need to develop a practical framework that builds on the “Rigor and Reproducibility” initiative to facilitate rigorous study design and scientific reproducibility.

However, there are no existing well-defined frameworks that consist of metadata elements or representation models, which can support reproducible science. Intuitively, provenance metadata, which describes the history or origin of data and incorporates a detailed description of the different procedures used to handle the data, is a natural candidate for supporting scientific reproducibility. Provenance metadata has long been used in computer science to keep track of the origin of data to validate data quality, compute trust values, and support scientific reproducibility. In 2013, the World Wide Web Consortium (W3C), which is the standards organization for Web technologies (e.g., Web Ontology Language (OWL2) and eXtensible Markup Language (XML)), recommended the PROV specifications for modeling provenance metadata. Provenance metadata is often represented using the W7 model describing the Why, When, What, Where, How, Which, and Who of scientific research (6). The W3C PROV specification consists of the PROV Ontology (PROV-O), which uses OWL2 as a formal representation language to model a minimum set of provenance terms (7). As described in the PROV specification, PROV-O is a reference or “upper-level” ontology,
which can be extended to model provenance metadata in various domains, including medical informatics and facilitate the use of provenance information in achieving the objectives of “Rigor and Reproducibility” guidelines.

In this paper, we introduce Provenance for Clinical Research and Healthcare (ProvCaRe) as a flexible framework to support management of provenance metadata and its application in biomedical research. ProvCaRe consists of an ontology model for representing provenance information and software tools to extract, integrate, and analyze provenance information from various sources (e.g., published articles). The ProvCaRe framework is being developed as part of the NIH Big Data to Knowledge (BD2K) program for data provenance. The ProvCaRe framework aims to address three provenance management challenges in medical research: (1) Development of a provenance ontology to model reporting standards for rigorous design of experiments for both hypothesis generation and hypothesis validation; (2) Integration of the provenance ontology into a Web-based provenance software tool to allow search and analysis of previous research studies; and (3) Development of a highly scalable search engine to allow search and analysis of previous research studies for both replication of previous studies and design of new experiments. This paper describes the development and evaluation of the ProvCaRe ontology, which represent provenance information by re-using many ontology classes from existing biomedical ontologies. For example, the Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT) (8), the Ontology for Biomedical Investigation (OBI) (9), and the Ontology for Clinical Research (OCRe) (10). The ProvCaRe project leverages data and metadata information from the National Sleep Research Resource (NSRR), which is funded by the NIH to create an integrated repository of sleep medicine data consisting of 50,000 studies from 36,000 participants (11).

**Background**

**Reporting Standards for Rigorous Study Design.** In 2014, the NIH organized a meeting involving 30 basic as well as preclinical science journal to develop a set of principles for supporting reproducible science (12). The principles can be broadly classified into three categories: (1) **Statistical Analysis:** describing the statistical analysis techniques used for data analysis to ensure accuracy of results, (2) **Study Reporting Standard:** consisting of 7 topics including terminological standard, number of repetition of experiments under range of conditions, and techniques for randomization, blinding, and sample-size estimation, and (3) **Data Management** as well as sharing (12). These three categories of study metadata form the foundation for the development of ProvCaRe framework. The framework aims to capture essential information to support both rigorous study design and scientific reproducibility. In this paper, we also use these NIH recommended principles to develop the ProvCaRe ontology.

**W3C PROV Ontology.** The PROV Ontology (PROV-O) models common provenance metadata terms and properties using the description logic-based OWL2 (13). The three foundational provenance terms modeled in PROV-O are **Entity**, **Activity**, and **Agent**, which are linked to each other using seven “core” properties, namely `wasDerivedFrom`, `wasAttributedTo`, `wasGeneratedBy`, `wasAssociatedWith`, `actedOnBehalfOf`, `wasInformedBy`, and `used` (Figure 1(a)) (7). Figure 1(b) illustrates the use of these PROV-O terms to create a provenance graph describing the history of an example patient. PROV-O is designed as an upper-level reference ontology that can be used as a common foundation to develop interoperable domain-specific applications using provenance ontologies, such as the ProvCaRe ontology for medical research.

**SNOMED CT.** SNOMED CT is the largest clinical terminology originally created by the College of American Pathologists (CAP) and currently maintained by the International Health Terminology Standards Development Organization (IHSTDO). The 2015AA version of the SNOMED CT with more than 31,000 terms was used in this paper to identify provenance-related classes. SNOMED CT consists of concepts that are connected by relationships, for example **temporal context** to relate occurrence of an event with a time value. The SNOMED CT terms (also called pre-coordinated concepts) can be combined using the SNOMED CT compositional grammar form to represent new concepts (also called post-coordinated concepts). This feature allows SNOMED CT to be used for representing new concepts that are not part of the original SNOMED CT class hierarchy.

![Figure 1: Core terms of the PROV Ontology and example provenance graph](image)
National Sleep Research Resource (NSRR). The National Sleep Research Resource (NSRR) is creating one of the largest repositories of de-identified physiological signals and clinical data elements that were collected from multiple research cohorts and clinical trials (11). NSRR aims to provide free access to about 50,000 sleep studies collected from about 36,000 participants, which include demographic, physiological, clinical, and other types of data. Researchers can use the curated and well-defined sleep data from multiple NIH studies to develop large cohort studies with more diverse population that was not possible with a single study cohort. This is expected to significantly accelerate the pace of research in role of sleep and sleep disorders in pathogenesis of chronic illness such as cardiovascular and metabolic diseases.

Related Work

There has been past work in development of formal models to represent biomedical research informatics, including the Biomedical Research Integrated Domain Group (BRIDG) model (14), the Ontology for Clinical Research (OCRe) (10), and the Eligibility Criteria Extraction and Representation (EliXR) project (15). The BRIDG model focused on developing a representation of clinical trial protocols involving trial design, temporal information, and events. The BRIDG model was used as reference for the development of the Clinical Data Interchange Standards Consortium (CDISC) Operational Data Model (ODM). The OCRe project was a comprehensive effort to develop a formal model of study design to support different phases of clinical research, including study design, execution, and interpretation of data. The OCRe model (revision 315 downloaded from the National Center for Biomedical Ontologies) uses formal logic-based OWL2 representation format to represent different categories of research studies, study characteristics, and statistical concepts. The OCRe project developed the Eligibility Rule Grammar and Ontology (ERGO) tool to annotate textual description of eligibility criteria for research studies (16). Similar to the ERGO tool, the EliXR project developed a pipeline to analyze and discover common semantic patterns in eligibility criteria description extracted from ClinicalTrials.gov. The proposed ProvCaRe project builds on these existing projects with addition of data and process provenance concepts to support scientific reproducibility, which is distinct in terms of scope, objectives, and scalability as compared to these projects. In the next section, we describe the use of “Rigor and Reproducibility” guideline template to develop the ProvCaRe framework and its implementation in the provenance ontology.

Method

Clinical researchers often use the Population, Intervention, Comparison, and Outcome (PICO) framework to represent clinical research questions, which are integral to practice of evidence-based medicine (EBM) (17). Many reports have found that formulation of research studies according to the PICO model improves the accuracy and quality of research results and also support better search strategies (18). However, the PICO model lacks support to represent critical metadata information regarding clinical studies to support scientific reproducibility. For example, the PICO framework does not model: (1) the data handling techniques (e.g. inclusion and exclusion criteria for study data), (2) the statistical methods used (e.g. randomization technique), (3) the technique used for data recording (e.g., blood pressure recorded in supine position), and (4) the instruments used for recording (e.g., multi-contact intracranial electrode used for recording electroencephalogram). To develop the ProvCaRe ontology, we followed a three-phase development workflow (Figure 2):

1. **Phase I**: In the first phase, we leveraged the “Reporting standards for rigorous study design”, which is used as the foundation to define the principles of the NIH “Rigor and Reproducibility” guidelines to extend the PICO model with provenance metadata concepts (Figure 2 illustrates the different components of the rigorous study design with PICO model components).

2. **Phase II**: In the second phase, the provenance concepts identified from the reporting standards were normalized and mapped to ontology concepts from existing biomedical ontologies using the National Center for Biomedical Ontologies (NCBO) BioPortal “term lookup” service. The re-use of existing ontology classes reduces redundant ontology development efforts and also facilitates interoperability of the ProvCaRe ontology with existing biomedical ontologies.

3. **Phase III**: In the final phase, the W3C PROV ontology is extended with the biomedical ontology concepts identified in Phase II of the development workflow using the subsumption (rdfs:subClassOf) relationship. The resulting ProvCaRe ontology can be used to annotate medical research study description as part of the ProvCaRe framework to characterize the replicability of results reported by research studies.

**Phase I: Identifying Provenance Metadata Terms from the NIH Reporting Standards for Rigorous Study Design.** Figure 2 illustrates provenance metadata elements representing three categories of information related to medical research studies: (1) Study Design, (2) Study Data, and (3) Study Instrument, which together form the
ProvCaRe S3 framework for supporting scientific reproducibility. The ProvCaRe S3 components include the constituents of the PICO model and the NIH Rigor and Reproducibility guidelines (1). The Study Design component is mapped to the Intervention and Comparison elements of the PICO model, which partially describe the treatment or intervention as well as the comparison approach that is used in a biomedical research study. In addition, the provenance metadata represents the requisite information to describe the technique used to ensure randomization of data to be collected and the allocation of animal or human participants in a study at appropriate level of granularity. Similarly, description of the blinding technique and the statistical method used to estimate the sample size of the study are also represented in the Study Design component. The data handling techniques in terms of inclusion/exclusion criteria used to select data to be used in the research study and the approach used to address missing data elements also forms part of the Study Design section. The details of the method used to design the conduct of the research study, which broadly represents process provenance, are essential for external researchers and groups to replicate results of the study (19).

Figure 2: The three-phase workflow used to develop the ProvCaRe ontology
The Study Data category includes the study data elements used in a research study, which can be mapped to the population and outcome elements of the PICO model. The various study variables used to record different aspects of the research study, for example demography, medication, medical history, anthropometry, and laboratory data describing the population under study as well as the outcome information constitute the Study Data. A systematic representation of the provenance information associated with the study variables, for example the minimum and maximum values for each variable, the threshold used to assign values to the study variables, and valid values, is required to allow results from previous studies to be replicated. The Study Tools category includes provenance metadata describing the details of instruments used to record, measure, analyze, and interpret data in research studies. The instruments used in research studies are a critical component in terms of recording bias due to the sensitivity and accuracy of the instruments, for example the minimum and maximum voltage that can be recorded by intracranial electrodes used to record electrophysiological signal data in neurological disorders. This provenance information can be used to ensure correct interpretation of the study data. Similarly, the characteristic of 12-lead Electrocardiogram (ECG) recordings of systolic and diastolic blood pressure in various sleep studies in the NSRR is important provenance information.

Together, the three components of the ProvCaRe S3 framework can be used to represent the relevant provenance information about medical research studies, which can be used by other research groups to reproduce the original study. Table 1 shows the structural patterns of the S3 framework and the corresponding provenance metadata information derived from the NIH Rigor and Reproducibility principles (SDe, SDa, ST represent Study Design, Data, Tools respectively). The formalization of the S3 provenance terms will allow consistent use and interpretation of the terms in different applications and tools, which can be addressed by incorporating the terms in a provenance ontology. However, instead of creating new ontology terms for the provenance information, it is important to re-use ontology classes from existing biomedical ontologies as recommended by ontology engineering best practices. This will also facilitate interoperability of the provenance ontology with existing biomedical ontologies. Therefore, in the second phase of the development process, we identified relevant classes in existing biomedical ontologies for use in the ProvCaRe ontology.

**Phase II: Mapping Provenance Terms to Ontology Classes.** Biomedical ontologies represent terminological systems using a formal knowledge representation language such as the OWL2 to enable consistent and accurate interpretation of the terms by both humans and software tools (20). The NCBO BioPortal lists more than 500 biomedical ontologies representing a wide variety of biomedical domains to allow researchers to search and use ontology terms for semantic annotation of biomedical data and also support knowledge-driven analysis of
biomedical data (21). We used the navigation feature of the BioPortal to look up ontology terms representing the provenance terms identified in Phase I of the ProvCaRe development process. We identified the SNOMED CT, OCRe and OBI as the top sources of ontology classes for representing provenance information. SNOMED CT has 19 top-level concepts and many of these class hierarchies contain terms that can be used to the provenance terms described in the S3 framework. For example, the Procedure and its subclasses, including Surgical procedure or Management procedure can be used to represent the different kinds of intervention used in research studies. Similarly, we identified the Social context top-level concept and all its subclasses as appropriate to model the population related provenance information. The Pharmaceutical/ biologic product and its subclasses are appropriate the provenance information of medication and drug prescription of study participants.

In addition to SNOMED CT, the Ontology for Clinical Research (OCRe) (Revision 315) contains many classes that can be used to represent provenance information. OCRe has defined a classification of research studies into two primary categories of Interventional and Observational studies (Interventional study design and Observational study design) (10). The OCRe Statistical concept class and its subclasses, including Statistical method and Variable dimension can be used to represent the data analysis techniques used during analysis of the study data. The Ontology for Biomedical Investigation (OBI) models different components of biomedical experimental processes with a focus on basic science research studies (9). OBI represents both the material and processes involved in scientific experiments, for example specimen and its subclasses, including cell specimen and tissue specimen. The process and its subclasses such as cellular process, disease course can be used to represent provenance of the symptom and diagnostic tests used in studies. In addition, OBI models temporal information, which can be used to represent provenance of various events (e.g., recording timestamps of blood pressure or date of laboratory tests) in research studies. Although these three ontologies included the maximum number of provenance related classes in the BioPortal search results, we plan to use the BioPortal Web services API (21) in future to automatically look up ontology classes for provenance terms as part of the ProvCaRe software tool.

**Phase III: Extending the PROV Ontology to Develop the ProvCaRe ontology.** As we discussed earlier, PROV-O consists of three core concepts of Entity, Activity, and Agent, which are linked together with 44 object properties (including 7 “core” properties), modeled using OWL2 RL (7). We extended PROV-O with provenance terms identified from Phases I and II. The Activity class was extended to model the Intervention, Data Handling, Exclusion/Inclusion criteria, Missing data protocol, and Data collection protocol. The class hierarchy used to model these classes follows the structure and description of the provenance terms described in the “reporting standards for rigorous study design” (1). Similarly, the Population, Comparison, and Outcome components of the PICO model are modeled as subclasses of Study Data, which is in turn modeled as a subclass of PROV-O Entity class. The provenance terms describing the Study Design, which is modeled as a subclass of PROV-O Plan class, are modeled as its subclass, namely Sample size estimation protocol, Blinding protocol, and Randomization protocol. The third component Study tool of the S3 framework is modeled as a subclass of the PROV-O Agent class.

Similar to the class expression approach used to model new concepts in SNOMED CT through post coordination using the SNOMED CT compositional grammar form, we propose to use post coordinated class expression to model new provenance terms using existing ProvCaRe ontology classes. This will allow modeling of a wide range of provenance terms in the ontology without requiring all potential provenance terms to be modeled in the “original” ProvCaRe ontology. For example, provenance metadata describing the method used to record polysomnogram in a sleep research study called Sleep Heart Health Study (S3HHS1), which is part of NSRR, can be represented using the post coordinated expression Polysomnogram | has a | measurement method | of | home overnight recording. To support this post coordination expression functionality, the SNOMED CT relationships will be imported into the ProvCaRe ontology. Figure 3 shows a screenshot of the ProvCaRe ontology class hierarchy.
Results

To evaluate the coverage and mapping functionality of the ProvCaRe ontology, we used study variables representing various aspects of clinical research from 6 sleep studies from the NSRR repository. The data from these sleep studies are being made publicly available on NSRR. A brief description of the sleep studies is provided below:

1. **Sleep Heart Health Study (SHHS1) Study**: SHHS1 is a multi-center cohort study funded by the NIH National Heart Lung and Blood Institute (NHLBI) to determine the consequences of sleep-disordered breathing on risk for coronary heart disease, stroke, all causes of mortality, and hypertension.

2. **Multi-Ethnic Study of Atherosclerosis (MESA) Study**: The MESA study is a multi-center project involving 6 field centers to study the characteristics of subclinical cardiovascular disease (CVD) and risk factors that predict progression to clinical CVD and to predict the progression of subclinical disease in 6815 participants aged between 45-84 years.

3. **Childhood Adenotonsillectomy Trial (CHAT) Study**: The CHAT study is a multi-center, single blind, randomized controlled trial to test whether children aged between 5 to 9.9 years with mild to moderate obstructive sleep apnea randomized to early adenotonsillectomy (eAT) show greater neurocognitive functioning as compared to children randomized to watchful waiting plus supportive care after a 7 month observation period.

4. **Heart Biomarker Evaluation in Apnea Treatment (HeartBEAT) Study**: The HeartBEAT study is a multi-center Phase II randomized controlled trial to evaluate the effects of supplemental nocturnal oxygen or Positive Airway Pressure (PAP) therapy compared to optimal medical preventive therapy over 3 months intervention period. The study involves patients with CVD or CVD risk factors, and moderate to severe obstructive sleep apnea. The primary outcome of the study is 24-hour blood pressure profile.

5. **Osteoporotic Fractures in Men (MrOS) Study**: The MrOS study is a large observational study of the determinants of fracture in older men involving 5994 participants living in communities with age of 65 years or older across 6 clinical centers. In a follow up study, some of the participants were recruited in a sleep study involving unattended polysomnography. The follow up sleep study aims to understand the relationship between sleep disorders, falls, fractures, mortality, and vascular disease.

6. **Cleveland Family Study (CFS)**: CFS is the largest family-based study of sleep apnea worldwide with 2,284 individual enrolled from 361 families and studied on 4 occasions over a period of 16 years.

We selected 124 study variables across the 6 research studies and evaluated them according to two criteria: (1) Coverage of the proposed S3 model in terms of representing provenance of the study variables, and (2) Mapping the ProvCaRe ontology classes to represent the provenance of the variables according to S3. The study variables are not exhaustive with respect to the 6 studies and are only representative of the various categories of data that were considered in the research studies. We classified them into five categories of Demography, Anthropometry, Medical History, Disease Metric, and Medication.

Mapping Research Study Variables to the Provenance Components of the S3 Framework. The mapping of the 124 study variables across the five categories to the three provenance components of Study design, data, and tools demonstrates that metadata information regarding many of these variables need to be captured across all the S3 components. For example, the variables categorized into the Medical history, Anthropometry, and Disease related
metrics require the capture of provenance information to describe the design, data, and tools of the research studies (Table 2). The provenance information includes the threshold used to assign participants to the study, for example a research study correlating sleep disorder related breathing with cardiovascular diseases might exclude obese persons with BMI higher than threshold values. Similarly, a sleep research study might include participants who have been diagnosed with insomnia by a clinician to ensure that only participants with clinically validated diagnosis are recruited in the study. In contrast, some of the variables in the Demography and Medication category do not have provenance information corresponding to the Study method component.

The results of this mapping allow us to achieve two objectives: (1) Evaluate the effectiveness of the S3 provenance framework to capture metadata information to support scientific reproducibility; and (2) Create a “provenance checklist” for researchers to ensure that the minimum set of provenance information is collected during reporting of results from a study. This will enable researchers to verify that if the relevant category of the provenance metadata for study variable is missing the study result may not be reproducible. The provenance checklist based on the S3 framework can be implemented in a software tool as a practical application to be used for reporting scientific results that can be reproduced and helps meet the desired goals of the NIH Rigor and Reproducibility guidelines.

Coverage of the ProvCaRe Ontology: Use of Classes to Model Research Study Variables. To evaluate the coverage of the classes currently modeled in the ProvCaRe ontology, we mapped the variables from the 6 research studies to the existing ProvCaRe ontology classes. Table 3 demonstrates that the current version of ProvCaRe ontology includes classes that can represent a majority of the research study variables across the 6 studies used in the evaluation. We analyzed the study variables that were not covered by the existing ProvCaRe ontology classes and identified that a significant number of study variables represented domain-specific information used in a study. For example, the existing ProvCaRe ontology classes do not represent participant responses, for example “frequency of feeling unrested” and “time to fall asleep” in the SHHS1 study. It is important to note that the ProvCaRe ontology is not designed to model domain-specific variables. A more efficient approach to address this challenge is to use post-coordinated concept expressions using pre-coordinated concepts in ProvCaRe ontology to represent these study specific variables.

It is interesting to note that many of the ontology classes used to represent the 124 study variables in the ProvCaRe ontology are re-used from existing biomedical ontologies, such as SNOMED CT (as described earlier in the Method section). The use of these classes in ProvCaRe ontology demonstrates that re-use of existing ontology classes to model knowledge in a new domain such as provenance is a practical and sound approach and validates the best practices of ontology engineering. In future, we aim to expand the ProvCaRe ontology with additional classes from existing biomedical ontologies through automation of the provenance term lookup service and use of automated
techniques to extract subset of class hierarchy from existing ontologies using open source tools, such as OWLAPI (22). We discuss the proposed approach to use automated ontology extraction and import technique using OWLAPI in the following section together with a description of how the ProvCaRe ontology and the S3 framework can play an important role in supporting scientific reproducibility.

Discussion

Role of provenance metadata in scientific research, including data quality and trusted EHR systems. In addition to scientific reproducibility, provenance metadata has an important role to play in ensuring data quality by allowing users and software tools to validate the quality of data. For example, the increasing automation of data processing and analysis steps using scientific workflows (23) can be leveraged to support automated collection, storage, and subsequent analysis of provenance information. This will allow us to ensure that the quality of data is not compromised as the volume and rate of data generation rapidly increases especially in the context of biomedical Big Data. Similarly, the increasing adoption of Electronic Health Record (EHR) systems across the nation highlights the significant need to track the collection, processing, and modification of patient data as it is transferred across the EHR systems and Health Information Exchange (HIE) platforms. The use of provenance metadata information to keep track of how patient information is modified and used across the healthcare system will allow different stakeholders to ensure that data is secure and it is being used in the intended manner.

The Standards and Interoperability (S&I) Data Provenance initiative by the National Coordinator for Health Information Technology (ONC) is working to incorporate provenance metadata in the Health Level (HL) Common Document Architecture (CDA). This will allow provenance metadata to be used as an integral component of the electronic health informatics infrastructure. Therefore, the development of the ProvCaRe framework with a provenance ontology and related software tools will allow the use of existing provenance standards such as the W3C PROV to be used in provenance-enabled medical informatics platforms and software tools.

Limitations. The current approach to manually select and import classes from existing biomedical ontologies is not a sustainable approach in the ProvCaRe project as the size and scope of the ontology increases with addition of new domains. For example, the ProvCaRe project in currently incorporating neurology data from a large multi-center project in epilepsy called the Center for SUDEP Research (CSR) involving 14 epilepsy centers across the US and UK (funded by the National Institutes of Neurological Disorders and Stroke, NINDS). Therefore, in the next phase of the ProvCaRe ontology development, we propose to use open source OWLAPI to extract targeted segment of ontologies, which we have successfully used in our earlier work to create the Epilepsy and Seizure Ontology (EpSO) (24).

Conclusion

Provenance metadata describing the origin or history of data is critical to support scientific reproducibility. In this paper, we introduced the ProvCaRe framework consisting of three categories of provenance information, namely Study Method, Data, and Tool (S3), and a provenance ontology by extending the W3C PROV Ontology. The ProvCaRe framework is being developed as part of the NIH Big Data to Knowledge (BD2K) data provenance initiative and it aims to formalize the NIH Rigor and Reproducibility guidelines using a 3-phase workflow. The ProvCaRe ontology re-uses classes from existing ontologies to represent critical components of the S3 model for recording provenance of scientific studies. We evaluate the effectiveness of the S3 model and the coverage of the ProvCaRe ontology using 124 study variables from 6 research studies in the NSRR repository. The evaluation results demonstrate that the S3 model captures the required provenance information for the 124 study variables. As part of our ongoing work, we are developing automated approaches to extend the ProvCaRe ontology that will be used for semantic annotation of research studies.

Abstract

We analyzed user interactions with a paper-based checklist in a regional trauma center to inform the design of digital cognitive aids for safety-critical medical teamwork. An initial review of paper checklists from actual trauma resuscitations revealed that trauma team leaders frequently wrote notes on the checklist. To understand this note-taking practice, we performed content analysis of 163 checklists collected over the period of four months. We found nine major categories of information that leaders recorded during resuscitations, including patient values, physical assessment findings, and pre-hospital information. An analysis of types and amount of notes written by leaders of different experience levels showed that more experienced leaders recorded more patient values and physical findings, while less experienced leaders recorded more notes about their activities and task completion status. These findings suggested that a checklist designed for a high-risk, fast-paced medical event has evolved into a dual function tool, serving both as a compliance and memory aid. Based on these findings, we derived requirements for designing digital cognitive aids to support safety-critical medical teamwork.

Introduction

A growing body of work has shown the value of checklists in general hospital care, suggesting that their use can be extended to other clinical domains prone to human error1. Checklists are now commonly used to support a range of complex medical activities, including verifying the steps of safe surgery, performing infection control procedures, and defining daily care tasks in a hospital setting2-4. Trauma resuscitation is a high-risk, time-critical and team-driven process of treating severely injured patients, posing a four-fold higher risk of death from errors than general care5. Due to the fast-paced and complex nature of the process, adoption of decision-support systems and cognitive aids in this environment, including the checklist, has been slow. To attain and retain resuscitation skills, providers rely on individual and team training, but training alone has been found insufficient for ensuring patient safety and long-term compliance with protocols6. Recently, however, several U.S. trauma centers have started implementing checklists in actual resuscitations, showing their positive impact on team performance and protocol compliance7-9.

Although initial reports showed the benefits of checklists in medicine, some follow-up studies have questioned their effectiveness10. Medical work is often characterized as messy, ad hoc, and unpredictable11, yet most medical checklists are static and linear. Checklists typically cover a mix of important and frequent activities, but do not take into account repeated tasks, changing patient and environmental conditions, and less frequent but critical tasks. These checklist limitations have led to both low adoption and poor compliance rates12,13. To achieve optimal performance, particularly in time-pressured and safety-critical settings such as trauma resuscitation, checklists may need to be more flexible and dynamic to allow for adaptability to different patient and user scenarios14.

To inform the design of a dynamic checklist for fast-paced medical settings, we studied the use of a paper-based trauma resuscitation checklist in an urban, pediatric teaching hospital, with a level I trauma center. A checklist is commonly seen as a tool for ensuring process compliance by performing and checking off a set of tasks. We found that trauma team leaders, in addition to checking the items, frequently wrote notes next to those items. The notes contained valuable information for task performance and decision making during trauma resuscitations. This finding suggested that the resuscitation checklist has evolved into a dual-purpose tool to support both the process compliance and leaders’ cognitive functions. In this paper, we performed a mixed-method study to analyze the nature of note taking and other observed checklist use practices, and to derive design requirements for augmenting the checklists to better support complex and highly dynamic teamwork.
The resuscitation checklist was designed to help trauma teams prepare for patient arrival and to guide their performance throughout the patient evaluation. Its goal was to ensure protocol compliance and reduce delays in treatments. The checklist contains 53 items grouped into four sections: pre-arrival plan, primary and secondary surveys, and departure plan (Figure 1). The pre-arrival section lists preparatory steps for patient arrival. The primary and secondary survey sections contain the protocol steps, including the ABCDEs, head-to-toe evaluation, and vital signs checking. The departure plan items facilitate discussion about diagnostic tests and patient disposition. Checklist administration was assigned to the physician leader, a role least likely to be hands-on during patient evaluation.

Methods

Research Site & Data Collection

Our research site was an urban, pediatric teaching hospital and a regional level 1 trauma center. Each year, the center treats about 600 high-acuity and high-risk injured children in the emergency department. Patients are treated in two adjoining rooms dedicated to the initial resuscitation. Each room is equipped with vital signs monitors, large wall displays for augmenting vital signs, and a wall clock and stopclock to help teams manage their time. Additional low-tech decision-support artifacts include a dry erase board for displaying the patient’s weight, trauma flowsheet for documenting the process, wall-mounted charts with patient parameters, and recently—the resuscitation checklist.

Data collection took place over a four-month period in 2012 (05/01/2012-08/31/2012), three months after the checklist was implemented. We obtained checklists from 163 resuscitations that occurred during this time. Checklists were administered by physician leaders, a role responsible for leading an interdisciplinary team of up to 15 specialists, assigning tasks, making decisions, and overseeing the process. This role is usually assigned to an attending surgeon, a surgical fellow, a senior surgical resident or an emergency medicine physician. The leaders rarely participated in hands-on evaluation, and mostly stood at the foot of the bed to maintain overview of the patient, team and resuscitation room. The study was approved by the hospital’s Institutional Review Board (IRB).

Data Analysis

All checklists were first transcribed into a spreadsheet. For each checklist, we transcribed its study ID, the physician leader’s experience level (surgical resident [PGY-4], surgical fellow, surgical attending, emergency medicine physician), weight information recorded in the pre-arrival plan section, list of notes written down by the leader, location on the checklist for each note that was written down, and items on the checklist that were left unchecked. This transcript was then reviewed to resolve any ambiguous and unreadable notes. Two experts in trauma resuscitation also reviewed the transcribed notes for clarity and accuracy.

We first performed quantitative analyses on the checklists to determine the frequency of checked and unchecked items, the number of checklists with and without notes, the amount of notes for each checklist section and item, and the amount of structured and free-form text notes. We then focused on the 125 checklists (77%) that contained handwritten notes. We used an open coding technique to identify and categorize types of information recorded by physician leaders. During the first pass, we identified 50 codes characterizing the notes. These codes were then discussed in a group session to determine which codes to keep, remove, or merge. This process resulted in nine high-level notes categories and 27 subcategories (Table 1). The transcript was updated with these final codes in the second pass to reflect these changes. We also determined the number of notes for each high-level category.
To gain additional insight into note taking, we compared the number and types of notes based on the leader’s experience level by grouping the checklists into those administered by surgical residents and fellows (less experienced) and those administered by attending surgeons and emergency medicine physicians (more experienced).

Findings

We report our findings in three parts. First, we present the results from our general observations of checklist use. We then describe the results of content analysis by categorizing and describing information types that physician leaders recorded on the checklists. We conclude by describing note-taking differences based on leaders’ experience levels.

To gain additional insight into note taking, we compared the number and types of notes based on the leader’s experience level by grouping the checklists into those administered by surgical residents and fellows (less experienced) and those administered by attending surgeons and emergency medicine physicians (more experienced).
General Observations about Checklist Use

Our analysis of the frequency of checked and unchecked boxes revealed two groups of checklist items (Figure 2(a)): (1) almost always checked, and (2) rarely checked. The first group consisted of primary and secondary survey items such as “Confirm O2 placement” and “State GCS [Glasgow Coma Score],” which were checked in 80% to 95% of the checklists. Optional items such as “For attending activations” in the pre-arrival plan section and “Prepare patient for travel” in the departure plan section were rarely checked (7%), as was the primary survey item “Give fluid or blood” (14%). These findings suggest that a multi-tiered organization and adaptation of the checklist to specific contexts may be useful. Although prior studies of checklist compliance showed that users sometimes check a box without performing the corresponding task or perform a task without checking the corresponding box\textsuperscript{15}, there is no evidence that physician leaders in our study chose to exclude any specific checklist items. It is therefore appropriate to assume that failures in completing checklist items are uniformly distributed across the checklist, and that the items that were rarely or never checked were also rarely or never performed and vice versa (Figure 2(a)).

We observed several styles of checklist use. Notes were sometimes written next to an item, but the item was left unchecked. In other cases, notes associated with an item appeared in the same checklist section as the item, but not next to it. Physician leaders appeared to prefer free margin space, filling both top and bottom margins with notes on most checklists. We also found a few checklists with all 53 items checked off but without a single note. Items with the largest number of notes were “State GCS” under step D(isability) and vital signs evaluation tasks under Vitals in the primary survey section. Items with the least number of notes included the “If intubating” box in the primary survey section, equipment preparation steps in the pre-arrival section, and departure plan items. A closer look at the relationship between the frequencies of item checking and note taking revealed that for items that were rarely checked, notes were almost never taken (left corner of Figure 2(c)). For items that were frequently checked, the number of notes varied uniformly between 0 and 83 (Figure 2(b) as well as the right side of Figure 2(c)).

We further observed that leaders’ handwritten notes belonged to three groups based on the note structure: (1) free-form text, (2) numeric, and (3) numeric with attributes. Free-form text notes were most common, comprising 63% of all notes taken. These notes appeared in the margins and in the secondary survey section, especially for head and cervical spine exams. The length of free-form notes varied between 1 to 46 characters per note. Most notes (78%), however, were short with fewer than 16 characters. Numeric notes comprised 30% of all notes, mostly appearing next to the vital signs, Glasgow Coma Score (GCS), and temperature assessment tasks. Numeric notes with attributes (e.g., “90/palpable” for blood pressure, “2 mm reactive” for pupil size) comprised 7% of all notes, and were also found next to vital signs, GCS score and pupil size. Here, we observed that the attributes were limited to a small set of choices. For example, leaders wrote one of the following for pupil size: “sluggish,” “brisk,” “reactive,” “blown,” “unreactive,” and “equal”. GCS score notes almost always showed its value broken down into three components: eyes, verbal and motor response. Attributes for the GCS score were therefore implied by the initial of the score component name (e.g., “E3V3M5”) or by the order in which they were recorded (e.g., “4, 3, 6, 13”).

Checklist Notes: Information Types and High-Level Categories

Our content analysis of physician leaders’ notes written on the checklists showed that leaders recorded a great deal of information during resuscitations. These checklists (including the leaders’ notes), however, were not part of the official medical record and were usually discarded after the resuscitation, unless kept for research purposes. We identified 27 information types and grouped them into nine high-level categories (Table 1). Below we describe each high-level category in greater detail.

**Patient Values:** Patient values were the most commonly found notes, comprising 35% of all notes written down on the checklists. These values included Glasgow Coma Score (GCS), temperature, pulses, pupil size, and vital signs such as heart rate, respiratory rate, oxygen saturation and blood pressure, and were usually recorded next to their corresponding checklist items (Figure 3). For example, GCS and pupil size values were found in section D of the primary survey, temperature was written in section E, and vitals were written down in the vitals section.

The amount of detail for each value also varied, especially for vital signs. Although most leaders wrote both systolic and diastolic numbers for blood pressure, we also found several instances with the systolic number only (e.g., 100), either alone or with an attribute (e.g., 145-sbp, 90/palpable). Oxygen saturation was sometimes accompanied by “RA” (e.g., 97% RA), meaning that the patient was breathing room air rather than 100% oxygen. Another patient value with varying levels of detail recorded was Glasgow Coma Score (GCS). Most often, physician leaders broke down the score into parameters and then wrote the final score summing up the individual scores, e.g., “4, 4, 6 = 14.” Other, less frequently observed variants of this value included noting only the final score (e.g., “15”) or describing each parameter (e.g., “eye injury, talks, obeys commands”).

In some instances, physician leaders wrote more than one note for the same value. For example, they recorded changes in oxygen saturation levels, as well as more than one blood pressure value (Figure 3). Although no time information was written next to these values, these notes suggested that some leaders used their checklists to record trends in patient data, especially in vital signs. Current vital signs monitors can be setup to show trends but teams do not have time to change the monitor settings and mostly use the default, continuous monitoring of vital signs. Similar findings were observed for the GCS values, with initial GCS assessments crossed out and new values recorded next to them. Although trends in the data were found in only 3% of the checklists, these findings suggest that trends are important during time-critical patient management.

**Physical Findings and Symptoms:** Physical findings and symptoms were the second most frequently observed category, comprising 22% of all notes. These notes were mostly related to findings from the secondary survey and were usually found in the secondary survey section of the checklist (Figure 4). Status for each secondary survey item was written next to its corresponding checkbox. The notes included both normal (e.g., stable, within normal limits [WNL], non distended [ND]) and abnormal (e.g., tenderness to palpation [TTP] diffusely, blood in nares, pain) findings. We also noted a few instances of patient complaints written as part of the findings (e.g., “Pt complains of chest tenderness”). Sometimes, however, leaders would jot down only general status notes using this space, without referring to any of the particular survey components (e.g., “multiple lac to scalp 10.5cm” accompanied by a sketch of the head with lacerations marked). Finally, leaders were observed

**Figure 3.**Instances of recorded vital signs trends: Oxygen saturation (top); Blood pressure (bottom).

**Figure 4.**Notes about physical findings.
specifying location of the findings and symptoms. For example, if an abnormality were found on the patient’s chest, the notes would also specify parts of the chest, as in “RUQ [right upper quadrant] tenderness.”

**Pre-Hospital Information:** Information about incoming patients, such as mechanism of injury, received treatments and patient medical history, serves a critical role in helping medical teams prepare for patient care\(^1\). It was not surprising then to see 12% of total notes dedicated to pre-hospital care, mechanism of injury and patient medical history. These notes were mostly written on the top or left margins, or between the patient label and primary survey section of the checklist (Figure 1). For injured patients coming directly to the trauma center, pre-hospital notes included estimated time of arrival, patient demographics (e.g., age, gender), mechanism of injury, physical findings, and injuries and complaints. For patients that were transferred from another hospital, leaders also added notes about their medical history (e.g., allergies, any chronic illnesses and current medications), as well as the results from previous tests, such as imaging and laboratory tests (Figure 5).

**Care Plan:** Care plan notes included notes on any decisions that leaders made about the subsequent steps in patient care. These notes accounted for 11% of total notes and were typically found in the margins, e.g., the lower right corner of the checklist, below the departure plan section (Figure 6, left). Most of the time, these notes specified laboratory tests (i.e., basic vs. comprehensive labs), imaging tests (e.g., head CT, shoulder x-ray), needed consults (e.g., neurosurgery, orthopedics), and patient disposition. The care plan notes were often presented in the form of an additional list of checklist items, with checkboxes drawn next them (Figure 6, right). This observation suggests that physician leaders who presented their care plan in this form felt that the corresponding items were missing from the checklist and should therefore be considered for a future iteration of the checklist.

**Injury Types and Location:** In addition to physical findings and symptoms, we observed notes about injuries identified during secondary survey. Similar to physical findings, physician leaders noted the location of injuries, e.g., left forehead bruise, R[ight] eye ecchymosis, or abrasion over right eyebrow. Although not as frequent as physical findings, injury notes accounted for about 9% of all notes written on the checklists. As part of these notes, physician leaders recorded injury types such as abrasions, lacerations, or fractures. Most of the time, notes about injury type and location were recorded along with physical findings in the secondary survey section.

**Task Completion Status:** We observed that leaders’ notes sometimes provided a rationale for either checking an item or leaving it unchecked. For example, for “Confirm O\(_2\) placement” in the primary survey section, leaders often wrote “N/A sats 100%” or “100% defer,” implying that oxygen mask placement was unnecessary because oxygen saturation was already at 100%. Or, for preparatory steps in the pre-arrival plan section, one leader crossed the entire section noting that they did not have time to complete the pre-arrival steps because the patient already arrived. Task completion status notes were found throughout the checklist, next to different items, and comprised 4% of all notes.
Treatments and Procedures: Although rare (only 3% of all notes), notes about treatments and procedures represent a significant finding because they suggest that some leaders needed to remember the type and amount of administered medications or fluids (Figure 7, left). Most commonly seen notes in this category were about location and size of intraosseous (IO) or intravenous (IV) placement. These notes typically appeared in the bottom margin of the checklist. Notes about procedures were even rarer because only few patients in our sample required procedures such as intubation or chest tube placement. When found, these notes contained the tube size and location.

Laboratory Results: The least frequently found notes were about laboratory results (3% of all notes). These notes mostly appeared on the checklists for transfer patients because test results came through documents accompanying the patient and were reported upon arrival (Figure 7, right). Some results from basic tests like blood gases and glucose levels were also written for patients that arrived from the injury scene, as these tests could be performed in the trauma bay.

Note Taking Differences between Physician Leaders

To gain more insight into leaders’ note taking, we also examined the differences in types and number of notes based on leaders’ experience levels.

First, we examined the percentage of leaders within each experience level that took notes during resuscitations (Figure 8). More than 70% of team leaders of any experience level took notes on their checklist sheets during resuscitations. We found that 75% of all attending surgeons, 77% of all surgical fellows, 71% of all surgical senior residents, and 83% of all emergency medicine physicians took notes on their checklists. Second, we looked at the average number of notes per checklist by leaders of all experience levels. Attending surgeons were the most prolific note takers, with an average of 15 notes per checklist, followed by emergency medicine physicians (on average, 12 notes per checklist), followed by senior surgical residents (on average, 10 notes per checklist), followed by surgical fellows (on average, 9 notes per checklist). An interesting observation is that more experienced team leaders (attending surgeons and emergency medicine physicians) took more notes than less experienced team leaders (surgical fellows and residents). Finally, we wanted to know if there were any differences in the types of information recorded by physician leaders of different experience levels (Figure 9). We found that more experienced leaders, on average, recorded more patient values (e.g., vital signs, temperature and Glasgow Coma Scores).
and findings from physical assessments (i.e., secondary survey findings), two types of information necessary for
decision making. They also recorded more notes about the patient’s subsequent care plan. On the other hand, less
experienced team leaders recorded more notes about their activities, such as treatments and procedures, and task
completion status. These differences in behaviors may be related to the patient injury severity level. Attending
surgeons act as leaders only during highly acute cases, while fellows and residents lead in less critical cases.

Discussion

Our findings showed that trauma team leaders of all experience levels write down a great deal of information on
their checklist sheets. Initially, this finding was not surprising because prior work has shown that paper records
afford many qualities that are critical in medical work, including mobility, flexibility, and visibility of work17,18.
Notes on paper are also used as transitional records for more efficient communication and coordination19. Upon
closer examination, however, we found that leaders’ notes contained valuable information about patient and task
performance during trauma resuscitations. Although the checklist was primarily designed to assist with protocol
compliance, its use was appropriated for additional purposes during resuscitations, such as memory externalization
and decision making. Prior research on distributed cognition systems has shown that cognitive aids (e.g., maps,
charts, diagrams, paper scraps) have an important role during complex, knowledge-based processes because workers
need to lessen their cognitive load by externalizing information20. These findings suggest that complex medical
processes such as trauma resuscitation require externalizing information from memory, much like navigating a ship
or piloting an airplane20,21. Although these other distributed cognition systems have computerized support for
externalizing critical process information, this kind of support is still paper-based in the resuscitation and other
critical care settings. Paper, however, is static (i.e., checklist items remain the same despite changing patient
conditions) and limited in size, which constrains the number of checklist items; otherwise, it would be inconvenient
to manage a large paper sheet. Also, paper checklists cannot be connected to electronic sources of information,
requiring manual capture of information. Our study offers several implications for computerizing checklists and
other cognitive aids to better support complex medical processes.

Provide Information about Patient Data Values over Time

The most common information type scribbled on the checklist was patient values. Physician leaders needed patient
vital signs, GCS values and temperature externalized to analyze the data and detect any abnormalities. It appeared
that leaders used their checklists for memory externalization, suggesting the need for additional cognitive aids to
support these tasks. Although vital signs monitors can provide information about patient values over time, clinicians
rarely set them to those modes because they preferred the continuous monitoring view. Even so, supplemental
displays in the room could facilitate access to patient data over time by capturing, analyzing and visualizing
information such as trends (upwards, downwards or flat), sudden changes of levels, or spikes in the data.

Make the Checklist Adaptive to Different Patient Contexts and Leaders’ Experience Level

Our findings about the frequency of checked and unchecked items suggested the need for checklist adaption to
different patient contexts. Current resuscitation checklist contains only one complex procedure (endotracheal
intubation), and ignores other major interventions, such as chest tube insertion, chest decompression, or pelvic
stabilization. Because of the limited amount of free space on the checklist and the need to keep the checklist
comprehensive but succinct for easy use, the number of checklist items will always be constrained, regardless of the
medium. The implication here is that only the items that apply to the current patient scenario should be displayed,
which can be achieved through real-time checklist adaptation. As we have observed, some physician leaders
performed “manual adaptation” of the checklist by listing action items under the plan of care as newly added
checkboxes. We also observed a few instances of this approach for items in the treatments and procedures category,
like medications and fluids (Table 1). These observations imply that leaders needed additional checklist items to
indicate the kinds of laboratory or imaging tests they wanted to perform, or to maintain a record of medications and
fluids they administered. An electronic checklist could afford such an extension by adaptive selection of checklist
items or by using multiple tabs. Additionally, items that were rarely checked could be called on demand using the
collapse and expand feature, or shown automatically based on patient-context recognition. Finally, we found that
leaders of different experience levels showed different preferences for types of information, suggesting that some
adaption based on user contexts may also be needed.

Allow Selection-Based rather than Description-Based Note Taking

We found that physician leaders marked not only task completions, but also task outcomes. These observations
suggest that interactions with checklists could be augmented by functionalities that allow easy input of descriptive
information. Writing descriptive notes requires more thought and effort than selecting an item. Documenting during resuscitations, however, requires efficiency due to the rapid information flow, which makes selection-based data entry more appropriate. This type of interaction could be supported by creating and structuring selection lists based on the notes we identified through the analyses. Given that most free-form notes were relatively short (≤15 characters), we expect that the selections lists will have a limited number of items (the shorter the note, the more limited the number of choices of what it can say).

We also observed that leaders sometimes explained the rationale for skipping some checklist tasks. Having a selection-based menu that was structured using their notes could make this practice faster and easier as well. With advancements in sensors and automatic data capture, some of the conditions for skipping a checklist task may be possible to automatically detect and alert the leader that a task is not applicable. For example, as described above, leaders often justified their skipping of the oxygen mask placement by noting that the patient was already at 100% O₂ saturation. Integrating the output of the O₂ saturation sensor into the system could automatically infer that the oxygen mask is not necessary.

Handwritten checklist notes depend on personal styles and preferences. For example, pupil size and response were variously described as “Pupils Equal and Equally Reactive to Light,” “Pupils Equal, Round, Reactive to Light,” and “Pupils Equal, Round & Reactive to Light & Accommodation,” all of which conveyed the same status. By structuring leaders’ observations and providing a selection list, we can ensure standardization across different leaders and checklist use cases.

Allow Free-Form Text Input for Note Taking

The mode of note taking should in general match the note structure. Numeric keypads should be considered for entering numerical notes, such as vitals, GCS, and temperature. Some types of notes cannot be easily reduced to a list of options. As we found, notes about patient medical history and mechanism of injury, as well as questions for the trauma services staff served an important role, even though they were less frequent than notes about task completion and outcome. Future checklists should allow the leaders to write these notes by providing a designated space and free-form text input. Rapid input of free-form text could be further facilitated by selection lists and auto-completion of unique text, which is again possible based on our analysis of note content. Using previously seen notes as completions is feasible because free-form notes are relatively short and it is very likely that the user will find a previously seen match for his or her intended note.

Conclusion

In this paper, we analyzed user interactions with a paper-based checklist in a regional trauma center based on content analysis of physician leaders’ notes scribbled on 163 checklists collected over a four-month period. Our findings showed that leaders recorded nine major categories of information during resuscitations, including patient values, physical assessment findings, pre-hospital information and care plan steps. We also found that more experienced leaders, on average, recorded more patient values and physical findings, while less experienced leaders recorded more notes about their activities and task completion status. These findings suggested that a checklist designed for a high-risk, fast-paced medical event evolved into a dual function tool, serving as both the compliance and memory aid. Based on these findings, we discussed several implications for designing future dynamic cognitive aids for high-risk medical events to better support fast response medical teams.

This paper represents our first look into the checklist note-taking phenomenon. Our future work will continue collecting and analyzing paper checklists to further examine the differences in physician leaders’ use practices based on experience level. We also plan to examine the extent to which factors such as patient scenarios and injury acuity affect types and amounts of notes. Physician leaders will be surveyed to provide their perceptions of the checklist effectiveness, as well as their reasons for note taking. Finally, we will continue refining design recommendations for dynamic checklists and other cognitive aids for complex medical processes.

Abstract

Personal health records available to patients today suffer from multiple limitations, such as information fragmentation, a one-size-fits-all approach and a focus on data gathered over time and by institution rather than health conditions. This makes it difficult for patients to effectively manage their health, for these data to be enriched with relevant information from external sources and for clinicians to support them in that endeavor.

We propose a novel conceptual architecture for person-centered health record information systems that transcends many of these limitations and capitalizes on the emerging trend of socially-driven information systems. Our proposed personal health record system is personalized on demand to the conditions of each individual patient; organized to facilitate the tracking and review of the patient’s conditions; and able to support patient-community interactions, thereby promoting community engagement in scientific studies, facilitating preventive medicine, and accelerating the translation of research findings.

Introduction

Recent, significant investments in health information technology (health IT) have resulted in an unprecedented increase in the “digitization” of the healthcare system in the US. However, the digitization of healthcare information has not automatically translated into increased utility and usability for patients and providers. Indeed, according to a recent report from the Office of the National Coordinator for Health Information Technology (ONC), “there is much work to do to see that every individual and their care providers can get the health information they need in an electronic format when and how they need it to make care convenient and well-coordinated …” 1.

An example of the practical limitations common today is the fact that patients often must interact with more than one patient portal, especially when they see clinicians in multiple health systems. This makes it difficult for them to review and synthesize their health information, and act efficiently and effectively on it. A second limitation is that the health information captured about patients is organized using a one-size-fits-all model. For instance, even in electronic systems male patients are routinely asked whether they are pregnant or not. Thus, in the words of the ONC report, health information is not easy for “individuals, their families, and care providers to send, receive, find, and use in a manner that is appropriate, secure, timely, and reliable”1. Against the backdrop of these limitations, the increasing penetration of health IT, coupled with our - now commonplace - expectation that we can manage almost all aspects of our lives electronically, presents an unprecedented opportunity to shape the health sector via a socially-driven, digital approach for person health record (PHR) management. This paper discusses some of the gaps preventing the mainstream adoption of PHRs and proposes a framework that can help bridge these gaps. The goal of this framework is the automated generation of a PHR customized to individual patients and their health and disease conditions. Through this framework, patients will have the opportunity to manage their own health information based on their specific medical conditions rather than a generic one-size-fits-all model. The expected benefits include:

- consolidating and organizing the underlying data in manner that makes information easily understandable and accessible to patients and health care providers;
- enabling targeted preventive medicine tailored to individual patients in an effective and efficient manner; and
- facilitating large scale studies, and promoting the active engagement of the patient in local, regional and national research.

The Health Information Digitization Roadmap

The roadmap for the digitization of the health sector emphasizes three main initiatives: 1) migrating legacy ad hoc electronic health records (EHR) into standardized enterprise-level EHR systems, 2) facilitating EHR-to-EHR interoperability and exchanges of health information, and 3) enabling EHR-to-Patient/PHR exchanges of this health information.
The success of the first initiative, the migration to standardized EHR systems, has resulted in:

- 93% of non-Federal acute care hospitals adopting certified EHR systems by 2014 according to the ONC2; and
- 200 million patients in the US expected to be covered by the Epic3 EHR system once all of its ongoing system deployments are completed.

With regard to the second initiative, EHR-to-EHR interoperability, the federal government launched an unprecedented nationwide effort in 2009 to help evolve a digital, interoperable health care system in the US4. This effort resulted in more than 50% of office-based professionals and 80% of hospitals using EHRs through which they are now able to electronically exchange standardized patient information in a basic fashion5,6. A similar state-wide EHR interoperability endeavor is the Indiana Network for Patient Care (INPC), which was started by the Regenstrief Institute in 1998 and is now operated by the Indiana Health Information Exchange. Today, the INPC connects 25,000 physicians, 106 hospitals, 110 clinics, surgery centers and many other healthcare organizations7, and maintains information about over 14 million patients.

In connection with the third initiative, EHR-to-Patient/PHR information exchange, it was estimated that as of 2012, 57% of healthcare providers had a patient portal solution in place allowing patients to access all or part of their health information8. Moreover, in order to investigate the challenges of supporting two-way information exchange between patients and health care providers (Figures 1 and 2), the ONC conducted a pilot through the National Association for Trusted Exchange (NATE)9. This pilot focused on data flow and exchange of information from the provider to the PHR (EHR-to-PHR) and vice-versa (PHR-to-EHR). The NATE pilot9 bi-directionally connected EHRs to PHRs using Blue Button10 and HealthVault11. Blue Button allows patients to electronically access their own health information from providers such as health plans, pharmacies, and hospitals. HealthVault is a PHR that allows patients to connect to health providers via Blue Button and download their health related information into a cloud-based account.

The three groundbreaking initiatives mentioned above are essential enablers to support the difficult “last mile” effort that will deliver much anticipated benefits of PHRs to the patient. Currently several patient-oriented software applications12 are being offered as solutions to bridge the last mile. However, the limitations of these solutions are still significant enough to have prompted the ONC to articulate its recent 10-year vision. This vision encourages “last mile” solutions that a) enable individuals to manage their own health information, b) share it with their health care providers and c) enable health care providers to individualize diagnosis and therapy and adapt it, as needed, to the patient’s condition in real-time by 20251.

In the following section, the features as well as the limitations of some of the existing patient-focused solutions are discussed in order to establish a baseline and motivate the need for a PHR framework that is capable to meet the ONC 2025 vision.
Current Patient-focused Software Applications

Different vendors offer patient-focused software applications such as personal health data-marts, process flow and decision support systems. We briefly review these different types of software applications in this section.

HealthVault, Google Health and Indivo-Dossia can be categorized as personal health data-marts. HealthVault provides the ability to organize patient health information (PHI), register medical devices (for acquisition of parameters such as blood pressure and glucose) and aggregate family accounts. Figure 3 shows the specific one-size-fits-all data model used by HealthVault. Under this model, patients have a “health” account on the cloud that is used to house their records retrieved from different health care providers’ EHRs, which are, in the overwhelming number of cases, completely independent of each other.

Google Health was an early PHR that used a model similar to that of HealthVault. It was discontinued in 2011. Indivo is an open source PHR which is supported by several large corporations including WalMart. It allows a limited level of personalization through the selection of apps such as immunization tracker and medication manager. These pioneering tools use a relational model with a focus on collecting data from different sources (Figures 2 and 3).

An additional feature of Indivo-Dossia is the ability to automate the process flow between the health service provider and the patient. For instance, a patient may request an examination by using Indivo. The doctor can then review the patient’s health profile and update it by entering a diagnosis or ordering a laboratory test. The request for the laboratory test is forwarded to the information management system of the corresponding laboratory. Once the test is completed, the results are entered and the doctor is notified. Indivo uses ontologies to semantically disambiguate concepts that may be expressed differently in the participating sub-systems.

MeTree and Health Heritage are decision support systems. MeTree focuses on collecting and organizing family history in order to help support primary care decision-making. Health Heritage focuses on matching the family history with recent scientific research in order to personalize care and prevention plans.

Given the variety and multitude of these types of patient-focused software applications, some of which have been in existence for nearly a decade, the obvious question is: Why is widespread community adoption lacking? The result of a survey of PHR penetration rates in the US indicated that, in 2010, only 7% of the survey participants had ever used a PHR and less than half of these continued using it. Among veterans, 71% of which utilize the Internet, about 20% reported using a PHR in a 2012 survey.

In an attempt to answer the above question and by using a process of elimination, cost can be excluded since most of the above-mentioned patient-focused software applications are free. Privacy concerns can also be excluded based on the findings of an earlier study. This study indicated that while a reasonable level of privacy is expected, a large percentage of the participants were willing to share their health information. The answer can then hypothetically be attributed to 1) the community interest level or 2) ease of use and the added benefit trade-off. In the next section, we present the results of a study that shows that community interest level can also be excluded. This conclusion is supported in the literature with a consensus around the fact that the adoption of PHRs is low in spite of the anticipated benefits. Some of the identified reasons for the low adoption include the need for additional education and training but most importantly for a better PHR model that can leverage technological advances while meeting the needs of patients and health care professionals.

Community Interest

In order to assess the potential interest level, we conducted a simple study to measure the current community engagement for a representative social media platform, Twitter. Twitter activities related to three common diseases, namely cancer, asthma and diabetes, were investigated for three consecutive semesters from 7/1/2014 to 12/31/2015. The results were obtained by querying the tweets for the keywords a) “cancer”, b) “asthma” and “asthmatic”, and c) “diabetes” and “diabetic”. In the case of cancer, the raw data was preprocessed to eliminate irrelevant tweets (e.g., tweets related to the astrological sign cancer).
For each period and disease, Table 1 shows the number of tweets and the number of followers for a given handle (i.e., user) that posted a tweet related to the specific disease during the period. Duplicate entries were removed such that the number of followers for a given handle are counted only once during any given semester. The last column shows the percentage of the total number of followers shared by the top three handles for each disease type.

Table 1 highlights the following general trends:

- The number of followers show a steady increase for all three disease types.
- Cancer shows the highest level of activity, followed by diabetes and asthma. The number of people in the US impacted by cancer (20.3m), diabetes (21.0m) and asthma (17.7m) are relatively close. However, the percentages of total deaths attributed to cancer and diabetes in 2013, are 22.5% and 2.9%, respectively. Asthma is not ranked as a leading cause of death. This comparison could possibly hint at a correlation between the activity level and the mortality rate.
- The top three handles account for 11%, 39% and 30% of the total number of followers for cancer, diabetes and asthma, respectively. This indicates that there are some influencers with large numbers of followers that have the potential to define the landscape of health social media.

The choice of Twitter as a social media platform was only meant as a representative example. Other social media platforms exhibit similarly high health-related activities. Examples of health-focused social platforms include healthboards.com and thepatientforum. Based on the above results, and the fact that Twitter is a widely used social media platform, the interest level can be excluded as a cause for the lack of widespread adoption of PHR systems. Ease of use and the perceived added benefit by the patient seem to be the determining factors in the mainstream adoption of PHR systems.

Conceptual Architecture

As discussed above, one main reason why current PHRs have not yet been able to deliver the benefits articulated in the 2025 ONC vision is likely to be ease of use. Despite the fact that the user-friendly nature of a software application is often associated with the personalization level of the application, most current PHRs have adopted a one-size-fit-all model. The tailor-made, on-demand experience that the community is now expecting from online services (e.g., on-demand TV, personalized marketing and personalized banking) should be reflected in the services provided by the PHR. Furthermore, a key factor in the success of this personalization is the adoption of a condition-driven health data model rather than the widely used event- and institution-based data model. One of the drawbacks of the event-based data model is that, when reviewing, for instance, a patient’s diabetic condition within current PHRs, clinicians must find and navigate to measurements, appointments, medications and procedures among a potentially large set of data points over time. The condition-driven model allows the individualized PHR to be organized around a) the conditions of concern to each individual, b) the potential correlation.
between these conditions, and c) the potential relation between the manifestations of these specific conditions in the
PHRs of the patient’s relatives.

Figure 4 shows the general framework of the proposed PHR framework. The main modules of this framework consist
of a) personalization and registration, b) data management, c) services and updates, and d) notification and
authorization modules. Each of these modules is discussed next.

a) Personalization and registration

The concept of personalizing the PHR by using a condition-based model is sustained throughout the life-cycle of the
PHR. When patients initially register, the personalization and registration module will dynamically and interactively
create a set of questions enabling the rapid capture of the patient’s health status. For instance, knowledge of the gender
of the patient will eliminate, in either case, a large number of gender-irrelevant questions. Similarly, entry of the date
of birth will allow the registration to be tailored to health conditions pertinent to the appropriate age group. In addition
to its efficiency, this approach offers the possibility to drill down and gather information for important health
conditions comprising historical information related to a given disease, family members suffering from the same
disease, and previous and current health care providers related to this condition.

The interactive and dynamic registration questionnaire is only the first step of the personalization process. The next
step consists of generating a personalized PHR that will organize the health information provided both by the patient
as well as that obtained through the healthcare provider in a semantically meaningful way. The details of this
personalization are covered throughout the remainder of the paper.

b) Data management

Our proposed data management scheme is based on MongoDB28, a NoSQL document database. MongoDB stores data
as documents by using an extension of JavaScript Object Notation (JSON) called Binary JavaScript Object Notation
(BSON) which includes primitive data types such as floating point. Most of the current EHR-EHR data exchanges
today transmit data directly through HL7 or use the Extensible Markup Language (XML). The debates about the
suitability of XML versus JSON or its variant BSON is ongoing. Our choice of BSON for both data representation
and data exchange is based on the fact that the latter supports arrays which is an essential data structure for the
representation of repetitive measurements especially when the data has a high velocity (e.g., reading of glucose levels
multiple times a day). Furthermore, the conversion from XML to BSON is straightforward and can be easily
accommodated to retrieve PHI from existing EHRs.

The use of the label “document” in MongoDB is a misnomer. In this paper, the term object is used instead. The
proposed data model is designed around basic primitive objects (i.e., documents in MongoDB technical terms). These
primitive objects include basic information, measurement, procedure, lab test, prescription and relation. The primitive
objects are subject to update and extension without incurring any disruption to the operation of the application. This
is a unique feature of MongoDB which simplifies the personalization process. For instance, it is conceivable in the
future to add a meal object that will support the nutrition aspect of the PHR as well as the individualization of the
managed delivery of insulin for a diabetic. Another possible extension is a physical exercise object that will be used
to support fitness activities.

Figure 5 shows a sample instantiation of four of the primitive objects, namely basic information, measurement,
observation and relation. These primitive objects are patient-specific and generated by the registration and
personalization module (Figure 4). All of the objects reference a “uid”. This is a unique health id for the patient. In a
previous study19, participants indicated that they did not object to the use of a unique health id. Furthermore, most of
the current users of social media platforms are accustomed to having a unique identifier. For instance, in Twitter this
identifier is called a handle and it was used to generate the statistics of Table 1. The health care provider is also
associated with a unique identifier (Figure 5-2), with the existing National Provider Identifier being the most logical
choice. Moreover, all measurements, observations and scanned documents also have a unique identifier. These latter
identifiers are constructed by prepending the uid of the patient to a unique sequence for each element type.

Several of the features of the primitive objects are worth noting:

− The measurement type includes a potential list of mappings. These mappings are added as needed to each individual
patient record in order to support interactions with health care providers that use different vocabularies. Mapping
between different vocabularies can be performed by using a metathesaurus such as the UMLS29. Furthermore, on a
longer term basis, this field can also be used to capture any vulgarization of different measurement names. In general, this functionality reduces the difficulties associated with semantic mapping.

- The primitive measurement object includes an aggregation type field which indicates how the data should be aggregated (e.g., sampling, monthly averages, cumulative averages, etc.). The aggregation type allows the definition of the most appropriate summative method for high velocity data. The method is customizable to each individual, condition and measurement. For instance, different conditions in the same patient may rely on different aggregations of weight or blood pressure readings.

![Sample Primitive Objects](image)

**Figure 5.** Sample Primitive Objects

- The reading sequence is a sequence of tuples consisting of a timestamp and a value. The sequence is updated with every reading associated with a measurement. Furthermore, a new measurement object will be instantiated if any of the underlying fields such as the ordering party or the device id are changed.

- The observation object is used to capture the results of an encounter between a patient and a health care provider. Depending on the result of the observation, the PHR may be restructured to highlight a new condition or the observation may be linked to an already existing health condition.

- The relation object will help identify the type of relation (e.g., parent, sibling, child, etc.) as well as the associated uid of the relative. The underlying application will then perform regular updates based on routine updates to the relative’s PHR or based on newly discovered research to establish the association among any of the individual’s
health conditions and those of a relative. Furthermore, a scoring mechanism is established and dynamically refined to indicate the strength of this association with each of the relatives and for each of the specific health conditions. Several indexing mechanisms are available in MongoDB that support this type of association.

c) Services and updates

Each individual interacts with the server and the health care provider through her personal digital assistant (PDA). Both the server application and the PDA-application have a three-tier architecture: 1) the front-end is implemented using HTML, CSS and JavaScript, 2) the middle layer is based on GoLang, and 3) the back-end uses MongoDB. On the server, MongoDB is used to store all the data related to the registration, personalization, authentication, services and updates. It also manages user profiles and displays data according to each user profile.

There are two main types of profiles: the patient profile and the health provider profile. The health provider profile is outside the scope of this paper. It essentially classifies the health providers into roles including physician, nurse, insurance, institution, etc. The physician profile allows the user to interact with the patient through messaging and enables the physician to organize the patients into different groups (e.g., a “critical watch list.”) The physician, once authorized by the patient, can also place the patient’s measurements under alert. This configurable functionality will enable the physician to receive an alert, for example, when the glucose level of the patient exceeds a certain level. The interaction between the health provider and the individual described above represents one layer of communication. The other communication layer consists of the interaction of the individual with the community.

One of the functionalities of the services and updates module in Figure 4 is to extract health information from different sources of specific interest to the patient. This information can be the result of recent research, a nutrition database or preventive health information. This functionality is key as it will help the timely translation of scientific findings into immediate benefit to the patient thereby promoting retention and mainstream engagement.

The services and updates module will also be responsible for recruiting participants for large scale studies. In this case, a given uid will send a request to the server for the distribution of a recruitment form to participants. The server will review the request and based on the uid’s trust level and a pre-authorized protocol will either decide to forward the request to the target participants or request additional endorsement/validation. Once this authorization step is completed, the server application will generate a list of qualified participants. Additional restrictions may apply during this step. For instance, the requesting party may be asked to refine the underlying query if the number of participants that qualify exceeds or is below a given threshold leading to resource exhaustion or privacy violation, respectively. This automated data validation process is currently under investigation.

Once the validation process is completed, the services module will contact the participants using a push notification technology and will register the uid of the users that accept to participate in the study. The anonymized and sanitized data corresponding to the participants will be extracted and forwarded to the requesting investigator. The investigator will be required to disclose the result of the study which will be made available to the participants and to the community at large. Furthermore, the users will be able to score these findings in terms of benefit to their health, thus impacting the accumulated contribution score of the individual investigator. This type of engagement allows the patients to feel empowered and is critical to their retention.

Most of the activities related to the engagement of the patient in community studies and research are handled by the server application without any involvement from the patient beyond the authorization and the feedback steps. In order to further facilitate this process, the user may decide to setup general rules that are applicable to all requests in a given category. An example rule may be to accept requests for participation for all studies sponsored by a given institution or a given individual. This type of rules promotes “brand” loyalty and facilitates stronger research-community relationships.

Typically, HIPAA prevents direct researcher-patient contact and mediation through a health care provider is mandated unless the participant clearly opted in to direct contact. In the proposed architecture, the patient has to provide prior authorization. Beyond this step, the exchange of information is mediated by the services and updates module which will have to be under the administrative management of a “trusted party”. The policy implication of this data exchange model and other models proposed in the paper is the subject of future investigation.

d) The notification and access authorization module

As previously mentioned the structure of the communication of the proposed framework consists of the combination of two layers. The first layer is a cloud server and supports the communication between the patient and the community.
This layer has a centralized architecture and includes the notification and access authorization module shown in Figure 4 which is responsible for:

- The authentication of all users, including patients, service providers and researchers.
- The management of patient-health care provider access authorizations which are given on a per condition basis by the patient to the health care provider. Connection rules are managed through the front-end and data access rules are managed through the back-end in MongoDB.
- The management of access authorizations required for the participation of the patient in research studies.

The second communication layer is a Peer-to-Peer network as illustrated in Figure 6. Peer-to-Peer networks are becoming increasingly popular in social computing (e.g., Napster). In this layer, peers are autonomous and self-organize in a private sub-network that co-exists with other patient-centric or provider-centric networks. Once a user is authenticated by the notifications and access authorization module in the first layer, she can exchange data directly with her selected peers without the involvement of the server. This mode of communication is used for the exchange of private data between the patient and the health care provider. In addition to scalability and congestion control, the Peer-to-Peer network offers better data exchange security.

The Personalized PHR

The role of the registration and personalization module is to generate the specific meta-model for the PHR and to populate it with the appropriate data by using the other modules including the services and updates module mentioned above. Figure 7 shows a high level representation of this model for a specific individual. The skeleton of the model is generated by the registration and personalization module when the patient first interacts with the platform. This model is then enhanced and updated as it is enriched by the user, the health care provider and the users’ network.

The services and updates module will rely on available application program interfaces (APIs) in order to extract the information needed from different EHRs and research data sites. The APIs can be triggered on a regular basis to update the PHR record of each individual patient. These data are stored in the MongoDB database by using the primitive objects and consolidated based on the uid. A copy of these data and the meta-model are available as part of the back-end database of the client application on the patient’s PDA.

In most traditional client-server applications, the client-side application retrieves data on-demand from the server. In the proposed architecture, the client and the server are both responsible for different types of data exchanges and services. The server application is responsible for the exchange of information between the patient and the community. The client application is responsible for the management of the patient’s private health data. For instance, direct capture of measurement from a home health device and its delivery to the health provider will be handled by the PDA through the patient-centric Peer-to-Peer network; whereas, the delivery of health data...
necessary for a study will be handled by the server application once patient approval is granted. This delineation allows the patient to focus on the health management issues that are of most concern to his condition. Furthermore, it facilitates managed control of time-critical exchanges with the patient and his personalized private health network (Figure 6).

**Data Retrieval and Indexing**

One of the major challenges of the proposed application is the ability to provide ease of access for a specific individual as well as across a large set of individuals. Most current database applications either provide one or the other. For instance, organizations often segregate among the two types of accesses by using a transactional database (e.g., EHR), as well as a data warehouse for analysis and reporting purposes. Combining the two is the subject of ongoing research. One of the emergent application of this combination is social computing. The social media model is relatively simple and based on relations such as “is a friend”, “is a follower”, etc. The proposed PHR model also needs to support both transaction-based interactions (e.g., health care provider – patient) as well as analytics-based processing for large scale studies. However, the health context makes the data retrieval and management complex. Therefore, communication has been segregated into two layers, services have been carefully assigned to the client or the server and data management has been associated with the most appropriate application depending on the context.

Patient local data are essentially managed by the client application and then bi-directionally synchronized with the server as needed. For high velocity data, aggregation can help reduce the size of the data that needs to be stored on the PDA. A detailed view of the data can be obtained on-demand through the server application. Although MongoDB is not an SQL database, it does support aggregation which can be used to implement the above functionality. The other type of data that may represent a burden for the client application is the document type (e.g., images). In this case, the original copy of the document can be stored on the server and the client application can access it on demand from the server using a hyperlink.

Because of the potentially large volume of data on the server, proper indexing becomes a critical requirement. Data on the server is organized by using collections of primitive objects (e.g., basic information, measurements, observations, relation, etc.). These collections are for all individuals and indexed by the uid. In order to facilitate large-scale queries, several other indexes (e.g., indexes by condition or geolocation) need to be maintained. Furthermore, compound indexes that are composed of more than one predicate will be developed overtime as the system matures and is enriched by complex user queries. These indexes may eventually hold the most interesting answer to large scale research questions as they will be able to associate, for example, individuals with different phenotypes or genotypes.

Tree and geospatial indexes can also be used to organize the relation of an individual’s PHR to that of her relatives’ PHRs, thus facilitating condition-based distance scoring. Finally, the Time-to-Live (TTL) index will be used to adequately manage the data in MongoDB. The TTL index is customarily used to automatically delete old data from the system. In this case, the TTL index will be used to archive data to a secondary database. This multi-tier database stack allows a) patient centric data to be close to the patient on his PDA, b) community current data to be close to the researchers and c) historical data to be available for long term studies.

**Conclusion**

The proposed platform will help close important gaps in the healthcare research, clinical practice and patient continuum by allowing patients to better manage their health, and benefit from up-to-date research efficiently and effectively. The proposed framework will link a patient’s health information to relevant health data about their family members, automatically determine the applicability of current medical evidence or recommendations to the patient, and enable the patient to enrich his record from external data sources. We believe that these features will facilitate mainstream adoption and, more importantly, sustained engagement by the patient in managing his health.

The innovative aspects of the proposed framework and its departure from the limitations of current approaches center on:

- developing methods to custom-build on-demand applications that will manage data for each individual patient in a personalized and focused manner; and
- identifying mechanisms that can translate research findings into practical and systematic methods for organizing patient health information.

We believe that this level of quality of service will keep patients engaged and interested in the management of their data. Furthermore, it will encourage patients to become willing participants in large-scale medical studies that can
further improve research. Our goal is to leverage the viral effect of social networks towards a customizable solution for patient-centered health record and a cost-effective mechanism to provide answers to important questions that are unattainable through traditional research studies.

Adoption of a Nationwide Shared Medical Record in France: Lessons Learnt after 5 Years of Deployment

Brigitte Séroussi, MD, PhD1,2,3, Jacques Bouaud, PhD1,4

Abstract

Information sharing among health practitioners, either for coordinated or unscheduled care, is necessary to guarantee care quality and patient safety. In most countries, nationwide programs have provided tools to support information sharing, from centralized care records to health information exchange between electronic health records (EHRs). The French personal medical record (DMP) is a centralized patient-controlled record, created according to the opt-in consent model. It contains the documents health practitioners voluntarily push into the DMP from their EHRs. Five years after the launching of the program in December 2010, there were nearly 570,000 DMPs covering only 1.5% of the target population in December 2015. Reasons for this poor level of adoption are discussed in the perspective of other countries’ initiatives. The new French governmental strategy for the DMP deployment in 2016 is outlined, with the implementation of measures similar to the US Meaningful Use.

Introduction

In 2000, the Institute of Medicine published a report about medical errors “To Err is Human: Building a Safer Health System” estimating that up to 98,000 deaths in the US may occur annually as a result of medical errors. This alarming number of deaths was debated, some people suggesting that it was over-estimated. In 2013, James updated the estimates about deaths caused by medical errors and reported that “the number of premature patient deaths associated with preventable harm could be as many as 400,000 per year”. No country is immune to the increasing number of avoidable premature patient deaths. Indeed, patient management has become critically complex. Patients have more and more often various pathologies and comorbidities that require input from multiple healthcare providers across many different care settings. If care is not adequately coordinated among the different providers in charge of a given patient, the quality of care experience for her and for her family can be frustrating at best, harmful at worst. Numerous studies have reported that quality improvement strategies focused on the coordination of care reduced hospital admissions among patients with chronic conditions other than mental illness and reduced emergency department visits among older patients.

The US AHRQ defines care coordination as “the deliberate organization of patient care activities between two or more participants (including the patient) involved in a patient’s care to facilitate the appropriate delivery of health care services”. However, care coordination goes beyond organized care activities. For instance, unscheduled patient encounters across providers escape the organized care coordination framework. Non-deliberately organized care activities may indeed occur when patients move or travel, or in case of accidents or emergency situations. The management of patients in such situations requires that information about their medical condition (current and past) be available to any “new” healthcare provider to ensure care quality and patient safety, and guarantee the continuity of care, e.g. medication reconciliation. This is of primary importance in emergency situations where the lack of knowledge on a given patient condition could yield unexpected adverse events, especially when the patient herself cannot provide vital information or current medications during the medical interview (unconsciousness, mental disabilities).

A solution to improve medical information sharing is digitalization that makes health information “‘liquid’ enough” to flow across healthcare institutions and providers. In most countries, policy makers have promoted the adoption
and use of electronic health records (EHRs) to address health information sharing and care coordination. Medical information is thus available to healthcare providers of the same care team, which is usually the case of healthcare providers within the same institution, from a single practice to a large hospital, or to wider managed care consortia. Clinical information remains locally stored in original health information systems, but may be accessed on demand through data exchange protocols. This is the model adopted by the US which promote health information exchange (HIE) between different EHRs.\textsuperscript{8} The challenge of this model is to achieve interoperability between multiple EHRs. The US Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 has offered substantial financial incentives for providers demonstrating meaningful use (MU) of EHRs. In this framework, virtually any patient data available in EHRs can be collected, whether it comes from affiliated physicians’ offices, hospitals, and clinics, or from completely disparate systems. In this way, clinical information follows patients as they move across different care settings, whether or not they share an organizational affiliation.

However, due to the challenges of standardization and interoperability, networking local EHRs through HIE to get a holistic view of a patient condition remains uncertain. An other solution to computerized medical information sharing is represented by a centralized framework where care records, centrally-stored in purpose-built platforms, are specifically created to serve information sharing. They usually do not contain the comprehensive information stored in all EHRs but only what is considered as necessary to support a coordinated management of the patient inside and outside care coordination practices. This information may be automatically extracted from EHRs or manually added. When a healthcare provider needs some medical information for a given patient, he may access the centralized care record with the consent of the patient. One of the most advanced example of such a centralized nationwide system is the electronic summary care record (SCR) implemented in the UK.\textsuperscript{9} In Scotland, the SCR contains elements such a patient’s name, address, age, allergies, current medications, diagnoses. It is connected to 100% of general practices, and is automatically updated from existing GP records.\textsuperscript{10} Its main objective is to be accessed in emergency and unscheduled care scenarios.\textsuperscript{11}

Based on the UK experience, Eason and Waterson\textsuperscript{12} reported that the centralized model is less feasible than the distributed model. In addition, it relies on a classic “top-down” approach to e-health whereas a “middle-out” approach is more likely to succeed.\textsuperscript{7} Quantin et al.\textsuperscript{13} also advocated for a distributed model of connected EHRs on the basis of pragmatic and cost reasons. On the contrary, Lapsia et al.\textsuperscript{14} suggested that the centralized model for nationwide health information infrastructure scales better than the distributed model in terms of data availability and integrity, with lower failure rates. However, literature about centralized nationwide care records generally reports poor actual adoption.\textsuperscript{11,15} The same difficulties in the adoption and deployment of HIE are reported with the distributed model despite MU incentives.\textsuperscript{16,18} A recent study reported that even among US HIT/EHR adopters, one third does not routinely receive the needed patient information for care coordination.\textsuperscript{17} Thus, sharing patient information from distributed locations through HIE has been questioned, and initiatives aiming at “recentralizing” the model have been launched. For instance, health record banking promotes the centralized storage of and access to care records fed by HIE. Such health record banks are not operated by governmental bodies and might rely on private organizations.\textsuperscript{18}

Beyond digitalizing medical information, another solution to improve the sharing of the same holistic view of a patient’s condition is to count on patients and their caregivers to serve as care coordinators, filling information gaps between providers, addressing conflicting instructions, and managing redundant orders and medications during care transitions. This is possible only if patients are informed, involved, and engaged. The Blue Button project has become a way for many Americans to download their health records. A recent survey reported that one third of patients at the VA were Blue Button users.\textsuperscript{19} The most highly endorsed benefit was that it helped patients understand their health history and thus be active in their management.

In 2004, the French government decided to develop a “personal” nationwide care record, called DMP or “Dossier Médical Personnel”. First elaborated as a set of distributed region-wide records, the DMP was re-engineered in 2009 using the centralized model and was officially launched in December 2010. Though personally-controlled to promote patient empowerment and built according to the centralized model to avoid interoperability-related technical issues, the DMP has had a chaotic history. This article provides a description of the historical background of the DMP in France, the rates of adoption of the DMP nationwide, an analysis of the reasons why, five years after its launching, DMP adoption rates did not match expectations, and the new solutions to be implemented to re-launch the program.
Background

Ups and downs of the DMP. The French health system is a centralized public system controlled by the government (Ministry of Health) with a regional support (Regional Health Agencies in charge of the regional implementation of National health policies). The government health insurance (in French “Assurance Maladie”) funds most care expenses of the population, mainly from the social contributions of active workers. All workers (either currently active or retired) benefit from the government health insurance: they are namely insured. Their health care coverage includes both their own medical expenses and the care costs of their spouse, when unemployed, and children. Care is provided in medical institutions, either public or private, monitored by the French Ministry of Health. Outside health care facilities, private self-employed health practitioners are monitored by the government health insurance (patients used to pay their doctors for medical consultations and were reimbursed by the government health insurance, but now the government health insurance directly pays the medical consultations to doctors). Some National pay-for-performance programs such as ROSP (“Rémunération sur Objectifs de Santé Publique”) have been implemented by the government health insurance that offer financial incentives to private physicians for meeting certain performance measures (29 criteria). Adoption of an EHR is one of these measures and yields €525 (US $580) per year. When fulfilling all criteria, private doctors may earn an additional bonus up to €6,000 (US $6,650) per year.

The DMP has been created in France by the Act of August 13th, 2004 reforming the government health insurance. Only individuals namely insured by the government health insurance may have a DMP. The DMP was expected to improve the quality of care, and to reduce health costs by €3.5 billion (US $3.9 billion) yearly. In 2005, a public interest group, the GIP-DMP, was set up under the supervision of the Ministry of Health, in order to manage the design and the implementation of the DMP throughout the country. The first DMP was relying on a distributed model involving regional medical records. From 2006, several experiments were launched in different regions. These experiments permitted the mobilization of the different stakeholders (healthcare practitioners, patients, and medical software vendors) on the strengths and weaknesses of digitalized data, and the need for legal and technical safeguards to preserve privacy. In 2007, serious concerns about the safety and the confidentiality of personal medical data recorded in DMPs were raised and the program considered as potentially unethical was stopped.

After numerous audits to determine how the program could continue with appropriate security warranties, the DMP was re-designed in 2009 as a nationwide centralized personal medical record with a focus on the protection of patients rights. DMP regulations were written in the Law (Code of Public Health) as stated by the HPST Act (in French, “Hôpital, Patient, Santé et Territoires”) confirming the DMP as a National public health program to serve patient empowerment. A national agency for the promotion of shared health information systems (ASIP Santé) was created to develop and implement the tool. At that time, it was forecasted to get 2 millions of DMPs the launching year (2010), 5 millions the second year (2011), 9 millions the third year (2012), 11 millions the fourth year (2013), and finally 13 millions at the end of the first cycle (2014), thus covering one third of the ultimate target population (38 million of individuals namely insured by the government health insurance, out of the 66.6 million inhabitants of France). However, the adoption of DMP was very slow. In 2012, a report from The Court of Auditors (in French “Cour des Comptes”), an independant public body in charge of conducting financial and legislative audits of most public institutions, proclaimed that the DMP costed about €210 millions, for only 150,000 records (in July 2012), and severely criticized the management of the program. This report almost killed the DMP program.

Model and Functionalities of the DMP. The DMP is a centralized, nationally shared, widely accessible, patient-centered electronic medical record. It is optional and free for all the individual recipients of the government health insurance. DMPs are created by health practitioners only after the patient gave her informed consent (opt-in model). The creation of a DMP requires that both the health practitioner and the patient are “strongly” authenticated. Currently, this strong authentication is achieved by the electronic reading of the smart identity card of the health practitioner and of the health insurance card of the patient.

Patients may access their DMP via a web-accessible DMP portal (patient access). They have to identify themselves using the login-password they were given at the moment their DMP was created.

Health practitioners involved in the management of a given patient need to be authorized by the patient to read infor-
ation recorded in the DMP. For accessing, reading, or pushing information in the DMP, health practitioners need to be strongly authenticated (health practitioner identity smart card or equivalent). However, unauthorized health practitioners may “break the glass” and then access the DMP without the patient’s consent only in case of emergency, when the patient is unable to give her consent. Similarly, practitioners must be strongly authenticated to break the glass.

Health practitioners may access their patients’ DMP through their own EHR. When the EHR software is DMP-compatible, both records are interoperable and smoothly interconnected. DMP information appears in the EHR interface and documents are tagged according to their origin. Figure 1 shows a screenshot of an EHR with the display of the list of the patients of the day in the left window, with a green DMP logo when the health practitioner is authorized to access their DMP, a grey DMP logo when she is not authorized, and no logo when patients don’t have a DMP. In the upper right window, news concerning some patients (that may be either planned for encounter on the same day or not) are displayed: new documents may be available in the DMP (green DMP logo) or have been received by secure messaging (grey envelope). Abnormal results are in red. DMP-compatibility relies on the interoperability framework defined by ASIP Santé and based on international standards (HL7 CDA r2).

![Figure 1. Screenshot of the home page of a DMP-compatible EHR for health practitioners (courtesy of ASIP Santé).](image)

When the EHR is not DMP-compatible, health practitioners may use the DMP portal (professional access) to access, read, and post information into the DMP of their patients. Once again, they need to be strongly authenticated. However, in this case, they have to manage two different environments, their EHR on the one side, and the DMP on the other side, which is known to be less convenient.

As opposed to the UK where patient information is automatically updated from GP records in the Emergency Care Summary, updating the DMP content is an active process: health practitioners are required to push into the DMP the documents they consider to be relevant for care continuity. With a DMP-compatible EHR, the list of the documents newly created for a given patient is displayed on the screen for the health practitioner to check if they should be shared in the DMP. She has then only to tick a box to select the documents to be sent to the DMP.

Because all the operations on a DMP require the operator to be strongly authenticated, the system logs each access to the DMP (name, date, time, break glass procedure, consultation, addition of a document, etc.) and this information is available to the patient as an audit log. The DMP owner and her primary care physician may see all DMP accesses.
Thus, the patient can check that only authorized health practitioners accessed her DMP. Other health practitioners than
her primary care physician only see their own traces. Unauthorized access is subject to criminal prosecution.

If the DMP is not expected to be reduced to a single patient summary as it is the case in UK with the SCR, it does not
aim at being exhaustive and providing the complete picture of a given patient medical history. The DMP should contain
only the relevant information a health practitioner considers necessary for other health practitioners in order to provide
efficient and secure care, be it scheduled or not. A non-exhaustive list of documents that may be posted into DMPs
according to best practices is provided. This list covers the main medical reports: updated patient care summary
(elaborated by the primary care physician), current prescriptions of drugs and care, hospital discharge summaries,
imaging reports, laboratory tests.

Currently, the DMP is essentially document-based with no structured medical data except some metadata (e.g. doc-
ument type, date of production, author). Documents may have three different statuses. They may be either open,
hidden, or sensitive. When they are open, they are accessible to all authorized health practitioners. When they are
hidden, they are only accessible to the author of the document and to the primary care physician. In this later case,
documents are “invisible” for all other authorized practitioners: they don’t even know that some documents they don’t
have access to exist (the hiding of the document is masked). Sensitive documents are documents that are temporarily
not accessible to the patient. This concerns for instance the anatomo and cytopathological reports that set a diagnosis
of cancer or a laboratory report that evidences a diagnosis of HIV stated by the ELISA test. Patients cannot become
aware of this kind of information by reading it alone in their DMP and they need to be assisted by their doctor. Once
the medical consultation announcing the sensitive information has occurred, documents are no more sensitive, and they
become open, unless the patient decides to hide them.

The DMP is a personally controlled health record preserving patient rights: the patient should give her consent for a
health practitioner to create her DMP, she decides what can be seen and what must be hidden in her record, as well
as which health professionals are authorized to get access. The patient is provided with the journal of every access
to check for illegal accesses. The DMP also provides a personal section where the patient has the liability to create
various documents and record personal information she wants to share with her physicians.

Methods

After the publication in 2012 of the report from The Court of Auditors, the French Minister of Health ordered a study
to analyze the reasons for the poor adoption of the DMP and the solutions that could be implemented to improve
the situation. The question at this time was to know what was the best option between stopping the DMP project,
redefining a totally new project, or going on with the existing project but improving it. ASIP Santé conducted a nation
wide satisfaction survey with unstructured interviews and focus groups of patients and health professionals. Within
the Ministry of Health, the Department of Health Information Systems Strategy (DSSIS) (where one author, BS, is
working part-time as DMP project leader) was in charge of working with the different key stakeholders to recommend
the best strategy to adopt.

The method applied was to build a working group to gather the different stakeholders and have the different opinions
expressed regarding the DMP. We included all unions of general practitioners, the National Council of physicians, the
National Council of pharmacists, the French Federation of Medical Specialties, the French Association of Emergency
Physicians, ASIP Santé, the French National Authority for Health (HAS), the National federation of vendors (EHRs
for hospitals and private practices), patient organizations, chief information officers of main university hospitals. A
series of five meetings of the working group was organized in 2013 to discuss the future of the DMP project with a
diagnosis step (what went wrong?), and a “therapeutic” step to collectively construct a consensual roadmap.

All quantitative results are given on the basis of data provided by the ASIP Santé (DMP adoption data monthly sent to
the DSSIS) and the government health insurance.
Results

A Weak Adoption of the DMP. Consolidated data were obtained from December 2010, which is the date from which the DMP infrastructure was operational, until the end of December 2015. By this date, there were 567,888 DMPs at the national level. Figure 2 provides the distribution of DMP creations per week as well as the evolution of the number of DMPs on the study period. More than two thirds (72%) of all DMPs belong to patients older than 45 years (35% between 45 and 65, and 39% for older patients).

![Figure 2. Distribution of DMP creation per week and cumulative number of DMPs at the national level between December 2010 and December 2015.](image)

On the basis of the 38 million people namely insured, which are the potential DMP owners, 1.5% of the target population has a DMP after 5 years of deployment. As mentioned in the historical background, in 2009, ASIP Santé prospectively delivered yearly expectations of DMPs for the next five years reaching 13 millions DMPs in 2014.

As for DMP contents, 42% of DMPs are empty. The 330,273 non-empty DMPs contain as a whole 2,080,171 documents, with an average of 6.3 documents per DMP. These include the 129,826 (6.2%) documents that have been added by the patients themselves in less than 5% of all DMPs. Among all documents, 1,616 have been hidden by patients (less than 0.1%) and 36,501 were made sensitive by physicians (less than 2%). Among the 34 types of documents stored in DMPs, the most frequent is the report of medical consultation which represents 34% of all documents. Table 1 lists the 13 main types of documents (each type represents more than 1% of all documents). It must be noted that documents stored by patients come in fourth position representing 6.2% of all documents and that drug prescriptions are in eighth position with 2.9%.

A DMP user is recognized as such once she had created, feeded, or consulted at least one DMP. 690 healthcare structures, including public and private hospitals and clinics, are DMP users on an estimated total of about 75,000 healthcare structures. 6,636 private healthcare professionals, including mostly GPs, are DMP users. As a baseline, medical doctors in the private sector are about 130,000, in 2015 and other private healthcare professionals are 318,700 (less than 1%). Patients are DMP users when they logged at least one time into their DMP. They are 79,965 and represent 14.1% of all DMP owners and 24.2% of those for whom the DMP has been actually used and is not empty.

About one half of non-empty DMPs have been consulted (151,563), among which more than one half are also consulted by patients. Considered as a care coordination instrument, only 139,745 DMPs (42.3% of non empty DMPs) have been shared by 2 or more healthcare professionals.
Reasons for the weak adoption of the DMP. The fortune of national programs of HIT adoption varies according to the history of the countries. In France, unlike some countries, we were not starting from scratch, and it was much more difficult to change the components of the current system. From the different meetings of the working group gathered to elaborate the new DMP strategy, it appeared that the problem was cultural rather than technical although some technical aspects were not totally solved. Below are some reported issues:

No clear political support: there was no clear strong political support of the DMP program, and an incredibly noisy silence of political personalities on the subject. Because the DMP program crossed a lot of difficulties since its creation, successive Ministers of Health were not very keen on supporting it. After the report from The Court of Auditors in 2012, it took six months for the Minister of Health to say the DMP was not stopped, then six more months to announce the DMP2, the new version of the DMP, and another six months to advertise the program as part of the national health strategy. However, between these scarce interventions of the Minister of Health on the subject, there was no public information towards the different stakeholders. Suppliers of medical software stopped implementing DMP functionalities in their products. Health practitioners stopped investing in a tool which future seemed to be compromised, as illustrated by the decreasing rate of DMP creation (Figure 2).

No culture of medical information sharing among health practitioners: winning the bet of DMP adoption was relying on the assumption that doctors were ready and in demand of a tool to support the sharing of the medical information concerning their patients. But the patient-centered culture required to understand the benefits of sharing medical information was actually missing. Resistance came from health practitioners, especially from unions of physicians from private practice. If they could easily adhere to the concept of exchanging medical information, and were ready to move from paper-based letters to emails sent to known colleagues, they were reluctant to the concept of sharing, i.e. making relevant medical information available, for emergency and unscheduled care episodes, to practitioners unknown at the moment the information was delivered, but who could happen to manage the patient in the future. As opposed to the secure electronic messaging which is something acceptable since it is “just” replacing a known paper-based practice by a numeric exchange, the DMP program was a new object to support new practices, i.e. sharing medical information for the sake of care continuity. This object did not exist previously in “paper” version, and the organization and practices underlying its use did not exist in a formalized way. Thus, the adoption of both the concept and the tool was a challenge.

No education of patients and citizens: another difficulty came from the fact that patients were not actively involved in the DMP program. There was no national publicity campaign towards patients, giving some space to a negative press exacerbating the DMP program’s political sensitivity, associated with a wider “surveillance state”, the risk on data confidentiality, and the lost of the physician-patient privilege (in French “medical secret”). In addition, despite the “P” of DMP was for “personal”, patients could not create their DMP by themselves, and had to
ask their physicians to do it whereas most of them either were against the tool, or were thinking the program was stopped. In 2013, according to an opinion poll∗, 85% of French people were in favor of the DMP; an exceptionally high adherence rate (40% even said they were “strongly in favor”), in a marked progression in three years (they were 74% to be favorable in December 2010). Thus, involving patients and making them companions of the program would surely have helped the adoption of DMP beyond the benefit of empowering patients.

Persistence of technical difficulties: although 100% of EHR commercial software available in France are DMP-compatible, not all vendors provide integrated user-friendly DMP-specific functionalities. Besides, numerous health practitioners did not use the last DMP-compatible version of their medical software. Without incentive to change, because of the cost of the new software, and of the risks that always exist to modify a functional equilibrium, sometimes acquired with difficulties, health practitioners kept on using the old non DMP-compatible versions of their system, keeping the DMP outside their usual workflow, and making the adoption of the tool much more difficult.

Discussion

By the end of 2015, five years after the launching of the program in 2010, only 1.5% of potential DMPs had been created with a total of about 570,000 DMPs, and only 27% of all DMPs have been accessed. Updated data report 584,000 DMPs six month later, at the beginning of July 2016. As of February 2016, UK’s Health & Social Care Information Centre reported that 55 million people in England, representing more than 90% of the population, have an SCR created from their GP records†. According to the same source, 2.5 million SCRs were accessed by authorised healthcare professionals. Such difference in nationwide care records adoption between France and UK could be explained by the opt-out model used in the UK, the automated extraction of medical information from GPs’ EHRs to update the SCR, and the authority exercised by the NHS on GPs. Another important difference is that though being patient-centered, the SCR is not a “personal” record belonging to the patient who cannot acces it, but a professional, medical, tool to be used by health practitioners in case of emergency.11

The French DMP seems more comparable to the Australian personally-controlled electronic health record (PCEHR). Although not built on the same architectural model, the functionalities of the PCEHR22 are similar to those of the DMP, with an initial opt-in model, a richer document-based medical content, and the on-line patient access. The 2013-2014 annual report on the PCEHR23 mentions that, on June 30th, 2014, 1.73 million people registered for a PCEHR, i.e. 7.4% of the population two years after its launching. However, PCEHRs are mostly accessed by patients (around 512,000 times), and weakly accessed by health practitioners (around 25,000 times). The comparison with the US is more difficult due to the decentralized model for sharing medical information distributed among multiple EHRs through HIE.8 The number of people having a “personal record” does not make sense, since most patients have many records distributed within the medical practices they visit. However, not all providers are equipped with an EHR. The US CDC reported that in 2013, 22% of office-based physicians still did not use any type of EHR.24 Nevertheless, all patients may potentially access and download their medical information distributed among EHRs using the “Blue Button” functionality.25 This functionality builds upon HIE. From the patient’s point of view, this functionality is similar to the DMP and the PCEHR, except that the patient has no control over the content and cannot add or push any personal information. Recently, Ford et al.26 reported a simulation-based study to forecast the level of adoption of personal health records in the US. They estimate that the MU stage 3 target of 50% of consumers having access to their entire health record could be reached by 2020.

Conclusion

A nationally shared, widely accessible, electronic care record has a powerful symbolic meaning; it may be perceived as improving the quality and safety of care or, alternatively, as threatening patient data confidentiality or the traditional role of doctors and nurses.10,27,28 It is thus important to communicate about the nature and the aim of the tool. In

---

France, the low adoption rate of the DMP highlights the complex socio-technical challenges of implementing HIT. In the DMP case, the most important difficulty comes from the cultural change DMP was involving. However, despite the reported poor level of DMP adoption, patients and most healthcare professionals seem now to be ready to use it, although some unions of private practice physicians are still against the program because they feel that it is the role of the GP (and not of the DMP) to be the hub of care coordination, without considering that one valuable aspect of the DMP is for non-coordinated and emergency care.

Following the announcements of the French Minister of Health in 2013, the DMP has been relaunched (again), and a DMP2 positioned as a professional tool to support care continuity and coordination for the benefit of patients has been advertised. It took then two years to publish the new French Health Act† (January 26th, 2016) that includes the promotion of DMP adoption and use (article 96). After considering that the name of the tool should be changed, it remained DMP but with “P” for “partagé” (shared) instead of “personal” to insist on its use to support care continuity among health professionals sharing the same relevant medical information. Instead on depending on busy doctors reluctant to perform administrative tasks, patients will be now able to create their own DMP which also helps to solve the problem of tracing the consent collection. Instead of ASIP Santé, it is now the responsibility of the government health insurance to conduct the DMP program. Indeed the poor DMP adoption has been partly explained by a principled opposition of private doctors and by some technical difficulties private doctors may face in updating their EHR system. Thus having the government health insurance that financially monitors private doctors and is already used to send computer technicians to doctors’ offices to check whether computerized billing tools are operational was a better candidate. In addition, the government health insurance represents a significant counterpower towards the medical software vendors, which should also improve their reactivity to make the appropriate technical developments for interfacing their medical software with the DMP functionalities. Another important point is that the government may push all health insurance claims information (including information about reimbursed medical consultations, reimbursed drugs, reimbursed biological exams, imaging prescriptions, among other clinical information), thus ensuring there would be no more empty DMPs. Finally, the government health insurance may use the ROSP program to offer financial incentives and make private doctors actually use (create, feed and read) the DMP in a kind of French Meaningful Use. The impact of this year’s new DMP initiative will have to be assessed and quantified.

Acknowledgments

Authors thank Dr Elie Lobel, from ASIP Santé, for the information he provided about the DMP program, as well as Philippe Burnel and Philippe Cirre from the DSSIS at the French Ministry of Health. Data and figures on DMP usage have been gracefully provided by ASIP Santé.

Abstract

Frailty is an important health outcomes indicator and valuable for guiding healthcare decisions in older adults, but is rarely collected in a quantitative, systematic fashion in routine healthcare. Using a cohort of 12,000 Veterans with heart failure, we investigated the feasibility of topic modeling to identify frailty topics in clinical notes. Topics were generated through unsupervised learning and then manually reviewed by an expert. A total of 53 frailty topics were identified from 100,000 notes. We further examined associations of frailty with age-, sex-, and Charlson Comorbidity Index-adjusted 1-year hospitalizations and mortality (composite outcome) using logistic regression. Frailty (≥ 4 topics versus <4) was associated with twice the risk of the composite outcome, Odds Ratio: 2.2, 95% Confidence Interval: (2.0-2.4). This study demonstrates the feasibility of identifying frailty indicators from clinical notes and linking these to clinically relevant outcomes. Future work includes integrating frailty indicators into validated predictive tools.

Introduction

Frailty is an important, but frequently overlooked, determinant and indicator of health outcomes in older adults1-4. It is distinct from comorbidity and disease, and is an age-related, multidimensional combination of fatigue, weakness, malnutrition, and greater vulnerability to stressors5-7. Increasing frailty is often co-existent among patients diagnosed with chronic conditions and it is associated with the severity of acute illness and intensity of healthcare utilization8, 9. Frailty is widely recognized as a risk factor for morbidity, including cognitive decline, mortality, as well as a barometer of how well patients respond to treatment5, 9. Therefore, this metric can be valuable for informing healthcare decisions, including recommended surgical procedures, end-of-life care, and living arrangements1. In order to provide an efficient and effective patient-centered care, providers should be aware of each patient’s frailty status for incorporation into clinical decision making.

Despite its importance, frailty measurements are rarely collected in a quantitative, systematic fashion in routine patient care9. Frailty extraction is complex, since information is rarely collected as coded/structured data and clinical note terminology varies significantly. This complexity limits the ability to evaluate the association between frailty severity and clinical outcomes, and prevents healthcare providers from using frailty information in clinical decisions9. However, healthcare providers commonly document various aspects of frailty in clinical notes, especially when treatment plans change and/or when patients’ quality of life is impacted. Therefore, clinical notes can provide the data for a quantitative frailty metric as well as a longitudinal record of frailty.

Extracting frailty from clinical notes is challenging because frailty is a complex and multi-faceted concept. The use of the term “frail” is not common, while the description of frailty indicators such as “tired,” “slow walk,” “unsteady gait” and “confused” are abundant. In a prior study, we identified terms describing functional status, one aspect of frailty10. Among the hundreds of functional status terms we collected from clinical notes and social media, only a fraction could be mapped to a controlled vocabulary. Furthermore, for the purpose of retrospective analysis or prospective decision support, frailty should not be treated simplistically as a binary variable. The Frailty Scale developed by Dr. Rockwood, for instance, categorized frailty status into 9 levels11. As a result, to determine frailty

1110
status from text, we cannot rely on a small number of known terms or the existing controlled vocabulary. Rather, it is necessary for us to identify a rich set of indicators of frailty and differentiate the degrees of frailty.

Topic modeling is a potential approach for identifying indicators of frailty in clinical notes. Briefly, topic modeling is a machine learning method based on statistical models that assess words in documents for identifying hidden themes in a corpus of free text documents\textsuperscript{12}. By first focusing on themes rather than individual words/terms, we hypothesize that it would allow us to capture a wide range of text descriptions potentially related to frailty.

Our aims are to 1) demonstrate the feasibility of using topic modeling of clinical notes to identify frailty indicators and 2) using these frailty indicators to examine associations with clinical outcomes among patients diagnosed with heart failure (HF). HF is a highly prevalent condition that results from structural or functional impairment of the heart’s ability to fill or eject blood. Recent projections estimate that >10 million Americans (3%) will have HF by 2030\textsuperscript{13,14}. Evidence suggests that frailty is worse among patients with HF compared to similarly aged adults, with similar comorbidities, from the general population\textsuperscript{15-17}. Commonly reported HF symptoms such as dyspnea and fatigue can lead to greater frailty\textsuperscript{14} and one of the treatment goals is to improve frailty status. Also, since HF patients may be referred for cardiac surgery or other invasive interventions as symptoms worsen (though less common among older HF patients), measurement of frailty can inform treatment strategies and facilitate examination of treatment response\textsuperscript{14}. A method to systematically estimate frailty among all HF patients is, therefore, critically important.

**Methods**

**Data**

We used Veterans’ electronic medical record (EMR) data which are maintained by the Veterans Administration Informatics and Computing Infrastructure (VINCI) database\textsuperscript{18}. VINCI includes data on healthcare utilization (inpatient and outpatient encounters), clinical parameters, and demographics (e.g. age, gender) as well as narrative text from clinical encounters or Text Information Utility (TIU) notes. We used the International Classification of Disease 9th Clinical Modification (ICD-9-CM) codes 428.0-428.9 from inpatient (primary/principal or secondary diagnoses) and outpatient records to identify patients with HF. We identified 12,000 patients with a HF diagnosis in Fiscal Year 2010, among which 4,000 experienced death or ≥2 HF hospitalizations during the year after diagnosis. Then we extracted Veterans’ gender, calculated their age and Charlson Comorbidity Index (CCI) at the first HF diagnosis. The Charlson Comorbidity Index is a measure of disease burden that is determined from comorbid conditions using methods described by Quan et al.\textsuperscript{19}. These Veteran characteristics were either directly or indirectly ascertained from the structured data tables. We also retrieved all the clinical notes from the patients included in our study dated within one year before the first HF diagnosis. There were a total of 709,389 notes available for the 12,000 Veterans diagnosed with HF. Frailty indicators, which were not available from the structured data, were extracted from these notes using a topic modeling technique. All data access and use was approved through local Institutional Review Board and VINCI policies and no human subjects were contacted for this study.

**Topic Modeling and Stable Topic Extraction**

We randomly sampled 100,000 notes from the corpus of 709,389 notes for topic modeling. Random samples (50,000 each) were balanced between the 4,000 patients with and the 8,000 patient without 1-year outcomes (≥2 HF hospitalizations or mortality). We tokenized these texts by converting all uppercase letters into lowercase, removing all numbers and punctuations except hyphens (“-”) that join two words. We used the Latent Dirichlet Allocation (LDA)\textsuperscript{20} program from the MALLET package, a topic modeling tool that is written in Java\textsuperscript{22}. LDA is one of the most widely used topic modeling approaches and makes assumptions that topics are probabilistic distributions over words and documents are mixtures of topics. It has found applications in many areas including biomedicine\textsuperscript{12,21}. We set the initial number of topics to be 700 and ran LDA on the 100,000 notes to obtain a list of 700 topics. Then we applied the learned topic model to the full collection of 709,389 notes using the topic inferring tool also included in MALLET. This step yields topic proportions per note for each note. By the design of LDA, every topic has a non-zero proportion within every note. We set 0.02 as the cut-off on the topic proportion in a note to select the topics present in the note.

One major issue when using LDA is the presence of a high amount of noise (irrelevant terms) in some topics, which results in high false positives. To overcome this problem, we designed a method to identify the non-noise topics which we called “stable” topics. Since LDA is an iterative algorithm that initially assigns terms randomly to topics, the topic model it generates varies each time LDA is applied to a test corpus. At the same time, certain topics re-
occur in repeated experiments. For example, in this study we observed the following two topics (only top 10 most probable words are listed here) from two independent runs:

<table>

</tbody>
</table>

Run 2, Topic 144

Although the topics do not have exactly the same probability distributions over the words, they are very similar, and should be viewed as the “same” topic that recur in different runs.

We postulate that non-recurring topics and topics terms are likely to be noise as they are influenced by the initial random seeds. To identify the recurring topics, we proceeded as follows. Given two topics \(a\) and \(b\) with word counts \(c_t^a\) and \(c_t^b\) respectively, we define the distance between \(a\) and \(b\) to be

\[
d(a, b) = 1 - \frac{\sum_w c_t^a(w) \times c_t^b(w)}{\sqrt{\sum_w (c_t^a(w))^2} \times \sqrt{\sum_w (c_t^b(w))^2}}
\]

which is known as the cosine-distance. To identify stable topics generated by LDA corresponding to some parameter set (e.g., number of topics, number of iterations, alpha), we ran LDA 3 times under the same parameter set (but with different random seeds) to produce 3 sets of topics, say, \(A, B, C\). Then, for each topic triple \((a, b, c)\) with \(a \in A, b \in B, c \in C\) we compute the size of the triple by taking the maximum of the 3 distances:

\[
d(a, b, c) = \max \{d(a, b), d(a, c), d(b, c)\}
\]

One can visualize a topic triple as a triangle, so that the terms such as “size”, “small”, “large” make more sense.

We aligned up the three sets of topics using a greedy algorithm as follows. We first found the triple \((a_1, b_1, c_1)\) of the smallest size from all such triples, and second found the triple \((a_2, b_2, c_2)\) of the smallest size from all the triples \((a, b, c)\) with \(a \in A \setminus \{a_1\}, b \in B \setminus \{b_1\}, c \in C \setminus \{c_1\}\), and third found the triple \((a_3, b_3, c_3)\) of the smallest size from all the triples \((a, b, c)\) with \(a \in A \setminus \{a_1, a_2\}, b \in B \setminus \{b_1, b_2\}, c \in C \setminus \{c_1, c_2\}\), and so on. Thus we aligned the three sets of topics by their size from small to large. For any topic triple \((a, b, c)\) smaller than an adjustable parameter \(r\) we made a new topic by averaging the counts of \(a, b\) and \(c\):

\[
c_{t_{avg}}(w) = \frac{1}{3}[c_t^a(w) + c_t^b(w) + c_t^c(w)]
\]

and we called the new topic a stable topic. In this study, we empirically set \(r = 0.7\) and obtained 556 stable topics.

To determine what stable topics were present in each note, we proceeded as follows. First we independently applied each of the 3 learned LDA models to the full collection of 709,389 notes using the topic inference tool included in MALLET. This step yielded 3 topic proportions per note for each note. Next, we defined a stable topic to be present in a note if at least 2 of the 3 topics in the topic triple corresponding to the stable topic had a proportion of 0.02 or higher in that note. This enabled us to make a list of stable topics present in a note for each note.
Topic Interpretation and Frailty Topic Identification

The “topics” generated by topic modeling methods are simply probability distributions over the whole vocabulary (consisting of thousands of words), and every word has a non-zero probability in every topic. Since we need to identify topics related to frailty, the first step is to interpret all the probability distributions over words. Obviously, not all the words are equal for making interpretations: words with higher probabilities are more important than those with lower probabilities. For our project, we list the top 20 most probable words for each topic and ask the human reviewers to focus on the top 10 words to make interpretation and use the next 10 words as auxiliary.

An informatics expert and a medical expert independently reviewed the list of 556 stable topics, interpreted them as described above, and identified those that represent certain aspect(s) of frailty. Then we calculated the inter-rater agreement on the identification of frailty topics. See Table 1 for examples of frailty topics and their interpretations.

Counting Frailty Topics for Patients

We counted the frailty topics for each patient from all the notes dated within one year of the first diagnosis of HF. The topics were counted only once, even if they appeared in multiple notes. These numbers were recorded as the frailty data. We hypothesized that the number of frailty topics a patient has can be used as an indicator of the frailty severity: the higher the number, the more severe the frailty.

Cases and Controls

We divided the 12,000 HF patients into case and control groups. Cases were defined as patients who died or had \( \geq 2 \) all-cause hospitalizations within the first year following their first diagnosis of HF (our composite outcome). Controls were patients who did not have the composite outcome within the 1-year period following their initial HF diagnosis. This yielded 5,207 cases and 6,793 controls.

Statistical Analyses

To explore the relevance of the frailty indicators, we ascertained the composite outcomes (mortality/hospitalization) and we conducted several statistical analyses.

1) Correlation Analysis

We computed the prevalence of patients with \( n (n=0, 1, 2, \ldots) \) frailty topics in the cases and also in controls. Then we calculated ratio of the prevalence in cases to those in controls for each \( n \). These ratios measure the population level (i.e., cases vs controls) difference in frailty of various levels of severity. Therefore, the correlation between the ratios and the number of frailty topics (i.e., \( n \)) is an indicator of the relationship between frailty and the composite outcome.

2) Logistic Regression Models

We used logistic regression models to analyze the association of frailty and the composite outcome at the individual level. We adjusted for age, gender, and CCI level. The outcome was modeled as a binary variable: case was coded as 1 and control was coded as 0 (reference). Age (in years) was measured at the time of the first HF diagnosis. CCI was an integer ranging from 0 to 33. Age and CCI were modeled as continuous variables. Gender was modeled as a binary variable: 0 for male and 1 for female. We parameterized the frailty variable in two ways: 1) as a continuous variable and 2) as a binary variable. As a continuous variable, frailty was coded as the number of frailty topics we counted for each patient. As a binary variable, frailty was coded as 0 (reference) if the number of frailty topics was \( \geq 4 \) topics and coded as 1 for \(<4\) topics. We chose 4 as the cut-off based on the results of correlation analysis (see Figure 1 and 2). For both cases, we calculated the odds ratio for the composite outcome associated with the frailty variable based on the coefficients output by the logistic regression models.

Results

We obtained 556 stable topics from the topic modeling step. An informatics expert reviewed these topics and identified 53 of them as frailty topics. A medical expert independently identified frailty topics resulted and had an inter-rater agreement of Kappa = 0.818 with the first reviewer, demonstrating that the first expert’s result was reliable. In Table 1, we list eight frailty topics for illustration.

The age, gender, and CCI characteristics of our study population of 12,000 Veterans with new diagnoses of HF are described in Table 2. Mean age was around 70 years old for cases and controls, most were male, and cases generally had a higher CCI compared to controls.
Table 1. Eight examples of frailty topics. The first column lists the labels assigned by the informatics expert as human interpretations. The second column lists the top 20 words in order of descending probability.

</table>

Among cases, 20.3% patients had no frailty topics mentioned in the notes, 8.7% had one frailty topic, 8.4% had two frailty topics, 6.5% had three, 6.5% had four, 5.5% had five, etc. Among controls, 35.4% patients had no frailty topics, 13.4% had one, 10.8% had two, 8.8% had three, 6.1% had four, 4.8% had five, etc.

Comparing the two distributions, when the number of frailty topics was less than 4, the prevalence of patients having that number of topics in the cases was lower than that in controls. However, patients with ≥ 4 topics, the prevalence of patients having that number of topics was higher in the cases than in the controls. This is illustrated in Figure 1. This led to the choice of 4 as the cut-off in making frailty into a binary variable in one of logistic regression models.

To make the contrast clearer, we calculated the ratio of the prevalence in cases to that in controls for each number of topics, except for 25 or more topics where we grouped them together into one category. The correlation of this ratio with the number of frailty topics is 0.879.
Figure 1. Patient distribution over different ranges of numbers of topics in cases and in controls. The ranges are: 1) 0 topics, 2) 1 ~ 3 topics, 3) 4 ~ 10 topics, 4) 11 ~ 24 topics, 5) 25 or more topics.

Figure 2. Ratio of prevalence of patients with various numbers of frailty topics in the cases to that in the controls. Correlation of this ratio to the number of frailty topics was 0.879.

Figure 2 indicates that the ratio was below 1 when the number of frailty topics (n) was below 4, between 1 and 2 when n was between 4 and 10, and above 2 when n was above 11 (the only exception was when n=20 should be viewed as an effect of random sampling).

The results of logistic regression models are presented in Tables 3 and 4, corresponding to treating frailty as a continuous variable and a binary variable (reference, <4 topics), respectively. In both models, frailty was associated with the outcomes and these results were statistically significant. The coefficient (0.07) of frailty in Table 3 can be interpreted as the odds ratio = 1.07 (=exp(0.07)), 95% Confidence Interval (CI): 1.07-1.08, for each additional frailty topic associated with the risk of the composite outcome. Thus, each additional frailty topic was associated with a 7% higher risk of the composite outcome. The coefficient (0.789) corresponds to an odds ratio of 2.20 (95% CI: 2.02-2.39) for the association between ≥4 frailty topics (vs <4) and the composite outcome, Table 4. In other words, ≥4
frailty topics was associated with two times the risk of having the composite outcome 1-year following an initial HF diagnosis.

**Discussion and Conclusion**

In this study we demonstrate the feasibility of extracting frailty-related topics from clinical text and that these topics are associated with clinically relevant outcomes. We are unaware of previous studies that have extracted frailty-related topics from clinical notes and associated these topics for clinical outcomes. Our results show that the frailty data we extracted is correlated with mortality and/or hospitalizations at both the population and the individual levels. In particular, the number of frailty topics for a given patient may serve as a proxy for the severity of frailty of the patient. A patient with one or two frailty topics does not necessarily mean the patient is frail: for example, that a patient needs mobility assistance may be a result of injury. However, with more frailty topics, it is more likely that the patient is frail.

Our results have the potential for significant impact. Healthcare providers use risk prediction models to estimate treatment risk. For example, the Society of Thoracic Surgeons uses a calculator to estimate the risk of adverse clinical outcomes following cardiac surgeries. This calculator is inaccurate for older adults—it underestimates risk in frail patients and overestimates risk in healthy patients. A tool that allows frailty to be incorporated into the STS, and other, models could improve the accuracy of risk prediction. We hope that our project can lead to a better measure of frailty that can be useful in routine use of clinical decision support.

Our findings are consistent with previous studies of frailty, not just indicators of frailty, and clinical outcomes. For instance three of the most commonly used measures of frailty include the Fried Frailty Phenotype model, the Frailty Index developed by Rockwood et al., and gait speed. These measures have been found to be associated with future risk of hospitalizations and mortality. However, these measures are not integrated in routine care for all patients, since they can be time consuming to complete and add additional burden to patients and providers. Thus, these measures are often reserved for randomized controlled studies, as in the recent landmark Systolic Blood Pressure Intervention Trial (SPRINT), or smaller target populations, such as among nursing home residents. Thus, the potential use of clinic notes from the EMR supports opportunities for larger and more generalizable or pragmatic studies of frailty and incorporation into routine healthcare decision making.

We can conclude that the topic modeling approach is capable of extracting the frailty information from text. This approach is also applicable to much larger datasets. Because LDA is a time-consuming program, instead of running LDA directly on all the notes (about 700,000 notes), we sampled a sufficiently large subset (100,000 notes) so that LDA can finish the job in a reasonable time. Then we applied the learned topic model to the all the notes to infer the topic distributions in each of them. The topic inferring program is much less time-consuming than LDA, so the process can finish in a reasonable time while still obtaining the outputs we need: the list of topics and the topic distributions in each note. One novelty of our topic modeling approach is the stable topic identification method.

Topic modeling is an unsupervised machine learning method, which means it does not require human annotations to train the model. Therefore our approach does not require much labor-intensive work such as reading notes and manual annotation. That being said, some manual work – interpreting the computer-extracted topics and identify those that could be indicators of frailty – is still required. However, the human labor is much less than annotating notes, because a reviewer only needs to read 20 words (in this study) for a topic rather than hundreds of words for a note.
Some frailty topics identified by our experts may appear to be cognition-related (see Table 1). This is because there is an association between frailty and cognitive impairment: frailty and cognition interact within a cycle of age-associated decline, therefore some researchers regard cognition deficits as indicators of frailty.

Since this study is our first attempt of identifying frailty from text, there are a number of limitations. 1) A note having a frailty topic could indicate absence of frailty. Using a number of (e.g. ≥ 4) distinct frailty topics as indicator greatly increases the chance of finding frailty, although the certainty is still not 100%. 2) When we used the number of frailty topics as an indicator of the severity of frailty, we implicitly assumed that all the frailty topics had the same contribution to the severity of frailty. In reality different frailty topics may indicate different levels of severity. 3) Our logistic regression analysis only took into account 3 commonly used predictors in HF patients for our composite outcome: age, gender and CCI. It is likely that many other factors that also correlate to the outcome of mortality/hospitalizations. 4) Although we attempted to identify Veterans with a new or incident diagnosis of HF, patients could have sought care outside the Veterans Health Administration for their initial diagnosis and would have been included in this study of incident HF patients. In addition to addressing these limitations, future studies are needed to replicate our preliminary findings and to extend our findings to other clinical domains. Also, further work is needed to examine changes in frailty indicators from clinical notes over time and to incorporate frailty indicators into validated predictive tools for clinical decision making.

Based on the results of this study, we conclude that it is feasible to identify indicator of frailty from routinely documented clinical notes. We also demonstrate that these indicators are related to clinically relevant outcomes in a population of Veterans diagnosed with HF.

Abstract

Researchers commonly use a tabular format to describe and represent clinical study data. The lack of standardization of data dictionary’s metadata elements presents challenges for their harmonization for similar studies and impedes interoperability outside the local context. We propose that representing data dictionaries in the form of standardized archetypes can help to overcome this problem. The Archetype Modeling Language (AML) as developed by the Clinical Information Modeling Initiative (CIMI) can serve as a common format for the representation of data dictionary models. We mapped three different data dictionaries (identified from dbGAP, PheKB and TCGA) onto AML archetypes by aligning dictionary variable definitions with the AML archetype elements. The near complete alignment of data dictionaries helped map them into valid AML models that captured all data dictionary model metadata. The outcome of the work would help subject matter experts harmonize data models for quality, semantic interoperability and better downstream data integration.

1 Introduction

Spreadsheets and other tabular formats have become the primary mechanism for representing much of the clinical research data that is published today. The simple format and easy-to-use interface has allowed researchers to customize and manage data with relative ease. Large projects like the Database of Genotypes and Phenotypes (dbGaP)\(^1\),\(^2\), the Phenotype Knowledge Base (PheKB)\(^3\),\(^4\) and The Cancer Genome Atlas (TCGA)\(^5\),\(^6\) have published their data dictionaries in a variety of formats. They have used either delimited values variants (CSV - comma-separated values) or Extended Markup Language (XML) schemas, where column headings or XML elements (and associated attributes) carry an implicit metadata about the study and its variables. While a simple representation makes it easier to procure, maintain and disseminate datasets and implementation artifacts in these formats, it presents a challenge to the semantic interoperability of the models that these data dictionaries define. These model assertions, even when they are standardized with external vocabulary resources, almost always require additional transformations to be effective and semantically interoperable outside their local context.

There is an emerging need for standard representation of these data dictionaries to facilitate their harmonization and for greater semantic interoperability\(^7\),\(^11\). A standard representation for a data dictionary would allow researchers to identify the minimal set of information that would be needed to align their model with other models that describe same set of semantics. This would also enhance the clarity of the individual model semantics and improve their interoperability when model and its datasets are shared. A standard template for the representation of a data dictionary could greatly reduce the transformations required to move between different environments.

The Archetype Modeling Language (AML)\(^12\) is one of formalisms approved by the HL7 Clinical Information Modeling Initiative (CIMI)\(^13\),\(^14\) to describe clinical models. An AML model is represented using the Unified Modeling Language (UML)\(^15\). The AML specification is based on elements from HL7 Detailed Clinical Models (DCM)\(^16\), OpenEHR ADL Archetypes\(^17\),\(^18\), the ISO 11179 Meta Data Repository (MDR)\(^19\) and the OMG Common Terminology Services 2 (CTS2)\(^20\) standards. AML archetypes employ constraint-based modeling approach, where the possible values of a starting reference model are incrementally restricted (constrained) as the target of the model is specialized.

The objective of the study is to create direct mappings between the metadata from a collection of three data dictionaries (from dbGAP, PheKB, and TCGA, respectively) with their variable definitions and the AML constraints on the CIMI Core Reference archetypes\(^21\), and demonstrate the utility of the mappings by implementing the transformation via a suite of semi-automated tools. The treatment of data dictionary variable definitions as AML constraints provides both a standardized representational form and facilitates their harmonization with other similar archetypes. Based on the mappings, we develop a platform known as D2Refine on top of an open-source...
OpenRefine platform. The platform provides a suitable interface that allows users to load data dictionaries in a variety of formats, align them to a standard template, and transform them into CIMI archetypes.

2 Materials and Methods

2.1 Materials

2.1.1 Clinical Study Data Dictionaries

We used three data dictionary formats identified from dbGaP, PheKB and TCGA. The data dictionaries from dbGaP and TCGA are in XML schema format whereas the format of PheKB is Excel spreadsheet. Each of the data dictionaries contains a collection of metadata including variable definition, constraints and links to standard terminologies. Some of these data dictionaries include references to standard terminologies like NCI Thesaurus and Common Data Elements from Cancer Data Standard Registry and Repository (caDSR) already embedded in most of the models they define.

2.1.2 OMG AML Specification

The AML specification, as an Object Management Group (OMG) standard, is composed of three UML Profiles - Reference Model Profile (RMP), Terminology Profile (TP) and Constraint Profile (CP). The Reference Model Profile defines stereotypes to identify the ground rules for constraining a target UML model. The Terminology Profile provides a set of stereotypes that all UML models to have multi-lingual names and comments, allows the assignment of multiple external identifiers (e.g. URIs etc.) and allows UML model elements to be associated with their intended semantics through links to elements from external ontologies. The Constraint Profile defines a set of stereotypes that allows the specification of constraints (archetypes) on the target classes, properties and data types in a target UML model. An AML archetype is a set of constraints on a target class in a target reference model. An AML archetype library is a collection of archetypes that constrain one or more classes in a given UML model (the Reference Model or RM). Note that additional AML documentation includes 1) the AML specification in GitHub (including a collection of normative and non-normative formats of AML artifacts), 2) the AML Archetype Examples, 3) the OpenEHR’s ADL and AOM Specifications and 4) an AML prototype project in GitHub.

2.1.3 The Reference Model

CIMI has specified a generic reference model, the CIMI Core Reference Model that underlies all archetypes published by the CIMI group. CIMI also publishes a set of “reference archetypes”, the CIMI Core Reference Archetypes. These archetypes constrain the CIMI Core Reference Model and form the basis of all other archetypes published by the CIMI group. In the clinical space, these reference archetypes provide basic structures to catalog the majority of the constraint definitions listed in data dictionaries. Figure 1 shows a selection of CIMI Core RM classes and a high level CIMI Core Reference Archetype 'Cluster' (an online version available at *).
2.1.4 OpenRefine - The Platform

We will use an open-source platform known as OpenRefine\textsuperscript{22}, which is a popular and widely used tool to manage and clean up data. OpenRefine provides a mechanism that allows users to programmatically extend its capabilities to add standard templates in a tabular form. The standard template enables users to define mandatory and optional variable definitions for a data dictionary. The OpenRefine’s built-in reconciliation feature (which is extensible) allows users to link the values with external terminology services. The set of constraints in a template can then be programmatically transformed into CIMI archetypes by extending the export/import functionality of OpenRefine. We plan to add these features without altering spreadsheet-like interface of OpenRefine intact. This greatly minimizes the learning curve for users.

2.2 Method

2.2.1 Create a Standard Template based on AML specification

The first step towards capturing the archetype requirements is the creation of a Standard Template. The Standard Template serves as a bridge between tabular metadata and their AML equivalents. The template provides a minimum set of requirements to be filled by variable definitions of a data dictionary and its metadata. The Standard template would need to be implemented once and hence it would eliminate the need for any additional transforms. For a data dictionary, what we need to do is to map it to the Standard Template and to get it transformed into an AML archetype.

The elements in the Standard Template are, directly derived from the AML specification profiles and are manually composed, as a set of three types of requirements to create a valid AML archetype and to link its terms to standard terminologies. These requirements are:

1. Archetype Metadata: archetype library, identification, constrained RM class, archetype specialization, organization, copyright, version and author information
2. Constraint Definition: constraint identification, constrained type, values, multiplicity, value set, archetype reference
3. Terminology Bindings: archetype term definitions, references to standardized terminology resources like code systems, concepts, value set and value-set members

2.2.2 Create mappings between data dictionary elements and standard template elements

We then establish the mappings between corresponding data dictionary elements and the standard template elements. The mappings helped us observe how the data dictionary properties align to create a valid archetype and yet keep the semantics of the data model represented by a data dictionary intact. The informative section ‘AML-UML Transformation Reference’ of OMG AML specifications, which describes core set of mappings between ADL and AML, guided the creation of these mappings. As illustrated in Figure 2, a data dictionary is defined by and composed of its study variables. This structure resembles with the CIMI Core Reference archetype Cluster (as shown in Figure 1), which could be constrained to create almost any hierarchical collection. A data dictionary maps to an archetype, which is defined by constraining the reference archetype Cluster. Each
variable definition is mapped to a leaf-level constraint node (modeled by further constraining the Cluster.Element). All these archetypes are created to reside in an Archetype Library, which maps from the domain or study of the data dictionary.

2.2.3 Implement using D2Refine platform and tooling

We previously implemented a set of extensions to OpenRefine known as D2Refine. D2Refine includes features that can represent the Standard Template developed above. We plan to add a new extension to the D2Refine platform that allows us to serialize data dictionaries to and from AML archetypes, and a second to determine whether a given data dictionary meets the requirements. D2Refine provides the extensible reconciliation services needed to standardize, validate and transform data dictionary variable values.

2.2.4 Evaluate with a case study using a sample data dictionary

To test the utility of these mappings, we performed a case study and manually converted a sample data dictionary into AML archetypes. Figure 3 shows a customized dbGaP data dictionary with three variables. These three variables represent the most common types of constraints we observed in a data dictionary. The example shown here contains an identifier, a value set definition and an interval combined with a coded value.

3 Results

3.1 The Mappings

The results of mappings between data dictionary elements and standard template elements are shown in Tables 1, 2, and 3. The second column of each table lists the target properties of the Standard Template, which were derived from various UML stereotypes in three AML Specification profiles. The prefixes RMP, CP and TP are used to show the namespace of the AML UML profiles - the Reference Model Profile, Constraint Profile and Terminology Profile respectively. The data dictionary variables and their attributes are described using either pseudo-XPATH syntax or by their column names.

Table 1 lists the first set of Standard Template elements for Archetype Metadata: Archetype library – a collection to which an archetype belongs, Archetype’s defining top-level constraint constraining RM Class or a parent archetype. The sub-constraints constraining RM Class properties follow the same pattern.

Table 2 shows the mappings satisfying requirements for data value types and value constraints like intervals and permissible values of a value set. In additional to the primitive types, the CIMI Core Reference Model defines all kinds of (concrete) Data Value Types like COUNT, QUANTITY, CODED_TEXT and others. All these data types are descendents of an abstract data value type DATA_VALUE. The target archetype constraint constrains an appropriate DATA_VALUE type, which depends on type of the values associated with a variable in the data dictionary. The ‘ArchetypeRoot’ constraint of an archetype is to create a reference to another archetype (composition).

Table 3 lists the mappings for an archetype’s terminology bindings for the terms and codes identified from data dictionary variables. These mappings translate into references to internal and external vocabulary resources (e.g. NCI Thesaurus). The stereotypes of the Terminology Profile combine the features of ISO 11179-3 model and Common Terminology Services 2 (CTS2) specifications. The ISO 11179-3 model guides us for identification, designation, definition and value/meaning binding aspects. The CTS2 specification provides model for Concept, Code System, Code System Version, Value Set and Value Set Definition references.

These mappings were reviewed and verified by a panel of subject matter experts and the utility of the mappings was demonstrated by a successful transformation of a testing data dictionary into AML archetypes. Figure 4 shows a sample dbGaP data dictionary implemented as an AML archetype. As per mappings listed in the tables earlier, we used the AML stereotypes of ‘ArcheypeLibrary’, ‘Arcehtype’, ‘ComplexObjectConstraint’, ‘EnumeratedValueDomain’ for modeling Archetype Library, Archetype, constraints and terms (and terminology bindings) respectively. The archetype named ‘pht003255’ constrains the Cluster reference archetype. It is composed of three sub-constraints: ‘SUBJID’, ‘SEX’ and ‘AGE_FIRST’ – that are directly mapped from the data dictionary variable names. The target type of these constraints is mapped to the AML Primitive and Data Value
Types. Figure 4 shows the size and complexity of a resulting UML model for three simple constraint definitions (an online version available at ‡).

Figure 4. The sample dbGAP data dictionary implemented as an AML archetype

Please note that data dictionary variable identifiers are replaced with identifiers that follow the AOM identification scheme for clarity. The AOM specification describes identifier prefixes as id (normal identifier), ac (value-set identifier) and at (value-set member). The numerical number after these prefixes helps identify specialization level quickly.

3.2 Implementation status of the D2Refine transformation tools

The subsequent tasks, collectively known as D2Refine workbench 30, are already in-progress, to:

- Prepare OpenRefine platform for configuration and validation of the Standard Template elements
- Extend the import/export plugins of OpenRefine to load, transform and persist data dictionaries as AML archetypes

‡ https://raw.githubusercontent.com/caCDE-QAD2Refine/master/PrototypeProject/model_images/dbGapDDAMLModel/ph003255_Archetype.png
• We have already implemented a prototype transform that transforms dbGaP data dictionary to OpenEHR’s ADL format. Similar extension is required to implement the transformation to AML archetypes.

• Configure and extend OpenRefine’s reconciliation services with internal vocabulary terms and external terminological resources like NCI T, SNOMED CT, LOINC, caDSR and FHIR Profiles and their implementation.

• We have an Eclipse Modeling Framework (EMF) implementation of the CIMI Core Reference Model, which we have already been using.

Recently, we have successfully augmented OpenRefine’s reconciliation capabilities using any CTS2 compliant repository, which enables users to create terminology bindings of data dictionaries. We believe that we are on track to implement these features of D2Refine Workbench (Figure 5) for real-world use cases in near future. With the workbench support, we can practically and effectively map all metadata of any data dictionary with the Standard Template elements, CIMI Core Reference Model and the CIMI Core Reference archetypes.

4 Discussion

Data dictionaries provide simplest form to capture and list metadata entries in a tabular format. The tabular format is usually derived from a spreadsheet, a structured XML document or a set of delimited values arranged as row and columns. This simple form, though providing fastest way to organize and understand the datasets, can be really diverse and rarely portable outside of their environment. The encouraging aspect of data dictionary is that they are all very similar in the way of capturing the details of the variables. A data dictionary lists variable definitions with their names, data types, value ranges and binding to local and external resources, which is analogous to how an archetype is composed. A data dictionary does not have a reference model, which is needed by an archetype to define constraints. We found that the reference model component of an archetype definition can easily be substituted either by organizing structures of data dictionaries into a reference model classes or utilizing an existing reference model that is sufficient. In addition, the data dictionary formats used in this study are identified from three large projects: dbGap, TCGA and PheKB. dbGap and TCGA are two NIH pilot data commons; and PheKB is a catalog of electronic phenotype algorithms and associated data dictionaries, and largely used in the eMERGE Research Network. We believe that the selected data dictionary formats represent well the current practice in the clinical research communities.

The simplified view of CIMI Reference Archetype - Cluster, shows a recursive structure definition by constraining CIMI Reference Model (RM) classes ITEM_GROUP and ELEMENT for grouping or representing leaf level entities respectively. Since data dictionaries do not have a reference model specified, we use CIMI Core Reference Archetypes and constrain them to model data dictionary constraints. In case of the TCGA data dictionary where a number of commonly used structure definitions were introduced, these definitions were augmented to the collection of CIMI Core RM types and the reference model extended into a TCGA Reference Model. The creation of TCGA RM made it possible to correctly map the TCGA data dictionary constraints to the standard template requirements.

The implementation of standard template is not only able to preserve the existing tabular, spreadsheet-like interface to create and manage data dictionaries, but also facilitates additional transforms to better utilize them in different environments. The standard template directly maps from AML profiles and hence guides the modelers to make sure that their models have the necessary model elements and could be persisted as archetypes. The ‘archetype modeling’ is the ‘constraint-based modeling’ where constraints are about the reference model classes. The Archetypes stand separate from the reference model that does not change in any way, which introduce flexibility and improve interoperability.

Figure 5. The D2Refine Workbench
Besides AML, the Archetype Definition Language (ADL)\(^1\) is the other supported formalisms approved by the HL7 CIMI for describing clinical models. A model in ADL format is described in Object Data Instance Notation (ODIN) text whereas an AML Model is represented in UML. We are also actively developing tools that enable the transformation of data dictionaries into the ADL representation. The transformed data dictionaries into the ADL format can leverage the tools and environment developed for ADL models and that can help harmonize them with thousands of existing ADL archetypes. On the other hand, the transformation of data dictionaries into CIMI archetype’s AML format (a non-proprietary UML model) is an important gateway to the Model-Driven Architecture (MDA)\(^3\). The MDA workflow provides a way to expedite development of flexible and robust dataset validation tools and user applications. The AML specifications are guided by ADL Object Model (AOM) and include transformation mappings to seamlessly move between the ADL and AML. These mappings between ADL and AML are being implemented by the community and will be available in near future.

The standard template in D2Refine preserves the spreadsheet-like tabular interface that allows users to review data dictionaries; at the same time it allows model metadata to bind to standard terminologies and metadata repositories with its extensible reconciliation services. D2Refine also provides built-in framework for implementing bi-directional transforms to store and manage data dictionaries using AML formalism.

The task of creating CIMI AML archetypes requires implementing the AML Profiles and using UML implementation to create AML’s UML artifacts. The open-source EMF\(^2\) and Eclipse UML2 Libraries are essential to this task. A library of convenient programming interfaces encapsulating the EMF and UML2 implementations is being developed. Ability to access these interfaces from OpenRefine extensions should be sufficient to realize and persist AML archetypes.

The manual process of creating the AML archetypes from data dictionaries is impractical, tedious and error-prone. As described earlier, we will need various items to programatically transform data dictionaries. The open-source EMF implementation of the AML Profiles is crucial to be able to create AML objects. We have worked on investigating the Model Driven Health Tools (MDHT)\(^4\), an Eclipse open-source project, to generate AML profiles implementation (using OMG AML specifications) as a library. We plan to use Eclipse’s UML2 libraries to create UML 2.5 objects.

5 Conclusions

In this study, we successfully created reliable mappings between three types of data dictionaries and the standard template elements informed by the AML specification. We have demonstrated that the mappings are very helpful in enabling the representation of a data dictionary in a CIMI archetype. We are actively implementing the mappings in a D2Refine platform\(^5\) to enable the transformation of data dictionaries into CIMI archetypes. The outcome of our work will enable the standard representation of heterogeneous clinical study data dictionaries, thereby facilitating effective metadata harmonization and downstream data integration, ultimately advancing clinical research studies.

The contents of this publication are solely the responsibility of the authors and do not necessarily represent the official views of the U.S. Department of Health and Human Services or any of its agencies. The funding agreement ensured the authors’ independence in designing the study, interpreting the data, writing, and publishing the report. The research presented was conducted by the awardee. Findings may or may not be consistent with or confirmed by the findings of the independent evaluation contractor.

This project was funded by the Center for Medicare and Medicaid Services (CMS) to expand the scope of services to a population of CMS beneficiaries, so the Health Sciences Institutional Review Board deemed the project to be a quality improvement initiative that did not require a formal patient consent process since the explicit purpose of data use was to improve patient care; the IRB number is 1212477.QI. The authors have no conflict of interest to declare.

ABSTRACT

Objective. To develop a systematic and reproducible way to identify patients at increased risk for higher healthcare costs. Methods. Medical records were analyzed for 9,581 adults who were primary care patients in the University of Missouri Health System and who were enrolled in Medicare or Medicaid. Patients were categorized into one of four risk tiers as of October 1, 2013, and the four tiers were compared on demographic characteristics, number of healthcare episodes, and healthcare charges in the year before and the year after cohort formation. Results. The mean number of healthcare episodes and the sum of healthcare charges in the year following cohort formation were higher for patients in the higher-risk tiers. Conclusions. Retrospective information that is easily extracted from medical records can be used to create risk tiers that provide highly useful information about the prospective risk of healthcare utilization and costs.

INTRODUCTION

The Chronic Care Model¹ proposed improving the effectiveness of interactions between patients and providers as a way of promoting the “triple aim” of healthcare:² (a) better health, (b) better care, and (c) lower costs.³ These positive outcomes may be anticipated on the basis of improved interactions between informed, activated patients and prepared, proactive providers ¹. Evidence also has shown that patients with care coordinators have fewer emergency department and urgent care episodes,⁴ hospital admissions,⁵ and readmissions.⁶
Care coordination is “… the deliberate organization of patient care activities between two or more participants (including the patient) involved in the patient’s care to facilitate the appropriate delivery of health service…” Care coordination is increasingly being used across the healthcare system to improve patient outcomes for populations of patients and is a core element of both the triple aim and the Chronic Care Model. In order for care coordinators to manage populations of patients, they must be able to identify the patients who are most in need of their services; one approach to this challenge is risk stratification. Indeed, risk stratification is crucial for effective population health management because it provides care coordinators the opportunity to focus their work on those patients who will benefit the most. By bridging the implementation gaps in the Chronic Care Model, well-designed risk stratification supports the transition from the traditional “reactive” model of medical care to one of maintaining health and avoiding preventable conditions. Risk stratification is a potentially powerful tool for predicting population health outcomes, and previous healthcare utilization has been shown to be a useful predictor of future healthcare needs.

Although the literature contains many studies and reviews of condition-specific risk stratification, most predictive indices have less than 90 percent accuracy and relatively few attempts have been made to stratify entire primary care populations. Notable examples include the Scottish SPARRA risk index for readmission of patients who had been recently discharged from the hospital and the Welsh Prism risk index for emergency admissions. In the United States, the Michigan Primary Care Transformation Project defined four functional tiers upon which intensity of services was based, rather than relying on a predictive index. The tiers are as follows: (a) Navigating the Medical Neighborhood, (b) Transition Care, (c) Care Management, and (d) Complex Care Management. The Senior Segmentation Algorithm, developed by the Kaiser Permanente healthcare system, also used four tiers that were more descriptive than functional; those were (a) Without Chronic Conditions, (b) With One or More Chronic Conditions, (c) With Advanced Illness or End-organ Failure, and (d) With Extreme Frailty or Nearing the End of Life. The Senior Segmentation Algorithm, while objective and reproducible, has been validated only in patients aged 65 years and older. Other models that have been applied to community-dwelling populations with varying degrees of success are Dr. Chad Boult’s work on risk scores to identify high risk patients from Medicare data, the Charlson and Elixhauser comorbidity indices, and the work by Dr. Hal Luft on the yearly stability of Medicare utilization and costs.

In this study, the objective was to develop a systematic, reproducible way to identify subgroups in a managed population at risk for higher utilization of healthcare resources as measured by healthcare episodes and charges.

**METHODS**

**Population**

In February of 2013, the LIGHT2 project (Leveraging Information Technology to Guide Hi-Tech and Hi-Touch Care, pronounced “light squared”) began enrolling adults who were primary care patients in the University of Missouri Health System and who were already enrolled in Medicare and/or Medicaid. LIGHT2 was a Health Care Innovation Award from CMS (Centers for Medicare and Medicaid Services) to achieve the Triple Aim of better health, better care, and lower costs by using advanced information technology and care coordination. In order to define a stable cohort,
this study limited data analysis to 9,581 patients who were enrolled before the first three months of care coordination was completed on July 1, 2013, and who were still enrolled when patients were first evaluated for risk stratification on October 1, 2013.

Primary Care Setting

Adult primary care in the University of Missouri Health System (UMHS) is provided by approximately 133 primary care physicians who practice in nine regional clinics; the Department of Family and Community Medicine operates five local outpatient clinics and two in nearby communities, and the General Internal Medicine section of the Department of Medicine operates two local clinics. This community-based, primary care focus is supported by an extensive UMHS tertiary-care system of six hospitals and more than 50 clinics, staffed by approximately 550 university physicians.

Data Source

All data on diagnoses, outpatient visits, and hospital episodes and charges were retrieved from the University of Missouri Health System electronic medical record as maintained by clinicians and staff between 2012 and 2014.

Rationale for Categorical Approach

For the purpose of differentiating levels of care coordination intensity, a categorical approach has some advantages over an index. Each category can receive a customized level of care coordination in a manner similar to the “functional tiers” of the Michigan Primary Care Transformation Project. One potential disadvantage to some previous approaches is that they sometimes rely on socioeconomic and other data for which characteristics can vary widely across settings. In order to predicate the risk tiers on more universally reproducible criteria, socioeconomic factors were not included in the development of risk tiers for this study using the general criteria of diagnoses and utilization. Specifically, the 27 chronic conditions that are included in the Chronic Conditions Data Warehouse provide a standard set of diagnoses that are relevant to population health management of Medicare/Medicaid patients in a primary care setting (see Figure 1). In addition, healthcare utilization was extracted for (a) outpatient visits, which may be encouraged or even increased as part of care coordination, and (b) the more costly hospital-based episodes, which include emergency department episodes, observation stays, and hospital admissions.

Number and Definitions of Tiers

Tier Definitions. The definitions of the four LIGHT2 risk tiers are shown in Table 1. These tiers were conceptualized to be generally similar to the “functional tiers” developed by the Michigan Primary Care Transformation Project and the “care groups” used in the Senior Segmentation Algorithm. For the purposes of risk stratification, the LIGHT2 tiers were defined as (1) No Chronic Conditions, (2) Chronic Conditions, Stable, (3) Chronic Conditions, Unstable, and (4) Chronic Conditions, Complex. These broad categories of chronic-disease acuity describe all members of a managed adult population with some specificity, but the categories also are general enough to be applied to a variety of environments and conditions.

Tier Calculations. The breakpoints between tiers were determined deductively in an effort to
reflect the intent of the functional tier definitions. The lowest or “No Chronic Conditions” category (Tier 1) was reserved for enrollees who had none of the 27 diagnoses included in the CMS Chronic Conditions Data Warehouse. For those enrollees with one or more chronic conditions, placement in either Tier 2, 3, or 4 was based on the frequency of outpatient clinic visits and hospital episodes (including emergency department episodes, observations stays, and hospital admissions) during the 12 months prior to analysis. Patients with one or more of the 27 CMS chronic conditions were stratified as “Chronic Conditions, Stable” (Tier 2) if they had four or fewer outpatient visits and no hospital episodes associated with their chronic conditions in the preceding 12 months. Based on the clinical experience of two authors (LS, LP), patients were stratified as “Chronic Conditions, Unstable” (Tier 3) if they had 5 to 12 outpatient visits or one hospital episode related to any chronic conditions during the preceding 12 months, and were stratified as “Chronic Conditions, Complex” (Tier 4) if they exceeded 12 related outpatient visits or had two or more related hospital episodes during the preceding 12 months.

Data Collection

Cohort Formation. In order to test the ability of these queries to predict risk for higher utilization of healthcare resources, the population was divided into tiers based on their clinical history as of a given date (October 1, 2013) and was treated thereafter as four fixed cohorts. For each cohort, the healthcare episodes and charges were calculated retrospectively for the 12 months before cohort formation (October 1, 2012, to September 30, 2013) to provide a baseline, and then prospectively for the subsequent 12 months (October 1, 2013, to September 30, 2014) to examine the utility of the risk stratification methodology.

Cohort Attrition. Attrition (e.g. death, relocation) during the 12 months after cohort formation reduced the size of the cohort by 208 patients, or 2.2%. Because excluding these patients was likely to bias the data collection toward healthier patients, their outcomes were included for those months in which they were alive and enrolled in the LIGHT2 program. A patient enrolled for one month after cohort formation, therefore, would contribute one-twelfth as much to the mean episodes and charges for his or her tier subgroup as another patient who was enrolled for the entire 12 months.

Inflation Adjustment. In order to compare baseline and prospective charges, all charges were adjusted to 2014 dollars. Since healthcare charges were adjusted upward by 3% on April 1 of each year during the study period, charges billed from April 1, 2013, to March 31, 2014, were adjusted by multiplying times 1.03. Charges billed from October 1, 2012, to March 31, 2013, were multiplied by (1.03 x 1.03) or 1.061.

Statistical Methods

Statistical comparisons of outcomes between tiers used the Kruskal-Wallis Test, a nonparametric analogue of the standard one-way ANOVA. Statistically significant (p < 0.05) overall tests were followed by pairwise rank-based comparisons; all comparisons were two-sided.

RESULTS

Demographic Description of the Cohort
Of 9,581 patients in the cohort, 63% (n = 6,014) were in Tier 2 on October 1, 2013, while Tiers 1 and 3 comprised 16% each (n = 1,554 for Tier 1; n = 1,555 for Tier 3), with the remaining 5% (n = 458) in Tier 4. More than three-fourths of the Tier 1 enrollees were younger than 65, but fewer than half of the enrollees in the other tiers were under 65. Overall, 4,185 of the 9,581 patients (44%) were younger than 65 years old. Approximately three-fifths of the enrollees in every tier were female. Figure 1 shows the prevalence of the Chronic Conditions Data Warehouse diagnoses in the LIGHT2 population.

Baseline Analyses of Hospital Episodes by Tier

During the 12 months before cohort formation, the mean number of emergency department episodes was 0.20, 0.18, 0.52, and 1.45 in each tier respectively; observation stays averaged 0.10, 0.09, 0.41, and 1.16 respectively; and there were 0.09, 0.09, 0.47, and 1.86 mean inpatient admissions in each respective tier. The number of episodes was significantly different overall among the tiers (p < 0.001) and progressively higher in successive tiers in pairwise comparisons (p < 0.001 for all comparisons), except that there were no significant differences between numbers of episodes in Tiers 1 and 2 (p = 0.304 for emergency, p = 0.967 for observation, and p = 0.739 for inpatient). Because the data were skewed, the median number of episodes of all types was zero for Tiers 1, 2, and 3. For Tier 4, the median number of emergency episodes was zero, and the median number of observation and inpatient episodes was 1. The median values of zero indicate that over half of the lower tier patients had no hospital episodes during the baseline year.

Baseline Analyses of Healthcare Charges by Tier

During the 12 months before cohort formation, mean healthcare charges in the four tiers (respectively $6,208, $10,889, $43,059, and $115,228) were significantly different overall and in pairwise comparisons (p < 0.001 overall and for all comparisons). Median charges in each tier (respectively $658, $2,641, $19,707, and $66,182) were likewise significantly higher in higher tiers (p < 0.001 overall and for all pairwise comparisons). Tiers 3 and 4, comprising only 21% of the total population, accounted for 61% of total healthcare charges. Because lower tiers were defined by fewer or no healthcare episodes, the finding that enrollees in these tiers had fewer mean hospital episodes and lower charges was expected. However, these numbers show the magnitude of the differences between the subgroups in each tier at baseline, and they provide the basis for tier categorization on the date of cohort formation (October 1, 2013).

Prospective Analyses of Hospital Episodes by Tier

Figure 2 shows the mean number of hospital episodes by type, within each tier, during the 12 months following cohort formation. For all episode types, the overall differences remained significant (p < 0.001). Tier 4 enrollees had significantly more episodes on average than Tier 3 patients; they, in turn, had significantly more episodes than Tier 2 or Tier 1 patients (p < 0.001 for all comparisons). There were no significant differences between Tier 1 and Tier 2 emergency episodes (p = 0.279), but the numbers of observation and inpatient episodes were significantly different between these two tiers (p < 0.001 for each type). For all tiers, the median number of episodes of all types was zero.

Prospective Analyses of Healthcare Charges by Tier

1133
Figure 3 shows the mean and total healthcare charges by tier during the 12 months after cohort formation. Tiers 3 and 4, comprising 21% of the total population, accounted for 43% of total healthcare charges. Overall differences were significant (p < 0.001). Tier 4 enrollees had significantly higher charges on average than Tier 3 patients, which had significantly higher charges than Tier 2 patients; and these in turn where significantly higher than for Tier 1 patients (p < 0.001 for all comparisons). Median charges in each tier (respectively $0, $2,343, $8,662, and $20,412) were likewise significantly different overall (p < 0.001) and higher in the higher tiers (p < 0.001 for all comparisons).

DISCUSSION

The primary conclusion is that the LIGHT2 risk stratification methodology successfully met the objective of identifying which subgroups of Medicare/Medicaid patients were at risk of utilizing more healthcare resources. Specifically, information about healthcare utilization and charges over the previous twelve months provided highly useful information about what is likely to occur going forward. This finding confirms the expectation that past utilization is a good predictor of future utilization. When viewed through a population health lens, the extraction of readily available retrospective data can provide care coordinators with useful information that allows them to focus their efforts on those patients who care needs are most expensive, and who may require more intensive management.

A second observation is that the risk tiers created in this study were defined on the basis of diagnoses that are included in the Chronic Conditions Data Warehouse and on utilization categories that are in general use in healthcare systems. Because these are easily reproducible, the LIGHT2 risk stratification framework is potentially applicable to other healthcare systems.

A third observation is that there were no differences between Tier 1 patients and Tier 2 patients in the mean number of hospital episodes during the retrospective (i.e., baseline) period. Similarly, in the prospective period, there was no difference in mean number of emergency department episodes between Tiers 1 and 2. Accordingly, the cost and utilization patterns of Tier 2 patients are, in some ways, not notably different from Tier 1. Therefore, from a population health standpoint, time and resources devoted to keeping Tier 2 patients from evolving into the much more costly Tier 3 category would appear to be a useful care coordination strategy.

Finally, Tiers 3 and 4, comprising only 21% of the total population, accounted for 61% of total baseline healthcare charges and 43% of total prospective healthcare charges. The decrease in this difference from the baseline to the prospective measure reflects that prior healthcare episodes and charges are not a perfect, but nevertheless, highly useful predictor of prospective utilization. Specifically, the consumption of a large proportion of healthcare resources by a relatively small minority of the population (Tiers 3 and 4), even in the prospective year, underscores the importance of the early identification of those patients (or subgroups) who are most “at risk” for high healthcare utilization.

Limitations

Measurement of baseline and prospective utilization included only healthcare episodes that occurred within the University of Missouri Health System. Accordingly, these results likely underreport utilization by excluding healthcare episodes at other local or out-of-town facilities; inclusion
of this additional data could possibly improve the accuracy of risk stratification. In addition, healthcare charges were used as a proxy for healthcare costs, although claims data would be a more accurate source of cost information. Lastly, the generalizability of the LIGHT2 risk stratification methodology to other settings remains an empirical question. The study sample included only adults who received Medicare or Medicaid services in central Missouri, which may limit the generalizability of these findings to the wider US population.

**Future Research**

This preliminary work would be strengthened by validation against other populations that may have different prevalence of chronic conditions, age-adjusted death rates, or rates of relocation as well as different distributions of race/ethnicity, educational attainment, economic status, and literacy. Because the data used in the LIGHT2 risk stratification methodology is available in any healthcare system, replication of this four-tier methodology in other settings would be instructive. Additional studies that incorporate claims data also could be conducted to examine whether the accuracy of risk stratification could be improved. While this study demonstrates the predictive power of a tiered model, continuous risk scoring may be even more powerful, and development of such a model would also be helpful.

Abstract
An electronic health record (EHR) can assist the delivery of high-quality patient care, in part by providing the capability for a broad range of clinical decision support, including contextual references (e.g., Infobuttons), alerts and reminders, order sets, and dashboards. All of these decision support tools are based on clinical knowledge; unfortunately, the mechanisms for managing rules, order sets, Infobuttons, and dashboards are often unrelated, making it difficult to coordinate the application of clinical knowledge to various components of the clinical workflow. Additional complexity is encountered when updating enterprise-wide knowledge bases and delivering the content through multiple modalities to different consumers. We present the experience of Mayo Clinic as a case study to examine the requirements and implementation challenges related to knowledge management across a large, multi-site medical center. The lessons learned through the development of our knowledge management and delivery platform will help inform the future development of interoperable knowledge resources.

Introduction
A core business of Mayo Clinic is the creation and application of integrated knowledge to deliver safe and high value care. As the first integrated not-for-profit medical group practice in the world\(^1\) Mayo Clinic pioneered a team-based multidisciplinary approach to medicine. That approach evolved into a system where all Mayo physicians relied routinely on direct interaction with colleagues from across the practice as the primary source for vetted, trusted clinical knowledge. As EHR-based automation and payment constraints put pressure on the formal structures that enabled this cultural approach, we sought to create a knowledge management program that captured Mayo’s collective, vetted practice knowledge as a clinical knowledge resource for our medical staff. The size of Mayo's clinical staff, which includes 4,200 physicians and scientists, 2,400 residents and fellows, and nearly 53,000 allied health personnel, as well as the geographic distribution of the practice (campuses in Minnesota, Arizona, and Florida as well as more than 70 communities within the Mayo Clinic Health System), makes the collection, curation, delivery, and maintenance of knowledge highly challenging. To help address these challenges, the Office of Information and Knowledge Management (OIKM) was developed in 2012. The Office, led by the Chief Medical Informatics Officer, is made up of the physicians and administrators responsible for information management, practice analytics, applied clinical informatics, and knowledge management and delivery. OIKM is responsible for creating the infrastructure, collaborative tools and methodologies required to manage our knowledge assets, perpetuate best practices, and deliver the right information seamlessly to providers and patients when and where it is needed.

AskMayoExpert
Clinicians in many settings fail to find answers to clinical questions many times each day\(^2\). Lack of time is reported to be the biggest barrier to finding such answers\(^3\). Nearly half of the time, clinicians don’t pursue answers, most often citing the expectation that no useful information would be found\(^4\). In response to these challenges, the AskMayoExpert (AME) application was developed to provide answers to clinical questions at the point of care. AME is based on the concept of medical “gist” – concise, relevant, and clinically applicable answers to clinical questions\(^5\). The application has been widely adopted and is an integral part of the practice\(^6\). It comprises more than 13,000 structured, concise, and actionable “knowledge elements” covering 1,300 clinical conditions. AME is available for both desktop browsers and mobile devices to clinicians at Mayo Clinic, within the Mayo Clinic Health System, and at sites within the Mayo Clinic Care Network. A controlled crossover study found AME enabled clinicians to answer clinical questions with greater accuracy and confidence than other resources\(^7\).

Generating Consensus-Based, Vetted Clinical Knowledge
At the same time that AME was being built, Mayo Clinic launched a significant initiative aimed at practice standardization. “Specialty Councils” were assembled to develop consensus regarding best practices and to converge, integrate and propagate vetted Mayo Clinic knowledge. AME was identified as the repository for...
standardized knowledge and best practices developed by the Specialty Councils. A knowledge management team works with the Specialty Councils to create interactive algorithms called Care Process Models (CPMs) to represent these best practices. CPMs are designed to guide a clinician through stepwise care of a patient with a suspected or identified condition, and to provide concise, actionable recommendations. They are delivered as static or semi-interactive web pages that can be embedded in or linked to from within AME content. In 2015, 155 CPMs were accessed 82,649 times. On average, a CPM is retrieved 10.2 times per week; the most commonly accessed CPM in 2015 was for hyperlipidemia (Figure 1).

One of the greatest challenges in building AME was developing the process for creation and capture of clinical knowledge that would assure its credibility and acceptance across the practice. Knowledge Content Boards (KCBs), groups of four to six physicians focused on a particular specialty area, are responsible for capturing best practices identified by Specialty Councils and vetting the AME content. The KCB members are given dedicated time, and their work is recognized as a scholarly activity for consideration in academic appointments. Currently, 234 clinicians participate in 38 different KCBs, directed by 47 Specialty Councils.

One of the greatest challenges in building AME was developing the process for creation and capture of clinical knowledge that would assure its credibility and acceptance across the practice. Knowledge Content Boards (KCBs), groups of four to six physicians focused on a particular specialty area, are responsible for capturing best practices identified by Specialty Councils and vetting the AME content. The KCB members are given dedicated time, and their work is recognized as a scholarly activity for consideration in academic appointments. Figure 1. Care Process Model (CPM) utilization in 2015

Core Clinical and Structured Knowledge

The body of knowledge created and maintained in AME was recognized as an asset with value beyond a reference at the point of care, and it became the basis for a formal knowledge management program charged with the creation, maintenance, and governance of a core body of clinical knowledge which can be delivered in multiple forms to diverse audiences. To support this goal, we established the concept of foundational or “core” clinical knowledge, from which other knowledge assets may be derived. For example, the “core clinical content” in AME now serves as the basis for derivative products such as patient education materials and consumer health information. It also serves as the basis for a broad range of clinical decision support mechanisms, including Infobutton content, alerts and reminders, and order sets (Figure 2).

AME has thus evolved to serve three purposes: answering clinical questions, representing care processes, and serving as the basis for other knowledge assets. Each of these purposes generated unique requirements for both the content and how that content was stored. To be useful in answering clinical questions, the content must be clear, concise, actionable, findable, and trusted. To represent CPMs, the content had to be categorized into decisions and actions that could be related visually, while at the same time ensuring that the content answers focused clinical questions. Introducing the notion of core clinical content from which other assets could be derived necessitated even more consistent structuring, richer annotation, and explicit relationships between content items.
To accomplish this, an in-depth analysis of the core content was performed by the content consumers and content structure specialists. A very detailed structure was proposed; however, testing found that while the structure accommodated a broad range of content, fragmentation reduced the usefulness in answering clinical questions or representing the care process (Table 1). Furthermore, while subject matter experts and support staff were advised that the structure was only a categorization scheme rather than a template to be completed, there was a temptation to “fill in the blanks,” thereby reducing the focus on the intended clinical content.

| Mitral valve stenosis-Imaging Tests | The presence of mitral valve stenosis is confirmed with transthoracic echocardiography, which allows:  
  - Evaluation of valve morphologic characteristics and severity of stenosis  
  - Evaluation of sequelae of left atrial enlargement and pulmonary hypertension  
  - Detection of other valve abnormalities  
  Selected patients may require transesophageal echocardiography to confirm the severity of mitral valve stenosis or to identify concomitant mitral regurgitation or cardiac thrombus (particularly if percutaneous balloon valvuloplasty is being considered). |

Table 1. Content Structuring – Comparison of Approaches
A subsequent external review (see below) recommended that the content be structured to the business purpose; that is, make the content as granular as the end user can tolerate, but no more so. As a result, the knowledge structuring framework was simplified to include broad categories. A "universal template" was constructed based on the principles behind Darwin Information Typing Architecture (DITA), including modularity and reuse, information typing, and separation of content from form. This template provides a common, consistent framework that makes it easier to model, ingest and reuse content. The universal templates follow a hierarchical structure of the form Topic-Concept-Section, where the Section is the smallest unit of content that can be delivered on its own. Each Topic, Concept, and Section is given a unique content identifier and can be maintained independently. To date, the universal template has been instantiated to create two "anchor topics": Condition and Procedure. The Concepts approved for use within each of those Topics are shown in Figure 3. To date, the KCMS contains 504,349 items of content (of which 117,349 items are related to Mayo Clinic employees) and the AME contains 1541 published topics and 12,229 published sections. In the 6 month period from September 2015 to February 2016, 55,795 AME users initiated 129,270 sessions and viewed 587,768 pages of content (averaging more than 3200 page views per day).

**Figure 3.** Instances of the universal template: Concepts for the Topics "Condition" and "Procedure"

### Derived Knowledge Assets

The "core clinical content" serves as a single "source of truth", from which other knowledge assets can be derived. Derived assets, which are produced manually, take two forms: Structured narrative content including patient education materials and consumer web content, and computable assets including rules, assessment tools, and order sets. The former are authored in KCMS. The latter are cataloged in the KCMS but instantiated in the EHR and other clinical systems. Representing these computable assets generates multiple components which are themselves knowledge assets, including value sets, calculations, and cohort definitions. (Figure 4). For example, the CHA2DS2-VASc score calculator, which is embedded within the CPM for anticoagulation in patients with atrial fibrillation, utilizes cohort definitions in addition to several clinical parameters. The catalog records for computable knowledge assets serve as a common, enterprise-wide definition that can be instantiated within local systems. For example, the "clinical decision support rule" knowledge assets are stored in a master rule catalog as structured algorithms in system-agnostic syntax. When those algorithms are implemented across our varied EHR systems as executable rules, metadata about those implementations are added to the catalog to provide a link between the centralized knowledge asset and the implemented rule.

The core content serves as a starting point for generating a new knowledge asset, but additional knowledge acquisition is required for each derived item since it is developed for a particular purpose. For example, a decision support rule requires the extraction of computable logic and defined clinical concepts from the narrative core content. An order set requires details about specific orderable items and unit routines. Patient educational materials require the addition of broader background content as well as directions for self-care. The core content is written primarily for a physician/advance practice nurse audience. A pilot is under way to add nursing-focused content. In general, the core content has sufficient depth such that additional content can be generated by clinical informaticians and other members of the care team (e.g. nurses, pharmacists, therapists) with minimal input from the subject matter experts.
While the early emphasis of the knowledge management program was on narrative or reference content specific to a condition or clinical situation, but not to a particular patient, we knew that in order to effectively apply knowledge to patient care it must be individualized to a particular patient. We also recognized that, even though electronic health records (EHRs) automate clinical data access and workflow – and thus are a tempting place to directly embed clinical knowledge – clinical workflow is fundamentally different from the medical knowledge and decision support assets that are the target of our knowledge management program. While knowledge buried in purely operational workflow is necessarily implicit, and thus difficult to manage and sustain, knowledge represented only in human-readable artifacts is not routinely actionable and is difficult to scale. Thus, an architecture in which clinical knowledge is separated from but integrated with the patient data and workflow delivery systems is critical to the ability to truly scale knowledge delivery.

A dedicated knowledge content management system (KCMS) serves as a primary source for clinical knowledge. The KCMS serves three functions: a) it provides the authoring environment for narrative content, b) it delivers content and search functionality on demand to users, and c) it functions as a catalog for other types of knowledge assets. Other systems that make use of the clinical knowledge in the KCMS can be considered as either knowledge staging or implementation systems. A knowledge staging system delivers knowledge content such as text, formatted text, images, or video to knowledge consumers. Staging systems can either store a copy of the content or retrieve the content from the KCMS on demand via an application programming interface (API). Knowledge implementation
systems execute actionable knowledge artifacts, such as alerts and reminders or order sets. The knowledge implementation systems generally store the executable version of knowledge artifacts, built using proprietary languages and information models, but could request an executable knowledge artifact from the KCMS if it is built in a standard executable format. A high-level overview of the KCMS architecture is illustrated in Figure 5.

Managing knowledge in a dedicated system requires an ontology of knowledge assets which clearly defines the various asset types, the metadata used to describe the assets, and their relationships. While a working list of asset types has been developed to meet local needs, a broadly accepted standard will be necessary to effectively enable the collaboration and exchange across organizations. The knowledge asset ontology describes what an asset is (content, a rule, a predictive model, an order set, etc.), but annotation with standard medical vocabularies (e.g. SNOMED-CT, LOINC®, ICD10-CM, and RxNorm) is required to describe what the asset is about. Four internally-developed vocabularies are used to support specialized uses, such as consumer health and research. Early experience with annotation of assets showed that while it was useful in understanding broad relationships between assets, it was not sufficient to describe the relationships between specific assets. Therefore, a mechanism was developed to allow declaration of explicit relationships between knowledge assets (Figure 4). For example, the treatment section of a care process model might recommend medications and therapies for a particular condition. The order set derived from that section would have an explicit relationship to the section, so that when the section is updated, notification goes to the order set team for review and update as needed. These relationships quickly grew in complexity; for example, a rule derived from a care process model might depend on a scoring model, which might depend on a cohort definition, which might depend on a value set. At this time, the types of item relationships created and maintained in the KCMS are limited to “dependencies” and serve to notify the owner of an asset about changes to related assets. Human intervention is required to analyze and react to the changes. Because the ability to define explicit relationships is a fairly recent enhancement, and requires business processes that cross multiple teams, the number of such relationships is relatively small but growing; as of this writing, there were 3131 relationships between items, 792 of which were subscriptions to changes in content. In the future, a more complete asset ontology that incorporates the medical semantics of asset to asset relationships is obviously desirable.
Integrating the KCMS with the EHR also poses challenges. While many of the assets themselves are built in the EHR, the knowledge about the asset, including descriptive and business metadata, and the relationship to other assets within and outside the EHR, are managed in the KCMS. The current mechanism for integration is cross-referencing. The KCMS record of a knowledge asset contains the unique identifier from the EHR configuration record, and the EHR configuration record contains the unique identifier of the KCMS catalog. Our intent is to leverage this cross-referencing to allow a user of the KCMS to view the EHR implementation details from within the catalog, and to allow a rule builder in the EHR to view the system-agnostic rule logic, the metadata, and relationships to other knowledge assets from within the EHR.

The motivation for this approach to knowledge management reflects both structural and operational goals. Structurally, we want to reflect an ideal conceptual model which requires the independence of clinical knowledge representing the standard of care at Mayo Clinic from the clinical workflow embodied in the EHR’s programming. Operationally, the design has to satisfy our need to “know what we know” – that is, to allow a Knowledge Content Board to efficiently access the entire body of knowledge related to a given condition, clinical situation, or treatment in order to validate the clinical relevance and appropriateness of the various knowledge artifacts and relationships, and to systematically update them as our recommended standard of care evolves.

Example: Updating Recommendations for Anticoagulation and Atrial Fibrillation

One of Mayo's CPMs addresses recommendations for anticoagulation in patients with atrial fibrillation. Several rules in the EHR and other systems calculate a patient’s risk of stroke and make recommendations regarding anticoagulation therapy. In 2014, the clinical guidelines were updated in response to rapidly developing continuous change in assessment and treatment, based upon the results of multiple randomized trials being conducted to determine the optimal therapy to decrease the risk of stroke in patients with atrial fibrillation. Examples of the changes include a) the introduction of the new oral anticoagulant medications with a superior effect and better patient compliance than warfarin, b) the creation of better models for risk prediction (i.e., the CHADS2-VASC vs CHADS risk score calculators), c) the deletion of treatments that had been passed down as effective but further analysis showing ineffectiveness (i.e. aspirin), and d) the need for a shared decision making process with the patient in which they make a decision based upon their own needs and preferences. After the new evidence was reviewed by clinical experts and a consensus was reached, Mayo staff was able to update the related rules in the KCMS quickly and efficiently, thereby ensuring that clinicians across the Mayo enterprise had access to the new information. Outdated information persisted in isolated reference documents on the intranet and on small departmental systems, however, and these sites were updated as they were identified. This example provided a tangible demonstration of the value of a formalized, semi-automated knowledge management approach.

Evaluation

In October 2014, Mayo hosted three renowned clinician-informaticians to conduct an external review of the Mayo Clinic Knowledge Management Program. The key questions posed to the external evaluation team included:

- What are the best practices for managing clinical guidelines and pathways?
  - Knowledge structure (including degree of granularity and relationships between topics)
  - Knowledge representation (from human-readable to executable)
  - Tools used to store and manage knowledge
  - Methods for indexing and retrieval (e.g., annotations, tags)
  - Knowledge delivery
- How should other knowledge assets be managed?
  - Types of assets (e.g., order sets, clinical decision support rules, educational materials)
  - Relationships between knowledge assets (if any)

The external evaluation team noted the breadth and depth of the information maintained, curated, and distributed on a daily basis at Mayo Clinic. The group also approved of Mayo’s use of clinical ontologies to act as building blocks of the information architecture, citing the importance of incorporating standards into the process and applying appropriate and usable semantic tags.

As with many large academic medical centers, Mayo’s knowledge asset development and curation process is necessarily dispersed throughout the practice. The team recommended the assets be managed by subject matter, regardless of the delivery system intended. This approach will require a greater level of coordination from the knowledge management program, but is necessary to ensure the knowledge delivered to multiple sources is created and vetted by the appropriate subject matter experts. The evaluation team also identified opportunities for
improvement in coordinating of multiple delivery systems, particularly based on target audiences of providers, patients, consumers and affiliated practices.

The external evaluation team commented favorably on Mayo’s information model and architecture for the technical management of clinical knowledge. The team encouraged Mayo to advance the technical capabilities to facilitate the ability of subject matter experts to use the central repository of knowledge assets, which will reduce errors in transcription from one tool to another and encourage a more complete and focused entry of the assets. In addition, it will reduce the likelihood of the assets stored in local repositories, which enforces the centralized source of truth. Finally, the team noted that many of the knowledge assets will ultimately be delivered through the electronic health record (EHR), and those assets (e.g., order sets, decision support rules, and representations of clinical pathways) should have a clear pathway between the central repository of knowledge and the EHR.

As shown in Table 2, the KCMS was also evaluated against the recommendations outlined by Sittig et. al. While those recommendations focus specifically on systems intended to manage clinical decision support knowledge, the principles apply more broadly to clinical knowledge management.

<table>
<thead>
<tr>
<th>Tool 1: external repository of clinical content with web-based viewer</th>
<th>The KCMS is an external repository many types of knowledge assets. Assets can be discovered by end users through a variety of interfaces and applications. Developers and knowledge management staff can access the computable knowledge assets via the Knowledge Asset Catalog web page.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tool 2: online, collaborative, interactive, Intranet-based tool to facilitate content development</td>
<td>The KCMS supports multiple workflows for collaboration, review, and approval and captures metadata about the knowledge asset life cycle. However, the workflows are not always intuitive and users express dissatisfaction with current processes. Enhancements are currently being made to the system to improve the experience. Multiple authoring tools for various asset types are being evaluated.</td>
</tr>
<tr>
<td>Tool 3: enterprise-wide tool to maintain controlled clinical terminology concepts</td>
<td>Mayo Clinic’s “TERMS” environment manages standard and home-grown terminologies and value sets. Currently, the rules must reference a terminology web page that lists the approved value sets, but we are working toward each value set having a URI to enable direct referencing from within the rule representation.</td>
</tr>
<tr>
<td>Tool 4: tool for CDS users to provide feedback regarding specific CDS interventions</td>
<td>There is no single tool for users to provide feedback on CDS; the alerts and reminders include links to email the rules team, AME include a feedback window which stores the feedback in a local database. The feedback is used to improve the program, but it is not managed as systematically as it could be.</td>
</tr>
</tbody>
</table>

Future Work

Although much progress has been made in leveraging a core body of clinical knowledge as an anchor for managing multiple derivative knowledge assets, Mayo Clinic continues to actively address the significant opportunities and challenges. This activity will be done in collaboration with other academic medical centers and healthcare experts to expand capabilities for all developers and consumers of clinical knowledge.

The current model of extracting executable logic from CPMs is an improvement over starting from a blank slate with a subject matter expert, but the process remains labor-intensive and requires significant effort to manually update the derived assets when the underlying knowledge changes. More exploration is needed in approaches to modeling the core knowledge in a way that streamlines the generation of executable derivatives while maintaining the value of the narrative representations.

Managing cohort definitions, scoring models, and other inputs to clinical rules as independent assets enables reuse and enhances scalability, but better mechanisms are needed to name, classify, and relate these knowledge assets. As a starting point, Mayo will lead a collaborative effort to develop a common ontology of knowledge assets. Agreement on clear definitions of knowledge assets and their relationships to each other is required to facilitate sharing of any complex representation of knowledge.

While there are many proposed representation formats and standards, they may not be uniformly adopted, may not be sufficiently expressive (e.g., Health eDecisions, HeD), or may lack sufficient specificity (e.g., HL7 FHIR) so...
that true exchange of computable, actionable knowledge is still a challenge. Ongoing collaboration between organizations, with an emphasis toward applying standards and models in practice, is critical to advancing knowledge management.

Further work is also needed to bring managed knowledge assets together with patient data within clinical workflow in a fashion that efficiently assists and supports the cognitive effort of clinicians using the knowledge assets. This requires precise alignment of the concepts in the knowledge assets with the data schema of the EHR, and a careful elaboration of how clinicians seek and interact with knowledge in the natural flow of diagnosis and treatment decisions.

Another facet of knowledge management which merits further exploration is knowledge discovery through measurement. The knowledge lifecycle depends on measuring the results of knowledge delivery and using that data to feed back into knowledge creation (Figure 6). Capturing data as a byproduct of knowledge delivery interventions in the EHR creates a rich pool of data that can be used to measure and analyze practice variation. This data can serve as an important mechanism for continuously improving the CPMs\textsuperscript{13}. Looking for ways to identify the data that will be used to measure the effectiveness of a knowledge delivery intervention as a part of the knowledge engineering process will become increasingly important in the evolution of learning health systems.

Figure 6. The knowledge lifecycle

Conclusion

Physicians make decisions that must be grounded in expert clinical knowledge almost continuously during the process of caring for patients. Mayo Clinic developed a highly collaborative model of care based on a unified patient record starting early in the 20\textsuperscript{th} century, and this developed over time into a system of both formal and informal knowledge sharing directly from physician to physician as the primary means of assuring access to clinical knowledge both broad and deep enough to facilitate optimal care decisions. In the 21\textsuperscript{st} century era of the EHR, Mayo has created a digital knowledge sharing system as a complement to the EHR, designed to allow clinicians direct electronic access to clinical knowledge that represents the Mayo Clinic standard of care for 1300 clinical conditions. This system has required elaboration of a formal system for knowledge development and stewardship as part of the medical responsibilities of Mayo physicians, and resulted in the construction of a Knowledge Content
Management System used to organize and deliver knowledge on demand in clinical and other settings. Full utilization of ontological knowledge management and integration of knowledge with patient data maintained in the EHR remain challenges and areas of ongoing development. While there are several national leaders in this area we believe that our approach to clinical knowledge management, which is centered on structured, vetted content that is used as the basis for a variety of derived assets, is unique and can serve as a model for other enterprise knowledge management efforts.

Abstract

Clinical trial coordinators refer to both structured and unstructured sources of data when evaluating a subject for eligibility. While some eligibility criteria can be resolved using structured data, some require manual review of clinical notes. An important step in automating the trial screening process is to be able to identify the right data source for resolving each criterion. In this work, we discuss the creation of an eligibility criteria dataset for clinical trials for patients with two disparate diseases, annotated with the preferred data source for each criterion (i.e., structured or unstructured) by annotators with medical training. The dataset includes 50 heart-failure trials with a total of 766 eligibility criteria and 50 trials for chronic lymphocytic leukemia (CLL) with 677 criteria. Further, we developed machine learning models to predict the preferred data source: kernel methods outperform simpler learning models when used with a combination of lexical, syntactic, semantic, and surface features. Evaluation of these models indicates that the performance is consistent across data from both diagnoses, indicating generalizability of our method. Our findings are an important step towards ongoing efforts for automation of clinical trial screening.

Introduction

With the amount of data collected during patient care growing, researchers have proposed a number of scenarios in which knowledge extracted from clinical data can be leveraged effectively\textsuperscript{1}. Information found in the Electronic Health Record (EHR) can have an important secondary use in identifying patients eligible for clinical trials\textsuperscript{2}. Identifying the patient cohort involves understanding the exact information sought by the eligibility criteria for trials and searching for it in the subject’s EHR. However, this manual process of eligibility determination is challenging and time-consuming\textsuperscript{3}. Therefore, a number of initiatives have been undertaken to introduce automation into this process\textsuperscript{4}.

The EHR captures patient information using both structured data, stored in the form of tables or flowsheets, and unstructured data, stored in the form of clinical notes or free-text reports. While structured data are comprised of laboratory values, demographics, diagnosis codes, etc., unstructured clinical notes are written by physicians, nurses and other health professionals to document a patient’s condition, prognosis, response to various clinical interventions, and future plans for treatment. Eligibility criteria based on data found in structured data fields can be processed easily using structured queries over databases (e.g., “At least 18 years of age at the time of enrollment.”). Although structured data enables quick and easy retrieval of data, unstructured text is a preferred means of documentation for physicians\textsuperscript{5}. Thus, the information need of eligibility criteria that involve clinical nuances (e.g., “Patients with a known severe symptomatic primary pulmonary disease.”) can only be answered using unstructured clinical notes or discussion with the treating physician.

Gaps between data found in the EHR and the desired data for trial recruitment have been studied\textsuperscript{6}. Köpcke et al.\textsuperscript{7} found that there was a significant gap (65\%) between the structured data documented for patient care and the data required for eligibility assessment. Li et al.\textsuperscript{8} studied the strengths and weaknesses of using structured or textual clinical data for clinical trials eligibility screening. They concluded that insights obtained from natural language processing of patient reports supplement important information for eligibility screening and should be used in combination with structured data. Therefore, researchers have devised methods\textsuperscript{9,10} using NLP to identify relevant text in clinical notes and resolve eligibility criteria to screen patients into clinical trials. However, using NLP techniques on clinical data is computationally expensive. Moreover, certain criteria (e.g., “Patients between the ages of 18 and 90.”) can be answered accurately and quickly using structured data alone. An ideal system for identifying
patients would maximize the use of structured data, and only use inference over clinical narratives when necessary. Thus, it would be desirable to know whether eligibility can be concluded for a criterion using structured data, or if it requires an NLP pipeline for its resolution. Such knowledge would not only result in identifying patient cohorts with better accuracy but also optimize the computational efficiency of the task.
